Let $\{T_n; n \geq 1\}$ be a sequence of random variables with finite expectations. If $E\{T_n|T_j, j \leq n-1\} = T_{n-1}$ almost everywhere for every $n \geq 1$ (where T_0 can be taken as a constant), then $\{T_n; n \geq 1\}$ is termed a martingale. If in the above (conditional) expectation, for all n, the $=$ is replaced by a $\geq$ (or $\leq$), then we have a submartingale (or supermartingale) sequence. A sequence $\{T_n\}$ forms a reversed martingale if for every n, $E\{T_n|T_{n+1}, T_{n+2}, \ldots\} = T_{n+1}$, almost everywhere, and a similar definition holds for reversed sub (or super) martingales. The sample mean, ***U*-statistics** and many other symmetric estimators can be characterized as reversed martingales. Similarly, sample sums, **likelihood ratio test statistics**, and other forms of **rank** statistics can be characterized as martingales. Score statistics, arising in parametric models [16] as well as in various nonparametric and semiparametric applications [10], are abundant in biostatistics (*see* **Likelihood**). In most of these cases, either a reversed martingale or a forward martingale characterization holds. The empirical distribution function F_n is also a reversed martingale (process). Such dependent sequences show up frequently in survival analysis and other areas in biostatistics. Most of the probability inequalities and LLNs have been extended to such dependent sequences, and hence they enjoy similar convergence properties. We refer to some of these later in the article.

Weak Convergence and CLT

Consider a sequence $\{T_n; n \geq n_0\}$ of random variables or statistics with distribution functions $\{G_n; n \geq$

$n_0\}$. Then T_n is said to converge weakly (or in distribution/law) to a possibly degenerate random variable T with distribution function G, if $||G_n - G|| \to 0$ as $n \to \infty$, i.e. G_n converges to G at all points of continuity of G. Of particular interest is the classical **central limit theorem** (CLT) which relates to the case of a normal G. In the case of iid random variables $\{X_i, i \geq 1\}$ with finite mean μ and variance σ^2, $T_n = n^{-1/2} \sum_{i=1}^n (X_i - \mu)/\sigma$ converges in law to T, where T has the standard normal distribution function. The *Liapounoff* theorem established this weak convergence result in the nonidentically distributed case under a moment condition of order higher than 2, while the classical *Lindeberg–Feller* CLT pertains to the same result under a less stringent *uniform integrability* condition: for all $\varepsilon > 0$.

$$s_n^{-2} \sum_{i=1}^n \mathrm{E}[(X_i - \mathrm{E}X_i)^2 I(|X_i - \mathrm{E}X_i| > \varepsilon s_n)] \to 0, \quad \text{as} \quad n \to \infty \tag{5}$$

where $s_n^2 = \sum_{i=1}^n \mathrm{var}(X_i)$. These CLTs have been extended to more general *triangular* schemes as well as to some multivariate situations. In this context, it may not be necessary to assume that the limiting distribution is of full rank, i.e. degenerate limit laws are also allowed. Moreover, the CLTs hold for various dependent summands, including the martingales and reverse martingales, under some extra mild regularity conditions [5]. In general, in biostatistics, often a statistic T_n does not have independent summands, and may not even be strictly a martingale or reversed martingale, so a CLT may not be applied on it. However, in this context the well-known *Slutsky* theorem, presented below, provides an easily verifiable approach.

Let $\{X_n\}$ and $\{Y_n\}$ be sequences of random variables not necessarily independent, such that $X_n \xrightarrow{\mathcal{D}} X$ and $Y_n \xrightarrow{\mathcal{P}} c$, a constant. Then the following results hold:

$$X_n + Y_n \xrightarrow{\mathcal{D}} X + c,$$

$$X_n Y_n \xrightarrow{\mathcal{D}} cX,$$

and

$$\frac{X_n}{Y_n} \xrightarrow{\mathcal{D}} \frac{X}{c}, \quad \text{if } c \neq 0. \tag{6}$$

In a variety of situations, we have the following *projection* result:

$$T_n = T_n^0 + R_n; \quad T_n^0 = \sum_{i=1}^n \mathrm{E}[T_n | X_i] - (n-1)\mathrm{E}[T_n], \tag{7}$$

and the remainder term, R_n, having the nice property that $\mathrm{E}(R_n^2) = \mathrm{E}(T_n - \theta)^2 - \mathrm{E}(T_n^0 - \theta)^2$, stochastically converges to 0 at a rate faster than the standard error of T_n^0, whenever the projection technique yields an asymptotic quadratic mean equivalence. In such a case, the CLT holds for $\{T_n^0\}$ (which has independent summands), while the Slutsky theorem leads to the asymptotic normality of the standardized form of T_n. Hoeffding [8] used this projection result for U-statistics, where T_n^0 is a sample average of iid random variables, and he also indicated how the nonidentically distributed clause can be accommodated in the same vein. During the past 50 years a vast amount of research work has been accomplished in this direction. We refer to Jurečková & Sen [10] for deeper results on *asymptotic representations* of possibly nonlinear statistics in terms of T_n^0 and a remainder term, wherein the algebraic complications underlying the projection technique's asymptotic quadratic mean equivalence has further been replaced by a less stringent weaker expansion. As a simple illustration, consider the case of the sample variance $S_n^2 = n^{-1} \sum_{i=1}^n (X_i - \overline{X}_n)^2$, where $\overline{X}_n = n^{-1} \sum_{i=1}^n X_i$ is the sample mean. Here $T_n^0 = n^{-1} \sum_{i=1}^n (X_i - \mu)^2$ and $R_n = O_p(n^{-1})$. Thus, the CLT applies to $\sqrt{n}(S_n^2 - \sigma^2)$, though it is itself not an average of iid random variables.

Some weak convergence results allied to the above CLTs deserve mention. First, the asymptotic version of the *Cochran* theorem. Let $\sqrt{n}(\mathbf{T}_n - \boldsymbol{\theta}) \xrightarrow{\mathcal{D}} \mathcal{N}_p(\mathbf{0}, \boldsymbol{\Gamma})$, and let $\mathbf{A}_n$ be a possibly stochastic matrix, converging (in probability) to $\mathbf{A}$, a generalized inverse of $\boldsymbol{\Gamma}$, with $\mathrm{Tr}(\mathbf{A}) = q(\leq p)$. Then $n(\mathbf{T}_n - \boldsymbol{\theta})' \mathbf{A}_n (\mathbf{T}_n - \boldsymbol{\theta})$ has an asymptotically **chi-square distribution** with q **degrees of freedom**. This theorem has many uses in biostatistics, and we will discuss some of them later in the article. As an illustration, we consider the case of the **Hotelling T^2 statistic** (in the multivariate one-sample model):

$$T_n^2 = n(\overline{\mathbf{X}}_n - \boldsymbol{\mu})' \mathbf{S}_n^{-1} (\overline{\mathbf{X}}_n - \boldsymbol{\mu}), \tag{8}$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are the population mean vector and **covariance matrix**, and $\overline{\mathbf{X}}_n$ and $\mathbf{S}_n$ are their sample counterparts. Whenever the underlying distribution function has finite second-order moments, $\mathbf{S}_n \xrightarrow{\mathcal{P}} \boldsymbol{\Sigma}$ and the multivariate CLT applies for $\sqrt{n}(\overline{\mathbf{X}}_n - \boldsymbol{\mu})$. Therefore, by the above version of the Cochran theorem, we claim that as n increases, T_n^2 has closely the central chi-square distribution function with p degrees of freedom. This result is useful in testing suitable null hypotheses on $\boldsymbol{\mu}$ as well as for obtaining *confidence sets* for $\boldsymbol{\mu}$, without specifically making the multinormality assumption. In the general context of linear models (without normality of the errors), the conventional least squares procedures lead to various estimates and test statistics where the Slutsky theorem and the above version of the Cochran theorem provide access to related asymptotic distribution theory. We refer to Sen & Singer [21] for most of these details.

Secondly, under the same setup, consider a real valued function $Z_n = g(\mathbf{T}_n)$ and define $\nu = g(\boldsymbol{\theta})$. Then under differentiability of $g(\cdot)$ at $\boldsymbol{\theta}$, we have

$$\sqrt{n}(Z_n - \nu) \xrightarrow{\mathcal{D}} \mathcal{N}(0, \gamma^{*2}), \tag{9}$$

where $\gamma^{*2} = (\dot{g})'\boldsymbol{\Gamma}(\dot{g})$, and $\dot{g}$ is the gradient (vector) of $g(\cdot)$ at $\boldsymbol{\theta}$, which is assumed to be nonnull (as otherwise we would have a degenerate normal law). This basic CLT result has numerous applications in biostatistics. As a simple illustration, we consider the case of the sample *coefficient of variation*, $V_n = S_n/\overline{X}_n$, where it is assumed that the population mean, μ, is nonnull (usually taken to be positive). Thus, V_n is a function of $(\overline{X}_n, S_n^2)$, and the above result directly yields the asymptotic normality of $\sqrt{n}(V_n - \xi)$, where $\xi = \sigma/\mu$. Sample correlation and regression coefficients are also notable examples of this type of statistics.

Thirdly, it should be clearly kept in mind that such *weak convergence results may not imply moment convergence*, i.e. the convergence of the mean, variance, and other moments of the statistics T_n or $g(T_n)$ to their asymptotic counterparts as specified by their asymptotic distributions. A simple example to this effect is the parameter θ, the reciprocal of the binomial (probability) parameter π, where T_n is the sample proportion, and $g(T_n) = T_n^{-1}$ is the natural plug-in estimator of θ. This model arises in the context of the well known **Capture–mark–release–recapture** (CMRR) procedure for estimating the size of a finite population; see, for example, Sen & Singer [21]. Since T_n can assume the value 0 with a positive probability $(1-\pi)^n$, no matter how large n is, $g(T_n)$ does not have any finite positive order moment. However, the asymptotic normality result pertains to $g(T_n)$ as long as $\pi > 0$. As a historical note it may be mentioned that during the 1940s and 1950s considerable attempts were made to obtain the exact **skewness** and **kurtosis** coefficients of sampling distributions of various statistics (or estimators) in showing that they are asymptotically null, so that their asymptotic distribution would be normal. While the *Fréchet–Shohat* theorem (based on moment convergence of all order) justifies such an approach, obviously, the convergence of the first four moments may not suffice. Moreover, this limits the scope to a more restricted class of statistics which have finite moments all of finite order. In (bio-)statistical applications, for example, for setting a (large-sample) confidence interval for a parameter or testing a null hypothesis on the same, all we need is the asymptotic distribution and estimates of the parameter(s) that appear in these laws. Thus, weak convergence results are generally enough, and moment convergence is usually not needed. Finally, in such applications we may like to have some deeper weak convergence results which can match with more complexities and also may accelerate the goodness of fit of the asymptotics for moderate to large samples. These are presented separately in the following three sections.

Weak Convergence: Conditional Distributions

In the context of *resampling plans*, such as **jackknifing** and **bootstrapping**, one encounters a somewhat different asymptotic situation which requires additional care. We illustrate this with the simple bootstrap methodology. Let $X_1, \ldots, X_n$ be n iid random variables drawn from a distribution function F, and let $T_n = T(X_1, \ldots, X_n)$ be a suitable statistic whose population counterpart is denoted by θ. In a variety of cases it may be possible to establish that under suitable regularity assumptions, the distribution function $G_n(\cdot)$ of $\sqrt{n}[T_n - \theta]$ converges to a limiting distribution function $G(\cdot)$ as n becomes large; however

this distribution function G may not be normal, or even if it is so, it may have a scale parameter γ which is an involved functional of F. Therefore, we may like to estimate G_n in a nonparametric manner. From $(X_1, \ldots, X_n)$, we draw with replacement a sample of n observations, and denote these by $X_1^*, \ldots, X_n^*$, respectively. Let $T_n^* = T(X_1^*, \ldots, X_n^*)$ be the bootstrap version of T_n, and let us denote by $Z_n^* = \sqrt{n}[T_n^* - T_n]$. Note that under the conditional law $\Pr\{X_i^* = X_k | X_1, \ldots, X_n\} = n^{-1}$, for all $i, k = 1, \ldots, n$, the exact (conditional) distribution of Z_n^* can be obtained by enumeration, though such a task becomes prohibitively laborious as n increases (check the growth of the number n^n). Moreover, this conditional (bootstrap law) is intended as an estimator of the unconditional law G_n. This naturally imposes some restraints on the type of G_n for which a passage from the conditional to the unconditional distribution is well lighted. For example, if G_n is not attracted by a normal limit, then this postulation may not be true. This objective often precludes small sample size cases, even when G_n has a normal limit. As such, when n is large, M (a large number of) repetitions of the bootstrapping yields conditionally independent and identically distributed copies of Z_n^*, and this set is used to estimate G_n as well as a measure of its scale parameter. A very similar case arises in multivariate nonparametrics where conventional rank statistics are not usually genuinely distribution-free even under suitable null hypotheses (of invariance), and hence, their permutation distribution (*see* **Randomization Tests**) (corresponding to the case of simple random **sampling without replacement** (SRSWOR)) is used to generate the (conditional) null distribution of such rank statistics. In such applications, too, the passage from the conditional to unconditional distributions is generally fortified for large samples when the asymptotic (multi-)normality can be incorporated in a suitable manner; we refer to Puri & Sen [15] for a detailed account of such permutational LST. In jackknifing, a similar SRSWOR scheme arises, and it rests on the permutational probability measure generated by the $n!$ equally likely permutations of the observations. In such a case, the classical weak convergence results may not directly hold, though under additional mild regularity assumptions, the passage from the conditional limit law to an unconditional one can be fortified. Usually the (multi-)normality of the conditional distribution and its asymptotic homoscedasticity suffice for the purpose. But that may exclude some important applications in practice. For example, if the limit distribution is (scale) mixed-normal, this convergence of conditional limit laws to their unconditional forms may not generally hold. A word of caution: contrary to the belief and heuristic practice of using such resampling schemes for moderate to small sample sizes as well, there is no sound methodological justification for such usages. In many cases, they may be misleading.

Weak Invariance Principles

Let $X_1, \ldots, X_n$ be n iid random variables with finite mean μ and variance σ^2. Set $S_k = \sum_{i \le k}(X_i - \mu), k \ge 1$, and let $S_0 = 0$. Then the CLT asserts that for large n, $S_n/\{\sqrt{n}\sigma\}$ has closely a standard normal distribution. Let us construct a stochastic process $W_n = \{W_n(t), t \in (0, 1)\}$, by letting $W_n(k/n) = \{S_k/\{\sigma\sqrt{n}\}, k = 0, 1, \ldots, n\}$ and completing the definition by linear interpolation on (0, 1). This way we map the *partial sum process* $\{S_k; k \le n\}$ into a stochastic process W_n with continuous sample paths on the unit interval (0, 1). Now let $W = \{W(t), t \in (0, 1)\}$ be a *Gaussian process* on the unit interval (0, 1), such that $\mathrm{E}W(t) = 0$ and $\mathrm{E}[W(s)W(t)] = \min(s, t), s, t \in (0, 1)$. Then W is termed a *standard* **Brownian motion process** on (0,1). As a generalization of the CLT, we have the following:

$$W_n \xrightarrow{\mathcal{D}} W, \quad \text{as } n \to \infty. \tag{10}$$

The implications of this weak convergence result are (i) the finite dimensional distributions of W_n converge to those of W, and (ii) like W, W_n is *tight* or relatively compact. The first result follows by using a multivariate version of the CLT, while (ii) can be established by using some maximal inequalities, and both accomplished under no extra regularity conditions. This result extends directly to martingales/reversed martingales and to the nonidentically distributed case as well.

A second weak invariance principle having a profound impact on LST in biostatistics is the following. Let $F_n(x) = n^{-1}\sum_{i=1}^n I(X_i \le x), x \in \mathbf{R}$, be the sample distribution function, and define a stochastic process $W_n^0 = \{W_n^0(t), t \in (0, 1)\}$ by letting $W_n^0(t) = \sqrt{n}[F_n(x) - F(x)]$, at $t = F(x)$, for $t \in (0, 1)$. Also, let $W^0 = \{W^0(t), t \in (0, 1)\}$ be a Gaussian function on (0, 1), such

that $E W^0(t) = 0$ and $E[W^0(s)W^0(t)] = \min(s,t) - st, s, t \in (0,1)$. W^0 is termed a *standard Brownian bridge* or a tied-down Brownian motion. Note that at $t = 0$ or 1, $W_n^0(t)$ is equal to 0 with probability 1, and hence the term *tied-down* has been affixed. Here also, we have for all continuous F,

$$W_n^0 \xrightarrow{\mathcal{D}} W^0, \quad \text{as } n \to \infty, \tag{11}$$

and the implications of this weak convergence result are the same as in (10). Extensions to higher dimensional distribution functions and more general functionals of the sample distribution functions have been considered at great depth. We refer to Jurečková & Sen [10], for some details. Some applications of these invariance principles will be discussed later in the article.

Variance Stabilizing Transformations

In a general setup, whenever $\sqrt{n}(T_n - \theta) \xrightarrow{\mathcal{D}} \mathcal{N}(0, \sigma^2)$, the asymptotic variance σ^2 may depend on the unknown parameter θ; therefore, we write $\sigma^2 = h(\theta)$ and assume that the form of $h(\cdot)$ is known. To use the above result for drawing a confidence interval for θ or to test a suitable null hypothesis on θ, it may be more desirable to consider a transformation: $T_n \to g(T_n)$, such that $\sqrt{n}(g(T_n) - g(\theta)) \xrightarrow{\mathcal{D}} \mathcal{N}(0, c^2)$, where $g(\cdot)$ is a manageable function and c does not depend on θ. While in general such a transformation may not exist, but for the single parameter case there are some well-known cases where it has worked out well; these are therefore termed variance stabilizing transformations (*see* **Delta Method**). It follows from (9) that a sufficient condition for this to be achieved is that

$$g'(\theta) = c\{h(\theta)\}^{-1/2} \quad \text{or} \quad g(\theta) = c \int \{h(y)\}^{-1/2}\, dy. \tag{12}$$

For **binomial**, **Poisson**, normal variance and **correlation** coefficient parameters, (12) work out well, and furthermore, in all these cases, some small corrections have been incorporated, mostly on empirical grounds, to provide a faster rate of convergence of the asymptotic normality result: the statistical motivation, however, stems primarily from LST. We refer to Sen & Singer [21, Chapter 3] for details. There are, however, some impasses in the multiparameter case where the dependence pattern of the coordinate estimators may violate the applicability of the variance stabilizing transformation for their covariance terms. A classical example is the **multinomial** distribution where for each cell probability one may use the arcs in transformation to stabilize its asymptotic variance but then their covariances would still be dependent on the unknown cell probabilities.

Order Statistics and Empirical Distribution

Order statistics and empirical distribution functions are interrelated (one-to-one) in the classical univariate setup, and together they play a fundamental role in LST, particularly in *robust* as well as *nonparametric* inference problems. In biostatistics, in the active area of **survival analysis**, their role is overwhelming. The order statistics are neither independent nor identically distributed, even when the unordered collection relates to iid random variables. Hence LST pertaining to sums of independent random variables may not be directly applicable here. But with a reformulation in terms of indicator functions, most of these standard LST's can be adopted for order statistics, for sample quantiles, as well as extreme values. For example, for LLNs for sample quantiles, the Borel SLLN applies with little modification, while for the CLT, under the positivity and continuity of the density function at the population quantile, this approach via Bernoulli variables works out better, not only for a single quantile in a univariate setup but also for multiple quantiles in a general multivariate setup. More conveniently with adaptations from weak invariance principles for the empirical distributional processes, the related LST for order statistics and empirical distributions has emerged in a very elegant form. Interestingly enough, reversed martingales also play a very prominent role in this context. We refer to Sen & Singer [10, Chapter] for some details. In **robust** estimation, covering both parametric and nonparametric models, we often use *L-estimators*, which are linear combinations of functions of order statistics, and *M-estimators*, which are solutions of implicit equations involving suitable *score functions* and the empirical distribution function. Likewise, *R-estimators* of location and regression parameters are based on suitable

rank-order statistics which can be expressed as functionals of the empirical distributions. In this way we can conceive of a statistic $T_n = T(F_n)$ as a general functional of the empirical distribution function, F_n, and use LST pertaining to invariance principles for such processes, as outlined in (11). Naturally, the nature of $T(\cdot)$ will dictate the LST approach, and suitable differentiability properties of such functionals provide the necessary tools. A detailed treatment of this area of LST is beyond the scope of this article, but we refer the reader to Jurečková & Sen [10, Chapters 3 and 7], where an up-to-date and unified account has been provided. Hoeffding's [8] *U-statistics*, von Mises [23] statistical functionals and their (multisample) generalizations occupy a prominent place in nonparametrics, and they are abundant in biostatistics applications. Fortunately, they are statistical functionals and there are various martingale–reversed martingale representations for such statistics, discussed in detail in Sen [19], which pave the way for adoption of standard LST tools for the study of asymptotics for such statistics.

LST for MLE and BAN Estimators

In biostatistics, in actual applications, often, for easier interpretations and simpler statistical analysis, suitable parametric statistical models are postulated, and this approach naturally tilts the flavor to using optimal parametric statistical estimators (and tests) for the model parameters. *Maximum likelihood estimators* (MLE) are known to have various optimality properties, at least asymptotically, and in this depiction LST plays a basic role. In the case of the so-called **exponential family** *of densities*, granted *sufficiency* and *continuous differentiability* of the *likelihood function* (of the sample observations), the LST is generally based on the standard tools described earlier. However, for a density not belonging to such a class (namely the **Cauchy**, *Laplace*), the treatment of LST becomes more complex and involves additional regularity assumptions. Basically the approach is to explore a *quadratic approximation* for the likelihood ratio statistic in a suitable neighborhood of the true parameter point, and this in turn provides an asymptotic representation for the MLE in terms of the *likelihood score statistics* which yield the desired asymptotic normality, consistency, as well as asymptotic efficiency properties of the MLE $\hat{\theta}_n$ (in the regular case). Basically, if we denote the score statistics $(\partial/\partial\theta)\ \ln L_n(X_1, \ldots, X_n)$ by $U_n(\theta)$, and the *Fisher* **information** *per observation* by $I(\theta) = n^{-1}\mathrm{E}\{U_n^2(\theta)\}$, then under appropriate regularity conditions we have a first-order asymptotic representation:

$$\hat{\theta}_n - \theta = \{nI(\theta)\}^{-1}U_n(\theta) + o_p(n^{-1/2}), \qquad (13)$$

where $U_n(\theta)$ involves independent summands with zero mean and variance $I(\theta)$, and hence the CLT applies there. This leads to the following:

$$\sqrt{n}[\hat{\theta}_n - \theta] \xrightarrow{\mathcal{D}} \mathcal{N}(0, I^{-1}(\theta)), \qquad (14)$$

where by the classical Fréchet–**Cramér–Rao information** inequality, $[nI(\theta)]^{-1}$ is the lower bound to the mean square error of an unbiased estimator of θ; this yields the asymptotic efficiency (and asymptotic unbiasedness) of the MLE. A similar situation holds in the multiparameter case. The regularity conditions, classically known as the *Cramér conditions*, have gone through some evolution during the past 50 years. Although least stringent regularity conditions may be formulated as in LeCam [12], from a biostatistical applications point of view, a somewhat intermediate set of conditions hinging on the following compactness condition of the second derivative of the log density function provides a much simpler and more easily verifiable scenario. As $\delta(>0)$ approaches 0,

$$\mathrm{E}\left\{\sup\left(\left|\left(\frac{\partial^2}{\partial\theta^2}\right)\ln f(X, \theta + h) - \left(\frac{\partial^2}{\partial\theta^2}\right)\ln f(X, \theta)\right| : |h| < \delta\right\} \to 0; \quad (15)$$

Cramér's conditions involve the third derivative instead of this compactness of the second derivative. For the exponential family of densities, the above condition follows from the continuity of the parametric functions, and in many other cases it can be verified by standard manipulations; we refer to Sen & Singer [21, Chapter 5] for details.

It is quite pertinent here to make some comments about LST for the MLE. First, in a nonregular case, the MLE may not be asymptotically normal, and may even lose its asymptotic efficiency property. Secondly, the MLE may not be the only estimator that is asymptotically efficient in the above sense.

There are alternate estimators which may often share the asymptotic normality and efficiency properties along with the MLE; such estimators are termed best asymptotically normal **(BAN) estimators**. In the context of *categorical data models*, such BAN estimators based on the *minimum chi-square* and *modified minimum chi-square* criteria have been extensively studied in the literature (see for example, Agresti [1] and Sen & Singer [21] where detailed references are also cited); often, they are computationally less cumbersome than the MLE. Thirdly, the MLE are generally not robust to plausible model departures, and in that respect, alternative estimators, particularly *adaptive* estimators, may combine the BAN property with robustness to a greater extent. Finally, with the increase in the number of parameters, the performance characteristics of the MLE may deteriorate, and they may even become inconsistent or inefficient; the classical Neyman–Scott problem with a large number of nuisance parameters is a glaring example. Hence, modifications are often made to enhance the efficiency of the MLE. Among various such modifications, we refer to (*partial*) PMLE based on suitable partial likelihood functions [4], and quasi- and profile MLE based on **quasi-** and **profile likelihood** functions, which in a semiparametric context will be treated briefly later in the article.

LST and WLSE

Linear models (*see* **General Linear Model**) and *linear statistical inference* are household words in biostatistics. With the primary objective of interacting with researchers in biomedical and environmental sciences, in biostatistics it is customary to pose simple linear models that can be easily interpreted to collaborative scientists and can thereby be adapted to conventional linear statistical inference tools. Yet, in many cases the basic assumptions underlying such conventional procedures may not be tenable, and hence suitable modifications are often necessary to cope with the valid and efficient use of statistical inference tools. In biostatistics often we have nonnegative response variables where suitable transformations are used to induce linearity of the model to a greater extent, albeit at the cost of having nonnormal distributions (or vice versa). Therefore in linear statistical inference the basic assumption of normality of the errors may not be always tenable, and without this, the MLE based on the normality assumption may lose its appeal of validity and efficiency. The classical least squares estimators (LSE) and (large-sample) tests based on them occupy a focal point in this situation, and for such linear statistics, standard LST applies well. Weighted (WLSE) and generalized (GLSE) least squares estimators are the hybrids of the LSE that suit such nonstandard applications to a greater extent. The *heteroscedastic* linear model, $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$, $E(\mathbf{e}) = \mathbf{0}$, $V(\mathbf{e}) = \text{diag}\,(\sigma_1^2, \ldots, \sigma_n^2)$, provides a typical application of the WLSE when the σ_j^2 are not equal but known up to an unknown scalar constant (*see* **Scedasticity**). Thus, if we take $\sigma_j^2 = c_j\sigma^2$, $j \geq 1$, where the c_j are known constants, not all equal, while σ^2 is unknown, and if we denote the ith row of $\mathbf{X}$ by $\mathbf{x}_i'$, $i = 1, \ldots, n$, then we can consider the weighted sum of squares due to residuals:

$$\sum_{i=1}^{n} c_i^{-1}\{Y_i - \mathbf{x}_i'\boldsymbol{\beta}\}^2 \tag{16}$$

and minimize this with respect to $\boldsymbol{\beta}$. This leads to the WLSE of $\boldsymbol{\beta}$. This procedure extends readily to the multivariate case where the $\mathbf{Y}_i$ are p vectors for some $p \geq 1$, provided the covariance matrices of the associated error vectors satisfy a similar heteroscedastic condition. In that setup it is generally referred to as the (generalized) GLSE, and if such a matrix is diagonal, it is termed the WLSE. The GLSE or WLSE are linear estimators, and hence the LLNs, CLTs, and other standard asymptotics apply here under some extra mild conditions on the c_i. However, in biostatistical applications, such as in **loglinear models** for categorical data, the exact variance–covariances of the transformed response statistics are not known, and are estimated from the sample itself. That brings the relevance of LST into a broader perspective. Estimated variance–covariances are used in the above minimization problem, often requiring an iterative procedure to update these estimates along with the estimates of the main parameters of interest. The two-step (Aitken) estimator belongs to this class. For details of related LST we refer to Sen & Singer [21, Chapter 7]. Other related procedures for linear (as well as location) models include the so called **trimmed** *LSE* (TLSE) and *regression quantiles* (*see* **Quantile Regression**); these are discussed in detail in Jurečková & Sen [10], and the related LST runs parallel to the case of WLSE.

From a robustness prospect, however, such TSLE or regression quantiles are more appealing than the classical LSE.

LST of Statistical Tests

For testing a simple null hypothesis H_0 against a simple alternative H_1, the **Neyman–Pearson** *Fundamental Lemma* characterizes the *likelihood ratio test* (LRT) as most powerful, and this extends to *uniformly* **most powerful** (UMP) tests for *one-sided* alternatives. However, in a general multiparameter case with possibly **nuisance parameters**, one has typically composite null and composite alternative hypotheses. Here an exact (similar) test may not always exist, and even if one exists, it may be difficult to characterize one that will be uniformly best. For this reason, characterizations of optimality of statistical tests have often been made in an asymptotic framework, and there are competing tests sharing such properties in some way or other. Among such classes of tests, the following (parametric) deserve special mention: (i) likelihood ratio test, (ii) Rao's score test, and (iii) Wald's test; we refer to Rao [16] for a nice comparative account. The LRT is based on two sets of MLE, computed under H_0 and H_1, respectively, providing the ratio of the two maximized likelihood functions. LST pertaining to such LRTs, covering their null as well as alternative hypothesis distributions, is interlinked with the LST for the MLE, and hence they involve parallel regularity assumptions. Rao's score test, on the other hand, is based on the likelihood score statistics and their modifications, so that their asymptotics can be studied directly by using the standard LST tools. Computationally, Rao's score test is usually less cumbersome than the LRT. Wald's test is directly based on the MLE and the parametric constraints imposed by the hypotheses, and hence the general asymptotics for the MLE provide the access for parallel results for this type of tests. For local alternatives all the three types of tests share common asymptotic properties (*see* **Locally Most Powerful Tests**), although for nonlocal alternatives the LRT may have some advantages in a special way of interpretation [9]. Here also, on robustness considerations, such likelihood-based tests may not be very suitable. Moreover, for *restricted alternatives*, such as one-sided multiparameter hypotheses, such tests may have quite complicated forms and may even lose their asymptotic optimality properties to a greater extent (*see* **Isotonic Inference**). Roy's [17] **union–intersection principle** has added a lot of flexibility to this testing scenario, and their asymptotics have been studied under similar regularity assumptions. From robustness and nonparametric considerations, alternative tests based on L-, M- and R-estimators and suitable U-statistics have been extensively studied in the literature; we refer to Jurečková & Sen [10, Chapter 10] for a good account of these. In these developments, naturally, the asymptotics for such estimators play a basic role. In passing, we should also comment on **sequential** and *multistage* tests which have been considered in the literature. In this context, the classical Wald [25] *sequential probability ratio test* (SPRT) and its generalizations are all aimed at capturing some optimality properties in an interpretable manner. In the general multiparameter (composite hypothesis testing) case, again such optimality properties in an exact sense are hard to establish, and there is a good deal of asymptotics in the interpretation and derivation of such plausible optimality properties. The domain is by no means restricted to classical parametric setups, and nonparametric as well as robust procedures have been developed along the same vein. These procedures exploit the weak convergence and invariance principles introduced earlier and inherit the robustness aspects of the estimators or test statistics on which they are based. For details, we refer to Sen [19]. Group sequential procedures and related repeated significance testing (RST) procedures in **clinical trials** and biomedical studies have received considerable attention during the past two decades (*see* **Data and Safety Monitoring**). In this domain, too, the development of the methodology inherits a lot of asymptotics, and LST plays a vital role. In these developments, exact computations of boundary crossing probabilities, even for binomial or normal distributions, may become prohibitively laborious, if not impossible, and weak convergence of the encountered stochastic processes to suitable Gaussian functions (e.g. Brownian motion or Brownian bridge) provides the adaptability of standard results for Gaussian processes, and a general account of these developments is given in Sen [19, Chapters 9 and 10]. There are some other variations of such schemes, and we shall refer to some of them later in the article.

Semiparametric and Generalized Linear Models

Linear models are abundant in biostatistics, and yet in many applications the *normality* of the error components, their *homoscedasticity*, or even the basic *linearity of the model* may not be tenable. The classical MLE in the normal case agree with the *least squares estimators* (LSE), and for such linear estimators, standard LST can be adopted without many problems [21, Chapter 7]. Nevertheless, the optimality of the LSE may no longer be true when there are model departures. Therefore alternate models have been introduced to deemphasize the three basic assumptions underlying the normal theory MLE or the LSE, and in that way alternative classes of estimators have evolved.

Box–Cox Type Transformations

In biomedical applications the response variables are mostly nonnegative with (highly) positively skewed distributions. Although in such a case asymptotic normality of the LSE can be justified methodologically, in applications it may require an enormously large sample size. For this reason, logarithm, square-root, or cube-root transformations (*see* **Power Transformations**) are used to induce more symmetry in these response distributions so that moderate sample asymptotics can be justified to a greater extent. On the other hand, if the original model is closely linear, such nonlinear transformations can affect the regression relation considerably. Thus, one may require some **nonlinear regression** *models* to validate such transformations in practice. Either way, the LSE may not retain their normal-theory optimality, even asymptotically, although consistency and asymptotic normality would be retained under fairly general conditions [21, Chapter 7].

Generalized Linear Models

In **biological assays** and many survival analysis models, a response variable may be *quantal* (i.e. all or nothing) in nature (*see* **Quantal Response Models**). For such dichotomous (or even polychotomous) response variables, standard LSE may not work out well. *Logit* (**logistic regression**), *probit* and other models in bioassay are the precursors of **generalized linear models** (GLM). A more unified approach to such GLMs is outlined in McCullagh & Nelder [14]; their treatment addresses mostly the finite sample (or exact) methodology, and the findings are quite relevant to a general exponential family of densities. Nevertheless, in biostatistical applications such exact GLMs may not be tenable in all cases, and often (weighted) WLSE methodology is incorporated to facilitate suitable large-sample solutions (see [21, Chapter 7]). Such GLMs yield suitable *estimating equations* (EEs) (*see* **Estimating Functions**) which provide the estimators (mostly) as implicit solutions; this way the situation is similar to the case of the MLE. However, to cope with variations from most ideal situations, such EEs are replaced by suitable **generalized estimating equations** (GEE), and in their asymptotic treatment one needs additional regularity assumptions and manipulations too; see [21, Chapter 7]. Viewed from a practical perspective in a biostatistics context, such as in bioassays, dosimetric and mechanistic models in *toxicological* studies, the doses may be subject to *measurement errors* (*see* **Errors in Variables**) or latent effects, so that even if a simple GLM were pertinent to the basic dose–response pattern, such perturbations may cause great damage to their adoption without reservation. In this manner, one ignores the GLM methodology and has to take recourse in alternative LST where robustness and nonparametrics may dominate the scenario.

Nonparametric Linear Models

While assuming the linearity or additivity of the basic model, no specific distributional assumption is made on the response variables. An extensive literature relates to L-, M- and R- procedures in a variety of linear models, and an up-to-date treatment of the related asymptotics is contained in Jurečková & Sen [10]. Such procedures are generally more robust, consistent, and have asymptotic normality properties. Within this bigger class, one can also have suitable *adaptive* estimators which are asymptotically efficient and robust as well.

Semiparametric Models

The **Cox model** [3] or **proportional hazards model** (PHM) is a very simple illustration of a semiparametric model. In a simple two-sample model, if F and G are the respective distribution functions,

and we denote the corresponding survival functions by $\overline{F}(x) = 1 - F(x)$ and $\overline{G}(x) = 1 - G(x), x \in \mathbf{R}$, then in a Lehmann [13] model (*see* **Lehmann Alternatives**), we set $\overline{G}(x) = [\overline{F}(x)]^c$, for some $c > 0$. The null hypothesis of the homogeneity of F and G then reduces to $c = 1$. If the distribution functions are absolutely continuous with densities f and g, respectively, then we define equivalently the **hazard** *functions* $h_F(x)$ and $h_G(x)$ as $f(x)/\overline{F}(x)$ and $g(x)/\overline{G}(x)$, respectively. Then the Lehmann model can be put equivalently as $h_G(x) = ch_F(x)$, for all x, i.e. the two hazard functions are proportional. Motivated by this simple observation, Cox [3] considered a general situation where conditionally on a set of concomitant variates, say, $\mathbf{z}$, the hazard function for the primary variate, denoted by $h(y|\mathbf{z})$, is assumed to satisfy the following model:

$$h(y|z) = h_0(y) \exp\{\boldsymbol{\beta}'\mathbf{z}\}, \tag{17}$$

where the nonnegative $h_0(y)$, the baseline hazard rate, is independent of the concomitant variates and is of arbitrary form (i.e. nonparametric in nature), and the regression on the concomitant variates is of a specified parametric form. This also leads to the following:

$$\ln h(y|\mathbf{z}) = \ln h_0(y) + \boldsymbol{\beta}'\mathbf{z}; \tag{18}$$

in the literature this is known as the *hazard regression*. In either setup, note that $h_0(y)$ is a functional while β is a finite dimensional (regression) parameter. For this reason, this is referred to as a semiparametric model. Typically, in a general setup one may have a functional parameter space, and in that way the MLE or other conventional estimators may lose their efficacy, and often, consistency properties too. It may be possible in some cases to reparameterize in such a way that the parameters of interest constitute a finite-dimensional vector, while the nuisance parameter space may be very large. In this setup, often a conditional approach leads to a **partial likelihood** function whereby the finite-dimensional parameters of interest can be estimated consistently by the (partial) PMLE and with reasonable efficacy. Martingale methods play a basic role in the related asymptotics, and in this context, *counting processes* have evolved to be of prime interest in the study of general asymptotics; we refer to Andersen et al. [2] for a nice account of related asymptotics.

Nonparametric Regression and Smoothing Techniques

The past 20 years have witnessed a phenomenal growth of research literature in this domain, and these developments are of considerable use in biostatistics. Both the *kernel* and *nearest neighbor* methods are popular in this context (*see* **Density Estimation**). In terms of model flexibility, such models are the most desirable ones. However, in terms of precision of derived estimators, such a model may have the opposite flavor. Compared to the usual $\sqrt{n}$-consistency of the classical estimators in the parametric or semiparametric models, here one has n^{λ}-consistency for some positive $\lambda < 1/2$. Moreover, the asymptotic bias and asymptotic standard error may be of comparable order of magnitude, and hence *adaptive bandwidth* selection procedures are often prescribed to achieve asymptotic optimality within this class. Generally, much larger sample size is required for the adaptibility of asymptotics in the nonparametric regression case than in other models; we refer to Thompson & Tapia [22] for a treatise of **nonparametric regression** and function estimation problems.

LST for Time-sequential Schemes

This is one of the most important areas of current research activities in biostatistics, and LST has a fundamental role in this field. In clinical trials or medical investigations, generally one obtains data sets accumulating over time, so that statistical conclusions are drawn at the termination of the study. On the contrary, most of these studies relate to comparisons of different treatments or subgroups, and involve human beings. Thus, for ethical reasons, it is often advised that if there is any real difference in the response patterns for the various subgroups, then the trial should be able to detect it as early as possible, and the better treatment be made available to the entire set of subjects for their better prospects. On the other hand, lacking any real difference, the trial, if conducted up to the end of the planned duration, may contain valuable information for other scientific studies as well. This motivates the need for *interim analysis* in such clinical trials, and these may be made either on a periodic (namely fixed calendar-month/year interval) basis or on a monitoring basis resulting in the so called time-sequential procedures. The main points of difference between the classical

sequential and time-sequential procedures are the following:

1. The number of subjects to be included in the study is prefixed in a time-sequential scheme, but is itself a random variable in a sequential one. Thus the formulation of an average sample number (ASN) is quite different in the two schemes.
2. The observations in a sequential scheme are typically iid, whereas in a time-sequential one they typically represent the ordered failure points along with other concomitant variables, and hence the iid clause generally is not tenable.
3. The emphasis on type I and type II errors in a sequential test is somewhat different from that in a time-sequential one.
4. **Censoring** (of various types) is a typical phenomenon in a time-sequential scheme, and to a greater extent the statistical modeling and analysis depend on such deviations.
5. Typically, in view of point 4, nonparametrics and semiparametrics play a more dominant role in time-sequential schemes than in the classical sequential schemes, where the probability (or likelihood) ratio statistics have a more visible parametric flavor.

Nonparametric and semiparametric procedures for time-sequential schemes have been studied extensively in the literature during the past two decades. The basic foundation was laid down by the development of martingale methodology for various rank statistics [19], as well as for counting processes related to such stochastic events [2]. In this context the classical LST may not be directly applicable; nevertheless, they are quite pertinent and justifiable through the modifications based on adoption of martingale theory. We conclude this discussion with a brief introduction to LST pertinent to the **Kaplan–Meier** [11] *product-limit* (PL) estimator of the survival function under random censoring. In random censoring schemes the set of censoring variables $T_1, \ldots, T_n$ are iid according to a distribution function G, and T_i and X_i are stochastically independent for every i; note that the X_i are iid with a survival function $\overline{F}$. The observable random elements are $Z_i = \min(X_i, T_i)$ and $I_i = I(Z_i = X_i), i = 1, \ldots, n$. Define $N_n(t) = \sum_{i \le n} I(Z_i > t), t$ real, and set $\alpha_i(t) = I(Z_i \le t, I_i = 1), i \ge 1, t$ real, and let $\tau_n = \max\{Z_i : i \le n\}$. Then the PL-estimator of $\overline{F}$ is given by

$$\overline{P}_n(t) = \prod_{i=1}^{n} \left\{ \frac{N_n(Z_i)}{N_n(Z_i)+1} \right\}^{\alpha_i(t)} I(t \le \tau_n)$$

$$= \prod_{\{i: Z_i \le t\}} \left\{ \frac{n\overline{H}_n(Z_i)}{n\overline{H}_n(Z_i)+1} \right\}^{I_i}, \qquad (19)$$

where $\overline{H}_n(t) = n^{-1} N_n(t), t$ real. Thus, this estimator (a stochastic process) can be viewed as a functional of the counting process $\{N_n(t), t \text{ real}\}$, and hence LST relating to such counting processes can be imported here to study the asymptotic properties of the PL-estimator. Alternatively, suitable martingale characterizations of the PL-estimator can also be incorporated in the study of related LST. We refer to Andersen et al. [2] for details, albeit at a much higher level of mathematical sophistication. Generally test statistics or estimators in time-sequential schemes are functionals of the PL-estimator (in the censored case) or the original empirical survival function (in the uncensored case), having some sort of time-sequential flavor, and hence suitable stochastic processes relating to such functionals can be incorporated to formulate the *stopping* and *decision rules*. For example, in survival analysis, the *mean residual life* (MRL) is an important tool to measure the effectiveness of treatment protocols (*see* **Life Table**). Corresponding to the population measure

$$\mu(x) = \{\overline{F}(x)\}^{-1} \int_x^\infty \overline{F}(y)\, dy, \qquad (20)$$

the sample measure is defined by $\hat{\mu}_n = \{\overline{P}_n(x)\}^{-1} \int_x^\infty \overline{P}_n(y)\, dy$, and one may like to study the weak or strong consistency and asymptotic normality of $\hat{\mu}_n(x)$ for a given x, and more generally for a range of values of x. Weak convergence of such stochastic processes naturally provides the key to subsequent developments, and a systematic account of this type of LST in the context of clinical trials is given in Sen [20].

Latent Class Analysis

Latent class analysis is a discrete variable analog of **factor analysis**. Latent class analysis was originally developed [11, 16] to investigate the classification of subjects according to an underlying categorical trait, such as an attitude or psychological state, that is not directly observable. Membership in a particular class of the underlying variable is estimated from a subject's responses to a set of categorical items. Overviews of latent class modeling are given by Lazarsfeld & Henry [17], Andersen [3], Henry [13], McCutcheon [19], and Clogg [6].

Examples

The following example is a simplified version of the items considered by Rimer [20] in a study of methods for promoting smoking cessation. Subjects were asked to agree or disagree with a series of items, a subset of which are:

1. Smoking cigarettes relieves your tension.
2. Smoking helps you concentrate and do better work.
3. You are more relaxed and more pleasant when smoking.
4. You like the image of yourself as a smoker.

In principle, responses to these items reveal an underlying attitude towards smoking, perhaps reflecting a subject's "resistance" to quitting smoking. The trait of "resistance" could be dichotomized into the categories: not resistant or resistant. The observed items, 1–4 above, are called the manifest variables, while the underlying trait is the latent variable. In the example, both the manifest variables and the latent variable are dichotomous, but latent class models can be applied more generally, with manifest and latent variables that are ordinal or polytomous categorical variables (*see* **Ordered Categorical Data**; **Polytomous Data**).

A fundamental assumption in latent class modeling is "local independence", which states that given the latent class membership, the manifest variables are conditionally independent. A numerical example serves to illustrate this assumption. Consider a population that can be cross-classified according to the manifest variables, A and B, in the proportions displayed in Table 1. Suppose that the population can be divided into equal proportions by a binary latent variable, and that within levels of the latent variable the population can be cross-classified according to the manifest variables A and B as displayed in Table 2. The values in the cells of the table represent the conditional probabilities associated with A and B, given the level of Z. Despite the marginal association between variables A and B displayed in Table 1, the variables A and B are conditionally independent, given the level of the latent variable.

In practice, displays such as Table 2 cannot be constructed because the latent variable is unobservable directly. In many cases, however, the existence of a latent variable can be derived from theoretical models of attitudes, behavior, or psychology. Latent class analysis can be used to investigate the degree to which inferences about the unobservable latent trait can be derived from the manifest or observed

Table 1 Cross-classification of two manifest variables

		A		
		Agree	Disagree	Total
B	Agree	0.4	0.2	0.6
	Disagree	0.2	0.2	0.4
	Total	0.6	0.4	1

Table 2 Illustration of local independence of manifest variables (A and B) given the latent variable, Z

$Z = 1$

		B		
		Agree	Disagree	Total
A	Agree	0.64	0.16	0.80
	Disagree	0.16	0.04	0.20
	Total	0.80	0.20	1

$Z = 0$

		B		
		Agree	Disagree	Total
A	Agree	0.16	0.24	0.40
	Disagree	0.24	0.36	0.60
	Total	0.40	0.60	1

variables. The next section provides a mathematical formulation of latent class analysis.

Mathematical Model

Suppose that each of n subjects is observed on K categorical manifest variables, $\mathbf{Y} = (Y_1, \ldots, Y_K)$, with each variable taking on one of C categories. The cells of the K-way cross-classification table are indexed by $\mathbf{y} = (y_1, \ldots, y_k)$, with $n_{\mathbf{y}}$ denoting the observed number of subjects and $\pi_{\mathbf{y}}$ denoting the probability associated with response profile $\mathbf{y}$. The cell frequencies are assumed to have a **multinomial distribution** with $\mathrm{E}(n_{\mathbf{y}}) = n\pi_{\mathbf{y}}$ and $\Sigma_{\mathbf{y}}\pi_{\mathbf{y}} = 1$. The latent variable, Z, is assumed to take on one of T classes, with θ_z denoting the proportion of the population in class $z, z = 1, \ldots, T, \sum_{z=1}^{T} \theta_z = 1$. In the segment of the population in latent class $Z = z$, the proportion of the population classified into the cell indexed by $\mathbf{y}$ is denoted $\pi_{\mathbf{y}|t} = \Pr(\mathbf{Y} = \mathbf{y}|T = t)$. The assumption of local independence states that given the latent class membership, the manifest variables are conditionally independent:

$$\Pr[\mathbf{Y} = \mathbf{y}|Z = z] = \prod_{i=1}^{K} \Pr[Y_i = y_i|Z = z]. \quad (1)$$

Estimates of the conditional response probabilities, $\Pr[Y_i = y_i|Z = z], i = 1, \ldots, K$, and the latent class proportions, $\theta_z, z = 1, \ldots, T$, are derived from the observed counts, $n_{\mathbf{y}}$, through the equations $\mathrm{E}(n_{\mathbf{y}}) = n\pi_{\mathbf{y}}$ and

$$\pi_{\mathbf{y}} = \sum_{z=1}^{T} \prod_{i=1}^{K} \Pr[Y_i = y_i|Z = z]\theta_z. \quad (2)$$

The latent class model can also be viewed as a **loglinear model** [10, 12] for the expected counts in a $(K + 1)$-way cross-classification of the K manifest variables $(Y_1, Y_2, \ldots, Y_K)$ and the latent variable, Z. Denoting the expected counts by $m_{y,z}$, and with the usual constraints on the parameters of the loglinear model [1], the loglinear model

$$\ln m_{y,z} = \mu + \lambda_z^Z + \lambda_{y_1}^{Y_1} + \cdots + \lambda_{y_K}^{Y_K} + \lambda_{y_1,z}^{Y_1 Z} + \cdots + \lambda_{y_K,z}^{Y_K Z} \quad (3)$$

expresses conditional independence of the manifest variables, $\mathbf{Y}$, given the latent class. Although the cell frequencies in the $(K + 1)$-way classification are not observed, estimates in the loglinear model (3), are derived from the observed frequencies in the K-way cross-classification of the manifest variables, n_y.

Maximum likelihood is the most widely used method for estimating the parameters of the latent class model. Goodman [10] proposed an iterative algorithm for obtaining maximum likelihood estimates; the algorithm is an example of a general procedure now known as the **EM algorithm** [8]. Once the maximum likelihood estimates, $\hat{m}_{y,z}$, have been computed, the goodness-of-fit of the latent class model can be tested. The most commonly used statistics for testing goodness-of-fit are the generalized **likelihood ratio test** statistic,

$$G^2 = 2\sum_{\mathbf{y}} n_y \ln\left(\frac{n_y}{\hat{m}_y}\right),$$

and the Pearson X^2 statistic,

$$X^2 = \sum_{y} \frac{(n_y - \hat{m}_y)^2}{\hat{m}_y},$$

where $\hat{m}_y = \Sigma_z \hat{m}_{y,z}$ (*see* **Chi-square Tests**). Under the null hypothesis that the latent class model fits, the statistics are asymptotically distributed as a χ^2 random variable, with degrees of freedom equal to the number of cells in the table cross-classifying the manifest variables, minus the number of parameters being estimated in (3). With K manifest variables, each representing C categories, and with one latent trait having T classes, the degrees of freedom for testing the goodness-of-fit of the model equals $C^K - T[1 + K(C - 1)]$. A comparison of these statistics is given in [14].

Despite the similarity in form to standard loglinear model analysis, fitting a latent class model involves the additional issue of the **identifiability** of parameters. For example, with K binary manifest variables $(C = 2)$ and T latent classes, for $T > 2^K/(1 + K)$, the number of parameters in the model exceeds the number of "observations", the number of cells in the cross-classification of the manifest variables. Having more observations than parameters is a necessary condition for all parameters to be identifiable, but it is not sufficient. The identifiability of parameters is discussed in [10] and [18].

Extensions and Other Applications

Clogg & Goodman [7] extended the single population latent class analysis to simultaneous modeling of latent classes across several populations. Latent class methods specific to ordinal manifest variables were considered by Clogg [5]. In addition to its original applications in the study of attitudes, latent class modeling has been applied to the study of inter-rater reliability [2, 23] (*see* **Observer Reliability and Agreement**), survey response errors [4], incomplete data [9, 24], chronic disease epidemiology [15], medical diagnosis [21], and repeated measurements (*see* **Longitudinal Data Analysis, Overview**) [22].

MARK R. CONAWAY

Latent Period

Latency or *latent period* is defined as the time interval between the initiation time, say t_0, of a disease process and the time, say t_1, of the first occurrence of a specifically defined manifestation of the disease. For infectious diseases (*see* **Communicable Diseases**), t_0 is the time of infection by the infectious agent and the manifestation may either be a specific serologic marker, or a laboratory abnormality, or a symptom [31]. If the manifestation is the occurrence of a symptom, then the latent period is the same as the **incubation period**, which is the term usually used by statisticians for infectious diseases (e.g. Alcabes [1]). In the case of cancer epidemiology, t_0 is the time of initial exposure to a carcinogen (cancer initiation) and t_1 the time of the first clinical occurrence of the disease [3, 14]. For example, the initial exposure may be the time of exposure to **radiation** or the time of exposure to a chemical carcinogen, and the first clinical occurrence may be detected by a biological marker for cancer or by clinical evidence of a tumor [15]. For A-bomb survivors such as those from Hiroshima or Nagasaki, Japan, t_0 is thus the actual time of explosion of the bomb whereas t_1 is the time the disease first appears.

Other Definitions

For infectious diseases, Bailey [5] and Anderson & May [2] have used "the time to first become infectious" as the specified manifestation so that they define the latent period of the disease as the time interval from the point of infection to the beginning of the state of infectiousness of the infected host. This latter definition is not necessarily synchronous with the incubation period except in cases (e.g. yellow fever) in which both the average intervals from the point of infection to the infectiousness of the host and from the point of infection to the onset of a symptom are very short. For many infectious diseases caused by parasites, a distinction can usually be made between infection according to some laboratory criteria and symptoms of illness [2]. For infectious diseases caused by viruses and bacteria, however, such a distinction may be difficult; furthermore, for some viral diseases such as smallpox and yellow fever, an infected individual may be immune to the disease so that illness may never occur in some individuals [2, 30].

For exposure to a carcinogen, distinctions have been made between the biologic latent period and the epidemiologic latent period. For exposure to radiation, such as in A-bomb survivors, the biologic latent period is defined in [39] as the interval during which an elevation of the risk of the disease occurs between the exposed and nonexposed individuals (see Example 3 in the next section for illustration), whereas the epidemiologic latent period is defined in [39] as the interval between the first exposure and the time of death from the cause of interest. For exposure to a chemical carcinogen, the beginning of the biologic latent period is the time that a DNA adduct of the carcinogen first appears because carcinogenesis starts with the interaction between the DNA adduct of the carcinogen and the genome of the host [18, 37]. The endpoint of the biologic latent period is the time of first occurrence of a cancer tumor cell; see [36]. For the epidemiologic latent period, the initial time is the time of first exposure to the carcinogen, whereas the endpoint is the time of first appearance of a detectable cancer tumor. It is shown in [18] that it is not the exposed dose but the dose of the DNA adduct of the agents that gives a linear **dose–response** curve for small doses; furthermore, detectable cancer tumors arise by clonal expansion from cancer tumor cells [45]. Thus, in most cases there are significant differences between the biologic latent period and the epidemiologic latent period.

Some Examples

The latent period of a disease may be very short and fairly constant. In some chronic infectious diseases, and in cancer, the latent period may be very long and varies greatly among individuals, in which case one should treat it as a **random variable** and work with the probability distribution of this variable.

Example 1. Yellow Fever

Yellow fever is an infectious disease caused by a yellow fever virus which is the prototype of the flavivirus genus (family Flaviviridae). It is an acute, mosquito-borne viral infection that occurs in epidemic and endemic form in tropical America and

Africa. Clinical symptoms of this disease include fever, headache, malaise, and lassitude which persist for 2 to 4 days and occur in 10%–20% of the infected individuals. For this disease, the incubation period is very short (3 to 6 days) and can be considered as fairly constant [30].

Example 2. Malaria

Malaria is an infectious disease caused by parasites called Plasmodia. This disease occurs mainly in tropical areas and is transmitted to humans by the bite of malaria-infected female Anopheles mosquitoes. The four major *Plasmodium* species are *P. falciparum* (Africa, Asia, Oceania, Central America, and South America), *P. vivax* (Asia, Oceania, Central America, and South America), *P. ovale* (Africa and Oceania), and *P. malariae* (Africa and South America). The incubation periods for these four *Plasmodium* species are 8–27 days (average 12 days), 8–27 days (average 14 days), 9–17 days (average 15 days), and 16–28 days, respectively [33]. For this disease the human host becomes infectious with the accumulation of gametocytes in the blood. Hence the interval from infection to infectiousness is the time from initial infection to the first appearance of gametocytes in the blood. (This is the definition of latent period used by Anderson & May [2].) For the above four species, this period is given by 9–10 days, 9–10 days, 10–14 days, and 15–16 days, respectively [2].

Example 3. Leukemia in A-Bomb Survivors

Land & Norman [24] have studied the biologic latent periods of radiogenic cancers occurring among Japanese A-bomb survivors in Hiroshima and Nagasaki, Japan. The leukemias (acute leukemia and chronic granulocytic leukemia) are particularly interesting since the cumulative distributions of those who have been exposed to an A-bomb with kerma doses of 100 rads or more lie on the far left of those who have not been exposed to an A-bomb or those who have been exposed to an A-bomb but with the kerma doses of 0–9 rads. The magnitude of the elevation of the cumulative probability of leukemia over the biologic latent period depends on the age of the survivor at the time of exposure, with the age group 10–19 years at exposure having the largest elevation followed by the age groups 20–34 and 35–49 years at exposure. The biologic latent periods for leukemia are intervals from five years since exposure (time of explosion of the bomb) to an endpoint, say t_1, which is less than 29 years since exposure and which depends on the age of the survivor at the time of exposure. For the age groups 10–19 and 20–34 years at exposure, t_1 is 29 years since exposure, but for age groups 0–9 and 35–49 years at exposure, t_1 is approximately 25 years since exposure.

Example 4. Incubation Period of AIDS

The infectious chronic disease **AIDS** is caused by a retrovirus called HIV (human immunodeficiency virus). This is an endemic fatal infectious disease without cure at the present time. (For a summary of basic facts about AIDS, see [34].) Following infection by HIV, it usually takes several months to develop HIV antibodies in the blood. (For the time interval from infection to the development of antibodies, the estimate by Horsburgh et al. [20] is 3.5 months.) According to the 1993 surveillance definition of AIDS used by the US **Centers for Disease Control** and Prevention (CDC), the incubation period is the time interval between infection by HIV and the first time that the total CD4 T-cell counts falls below 200/mm^3 or the first time that the absolute percentage of CD4 T-cells falls below 14% or the first time that one of the 25 symptoms listed in [12] appears. This period is usually several years and depends on age [35], treatment with antiviral drugs [29], the presence of mutations of the gene CCR5 [16] (long or short AIDS survivors), and possibly other **covariates**. For untreated subjects aged 20–50 years at infection, the average incubation period is about 10 years. Note, however, that the AIDS definition used by CDC has been broadened three times, first in June 1985, next in July 1987, and then in December 1992. Hence, the incubation times measured before 1993 tend to be longer than the incubation times based on the 1993 AIDS definition.

The Latent Period of Infectious Diseases

For some infectious diseases such as yellow fever and malaria, the incubation period is relatively short and can be regarded as approximately constant. However, for some chronic infectious diseases such as AIDS,

the incubation period is long and variable. In this latter case it makes more sense to treat the incubation period as a random variable, rather than as a fixed constant "latency", and to describe the process in terms of the probability distribution of incubation times. For example, the probability distribution of the incubation period of AIDS has been studied extensively, as summarized in Brookmeyer & Gail [9], Becker & Motika [6], and Tan et al. [38]. This probability distribution has been estimated by both parametric and **nonparametric methods**. However, all the estimates in the literature are based on the 1987 definition of AIDS: estimates of the HIV incubation period based on data and the 1993 AIDS definition have yet to be published.

The Latent Period of Cancer

Some researchers have used the concept of latency and average latent period to describe the interval between exposure to the A-bomb and the subsequent cancer onset in Hiroshima and Nagasaki, Japan [24, 7]. For example, leukemias tend to arise about five years following exposure to nuclear radiation [7]. However, Brookmeyer [8] pointed out that such estimates might be misleading because of censoring (*see* **Censored Data**) and competing causes (*see* **Competing Risks**) of death.

Many investigators prefer to consider the distribution of time to cancer onset, especially investigators who study cancer onset in animals exposed to low doses of a carcinogen [15]. In such cases the latent period is usually very long, and the expected time-to-tumor may exceed vastly the normal life span of the animal. In such circumstances, information on the mean latent period is not sufficient to determine the probability of developing a tumor before dying of some other causes. Moreover, different distributions may have the same **mean** time to tumor in the high dose range but give vastly different risk estimates when extrapolated to low doses [17, 43]. Thus, some scientists have avoided the use of mean latency for risk assessment based on low dose extrapolation (*see* **Extrapolation, Low Dose**) [15]; rather, they describe carcinogens as altering the probability distribution of time to detectable cancer. This probability distribution depends on the mechanism of carcinogenesis and is influenced by many factors. In particular, the incidence of cancer is altered by changing the dose of the carcinogen to which the individual is exposed.

Armitage & Doll [4] developed the first stochastic model of carcinogenesis for the time-to-tumor distribution. This model is referred to as the multistage model (*see* **Multistage Carcinogenesis Models**) as described in reviews by Whittemore & Keller [42] and Kalbfleisch et al. [21]. The Armitage–Doll multistage model (*see* **Dose–Response Models in Risk Analysis**) assumes that a tumor develops from a normal stem cell by k ($k \geq 2$) consecutive and irreversible genetic changes. These assumptions and the assumptions of low transition rates imply a **Weibull** model for the cancer **incidence rate**, $\lambda(t)$, and the following dose–response relationship between cancer incidence rate and the dose, d, of carcinogen:

$$\lambda(t) \propto \eta(d) \times t^{k-1}, \tag{1}$$

where $\eta(d)$ is a function of the dose d and is independent of time t.

The Armitage–Doll multistage model has been widely used by statisticians to assess how exposure to carcinogens alters the cancer incidence rates and the distributions of time-to-tumor. Breslow & Day [7] and others [13, 10] applied this model to study the effects of cigarette smoking on lung cancer risk, of asbestos exposure on risk of lung cancer and mesothelioma, and of radiation exposure on risks of leukemia, breast cancer, and bone cancer. While it is widely accepted that cancer results from a multistage process, recent results from molecular biology and molecular genetics have raised questions about some details of the assumptions in the Armitage–Doll multistage model (see [36] and [19]).

For risk assessment of carcinogens by low dose extrapolation, it has been documented that the same observable data can be fitted equally well by different models that yield very different estimates of risk at low doses [41]. Such extrapolation should be based on biologically plausible models, preferably models suggested by data. Thorslund et al. [40] and Moolgavkar et al. [32] proposed the MVK two-stage model (see [36]) for risk assessment. In this model, the first stage is a **Poisson process** describing how normal stem cells are changed into initiated cells by mutation (initiation); in the second stage the model incorporates stochastic birth and death (*see* **Stochastic Processes**) for proliferation of initiated cells (promotion), that change into malignant tumor cells by another mutation. Dose–response curves based on the MVK two-stage model have been developed by Chen & Moini [11], and by Krewski &

Murdoch [23]. They have used these dose–response curves to assess how a carcinogen alters cancer incidence through its effects on initiating mutations or on the rate of proliferation of initiated cells. If the carcinogen is a pure initiator, then the dose–response curve for cancer incidence can be factorized as a product of a function of dose and a function of time and age; in these cases, the pattern of dose–response curves of the MVK model is quite similar to that of the Armitage–Doll multistage model. However, if the carcinogen is a promoter or a complete carcinogen, then the dose–response curves of the MVK model cannot be factorized, and they differ qualitatively from the Armitage–Doll model.

The MVK two-stage model, and extensions of it, together with many other biologically supported models have been analyzed in Tan [36] and in Yakovlev & Tsodikov [44]. Some extensions and modifications have recently been developed by Little and his colleagues [25–28]. (Little [25, 26] has called the multievent model in Tan [36] the generalized MVK model.) By merging initiation and promotion, alternate modeling approaches have been proposed by Klebanov et al. [22] for radiation carcinogenesis.

Latin Square Designs

A Latin square design is a **balanced incomplete block design** for comparing t treatments in which heterogeneity is eliminated in two ways. It is an **incomplete block design** insofar as not every combination of row, column, and treatment is assigned to an experimental unit. It is a *balanced* design insofar as the number of treatments is equal in each row and in each column.

Example 1

Suppose a toxicologist wants to compare a series of t treatments. Suppose the experiments are to be carried out in r different laboratories $L_1, \ldots, L_r$ on c different animal species $S_1, \ldots, S_c$. The experimenter wants to take into account the heterogeneity coming from both these factors. The simplest experimental design would be a **randomized complete blocks design** in which every treatment is assigned to every combination of both heterogeneity factors. In this whole experiment we would have rct experimental units corresponding to rc blocks and t treatments. This number of experimental units can become enormous, even for moderate r, c, and t. If $r = c = t$, this design can be replaced by a Latin Square Design (LSD) in which each treatment, traditionally denoted with Latin letters, occurs exactly once in each row and once in each column, so that the number of experimental units is only t^2.

In other settings a complete block design is physically impossible, as in Examples 2 and 3, and Latin square designs are a natural alternative.

Example 2

In a field experiment where the experimental field exhibits a gradient in two orthogonal directions, each spot can only be assigned to a single treatment.

Example 3

In a **clinical trial** the **blocking** factors may be the individual subject and successive time periods. If the objective of the trial is to compare treatments, then only one treatment can be given to a given subject at a given time. This design is called a **crossover** trial (see [5]).

Construction of the Design

If we want to use an LSD, we have first to choose a Latin square. A Latin square of order t is an arrangement of t letters or numbers (representing the treatments) in a square of t columns and t rows (representing the two heterogeneity factors), such that each letter appears once and only once in each column and each row (whence the balance of the design). Latin squares of any order exist, as can be seen from Figure 1.

The enumeration of all the Latin squares of any order t becomes tedious as t increases. However, permuting rows, columns or treatments of a Latin square gives another Latin square. Particular Latin squares are those for which the first column and the first row are ordered (A, B, C, ...); these are called *standard* Latin squares. By permuting rows and columns of a standard Latin square we can obtain $t!(t-1)!$ different Latin squares.

Thus, sampling a Latin square consists in:

1. sampling a standard Latin square with equiprobability among all the standard Latin squares;
2. randomly permuting the t rows, the $t-1$ first columns and the t treatments.

For more details of this procedure and tables of standard Latin squares, see [2]; for tables of random permutations, see [1].

The **randomization** procedure of a Latin square is equivalent to the observation of the t^3 random variables δ_{ijk}, where $\delta_{ijk} = 1$ if the treatment k is affected in row i and column j, and 0 otherwise. These random variables have the following

1	2	3	...	$t-1$	t
2	3	4	...	t	1
3	4	5	...	1	2
...					...
t	1	2	...		$t-1$

Figure 1 Example of Latin square of order t

properties:

$$\sum_i \delta_{ijk} = \sum_j \delta_{ijk} = \sum_k \delta_{ijk} = 1. \tag{1}$$

$$\mathrm{E}(\delta_{ijk}) = \frac{1}{t}, \quad \text{for all } i, j, k. \tag{2}$$

$$\mathrm{E}(\delta_{ijk}\delta_{i'j'k'}) = \begin{cases} 1/t, & \text{if } i = i' \text{ and } j = j' \text{ and } k = k', \\ 0, & \text{if either } i \neq i' \text{ or } j \neq j' \text{ or } k \neq k', \\ 1/t(t-1), & \text{if either } i = i' \text{ or } j = j' \text{ or } k = k', \\ 1/t(t-1)^2(t-2), & \text{if } i \neq i' \text{ and } j \neq j' \text{ and } k \neq k'. \end{cases} \tag{3}$$

Estimation and Analysis of Variance

Let Y_{ijk} be the response that would be observed if the kth treatment were assigned on the ith row and the jth column. Under unit-treatment additivity (in the terminology of Hinkelmann & Kempthorne [3]), i.e. under the hypothesis that there are no **interactions** between the treatments on one side and rows or columns on the other side, we can write:

$$Y_{ijk} = \mu + \alpha_i^{\mathrm{C}} + \alpha_j^{\mathrm{R}} + \alpha_k^{\mathrm{T}} + \alpha_{ij}^{\mathrm{RC}} + \varepsilon_{ijk}, \tag{4}$$

where superscripts C, R, and T indicate columns, rows, and treatments respectively. The technical errors ε_{ijk} are assumed independent with zero **mean** and equal **variance** σ_ε^2, and are independent of the randomization procedure. We can also write the usual side conditions which imply no loss of generality:

$$\alpha_\cdot^{\mathrm{C}} = \alpha_\cdot^{\mathrm{R}} = \alpha_\cdot^{\mathrm{T}} = \alpha_{i\cdot}^{\mathrm{RC}} = \alpha_{\cdot j}^{\mathrm{RC}} = 0, \quad \text{for all } i, j. \tag{5}$$

We note that within an LSD not all Y_{ijk} are actually measured but only those for which the **random variable** δ_{ijk} is equal to 1.

The observed means can thus be written:

$$Y_{i\cdot\cdot} = \frac{1}{t}\sum_j \sum_k \delta_{ijk} Y_{ijk},$$

$$Y_{\cdot j\cdot} = \frac{1}{t}\sum_i \sum_k \delta_{ijk} Y_{ijk},$$

$$Y_{\cdot\cdot k} = \frac{1}{t}\sum_i \sum_j \delta_{ijk} Y_{ijk},$$

$$Y_{\cdots} = \frac{1}{t^2}\sum_{ijk} \delta_{ijk} Y_{ijk}. \tag{6}$$

If we substitute Y_{ijk} in (6) by its expression from (4), then, after applying the side conditions (5) and the relations (1), we obtain:

$$\begin{aligned} Y_{i\cdot\cdot} &= \mu + \alpha_i^{\mathrm{R}} + \frac{1}{t}\sum_j \sum_k \delta_{ijk}\varepsilon_{ijk}, \\ Y_{\cdot j\cdot} &= \mu + \alpha_j^{\mathrm{C}} + \frac{1}{t}\sum_i \sum_k \delta_{ijk}\varepsilon_{ijk}, \\ Y_{\cdot\cdot k} &= \mu + \alpha_k^{\mathrm{T}} + \frac{1}{t}\sum_i \sum_j \delta_{ijk}\varepsilon_{ijk}, \\ Y_{\cdots} &= \mu + \frac{1}{t^2}\sum_i \sum_j \sum_k \delta_{ijk}\varepsilon_{ijk}. \end{aligned} \tag{7}$$

The total sum of squares $SS_{\mathrm{tot}} = \sum_{ijk} \delta_{ijk}(\varepsilon_{ijk})^2$ can be decomposed as follows:

$$SS_{\mathrm{tot}} = t\sum_i (Y_{i\cdot\cdot} - Y_{\cdots})^2 + t\sum_j (Y_{\cdot j\cdot} - Y_{\cdots})^2 + t\sum_k (Y_{\cdot\cdot k} - Y_{\cdots})^2 + SS_{\mathrm{e}}. \tag{8}$$

The **expectations** of these sums of squares depend on the **moments** of the δ_{ijk} given in (2) and (3). Somewhat tedious computations yield the **analysis of variance** table given in Table 1 where:

$$\sigma_{\mathrm{R}}^2 = \frac{1}{t-1}\sum_i (\alpha_i^{\mathrm{R}})^2,$$

$$\sigma_{\mathrm{C}}^2 = \frac{1}{t-1}\sum_j (\alpha_j^{\mathrm{C}})^2,$$

$$\sigma_{\mathrm{T}}^2 = \frac{1}{t-1}\sum_k (\alpha_k^{\mathrm{T}})^2, \tag{9}$$

and

$$\sigma_{\mathrm{RC}}^2 = \frac{1}{(t-1)^2}\sum_i \sum_j (\alpha_{ij}^{\mathrm{RC}})^2.$$

To test the hypothesis (*see* **Hypothesis Testing**) of equality of the treatment effects (i.e. $\sigma_{\mathrm{T}}^2 = 0$), we are

Table 1 Analysis of variance of an LSD

Source	df	SS	E(MS)
Rows	$t-1$	$t\sum_i (Y_{i\cdot\cdot} - Y_{\cdots})^2$	$\mathrm{E}(MS_{\mathrm{T}}) = \sigma_\varepsilon^2 + t\sigma_{\mathrm{R}}^2$
Columns	$t-1$	$t\sum_j (Y_{\cdot j\cdot} - Y_{\cdots})^2$	$\mathrm{E}(MS_{\mathrm{C}}) = \sigma_\varepsilon^2 + t\sigma_{\mathrm{C}}^2$
Treatments	$t-1$	$t\sum_k (Y_{\cdot\cdot k} - Y_{\cdots})^2$	$\mathrm{E}(MS_{\mathrm{T}}) = \sigma_\varepsilon^2 + \sigma_{\mathrm{RC}}^2 + t\sigma_{\mathrm{T}}^2$
Error	t^2-3t+2	by subtraction $= SS_{\mathrm{e}}$	$\mathrm{E}(MS_{\mathrm{e}}) = \sigma_\varepsilon^2 + \sigma_{\mathrm{RC}}^2$
Total	t^2-1	$\sum_{ijk} \delta_{ijk}(Y_{ijk} - Y_{\cdots})^2$	

led by Table 1 to consider the ratio

$$F = \frac{MS_{\mathrm{T}}}{MS_{\mathrm{e}}}. \tag{10}$$

This statistic can be referred to $F(t-1, t^2-3t+2)$ under normal theory (*see* ***F*** **Distributions**). Nevertheless, Welch [6] investigates its distribution under the randomization process for LSD described above and Hinkelmann & Kempthorne [3], reviewing this work, "assume that normal theory gives satisfactory approximations to corresponding randomization tests".

Another immediate consequence of Table 1 is that there do not exist any legitimate tests for row and column effects unless we suppose absence of interaction between them ($\sigma_{\mathrm{RC}}^2 = 0$).

Other Topics

Departure from Additivity

The effects of row × treatment, column × treatment, row × column × treatment can severely affect the results obtained above, as discussed in detail by Scheffé [4]. Nevertheless, Wilk & Kempthorne [7] show that the usual F test is still appropriate, even in the presence of interactions, if the t rows have been sampled from a population of R rows, the t columns have been sampled from a population of C columns, the t treatments have been sampled from a population of T treatments with $R >> t, C >> t$, and $T >> t$ (*see* **Random Effects**).

Limitations of the LSD and Some Extensions

It can be argued that the LSD is limited from a practical point of view. Some extensions have been proposed for the following problems (see [3]):

1. the numbers of rows, columns and treatments have to be the same (**Youden squares** and Latin rectangles are some alternatives);
2. for small values of t the number of **degrees of freedom** for error is insufficient (this can be mended by replicating the LSDs);
3. the number of heterogeneity factors is restricted to two (**Graeco–Latin squares** deal with three or more heterogeneity factors).

Lattice Designs

The term *lattice design* encompasses two different types of equireplicate designs. The first type, *square lattice designs* and their extensions, are resolvable (0, 1) incomplete block designs. The second type, *lattice squares* and their extensions, are nested *row-column designs* (*see* **Youden Squares and Row–Column Designs**) for which each block is a complete replicate.

An **incomplete block design** for t treatment each replicated r times with all blocks of size $k < t$ is *resolvable* if the b blocks can be grouped into $r = bk/t$ sets of $s = t/k$ blocks, such that each set is a complete replicate. A (0, 1)-*design* has each pairwise treatment concurrence equal to 0 or 1. A square lattice design, introduced by **F. Yates** in 1936, has $t = k^2$ and $s = k$. It can be constructed by writing the numbers 1 to t in a $k \times k$ array. The *simple square lattice design* has $r = 2$. The k blocks of the first replicate are the rows of the array. The second replicate uses the columns. The *triple square lattice design* has $r = 3$. The third replicate is found by superimposing a **Latin square** of order k on the array, and using the Latin square symbols to define the blocks.

If $k \neq 6$, then the Greek letters of a **Graeco–Latin square** can be used to get a fourth replicate (*quadruple square lattice design*). If $k \neq 3$, 6, 10, then at least five replicates can be obtained using *mutually* **orthogonal** *Latin squares* (MOLS). If k is a prime power, a complete set of $k - 1$ MOLS exist, and up to $k + 1$ replicates are possible. If, in this case, $k + 1$ replicates are used, then the variance-balanced design, called a *balanced square lattice*, is a symmetric **balanced incomplete block design** BIBD $[k^2, k(k + 1), k]$.

For example, using the three MOLS of order 4:

1	2	3	4
2	1	4	3
3	4	1	2
4	3	2	1

1	2	3	4
3	4	1	2
4	3	2	1
2	1	4	3

1	2	3	4
4	3	2	1
2	1	4	3
3	4	1	2

on the array

1	2	3	4
5	6	7	8
9	10	11	12
13	14	15	16

gives the balanced square lattice design (parentheses denote blocks, each replicate is a row):

(1 2 3 4),	(5 6 7 8),	(9 10 11 12),	(13 14 15 16);
(1 5 9 13),	(2 6 10 14),	(3 7 11 15),	(4 8 12 16);
(1 6 11 16),	(2 5 12 15),	(3 8 9 14),	(4 7 10 13);
(1 7 12 14),	(2 8 11 13),	(3 5 10 16),	(4 6 9 15);
(1 8 10 15),	(2 7 9 16),	(3 6 12 13),	(4 5 11 14).

For $r < 5$, the first r replicates (say) can be used.

The need for t to be a perfect square (and not 36 if more than three replicates are required) can be a severe restriction. In some experiments, such as variety trials which often use a large number of varieties and few replicates (two or three), it may be possible to add a few extra treatments, or even remove some, to get $t = k^2$. Various extensions have been proposed to allow some other values of t. *Cubic lattices* have $t = k^3$ and $s = k^2$ in a similar way using a cubic array and orthogonal Latin cubes; and m-dimensional lattices with $t = k^m$ for $m > 3$ are possible if k is prime. A *rectangular lattice* with $t = k(k + 1)$ and $s = k + 1$ can be constructed in a similar way to the square lattices using the numbers 1 to t in a $(k + 1) \times (k + 1)$ array with the leading diagonal omitted. For $r > 2$ the Latin squares used must have each symbol occurring on the main diagonal. The idea for constructing the rectangular lattice can be used for any $s > k + 1$ by, if possible, omitting further (wrap-around) diagonals. The α-*designs* are an extension to resolvable designs with any s – see John [3, Section 4.8] and John & Williams [4, Sections 4.4 and 4.5]. Optimal two-replicate resolvable designs are discussed by John & Williams [4, Section 4.7].

Although specific formulas can be given, as in John [3, Section 3.4], John & Williams [4, Sections 4.2 and 4.3], the usual *intrablock* analysis for the model with fixed treatment and block effects – see John [3, Sections 1.3–1.5] and John & Williams [4, Sections 1.4–1.6] – is easily carried out on a computer. If s is not small, then it may be worth using the *interblock* information also. Various methods are available for combining the information, but a good choice nowadays would be to use a computer package (*see* **Software, Biostatistical**) such as GENSTAT or SAS which performs REML (**restricted maximum likelihood**) estimation – see John & Williams [4, Sections 7.5 and 7.6].

Lattice squares, introduced by F. Yates in 1940, are nested row–column designs for $t = k^2$ in $r > 1$ complete blocks (or groups) of k rows and k columns.

If k is a prime power, then a variance-balanced design, the *balanced lattice square*, is possible. This needs $r = (k+1)/2$ for k odd, and $r = k+1$ for k even. The balanced lattice square can be constructed from the balanced square lattice design. If k is odd, then each replicate of a balanced square lattice forms either the rows or the columns of one block. If k is even, then each replicate of a balanced square lattice forms the rows of one block, and the columns of another. For example, the balanced lattice square with $t = 3$ is

1	2	3
4	5	6
7	8	9

1	6	8
9	2	4
5	7	3

and one with $t = 4$ is

1	2	3	4
5	6	7	8
9	10	11	12
13	14	15	16

1	5	9	13
6	2	14	10
11	15	3	7
16	12	8	4

1	6	11	16
12	15	2	5
14	9	8	3
7	4	13	10

1	7	12	14
8	2	13	11
10	16	3	5
15	9	6	4

1	8	10	15
2	7	9	16
3	6	12	13
4	5	11	14

If k is odd, then a balanced lattice square with $r = k+1$ repeats the original design with the rows and columns interchanged.

Lattice squares which are not variance-balanced are obtained if other numbers of replicates are used. Care is then needed in the choice of the r replicates to ensure that the combined row and column treatment concurrences are as equal as possible – see Cochran & Cox [1, Section 12.12] and John & Williams [4, Section 6.2]. Designs may be possible for some $r > 1$ if k is not a prime power, depending on the maximum number of MOLS of order k. Balanced lattice squares for $k = 3, 4, 5, 7, 8, 9, 11, 13$ are given by Cochran & Cox [1, Chapter 12].

As before, the restriction on the possible values of t may be severe. Extensions to *lattice rectangles* are possible. John & Williams [4] discuss other resolvable nested row–column designs: α-designs (Section 6.3), two-replicate designs (Section 6.6), and designs generated using **algorithms** (Section 6.4). If the design is not balanced, then the usual intrablock analysis can again be easily carried out on a computer. There is no interblock information when each block is a complete replicate, but there may sometimes be useful interrow or intercolumn information, which again is best combined using REML estimation.

The lattice square designs and square lattices can be used for replicated blocked **factorial experiments** if the product of the levels is k^2 – see Cochran & Cox [1, Sections 10.12 and 12.11]. For the balanced designs, main effects and **interactions** are equally partially **confounded**. If $t_1 = t_2 = k$, then the first replicate of the square lattice design confounds one main effect, and the second replicate confounds the other.

Some further details on lattice designs are given by Cornelius [2].

RICHARD J. MARTIN

Law of Large Numbers

The first theorem recognizable as a precise form of a limiting-frequency statement (or "law of large numbers" in the terminology introduced by Poisson) is the famous "*weak law of large numbers for Bernoulli trials*" of James Bernoulli (1654–1705) [2] (*see* **Bernoulli Family**). In our current notation and terminology his theorem, published posthumously in *Ars Conjectandi* (1713), now reads as follows. Let $X_1, \ldots, X_n$ be the outcomes of n independent 0–1 trials (Bernoulli trials) with success probability p. With $S_n = \sum_{i=1}^{n} X_i$ the number of successes (the number of ones) and $\overline{X}_n = S_n/n$, we have for each $\varepsilon > 0$

$$\lim_{n\to\infty} \Pr\left(|\overline{X}_n - p| > \varepsilon\right) = 0.$$

In words: the ratio of the number of successes and the number of trials or the proportion of successes **converges in probability** to the success probability p. A universally applied notation is $\overline{X}_n \xrightarrow{\Pr} p$ (i.e. $\overline{X}_n$ converges to p in probability).

Remark 1. The result provides some empirical confirmation for the axioms of probability theory [7, Chapter 1] (*see* **Foundations of Probability**). See also [3, pp. 20–21] for an introductory discussion.

Remark 2. The proof is a simple application of the Chebyshev inequality:

$$\Pr\left(|\overline{X}_n - p| > \varepsilon\right) \le \frac{1}{\varepsilon^2}\mathrm{E}\left(\overline{X}_n - p\right)^2$$
$$= \frac{p(1-p)}{n\varepsilon^2} \longrightarrow 0, \quad n \longrightarrow \infty.$$

For $X_1, \ldots, X_n$ a sequence of independent random variables with common distribution function F, let $S_n = \sum_{i=1}^{n} X_i$, $\overline{X}_n = S_n/n$ and $\mu = \mathrm{E}(X_1)$. Then the following generalization of Bernoulli's theorem has been obtained.

Theorem 1. Khinchin's law of large numbers

$$\mathrm{E}|X_1| < \infty \text{ implies } \overline{X}_n \xrightarrow{\Pr} \mu.$$

In words: the sample mean $\overline{X}_n$ is a "weakly consistent" estimator of the population mean μ.

A refined version of this result is the following characterization due to Kolmogorov (see [2] for further details).

Theorem 2. In order that there exist constants μ_n such that for each $\varepsilon > 0$

$$\lim_{n\to\infty} \Pr\left(|\overline{X}_n - \mu_n| > \varepsilon\right) = 0,$$

it is necessary and sufficient that

$$n \Pr\left(|X_1| > n\right) \longrightarrow 0, \quad n \longrightarrow \infty.$$

In this case, $\mu_n = \int_{-n}^{n} x \, \mathrm{d}F(x)$.

Strong Law of Large Numbers

Almost sure (a.s.) convergence is a mode of convergence that describes the behavior of a statistic (e.g. the sample mean, $\overline{X}_n$) outside an unspecified set of probability zero. Almost sure convergence is stronger than convergence in probability (see Remark 4 below). Synonyms for almost sure convergence are convergence with probability one and convergence almost everywhere.

The Kolmogorov strong law of large numbers, the a.s. version of Khinchin's law, reads as follows.

Theorem 3. For $X_1, \ldots, X_n$ a sequence of independent random variables with common distribution function F:

$$\mathrm{E}|X_1| < \infty \text{ if and only if } \Pr\left(\lim_{n\to\infty} \overline{X}_n = \mu\right) = 1$$

with $\mu = \mathrm{E}(X_1)$.

Remark 3. The standard way to write this result is $\mathrm{E}|X_1| < \infty$ if and only if $\overline{X}_n \to \mu$ a.s.
In words: the sample mean $\overline{X}_n$ is a "strongly **consistent**" estimator of the population mean μ.

Remark 4. This simple characterization of strong convergence makes it clear why probabilists like the a.s. convergence mode. For statisticians the difference between the weak and the strong law of large numbers is subtle and cannot be adequately explained without measure theory. See [3, p. 233] for an intuitive discussion and some amusing quotations. From an applied point of view, most statisticians seem to be satisfied with convergence in probability.

Applications

Application 1

For $X_1, \ldots, X_n$ a sequence of independent random variables with common distribution function F let $\mathbb{F}_n$ denote the empirical distribution function, i.e.

$$\mathbb{F}_n(x) = \frac{\#\{i : X_i \le x\}}{n} = \frac{1}{n}\sum_{i=1}^{n} \mathrm{I}\{X_i \le x\}, \quad x \in \mathbb{R}$$

(*see* **Goodness of Fit**). For fixed x, $\mathbb{F}_n(x) \to F(x)$ a.s. by the strong law of large numbers. This property strengthens to almost sure convergence uniform in x.

Theorem 4. Glivenko–Cantelli theorem.

$$\sup_{x\in\mathbb{R}} |\mathbb{F}_n(x) - F(x)| \longrightarrow 0 \text{ a.s.}$$

In words: uniformly in x we can rediscover F from the data. Taking n large enough, this can be done to any desired degree of precision.

Application 2

We now discuss the statistical relevance of the consistency results given in the previous sections. Many problems in statistics are of the following type: for a given (unknown) parameter θ ($\mathbb{R}$-valued, $\mathbb{R}^d$-valued, or a function), find a consistent estimator T_n and obtain the limit distribution of $n^\gamma(T_n - \theta)$. Typical values for γ are $\gamma = 1/2$ for the classical **central limit theorem** (normality) and $\gamma = 1$ for a limit distribution that corresponds to a weighted sum of centered **chi-square distributed** random variables. Typically, $\mathrm{var}[n^\gamma(T_n - \theta)] \to \sigma^2$, with σ^2 a **nuisance parameter** that needs to be estimated in a consistent way in order to construct, for example, approximate **confidence intervals** for θ.

To make this point clear, consider the following simple example. Given a sequence of independent identically distributed random variables $X_1, \ldots, X_n$ let $\theta = \mu$ and $T_n \equiv \overline{X}_n$. If $0 < \sigma^2 = \mathrm{var}(X_1) < \infty$, then the limit distribution of $n^{1/2}(\overline{X}_n - \mu)$ is a zero mean **normal distribution** with variance σ^2. The sample variance

$$S_n^2 = \frac{1}{n-1}\sum_{i=1}^{n}\left(X_i - \overline{X}_n\right)^2 = \frac{n}{n-1}\left\{\frac{1}{n}\sum_{i=1}^{n} X_i^2 - \overline{X}_n^2\right\}$$

is a (strongly) consistent estimator for σ^2. To see this note that

$$\overline{X}_n \longrightarrow \mu \text{ a.s. implies } \overline{X}_n^2 \longrightarrow \mu^2,$$

and that the strong law of large number gives

$$\frac{1}{n}\sum_{i=1}^{n} X_i^2 \longrightarrow \mathrm{E}X_1^2 = \sigma^2 + \mu^2.$$

Hence we have $S_n^2 \to \sigma^2$ a.s.

We therefore obtain, using Slutsky's theorem (for which weak consistency is sufficient) that the limit distribution of $n^{1/2}(\overline{X}_n - \mu)/S_n$ is standard normal. Hence, an approximate $100(1-\alpha)\%$ confidence interval for μ is of the form $\overline{x}_n \pm z_{1-(\alpha/2)}(s_n/n^{1/2})$ with $\overline{x}_n$ and s_n^2 the actual values of $\overline{X}_n$ and S_n^2 and $z_{1-(\alpha/2)}$ the $[1-(\alpha/2)]$-percentile of the standard normal distribution.

Extensions

Extension 1

Let $X_1, X_2, \ldots$ be a sequence of random variables with a common distribution function F and replace the independence assumption by the **stationarity** assumption: for every n the joint distribution of $X_1, \ldots, X_n$ is the same as the joint distribution of $X_{1+k}, \ldots, X_{n+k}$ for all positive integers k.

On the basis of general results from ergodic theory one can show that, given the stationary process, $X_1, X_2, \ldots, \overline{X}_n$ still obeys laws of large numbers. Note that ergodic theory applies to a large number of problems in probability theory and analysis. See [8] for further reading.

Extension 2

Given a sequence of independent zero-mean random variables $\Delta_1, \Delta_2, \ldots$, define $X_n = \sum_{i=1}^{n} \Delta_i$. With $\mathcal{F}_n = \sigma(X_1, \ldots, X_n)$, the σ-algebra generated by $X_1, \ldots, X_n$, we then have that

$$\mathrm{E}(X_{n+1}|\mathcal{F}_n) = X_n.$$

This simple property delineates a very useful class of **stochastic processes**: martingales. The study of laws of large numbers for martingales is an intrinsic part of modern probability theory and the results

are extremely important for a variety of applications in, for example, survival analysis [5] (*see* **Counting Process Methods in Survival Analysis**). Further discussion is beyond the scope of this article; we refer to [1, Section 35] for an excellent introductory discussion and a number of interesting examples. A specialized reference is [6].

Finally, note that thorough discussions on the law of large numbers can be found in [4, 9], and [10].

PAUL JANSSEN

Lawley–Hotelling Trace

To test the equality of mean vectors of k p-variate normal distributions (*see* **Multivariate Normal Distribution**) with common but unknown **covariance matrix**, Hotelling [14] proposed a test, known as the Hotelling's generalized trace (or T_0^2) test, which could be considered as a generalization of **Hotelling's T^2 test** proposed for $k = 2$. This test statistic was also considered by Lawley [21], Bartlett [4], and Hsu [16]; it is often known as the Lawley–Hotelling trace. The test can be expressed as follows in its canonical form.

Consider random matrices $\mathbf{U} : p \times r$, $\mathbf{V} : p \times m$, and $\mathbf{W} : p \times n$, such that the columns of $\mathbf{U}$, $\mathbf{V}$ and $\mathbf{W}$ are independently distributed as p-variate normal distributions with a common covariance matrix $\mathbf{\Sigma}$. The problem is to test $\mathrm{H}_0 : \mathbf{\Theta} \equiv \mathrm{E}(\mathbf{U}) = \mathbf{0}$ against $\mathrm{H}_1 : \mathbf{\Theta} \neq \mathbf{0}$, given that $\mathrm{E}(\mathbf{W}) = \mathbf{0}$, $\mathbf{\Sigma}$ being unknown. The Lawley–Hotelling's trace test rejects H_0 if and only if

$$T_0^2 \equiv \mathrm{trace}[(\mathbf{U}\mathbf{U}')(\mathbf{W}\mathbf{W}')^{-1}]n$$

is too large; it is assumed that $n \geq p$. The **multivariate analysis of variance** (MANOVA) problem can be reduced to the above canonical form; in that case, $\mathbf{U}\mathbf{U}'$ and $\mathbf{W}\mathbf{W}'$ denote the sums of products and cross products matrices due to the hypothesis H_0 and due to error, respectively. This trace test can be deduced from Roy's **union–intersection principle**; see Mudholkar et al. [25].

The Lawley–Hotelling trace criterion can be considered for testing independence between two sets of variates jointly distributed as a normal distribution, as well as for testing equality of covariance matrices of two p-variate normal distributions; for this correspondence, see the article on **Pillai's trace test** and the review papers by Pillai [30, 31].

Hotelling [15] derived an explicit form of the null distribution of T_0^2 for $p = 2$; see Hsu [16] and Anderson [1]. Constantine [5] expressed the density of T_0^2 as an infinite series in generalized Laguerre polynomials, and also as an infinite series in zonal polynomials; for details, see Muirhead [27]. Pillai [29] suggested to approximate the null distribution of T_0^2 as follows:

$$F_{\nu_1,\nu_2} = \frac{\nu_2}{\nu_1} \times \frac{T_0^2}{ns},$$

where $s = \min(p, r)$, $\nu_1 = s(t + s + 1)$, $\nu_2 = s(n - p - 1)$, $t = |r - p| - 1$, and $F_{a,b}$ denotes the ***F* distribution** with a and b df; for details on this approximation, see Pillai [29].

Tables of the significance points of T_0^2 have been given by Grubbs [13] for $p = 2$, and by Davis [7–9] for $p = 3(1)10$; see Anderson [1]. Approximate significance points of T_0^2 have been suggested by Pillai [29]; see also Pillai & Samson [33] and Hughes & Saw [17].

The asymptotic (as $n \to \infty$) null distribution of T_0^2 is the **chi-square distribution** with rp **degrees of freedom**. For asymptotic expansion and approximation of the null (nonnull) distribution of T_0^2 in terms of chi-square (noncentral chi-square) distributions, see Itô [18, 19], Fujikoshi [10, 11], Siotani [37], Davis [8], Pillai [30, 31], Khatri & Pillai [20], Pillai & Young [35], and Muirhead [26, 27], in particular.

The power function of the Lawley–Hotelling trace test depends on the parameters through the characteristic roots $\nu_1, \ldots, \nu_p$ of $\mathbf{\Theta}\mathbf{\Theta}'\mathbf{\Sigma}^{-1}$ in the above set-up (*see* **Eigenvalue**). Ghosh [12] has shown that this test is admissible; for a different proof, see Anderson [1]. DasGupta et al. [6] have shown that the **power** of this test increases monotonically as each of the ν_i's increases. For monotonicity of the power function of the trace test for testing independence between two sets of variates, see Anderson & DasGupta [3], and for testing equality of covariance matrices, see Anderson & DasGupta [2]. Simultaneous confidence regions for $\mathbf{\Theta}$ based on the Lawley–Hotelling's trace criterion are given in [1].

The power of the Lawley–Hotelling test has been compared with the powers of the other standard tests for the MANOVA problem by a number of authors; see Mikhail [24], Schatzoff [36], Pillai & Jayachandran [32], Fujikoshi [11], and Lee [22]. If the characteristic roots ν_i are substantially unequal such that the coefficient of variation of the roots is large enough, then the Lawley–Hotelling test is more powerful than the **likelihood ratio test**, which, in turn is more powerful then Pillai's trace test; the reverse is true if the ν_i's are close. Lee [22] has noted that the power of the Lawley–Hotelling test is nearly constant on the region trace $[\mathbf{\Theta}\mathbf{\Theta}'\mathbf{\Sigma}^{-1}] =$ constant. For **robustness** of the Lawley–Hotelling test, see Mardia [23], Olson [28], Pillai & Sudjana [34], the review papers by Pillai [30, 31], and the article on **robustness of multivariate techniques**.

SOMESH DASGUPTA

League Tables

When making comparisons between, say, hospitals, it is very tempting to summarize the results into a set of scores, which are then sorted into a "league table", thus giving an explicit rank to each hospital (*see* **Profiling Providers of Medical Care**). This follows the sporting model in which attention is focused on which "team" is at the top and which at the bottom, and what movements have occurred since the last ranking exercise. Consider, for example, risk-adjusted 30-day mortality rates following cardiac artery bypass grafts in New York State between 1997 and 1999. Figure 1 shows the ranked rates for individual surgeons with 95% **confidence intervals** – in the original publication [6] the surgeons are named.

Such exercises can be easily criticized: someone always has to be top and bottom, even if there is really no difference between the surgeons and the league table is only the consequence of the play of chance. The widths of the intervals express the considerable uncertainty about the true underlying mortality rates, and yet none of this uncertainty is reflected in the rank given to a surgeon. The crucial insight is that the rank is itself a summary statistic that can be subject to standard **inferential** procedures [3–5], although the **sampling distributions** of observed ranks are not generally amenable to closed-form analysis. The simplest solution is to use **Monte Carlo** techniques: essentially, by thinking of the intervals in Figure 1 as expressing probability distributions for the true mortality rates, sampling from those distributions, ranking each of the generated samples, and so obtaining a set of plausible "true ranks" for the surgeons. This can be a fully **Bayesian** procedure in which the intervals summarize posterior distributions, or an approximate **maximum likelihood** analysis based on a "parametric **bootstrap**''.

Figure 2 shows the results of the ranking exercise (carried out using a Bayesian **Markov chain Monte Carlo** technique). It is clear there is substantial uncertainty concerning the true ranks, with the majority of surgeons having a very wide interval; only 2 out of

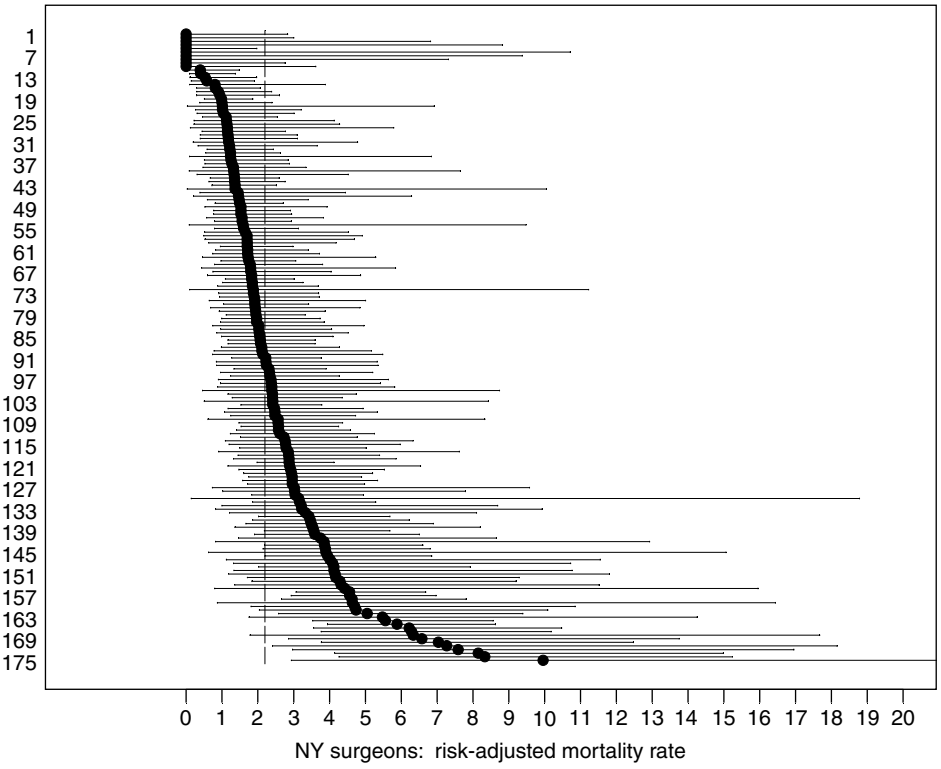

Figure 1 Observed mortality rates for 175 surgeons, with 95% confidence intervals

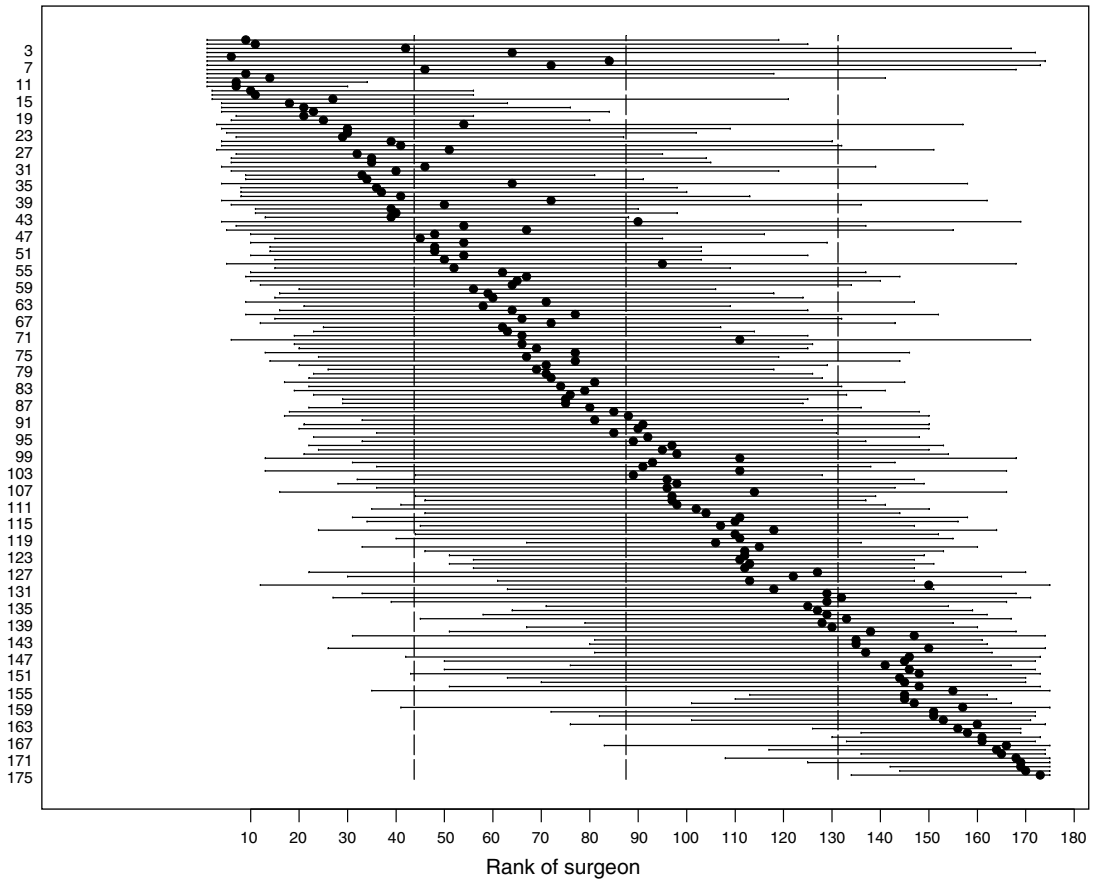

Figure 2 Median estimates and 95% intervals for true ranks of 175 New York surgeons

175 can be confidently placed in the "best" quarter, and only 6 in the "worst" quarter.

This procedure is straightforward to carry out if the league table has been based on a single indicator with a known sampling distribution. In practice, a league table may be based on a composite score, which may comprise both objective measures and subjective assessments of, for example, "reputation". Nevertheless, it should still be possible to assign a plausible measure of error to each of the items making up the score, and hence simulate a distribution of the "true" score, and obtain a distribution for the "true" rank. The ranking procedure can also apply after more complex models have been fitted. In particular, **hierarchical models** are often recommended in this context [1–3, 7] as a means of dealing with the inadequacies of risk-adjustment and "**regression-to-the-mean**", and the resulting "shrunk" estimates (*see* **Shrinkage Estimation**) will tend to lead to even more uncertainty about the true ranks.

Inferences on ranks may be useful in many other contexts, such as selecting promising entities for further research from among a large number of, say, drug compounds, crop varieties, or genes being screened.

The consequence of formal inference on ranks is generally to realize that little can be said and that any "league table" is largely spurious, apart from possibly identifying some extreme cases that can confidently be placed in, say, the top or bottom quarter. An alternative comparative tool that does not make an explicit ranking and yet draws attention to genuine extremes is the *funnel plot* (*see* **Meta-analysis of Clinical Trials**), which can be thought of as a Shewhart control chart (*see* **Quality Control in Laboratory Medicine**) around a target performance measure [8]. The outcome is plotted against volume and predictive

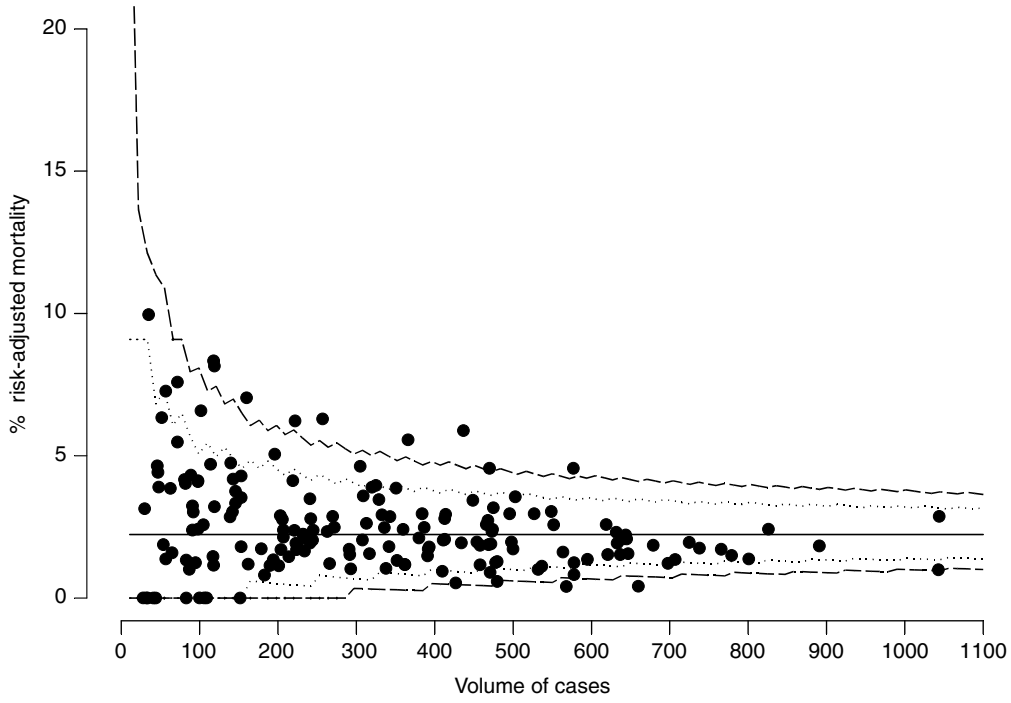

Figure 3 Funnel plot of risk-adjusted mortality rates for 175 New York surgeons: 95% and 99.9% prediction intervals are shown

limits superimposed, say 95% (≈2 standard deviations) and 99.9% (≈3 standard deviations). Figure 3 shows this applied to the New York surgeons data, and it is immediately apparent that the vast majority follow precisely the pattern expected and the only ones worthy of some attention are easily identified. The plot makes clear that there is no point in carrying out a ranking exercise on those in the "funnel".

Least Squares

Because of the controversy between Legendre and **Gauss** about the priority in the discovery of least squares, it is useful to distinguish between the principle of least squares and the theory of least squares.

Let $\mathbf{y}, \boldsymbol{\xi}(\boldsymbol{\theta})$, and $\mathbf{e}$, be $n \times 1$ vectors of observations, of known parametric functions of $\boldsymbol{\theta}$, and of random observational or experimental errors, respectively, where $\boldsymbol{\theta}$ is a $k \times 1$ vector of unknown parameters, $k < n$. The model is

$$\mathbf{y} = \boldsymbol{\xi}(\boldsymbol{\theta}) + \sigma \mathbf{e}, \tag{1}$$

where σ is a scalar parameter specifying the measurement scale. The problem is to estimate $\boldsymbol{\theta}$. If the observations were free from errors, $\mathbf{e} \equiv \mathbf{0}$, and if the model were exactly correct, the resulting n equations $\mathbf{y} = \boldsymbol{\xi}(\boldsymbol{\theta})$ in the k parameters $\boldsymbol{\theta}$ would have to be consistent in the mathematical sense that there exists a value of $\boldsymbol{\theta}$ satisfying all n equations. However, in general this is not the case, and the equations are inconsistent – there is no value of $\boldsymbol{\theta}$ satisfying (1). The observations are assumed to have been taken with equal care, so that all observations should contribute equally to the estimation of $\boldsymbol{\theta}$. The problem is therefore to combine the observations to extract all of their information about $\boldsymbol{\theta}$. This problem used to be referred to as the combination of observations. There is no value of $\boldsymbol{\theta}$ that in general minimizes the errors $\mathbf{e}$ uniformly. They therefore have to be minimized in some global sense. Laplace suggested minimizing the sum of absolute deviations $\sum |e_i|$, sometimes called L_1 regression (*see* **Robust Regression**). The principle of least squares minimizes the sum of squared deviations $Q = \sum e_i^2 = \sum [y_i - \boldsymbol{\xi}_i(\boldsymbol{\theta})]^2$. The resulting least squares estimate, $\hat{\boldsymbol{\theta}}$, is a solution of the least square equations $\partial Q / \partial \boldsymbol{\theta}_j = \sum (y_i - \boldsymbol{\xi}_i) \partial \boldsymbol{\xi}_i / \partial \boldsymbol{\theta}_j = 0$.

In the special but widespread case where $\boldsymbol{\xi}(\boldsymbol{\theta})$ is a linear function of $\boldsymbol{\theta}$, $\boldsymbol{\xi} = \mathbf{X}\boldsymbol{\theta}$, $\mathbf{X}$ being an $n \times k$ matrix of rank k of known constants x_{ij}, (1) becomes

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \sigma \mathbf{e}, \tag{2}$$

the Gauss linear model, discussed in text books as linear regression. The corresponding least squares equation and least squares estimate are

$$(\mathbf{X}'\mathbf{X})\hat{\boldsymbol{\theta}} = \mathbf{X}'\mathbf{y}, \qquad \hat{\boldsymbol{\theta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}. \tag{3}$$

Legendre has priority in the principle of least squares, having published in 1805 [4], whereas Gauss's first publication on least squares was in 1809 [2]. Legendre derived the models $\mathbf{y} = \boldsymbol{\xi} + \sigma \mathbf{e}$ and the special case (2), and the corresponding least squares equations including (3). But Gauss [2, 3] went on to develop the theory of least squares, producing the treatment of linear regression as given in textbooks today. In fact, according to Fisher [1, p.88], Gauss's method only lacked for completeness the refinement of the use of **Student's *t* distribution**, appropriate for samples of rather small numbers of observations.

Standard Normal Errors

This is Gauss's first, or parametric inferential, approach [2]. Gauss assumed the errors $\mathbf{e}$ to be n independent random variables having density function $\prod f(e_i) = \prod f(y_i - \boldsymbol{\xi}_i)$. He then used a typically Bayesian argument assuming independent uniform prior distributions for $\boldsymbol{\theta}_i$ to obtain a posterior density function for $\boldsymbol{\theta}$. The estimate $\hat{\boldsymbol{\theta}}$ was chosen to be the mode of this posterior density function. Since the posterior distribution of $\boldsymbol{\theta}$ is proportional to $\prod f(e_i)$, which is proportional to the likelihood function of $\boldsymbol{\theta}$, the resulting equations of estimation are

$$\sum_{i=1}^{n} \left[\frac{\partial f(y_i - \boldsymbol{\xi}_i)}{\partial \boldsymbol{\xi}_i} \right] \left(\frac{\partial \boldsymbol{\xi}_i}{\partial \boldsymbol{\theta}_j} \right), \quad j = 1, \ldots, n, \tag{4}$$

which are equivalent to the equations of maximum likelihood, and $\hat{\boldsymbol{\theta}}$ is the **maximum likelihood** estimate. To proceed further requires specifying f. To do this Gauss assumed that for the single-parameter model in which $\boldsymbol{\xi}_i \equiv \boldsymbol{\theta}, i = 1, \ldots, n$, the appropriate estimate of the scalar $\boldsymbol{\theta}$ is $\overline{y}$. This was the procedure commonly used in the physical sciences, such as astronomy. Substituting $\boldsymbol{\xi}_i \equiv \boldsymbol{\theta}$ into (4), and requiring the solution $\hat{\boldsymbol{\theta}}$ to be $\overline{y}$, implies that $f(e_i)$ is the normal N(0, 1) density. Then $\prod f(e_i) \propto \exp(-Q^2/2)$, where $Q = \sum (y_i - \boldsymbol{\xi}_i)^2$. Maximizing f is equivalent to minimizing Q, which is the method of least squares. Gauss then specialized to the linear model (2), produced (3), and went on to develop the theory of normal linear regression as presented in textbooks today. He also generalized (1) to $\sigma = \text{diag}(\sigma_i)$, where the observations have different scale

parameters σ_i. This results in weighted least squares in which $Q = \sum[y_i - \xi_i(\boldsymbol{\theta})]^2/\sigma_i^2$ is to be minimized. This approach to least squares can be considered as a generalization of the use of the arithmetic **mean**. It is based upon the normal error distribution, in which case its use is equivalent to the use of the more general method of maximum likelihood.

Unspecified Distribution

This is Gauss's second, or nonparametric decision-theoretic, approach [3] based on the following assumptions.

1. The model. The model is (2) where the errors have zero means, unit variances, and are uncorrelated.
2. Linear estimates. The measuring instrument is sufficiently precise that the squares and higher powers of the errors **e** can be ignored, thus restricting attention to linear error-consistent estimates
$$\tilde{\boldsymbol{\theta}} = \mathbf{C}\mathbf{y}, \quad \text{where } \mathbf{C}\mathbf{X} = \mathbf{I}, \tag{5}$$
and **C** is a $k \times n$ matrix. The error-consistency requirement, $\mathbf{C}\mathbf{X} = \mathbf{I}$, is to ensure that when the observations are free from errors, $\mathbf{e} \equiv \mathbf{0}$, the estimate should be the true value, $\tilde{\boldsymbol{\theta}} \equiv \boldsymbol{\theta}$.
3. Squared error loss. Estimation is a game with a potential loss (*see* **Loss Function**) and no hope for gain. The loss is taken to be proportional to the squared error $(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})^2$.

The requirement is that the estimate (5) should minimize the expected loss, the well-known **mean square error** (EMS) criterion, $\mathrm{E}(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})^2$. Gauss's Theorem proves that among all estimates (5), the least squares estimate $\hat{\boldsymbol{\theta}}$ minimizes the EMS.

Gauss then went on to examine various decompositions of sums of squares, and essentially develop the **analysis of variance**. He also showed that if $Q_{\mathrm{m}} = (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\theta}})'(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\theta}})$ is the residual or minimum sum of squares, then $\mathrm{E}(Q_{\mathrm{m}}) = (n-k)\sigma^2$. He thus recommended $s = [Q_{\mathrm{m}}/(n-k)]^{1/2}$ as the appropriate estimate of σ. Notice that while s^2 is an unbiased estimate of σ^2, s is a biased estimate of σ. Thus Gauss did not seem to be preoccupied with unbiased estimates.

Discussion

This last point is particularly relevant as textbooks almost always treat (5) as a requirement of **unbiasedness**, implying that the purpose of least squares is to seek **minimum variance unbiased estimates**. The resulting formalized theorem is usually referred to as the Gauss–Markov Theorem.

Textbooks also usually ignore the justification of the linearity requirement (assumption 2), and assume it is simply reasonable to restrict attention to linear estimates. This, together with unbiasedness and variance, lead to best linear unbiased estimates (BLUEs) and uniformly minimum variance (UMV) estimates. Justification for such estimates thus appears to be based more on their mathematical convenience than on their scientific relevance.

The domain of the application of least squares to parametric models is (1) where **e** is a vector of independent N(0,1) errors. In this case least squares is identical to maximum likelihood. When **e** is not normal, least squares is no longer relevant, but maximum likelihood usually is applicable to the estimation of components $\boldsymbol{\theta}_i$ if due attention is paid to the shape of the likelihood functions of $\boldsymbol{\theta}_i$.

The domain of application of the nonparametric approach, where the model is not specified, is to areas where it is appropriate to assume **e** is small, so that it makes sense to restrict attention to linear estimates and to a squared error loss function. For example, Gauss originally applied least squares to the calculation of a planetary orbit, and the prediction of where the planet will be seen. He also used it in map-making, or geodesy, where the above assumptions are fulfilled. These assumptions may not be generally appropriate in many applications in biology and the life sciences, and hence in biostatistics. There the principal source of error is usually the variability of the experimental material, which may be large and asymmetric.

These considerations make it seem unlikely that least squares, as a method of estimation per se, has a widespread application in biostatistics. However, *weighted* least squares has computational applications in iterative procedures required to find the maximum likelihood estimate (*see* **Optimization and Nonlinear Equations**). In particular it is useful in obtaining an initial value $\boldsymbol{\theta}_0$ to start the iterations using the Newton–Raphson or Fisher's scoring methods. For example, consider the binomial **logistic**

regression $\mathbf{y} \sim \text{bin}(\mathbf{s}, \mathbf{p})$, where $\zeta = \log[\mathbf{p}/(1 - \mathbf{p})] = \mathbf{X}\boldsymbol{\theta}$. If $\hat{\zeta} = \log[\hat{\mathbf{p}}/(1 - \hat{\mathbf{p}})] = \log[\mathbf{y}/(\mathbf{s} - \mathbf{y})]$, an initial value $\boldsymbol{\theta}^{(0)}$ is the weighted least squares estimate of $\boldsymbol{\theta}$ in the regression of $\hat{\zeta}$ on $\mathbf{X}$. This is obtained by minimizing with respect to $\boldsymbol{\theta}$ the weighted sum of squares

$$Q = \sum_{i=1}^{n} \left(\hat{\zeta} - \sum_{j=1}^{k} x_{ij}\theta_j \right)^2 n_i \hat{p}_i (1 - \hat{p}_i)$$
$$= (\hat{\zeta} - \mathbf{X}\boldsymbol{\theta})' D (\hat{\zeta} - \mathbf{X}\boldsymbol{\theta}),$$

where D is the diagonal matrix of elements $n_i \hat{p}_i (1 - \hat{p}_i)$, the reciprocals of the estimated variances of the $\hat{\zeta}_i$. The successive correction terms in the Newton–Raphson iterations can be obtained in a similar way (*see* **Optimization and Nonlinear Equations**).

For further details on Gauss and least squares, see Sprott [5].

Lehmann Alternatives

To study the effect of a drug one often needs to make a **nonparametric** comparison of the cumulative distribution function, G, of **scores** from treated subjects, with the distribution, F, of scores from the untreated control group. In such comparisons, Lehmann [5] pointed out that under any alternative hypothesis the test is not distribution-free. To overcome this difficulty, Lehmann suggested a functional relationship $G = f(F)$, where f is a specified function between G and F. The importance of this formulation is that the distribution of the **rank** vector under the alternative hypothesis will depend only on f and hence every rank statistic will have a nonparametric distribution-free property. As an illustration, Lehmann derived the power of various rank tests for simple alternatives $G = F^2$ and $G = F^3$.

One of the major applications of the Lehmann alternatives has been in the formulation of the alternative hypothesis for testing the effect of a drug when some subjects in the treatment group are not affected by the treatment. This so-called "nonresponse" phenomenon occurs, for example, in the development of a new drug. In such studies, one may exhibit greater variability as well as mean response in the treatment group. This increased variability can be considered to be due to the presence of subjects in the treatment group who are unaffected by the treatment. Thus, if p is the proportion of subjects in the treatment group who respond to the treatment, then Salsburg [9] suggests testing the null hypothesis of no treatment effect,

$$\mathrm{H}_0\colon G(x) = F(x), \tag{1}$$

against a Lehmann-type alternative of the form

$$\mathrm{H}_1\colon G(x) = (1-p)F(x) + p[F(x)]^{\gamma}, \tag{2}$$

where $\gamma > 1$ is a known constant. Salsburg's argument is based on maintaining the same range of observations in the treatment and control groups. In this form of the Lehmann alternative the response of each subject in the treatment group who is affected by treatment is assumed to have the same distribution as the maximum of γ responses in the control group. Salsburg suggests using a rank test, where the two samples are ranked together and the score for a given subject is

$$s(i) = \left(\frac{i}{N+1}\right)^k, \quad k > 1, \tag{3}$$

where i is the combined rank of that subject and N is the total number of subjects in the combined set. Conover & Salsburg [1] show that when $\gamma = 5$ and $k = \gamma - 1 = 4$, then a rank test based on (3) provides a test with maximum **asymptotic relative efficiency**. The recommended value of $\gamma = 5$ is based on some empirical results. Razzaghi & Nanthakumar [8] formulated the problem of testing for treatment effect in terms of the parameter p as

$$\mathrm{H}_0\colon p = 0$$

against

$$\mathrm{H}_1\colon p > 0$$

and derived a **locally most powerful test**. Such a test is based on the statistic

$$S_{n,m} = \sum_{i=1}^{n} F_m^{\gamma-1}(y_i), \tag{4}$$

where m is the number of subjects in the control group and F_m is the empirical distribution of the control observations defined at any point x as the proportion of the control observations not exceeding x, and $y_1, \ldots, y_n$ are the observations from the treatment group. The test of H_0 against H_1 will reject the hypothesis of no treatment effect when

$$S_{n,m} > \frac{n}{\gamma} + \frac{\gamma-1}{\gamma}\left(\frac{n}{2\gamma-1}\right)^{1/2} Z_\alpha,$$

where Z_α is the $100(1-\alpha)$th fractile (or **quantile**) of the **standard normal distribution.** The power of the test based on (4) increases as the proportion of the responders, p, rises. A value of $\gamma = 5$ is again recommended on the basis of an analysis of the **power** of the test.

Conover & Salsburg [1] also present an argument for using the other form of the Lehmann alternative and expressed the distribution of the treatment in the presence of nonresponders as the hypothesis

$$\mathrm{H}_2\colon (1-p)F(x) + p\{1 - [1-F(x)]^{1/\gamma}\}, \quad \gamma > 1, \tag{5}$$

which implies that the distribution of each control score is assumed to have the same distribution as the minimum of γ responses from the treatment group. Razzaghi & Nanthakumar [7] proposed a locally optimal test for the alternative (5). The test is based on the score statistic (*see* **Likelihood**)

$$T_n = \sum_{i=1}^{n} [1 - F(y_i)]^{-(\gamma-1)/\gamma}. \tag{6}$$

It is shown that when $\gamma = 2$, the asymptotic distribution of T_n under the null hypothesis is normal, while for $\alpha > 2$ this distribution is in the domain of attraction of a stable distribution. More specifically, a locally most powerful test of H_0 against H_2 with $\gamma = 2$ rejects the null hypothesis, H_0, when

$$T_n > 2n\left[1 - (n \ln n)^{-1/2}\right] + (n \ln n)^{1/2} Z_\alpha, \tag{7}$$

and the test for $\gamma > 2$ rejects H_0 when

$$\frac{\{T_n - n\gamma(1 - a_n^{-(\gamma-1)^{-1}})\}}{a_n} \tag{8}$$

exceeds the $(1 - \alpha)$th fractile of a stable distribution with indices $\gamma/(\gamma - 1)$ and -1. In (8), a_n is given by

$$a_n = \frac{\left\{\left[\frac{8\gamma n}{\ln n}\right]^{(\gamma-1)/\gamma} - \left[\frac{16n}{\ln n}\right]^{1/2}\right\}}{(\gamma - 2)^{2(\gamma-1)/\gamma}}. \tag{9}$$

Example

To illustrate the methodologies described here, we use a data set from an experiment on **pain** scores. The data first appeared in Conover & Salsburg [1]. Values for patients from a study of acute painful diabetic neuropathy were recorded at baseline and after four weeks of treatment on an analog scale. The changes from baseline were described as the natural logarithm of the ratio of baseline to final scores. Table 1 is reproduced from Conover & Salsburg for completeness. For these data using $\gamma = 5$, the value of $s(i)$ is 0.261 for the treated patients and 0.133 for the control subjects, leading to a P value of 0.031. The value of $S_{n,m}$ is 2.10, leading to a P value of 0.0179. Computation of T_n for these data gives

$$T_n = \begin{cases} 100.13, & \gamma = 2, \\ 210.31, & \gamma = 3, \\ 421.28, & \gamma = 5, \end{cases}$$

and in all cases the test indicates a highly significant treatment effect. The fractiles of a stable distribution may be obtained from Cross [3].

There is a vast body of literature on the theoretical development and applications of Lehmann alternatives. Wijsman [10] provides a comprehensive and thorough list of early references. Halperin & Ware [4], Cox [2], and Peto [6] discuss the use of Lehmann alternatives in the analysis of data from **clinical trials**. The intent here has been to demonstrate more recent applications in biostatistical problems.

MEHDI RAZZAGHI

Length Bias

The length-biased distribution is a **probability** distribution resulting from a biased sampling scheme in which the probability of observing a positive-valued **random variable** is proportional to the value of the variable.

Length Bias in Renewal Theory

The presence of length bias is a natural phenomenon in **renewal** theory. Consider a sequence of random variables

$$X_1, \quad X_1 + X_2, \quad X_1 + X_2 + X_3, \ldots,$$

where the Xs are positive-valued, nondegenerate, independent and identically distributed (iid) random variables. Suppose the process starts from time 0 and is observed at the time τ_0, where τ_0 is a positive constant. Let α be the index so that

$$\sum_{i=1}^{\alpha-1} X_i < \tau_0 \leq \sum_{i=1}^{\alpha} X_i.$$

Let Y, T, and R respectively denote the length of the interval containing τ_0, the backward recurrence time, and the forward recurrence time, or equivalently,

$$Y = X_\alpha, \qquad T = \tau_0 - \left\{\sum_{i=1}^{\alpha-1} X_i\right\},$$

$$R = \left\{\sum_{i=1}^{\alpha} X_i\right\} - \tau_0.$$

Let f, S, and μ represent the density function, survivorship function, and mean of X_1, respectively. When τ_0 is sufficiently large so that an *equilibrium condition* is reached [3], the joint density of (T, R) can then be derived as

$$p_{T,R}(t, r) = \frac{f(t + r)I(t \geq 0, r \geq 0)}{\mu}. \tag{1}$$

The marginal density functions of Y, T, and R can be derived, based on (1), as

$$p_Y(y) = \frac{yf(y)I(y \geq 0)}{\mu}, \tag{2}$$

$$p_T(t) = \frac{S(t)I(t \geq 0)}{\mu}, \tag{3}$$

$$p_R(r) = \frac{S(r)I(r \geq 0)}{\mu}. \tag{4}$$

The distribution of (2) is generally referred to as the *length-biased distribution*.

Although the length-biased distribution in renewal theory is usually derived under the iid assumption on the Xs, as a general result the independence assumption can be removed and the density formulas (1)–(4) still remain valid [6].

Statistical Methods

Length-biased sampling is recognized in many research fields including epidemiology, ecology, and reliability. A number of methods for length-biased data have been developed in the statistical literature. Cox [4] proposed estimating the survivorship function by a weighted empirical distribution function (*see* **Goodness of Fit**), with weight inversely proportional to y_i:

$$\hat{S}_n(y) = n^{-1}\hat{\mu}\sum_{i=1}^{n}\left[y_i^{-1}I(y_i > y)\right],$$

where $\hat{\mu} = \{n^{-1}\sum_j y_j^{-1}\}^{-1}$ serves as an appropriate estimate of μ, since $n^{-1}\sum_j y_j^{-1}$ estimates μ^{-1}. The estimator $\hat{S}_n$ can be proven to be the **nonparametric maximum likelihood estimator** of S, a special case under Vardi's **selection bias** models [12, 13]. Following the same weighting procedure, a kernel estimator of the density function f (*see* **Density Estimation**) was proposed in [7] as

$$\hat{f}_n(y) = n^{-1}\hat{\mu}\sum_{i=1}^{n}\left[y_i^{-1}K_h(y - y_i)\right],$$

where $K_h(x) = h^{-1}K(h^{-1}x)$, $h > 0$, with K a kernel function. Alternatively, one could first estimate the length-biased density, (2), by an ordinary kernel estimator and then use the relationship of (2) and f to obtain an estimator of f [2]. Under the proportional hazards model [5], a risk set sampling technique was developed in [17] for estimating regression parameters. For $y_j \geq y_i$, let $\Delta_j(y_i)$ be a binary variable which equals 1 with probability y_i/y_j, and 0

with probability $1 - (y_i/y_j)$. The indicators $\Delta_j(y_i)$ are used to identify bias-adjusted **risk sets** and to construct **pseudo-likelihood** equations. Regression parameter estimates are then derived by solving the score equations (*see* **Likelihood**).

Length Bias in Prevalent Cohorts

Length-biased sampling could arise in many epidemiologic studies when survival data are collected from a disease population (*see* **Prevalent Case**). As an illustration, suppose a random sample of women with breast cancer (b.c.) are recruited for observation of survival. Assume (i) the rate of occurrence of b.c. remains constant over time, and (ii) the density function of the time from b.c. to death, f, is independent of the calendar time when b.c. occurred. Conditions (i) and (ii) together are referred to as the *equilibrium condition*. Denote by τ_i the calendar time when woman i with b.c. is recruited, t_i the time from the initial diagnosis of b.c. to τ_i, and y_i the time from the initial diagnosis of b.c. to death. Under the equilibrium condition, the joint density of (t_i, y_i) is an equivalent of (1), namely

$$p_{T,Y}(t, y) = \frac{f(y)I(y \geq t \geq 0)}{\mu}, \qquad (5)$$

and the distribution of y_i is length-biased with density (2). Suppose a sample of iid $(t_1, y_1), \ldots, (t_n, y_n)$ is observed. By the factorization theorem, the observed failure times $\{y_i\}$ serve as **sufficient statistics** for parameters of f. In this case, the variables $\{t_i\}$ do not contain additional information for f.

The preceding length-biased sample can be described more generally as disease prevalent data. Suppose there are two chronologically ordered and nonrecurrent events, termed the initiating and terminating events. Replacing the events of b.c. and death by the initiating and terminating events, the sample $\{y_i\}$ is length-biased when study individuals are recruited from those who have experienced the initiating event but have not experienced the terminating event [16]. Samples of this type could also be collected in a **screening** program for chronic diseases. It was indicated by Zelen & Feinleib [20] that the screen does not detect people at random, but detects people with longer preclinical **sojourn times**.

Although statistical methods can be formulated on the basis of length-biased observations as discussed earlier, the analysis could be further complicated by the presence of right **censoring**. We next make connection between length-biased sampling and left **truncation** in this context.

Length Bias and Left Truncation

Using formula (5), the density function of y_i given t_i can be derived as $f(y)I(y > t)/S(t)$, a truncated density function. The observed t_i in left truncation models [8, 10, 11, 15, 16, 19] is usually termed the *truncation time* and has density function $S(t)I(t > 0)/\mu$. Given the observations $(t_1, y_1), \ldots, (t_n, y_n)$, the full density can be expressed as the product of the marginal density of the t_i,

$$\prod_{i=1}^{n} \left[\frac{S(t_i)}{\mu} \right],$$

and the conditional density of y_i given the t_i,

$$\prod_{i=1}^{n} \left[\frac{f(y_i)}{S(t_i)} \right]. \qquad (6)$$

In length-biased models the truncation times in general do not serve as **ancillary statistics** for parameters of f, and thus the conditional likelihood (6) is used subject to loss of information.

Suppose now the observation of the terminating event is subject to right-censoring. Assume the following independent censoring condition: conditional on the observed t_i, the time from τ_i to the terminating event, r_i, is independent of the time from τ_i to censoring, d_i. This independent censoring condition does not, however, imply independence between the length-biased time, $y_i (= t_i + r_i)$, and the censoring time, $c_i (= t_i + d_i)$ [14, 16]. Let $w_i = \min\{y_i, c_i\}$ be the time from the initiating event to the end of observation, and $\delta_i = I(w_i = y_i)$ the censoring indicator. Conditional on t_i, under the independent censoring condition the density of (w_i, δ_i) is proportional to $f(w_i)^{\delta_i} S(w_i)^{1-\delta_i}/S(t_i)$. Given a sample of iid observations $(t_1, w_1, \delta_1), \ldots, (t_n, w_n, \delta_n)$, statistical approaches based on the conditional likelihood,

$$\prod_{i=1}^{n} \left[\frac{f(w_i)^{\delta_i} S(w_i)^{1-\delta_i}}{S(t_i)} \right],$$

are considered as methods for left-truncated and right-censored data. These approaches replace the usual risk sets $R(w) = \{w_i : w_i \geq w\}$ by $R^*(w) = \{w_i : t_i \leq w \leq w_i\}$ and result in an interesting contrast with the familiar techniques used in survival analysis [11, 15, 16, 19]. These methods can be alternately derived using **counting process** techniques with left-filtering [1, 8, 10]. The connection between renewal processes and left truncation can also be made by various approaches [9, 18]. While the methods provide "simple solutions" for analyzing censored length-biased data, these conditional approaches, similar to the left-truncation case, are used subject to loss of **efficiency** because marginal information from the truncation times is not used in the construction of the methods. Furthermore, the applicability of these methods requires that the truncation time, t_i, be observable, and such a requirement might not be met in some applications.

Length Bias and Cross-sectional Sampling

In the example of prevalent cohorts, the initiating and terminating events are required to be nonrecurrent. Nevertheless, the problem of length bias could also be encountered in studies that adopt **cross-sectional** sampling techniques to collect failure times from univariate or bivariate recurrent event processes (*see* **Repeated Events**). In these studies the outcome variable of interest is the length between two successive events. The crucial condition assumed, for the validity of length-biased distribution, is the equilibrium condition for the recurrent events. With cross-sectional samplings, the intervals which contain the sampling times are observed and form the length-biased sample. Examples include cross-sectional samples of (i) fibre length [4], where the recurrent events are of the same type and the location of an event is specified as the left end of a fibre, and (ii) length of stay in a hospital, in which the bivariate recurrent events are admission to and discharge from a hospital.

MEI-CHENG WANG

Leukemia Clusters

Interest in the possibility that cases of cancer and leukemia tend to occur in clusters has a long history [6]. Early reports were of cancer in particular families or houses; more recently interest has centred on spatial and space–time **clustering**. Most recent interest concerns leukemia in children and has been stimulated by suspicions of an environmental etiology.

The possible explanation of clusters most considered is that environmental **radiation** might be responsible for leukemia in children, and public concern is so great that it has had a major impact on the development of civil nuclear power programs. Natural though such apprehensions may be, they are out of all proportion to the strength of the epidemiologic evidence. Radiation is certainly a known leukemogen, but most environmental doses are too low to account for significant risk. Recently, other leukemogenic mechanisms have been receiving more attention, notably the possibility of an infectious etiology. Although there is some evidence of geographical clustering, this is not strong and, despite intensive investigation, no actual leukemia cluster has led to the identification of a specific cause.

The Nature of Leukemia

Acute leukemia is a malignant disease characterized by rapid proliferation of leucocytes from a single malignant clonal cell; chronic forms develop slowly over a long period of time but are capable of becoming acute. The tumor is relatively rare in adults, but commonest in children, accounting for around a third of all cases of malignant disease under the age of 15. The most distinctive of the numerous forms is acute lymphocytic leukemia (ALL). In practice, many epidemiologic investigations distinguish only between ALL and acute nonlymphocytic leukemia (ANLL).

Types of cancer generally, and leukemia in particular, show very different relative frequencies in children and adults. Thus ALL accounts for around 80% of all leukemia in children, with a peak at around 3 years of age [15]. Most of the remaining cases are of ANLL, chronic leukemia being rare in childhood. Among adults, however, the commonest form is chronic lymphocytic leukemia, ALL being less common than either the chronic or acute myelocytic forms [25].

Reported **incidence rates** of leukemia show some variation internationally; these may be partly due to genetic factors, but are probably also a consequence of differences in reporting and diagnostic procedures [25]. In addition, the disease tends to be masked by acute infections, which may explain some of the international differences and the more marked historical trends [24]. Intranational rates show less variation for children [14] than for adults [7].

The Etiology of Leukemia

The etiology of leukemia is only partly understood. The importance of genetic factors is clear from its association with certain conditions having a clear genetic etiology, notably Down's syndrome (trisomy 21), in which the risk of childhood leukemia is increased about 15-fold [35].

Of the various exogenous factors that have been proposed as having etiological significance for leukemia, ionizing radiation is by far the most important. That it causes leukemia in high doses (of the order of 100 mSv or more) has been established beyond doubt by various epidemiologic studies [29, 34], which, however, predominantly involved adults. There is also significant evidence that the much lower doses exposing the fetus in obstetric X-ray investigations (typically 2–20 mSv) are leukemogenic [4, 13]. The epidemiologic evidence therefore justifies the interest in environmental radiation, especially the possibility of a risk near nuclear installations [33] or following nuclear accidents. In most cases, however, the excess radiation levels in such environments are small compared with the natural background radiation and are unlikely to explain observed excesses of leukemia [11].

A viral component of the etiology has also been suspected for a long time. The first strong epidemiologic evidence relates to a cohort of children born in March 1958 in the UK [17], for which there was a ninefold increase in the risk of leukemia and lymphoma among children whose mothers contracted influenza during pregnancy. Chance may have at least partly exaggerated the finding, and it is noteworthy also that the relevant exposure was to a particularly virulent epidemic of the Asian strain; in any event, subsequent corroboration was only partial [30]. More

recently, Greaves [21] has postulated that children exposed to below average levels of infection postnatally may fail to develop a fully effective immune system, making them more vulnerable to tumor initiation. Such a mechanism might explain the known association between childhood leukemia and high socioeconomic status [14] and also the population-mixing phenomena demonstrated by Kinlen [23] and discussed below.

Other known or possible causes of leukemia include chemotherapeutic agents [12]; exposure to chemical carcinogens, which is normally occupational and may be parental [28]; and exposure to electromagnetic fields [10]. With the exception of the last of these, for which the evidence is least convincing, a genuine causal relationship would be unlikely to result in demonstrable **geographic patterns**.

The Nature of Clustering

Clustering may be defined as the tendency of observations to be situated closer to one another than would be expected. The reference space within which a cluster appears may be discrete or continuous, the former being exemplified by clustering within families. The problem of analyzing excesses within family or other groups raises few special problems, however. Greater interest, both theoretically and practically, attaches to clustering in a continuum, which is normally taken to be geographical space, time, or their product, the latter giving rise to space–time clustering.

Clustering in time only would presumably be indicative of a widely dispersed short-term hazard; few instances of such hazards have been proposed for leukemia. Seasonal variation (*see* **Seasonal Time Series**) could also induce this form of clustering, though the term would not normally be taken to include such an effect and specific, period-related methods of analysis would be more appropriate than general tests. Rather little evidence of seasonality in leukemia incidence has been advanced [16].

Clustering in space could be ascribed to a number of possible mechanisms, mostly involving geographical variation of risk. Local variation of genetic factors could in principle produce spatial clustering, but there is little or no evidence of this in the case of leukemia. Spatial variation is more likely to be due to local variation in risk due to some environmental factor.

Space–time clustering – i.e. an **interaction** between the space and time distributions – could be indicative of some infective mechanism in the etiology of the disease. The evidence for this is briefly summarized below. Space–time interaction tests have the apparent attraction that they can be executed without knowledge of the marginal distributions in time and space, the latter being particularly hard to estimate accurately. However, they are vulnerable to space–time interactions in the denominators, i.e. to changes in population distribution over the study period (*see* **Denominator Difficulties**). Little work has been done on how sensitive they are to such changes and how much this may affect published findings.

Assessment of clusters is inevitably bound up with the methods used to detect them (*see* **Geographic Epidemiology**). Here we emphasize only the importance of distinguishing between situations where there is or is not a hypothesis identified a priori; the distinction crucially affects the choice of method as well as the interpretation of the results.

Evidence of Leukemia Clustering

Most of the study of leukemia clustering has concentrated on childhood leukemia, and this is reflected in the following brief review.

Nuclear Installations

The specific environmental issue that has received greatest attention is that of possible risk in proximity to nuclear installations. Early concern following the accident at Three Mile Island in the US gained new impetus in the UK, particularly after a television program in 1983 identified an abnormally large number of cases in Seascale, a village near the nuclear reprocessing plant at Sellafield in Cumbria.

Although Sellafield is one of the largest nuclear reprocessing plants in the world and has released significant quantities of radiation into the environment, detailed radiologic analyses considering available estimates of risk coefficients and parallel exposures from nuclear fallout make it very unlikely that radiation alone could account for the observed **relative risks** [11, 33]. The hypothesis that paternal preconception irradiation might be the crucial pathway [19] is inconsistent with current dosimetric estimates of genetic risk and with other epidemiologic studies [26].

Nevertheless, public concern remains high and a number of clusters in the vicinity of other nuclear installations have been reported more or less anecdotally; significantly, perhaps, these include excesses at other reprocessing plants at Dounreay in Scotland [8] and La Hague in France [32]. Public concern has extended to nuclear power generating stations although they normally have very much lower emissions. This concern has prompted a number of studies of nuclear installations in the UK [5], the US [22], and Canada [27]. These studies have not generally uncovered further significant excesses.

The excess in Seascale is particularly difficult to interpret in view of the mode of its discovery and initial reporting. Its statistical significance is in some measure diluted by the observation that Seascale is one of almost 10 000 similar areal units in the UK. The fact remains, however, that the Sellafield plant is unique in terms of its history and activity and any prior hypothesis would presumably have put high odds on this being the most likely location of any excess. It is disturbing too that, since the initial finding, further cases have occurred: between 1984 and 1992 there were a further three cases of ALL and non-Hodgkin lymphoma, bringing the total since 1963 to eight, compared with around 0.65 expected [9]. A useful collection of abstracts and papers on childhood cancers near nuclear installations was published in 1993 and dedicated to the late **Martin J. Gardner** [3].

Viral Etiologies

The difficulty of explaining the Seascale cluster in terms of radiation has prompted a search for other possibilities. Foremost of these is the possibility that the risk of childhood leukemia is increased by exposure to an infective agent consequent on increased levels of "population mixing". In a remarkable series of papers, Kinlen and colleagues studied other populations in which a similar mixing effect could be expected [23]. These include new towns, the vicinities of major construction sites, and communities receiving wartime evacuees; they showed consistently raised risks of childhood leukemia. An explanation might be that children in the indigenous population are vulnerable to an infectious agent or agents not previously encountered or, in line with Greaves' argument [21], that they have a generally higher susceptibility to leukemogenesis resulting from a reduced exposure to infections in the postnatal period. The geographic data do not permit the identification of a specific organism and are consequently unlikely to throw more light on these possible mechanisms.

Generalized Clustering of Childhood Leukemia

The evidence discussed above is noteworthy, and perhaps more convincing, because it stands out from the relative uniformity of childhood leukemia incidence. Attempts to demonstrate widespread and generalized clustering have not, generally speaking, produced striking results. An atlas of leukemia incidence covering around a third of the population of England and Wales in the years 1984–1988 [7] demonstrates moderate variation between counties; this is probably largely due to the contribution for adults, which was not separated out. Tests of spatial clustering at a more local level, however, were broadly negative.

As far as childhood leukemia is concerned, the largest register of data in the world is the (UK) National Registry of Childhood Tumours maintained by the Childhood Cancer Research Group in Oxford (*see* **Disease Registers**). Geographically referenced cases occurring in Britain in the years 1966–1983 were made available to a group of researchers, who tried out their different methodologies; the results were reported in a monograph [14]. The evidence of generalized spatial clustering was rather slight, was related to ALL under the age of 5 and appeared to be strongest in rural areas [1]; the latter association may be a reflection of the socioeconomic effect already noted. An analysis of space–time clustering by Gilman et al. [20] reported some statistically significant results, but these were hard to interpret because of the problems of multiple testing (*see* **Multiple Comparisons**) and of sensitivity to population changes referred to above; the latter problem is especially severe in the analysis of large data sets, where statistically significant results may correspond to very small real effects. The overview by Gardner [18] concluded: "Overall, there are apparently no dramatic findings in the results of the analyses carried out for this volume."

This negative view of the importance of generalized clustering is consistent with many other papers and reviews [25, 31], though the review by Alexander [2] concludes that the data as a whole are "consistent with their interpretation as an imperfect reflection of

some underlying population infective process". It is only to be expected that some significant findings will be reported. They should certainly not be discounted, but need critical appraisal, particularly where there may be doubts about the methodology.

Discussion

We conclude from this review that the evidence for any significant general tendency of leukemia to exhibit clustering is equivocal at best. It would be as unsatisfactory to conclude that there is no such effect as to conclude that the evidence is strong enough to provide real pointers toward the etiology. Although there is some evidence of geographic and of space–time clustering, the effects are at most weak and the scope for methodologic and data error is considerable. Methodologic limitations work both ways: it is possible that some stronger effects are being masked by inefficient methods and inadequate data. In particular, it is likely that place of birth is at least as important as place of residence in the etiology of childhood leukemia; unfortunately, it is in practice harder to obtain extensive data on place of birth and most published results relate to residence at diagnosis or death.

There is no particular reason why geography should hold the clue to the etiology of leukemia. Even if environmentally varying factors were known to be very important, the mobility of the population will inevitably dilute the impact on individuals. In practice, so little is known about the etiology of the disease that we cannot assume prima facie that environment should be significant. None of this is likely to allay the anxieties of people who believe that their own form of the disease is directly related to their own circumstances. If only to put their anxieties into perspective and offer the best possible reassurance, it is necessary to maintain research effort on the possibility that there is a much stronger environmental component in the etiology of the disease than appears likely at present.

Level of a Test

The level of a statistical test, often called the level of significance, is the probability of rejecting the **null hypothesis** of "no effect" when in fact it is true. In classical **hypothesis testing** a null hypothesis, denoted by H_0, is assumed to be true, and the observed data are evaluated by a statistical test procedure to decide if the data provide sufficient evidence to reject this hypothesis. The possible outcomes of this test procedure are summarized in Table 1.

The level of the test is the probability of making a type I error. The decision to accept or reject H_0 is based on a comparison of the prespecified level of the test (generally 0.05 or 0.01) with the test procedure's ***P* value**, i.e. the calculated probability of finding a difference at least as great as the one actually observed, assuming that H_0 is true. If the P value is less than the level of the test, then the experimental data are considered to be inconsistent with the null hypothesis, H_0 is rejected, and the result is declared to be "statistically significant" at that particular level. If the P value is greater than the level of the test, then H_0 is accepted. A statistically significant departure from the null hypothesis may or may not be of practical importance in a given study.

Table 1

		State of Nature	
		H_0 true	H_0 false
Decision	Accept H_0	Correct	Type II error
	Reject H_0	Type I error	Correct

Although the level of a test is traditionally taken as 0.05 or 0.01, this choice may vary, depending upon the probability of type I and type II errors that the experimenter is willing to accept. The level of a test is also one of several factors (together with sample size, the magnitude of the difference to be detected and the underlying variability) that determine the **power** of a test procedure for detecting departures from the null hypothesis (power is defined as one minus the probability of a type II error). Thus, for example, if 0.01 rather than 0.05 is selected as the level of the test, the probability of a type I error is reduced, but so is the power for detecting departures from H_0.

Other statistical terms that are often used to refer to the level of a test include the size of the test, the alpha error, and the **false positive rate**.

JOSEPH K. HASEMAN

Levinson–Durbin Algorithm

The Levinson–Durbin **algorithm** is a method for finding the solution $\boldsymbol{b} = [b_1, b_2, \ldots b_p]^{\mathrm{T}}$ to a system of p linear equations

$$\mathbf{A} \times \boldsymbol{b} = \mathbf{c}, \tag{1}$$

where $\mathbf{A}$ is a $p \times p$ symmetric Toeplitz **matrix** (a Toeplitz matrix is composed of elements that are constant along the diagonals)

$$\mathbf{A} = \begin{bmatrix} a_0 & a_1 & \ldots & a_{p-2} & a_{p-1} \\ a_1 & a_0 & \ldots & a_{p-3} & a_{p-2} \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ a_{p-2} & a_{p-3} & \ldots & a_0 & a_1 \\ a_{p-1} & a_{p-2} & \ldots & a_1 & a_0 \end{bmatrix} \tag{2}$$

and $\mathbf{c}$ is a known p-dimensional column vector.

Systems like (1) with $\mathbf{A}$ both symmetric and Toeplitz can be found in several applications, like **spectral** estimation, filter design (*see* **Kalman Filter**), or linear **prediction**. For instance, given two N-point sequences $\{x_k\}$ and $\{y_k\}$, the linear prediction problem deals with finding the coefficients of a moving-average filter of order p that predicts $\{y_k\}$ from $\{x_k\}$, minimizing the sum of the squared-errors S:

$$S = \sum_{k=0}^{N-1} [y_k - (b_1 x_k + \cdots + b_p x_{k-p})]^2. \tag{3}$$

The coefficients $\boldsymbol{b} = [b_1, b_2, \ldots b_p]^{\mathrm{T}}$ are the solution to (1), when $a_i = r_{xx}(i)$ are the **autocorrelation** coefficients of $\{x_k\}$, and $\boldsymbol{c} = [r_{xy}(0), r_{xy}(1), \ldots, r_{xy}(p-1)]^{\mathrm{T}}$ are the cross-correlation coefficients (Wiener–Hopf equations).

Another application is finding the coefficients b_k of an autoregressive model (*see* **ARMA and ARIMA Models**) of order p approximating a time series $\{y_k\}$

$$y_N = -\sum_{k=1}^{p} b_k y_{N-k} + e_N \tag{4}$$

when the autocorrelation coefficients $[r_{yy}(i)]$ are known, or estimated from $\{y_k\}$. The solution $\boldsymbol{b} = [b_1, b_2, \ldots, b_p]^{\mathrm{T}}$ satisfies (1), where $a_i = r_{yy}(i)$, and $\boldsymbol{c} = [-r_{yy}(1), -r_{yy}(2), \ldots, -r_{yy}(p)]^{\mathrm{T}}$ (**Yule–Walker equations**).

To solve the matrix equation (1), one should calculate $\boldsymbol{b} = \boldsymbol{A}^{-1} \times \mathbf{c}$. Common general methods require a number of operations proportional to p^3 to compute $\boldsymbol{A}^{-1}$. By exploiting the special structure of the Toeplitz matrix in connection with the linear prediction problem, N. Levinson developed a computationally efficient algorithm [2] that requires a number of operations proportional only to p^2. The method was rediscovered by J. Durbin, who applied it to fit an autoregressive model to a given correlation sequence [1]; therefore, the algorithm is commonly referred to as the "Levinson–Durbin" algorithm.

The method is an iterative procedure that solves a series of truncated problems. It is initialized by solving the equation $a_0 b_1^{(1)} = c_1$. Then, at each step m the size of the problem is incremented by considering a new row and column of $\boldsymbol{A}$, that is, the set of m-linear equations:

$$\sum_{i=1}^{m} a_{i-1} b_i^{(m)} = c_j (j = 1, \ldots, m). \tag{5}$$

When $m = p$, the vector $\boldsymbol{b} = [b_1^{(p)}, b_2^{(p)}, \ldots b_p^{(p)}]^{\mathrm{T}}$ is the solution to (1). Figure 1 shows a scheme of the algorithm when it is used to solve the Yule–Walker equations; further details can be found in [4]. A generalization to the case of the nonsymmetric Toeplitz matrix is given in [6].

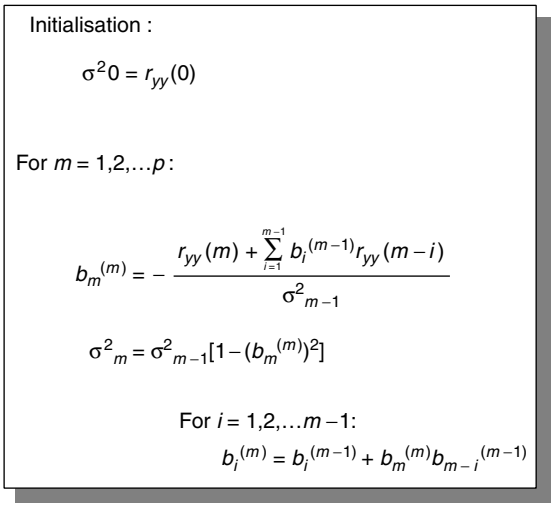

Figure 1 Scheme of the Levinson–Durbin algorithm for solving the Yule–Walker equations

The algorithm has been widely applied in several biomedical fields like speech analysis [3] and spectral analysis of EEG [5, 7] and cardiovascular signals [8] (*see* **Clinical Signals**). The popularity of the Levinson–Durbin algorithm in biomedicine is based on its effectiveness in solving the Yule–Walker equations. In fact, many nonstationary biomedical signals–like the EEG or the beat-by-beat series of cardiovascular data–can be considered "locally stationary" over short time windows. Sometimes these segments of local stationarity are too short to be analyzed by traditional **Fast Fourier transform** (FFT) spectra, which might not provide the required frequency resolution. Alternatively, the best autoregressive model of order p fitting the data is identified by solving the Yule–Walker equations (owing to its recursive structure, the Levinson–Durbin algorithm also provides all the models of order $m < p$), and a high-resolution spectrum is calculated from the theoretical expression for autoregressive processes [4].

In the following example, the algorithm is applied to model a respiratory signal $\{y_N\}$. Respiratory waves can be derived from the ECG by assessing beat-by-beat changes in the cardiac electrical axis. From a short ECG recording consisting of 15 consecutive heartbeats, the following 14 samples of a respiratory time series $\{y_N\}$, in mV, were derived:

$$\{88; -141; -154; 129; 7; -135; -26;$$
$$161; -72; -13; 262; -48; -134; 75\}.$$

The sampling frequency of $\{y_N\}$ is the mean heart rate that, in this case, was 70 bpm. The coefficients $b_i^{(3)}$ of the best autoregressive model of order $m = 3$ fitting the data

$$y_N = -b_1^{(3)} y_{N-1} - b_2^{(3)} y_{N-2} - b_3^{(3)} y_{N-3} + e_N \quad (6)$$

are found solving the Yule–Walker equations. First, the autocorrelation coefficients are estimated from $\{y_N\}$ obtaining $r_{yy}(0) = 15\,195$, $r_{yy}(1) = -3196$, $r_{yy}(2) = -10\,776$, and $r_{yy}(3) = 9640$. Then, the algorithm is applied as shown in Figure 1. From

$$\sigma_0^2 = r_{yy}(0) = 15\,195 \quad (7)$$

we iteratively obtain

$$m = 1 : b_1^{(1)} = \frac{-r_{yy}(1)}{\sigma_0^2} = \frac{3196}{15\,195} = 0.210$$
$$\sigma_1^2 = \sigma_0^2[1 - b_1^{(1)2}] = 15\,195$$
$$\times (1 - 0.210^2) = 14\,525, \quad (8)$$

$$m = 2 : b_2^{(2)} = \frac{-(r_{yy}(2) + b_1^{(1)} r_{yy}(1))}{\sigma_1^2}$$
$$= \frac{10\,776 + 0.210 \times 3196}{14\,525} = 0.788$$
$$b_1^{(2)} = b_1^{(1)} + b_2^{(2)} b_1^{(1)} = 0.210 + 0.788$$
$$\times 0.210 = 0.375$$
$$\sigma_2^2 = \sigma_1^2[1 - b_2^{(2)2}] = 14\,525$$
$$\times (1 - 0.788^2) = 5506, \quad (9)$$

and finally, for $m = 3$:

$$b_3^{(3)} = \frac{-(r_{yy}(3) + b_1^{(2)} r_{yy}(2) + b_2^{(2)} r_{yy}(1))}{\sigma_2^2}$$
$$= \frac{-(9640 - 0.375 \times 10\,776 - 0.788 \times 3196)}{5506}$$
$$= -0.559$$
$$b_1^{(3)} = b_1^{(2)} + b_3^{(3)} b_2^{(2)} = 0.375 - 0.559 \times 0.788$$
$$= -0.065$$

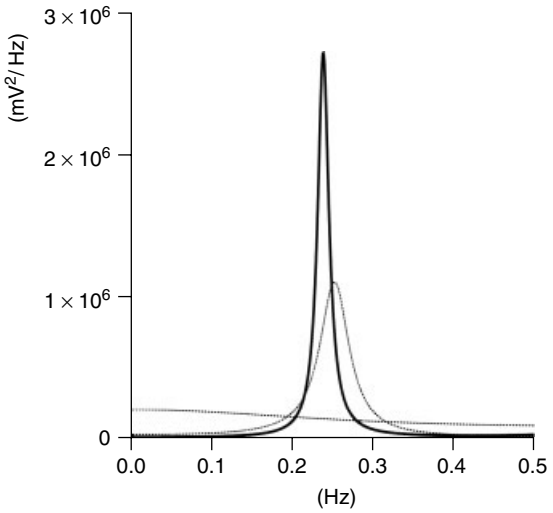

Figure 2 Power spectrum of the autoregressive model of order 3 fitting the respiratory signal of the example (see text); the model coefficients were identified by solving the Yule–Walker equations through the Levinson–Durbin algorithm. Spectra corresponding to models of order 2 and 1 are also shown (dotted lines)

$$b_2^{(3)} = b_2^{(2)} + b_3^{(3)} b_1^{(2)} = 0.788 - 0.559 \times 0.375 = 0.578$$
$$\sigma_3^2 = \sigma_2^2[1 - b_3^{(3)2}] = 5506 \times (1 - 0.559^2) = 3785. \quad (10)$$

In this way, we identify not only the coefficients $b_i^{(3)}$ but also the power of the model error, σ_3^2. Figure 2 shows the power spectrum of $\{y_N\}$ calculated from this model.

PAOLO CASTIGLIONI

Lexis Diagram

A Lexis diagram is a (time, age) coordinate system, representing individual lives by line segments of unit slope, joining (time, age) of birth and death [14] (see Table 1 and Figure 1). The Lexis diagram is an important descriptive tool in epidemiology and **demography**. However, it also has several applications in **survival analysis** and analytical epidemiology as a tool for several classes of statistical models, as surveyed by Keiding [8]. These uses of the Lexis diagram are less common and it is the aim of this article to indicate some recent developments.

Lexis [14] in his Figure 1, reproduced here as Figure 2, originally considered a diagram of (calendar time at birth, age) in which life lines will be vertical rather than having unit slope. In his Figure 2, reproduced here as Figure 3, he also mentioned an equilateral diagram in which the time units in the calendar time, age, and cohort (i.e. time of birth) directions are of the same length. See [11] for more on the early history of the Lexis diagram. Lexis further discussed a three-dimensional extension allowing for an intermediate (irreversible) life event, in Lexis's case exemplified by marriage. This corresponds to the three-state model basic to the modern statistical description of **incidence** and **prevalence** (cf. [9, 15]).

Despite its long history, the Lexis diagram is still being rediscovered among statisticians, cf. Goldman [6] for the standard Lexis diagram and Weinkam & Sterling [20] for the equilateral Lexis diagram.

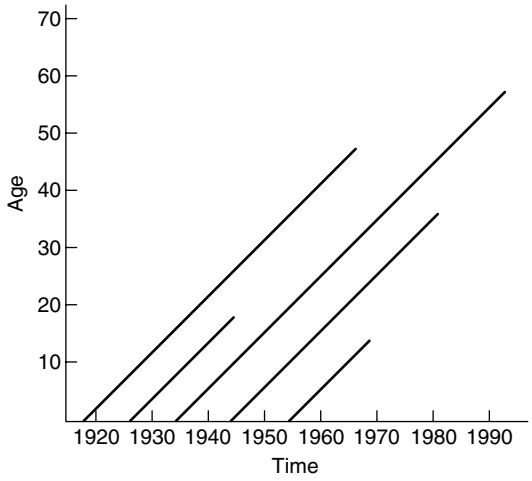

Figure 1 A Lexis diagram representing the five lives of Table 1

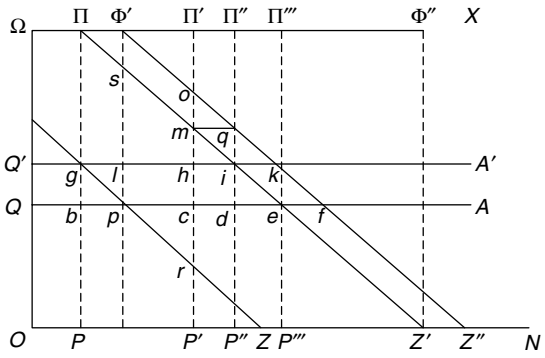

Figure 2 Lexis's diagram [14, Figure 1]

Applications of the Lexis Diagram in Survival Analysis and Analytical Epidemiology

Clinical Trials with Staggered Entry

In many **clinical trials** patients arrive sequentially in calendar time but the substantive interest is on survival time since entry. As explained in the articles **Interim Analysis of Censored Data** and **Staggered Entry**, the resulting interplay between the two time scales (calendar time and duration) has generated considerable complications in the development of a satisfactory statistical theory, particularly if comparisons between treatments are intended along the way at certain fixed time points (interim analysis) or sequentially (*see* **Data and Safety Monitoring**).

As mentioned by Keiding et al. [12] (*see* **Delayed Entry**), it is sometimes feasible to exploit the remaining life times of individuals (counted with delayed entry) from an interim analysis to supplement new individuals in a confirmatory analysis. This idea is explained in the Lexis diagram of Figure 4.

Table 1 Five lives illustrated in Figure 1

Born	Died	Age at death
1918	1966	48
1926	1944	18
1934	1992	58
1944	1978	34
1954	1968	14

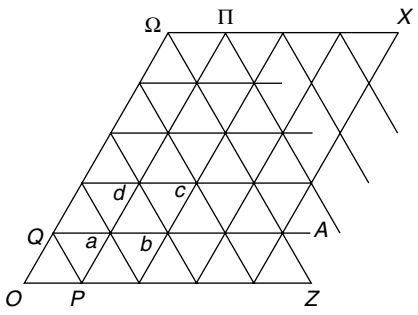

Figure 3 Lexis's equilateral diagram [14, Figure 2]

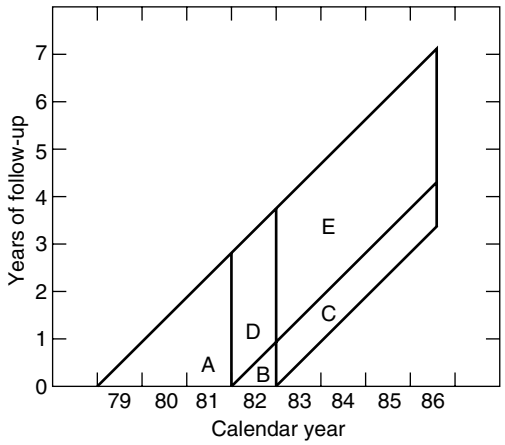

Figure 4 Lexis diagram of the DBCG-77 clinical trials on adjuvant treatment of breast cancer. The traditional independent data set for verifying an unexpected finding in A would be based on B and C. However, much more information is obtained by including also D and E, and in fact B and D already would have yielded the independent confirmation not achieved by B and C. Reproduced from Keiding et al. [12] by permission of John Wiley & Sons Ltd

Disease Incidence Studies

Lexis diagram representations of classical (often historically) prospective studies (*see* **Cohort Study**; **Cohort Study, Historical**) of (calendar time, age)-specific disease incidence are common, and we return to some of the statistical issues below. More intricate sampling plans may also take advantage of this representation, such as the **retrospective** incidence study of a **cross-sectional** sample of prevalent diabetics by Keiding et al. [13], where each incident and surviving case needed to be weighted (in a **Horvitz–Thompson** fashion) by its inverse survival probability from disease onset to the sampling date.

Prevalent Cohort Studies

A prevalent cohort study is based on a cross-sectional sample of diseased patients, with or without retrospective information on disease onset. Patients are followed until death or a fixed later calendar time, whichever comes first, (see Figure 5, and also [7] for additional examples and the link to the Arjas–Haara theory of innovative and noninnovative marks in the marked **point process** that accounts for the partial observation). The articles **Biased Sampling of Cohorts in Epidemiology** and **Delayed Entry** provide surveys of design and analysis problems for such studies.

Statistical Inference in the Lexis Diagram

Piecewise Constant Intensity Models

Many disease incidence and mortality studies (perhaps particularly in cancer) have taken piecewise constant intensity models (*see* **Grouped Survival Times**) as method of choice (see Clayton & Schifflers [4, 5] for a definitive survey). As is also well known in sociology, there is an inherent

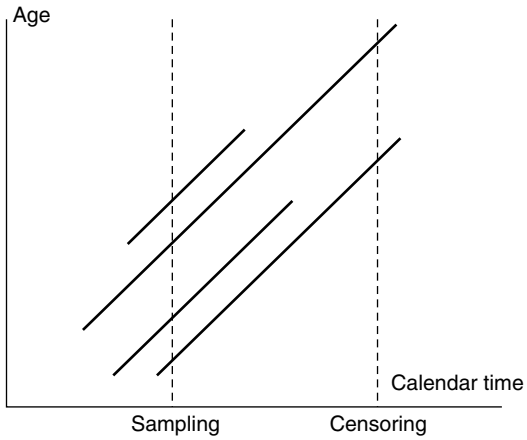

Figure 5 Lexis diagram of a prevalent cohort study. Four patients are sampled and their disease onset is known. During the follow-up period two of them die; the other two are still alive at the end of follow-up, where they are censored

unidentifiability of the linear component in a model allowing for dependence on both **age, period and cohort** (*see* **Identifiability**), although Nakamura [17] showed that a **Bayesian** framework allowed roughness penalties in the three directions to decide the matter.

Point Processes, Continuous Time

Brillinger [3] initiated an exact use of point processes as a basis for statistical models for incidence and mortality in the Lexis diagram, generalized to morbidity (incidence) and prevalence by Keiding [9, 10] (see also [19]). Without parametric assumptions, statistical analysis requires smoothing formally studied by McKeague & Utikal [16] and embedded in an **empirical Bayes** interpretation of **penalized likelihood** by Berzuini et al. [2], Berzuini & Clayton [1] and Ogata et al. [18], who reanalyzed the retrospective diabetes incidence study by Keiding et al. [13] quoted above.

NIELS KEIDING

Life Expectancy

Life expectancy is both the most summary and the most significant measure derived from a **life table**. Life expectancy at age **x** is the average number of years a person aged **x** will live if subject to the mortality rates contained in the life table.

In life table notation, life expectancy at age **x**, $\mathring{e}_x$, is given by

$$\mathring{e}_x = \frac{T_x}{l_x},$$

where T_x is the total years lived in the life table population after exact age **x**, and l_x = the number of survivors in the life table population at exact age **x**. The method for calculating these quantities can be found in standard textbooks [3].

Like the life table itself, life expectancy is determined by the force of mortality or mortality hazard function, $\mu(x)$, over the entire age range (*see* **Hazard Rate**). In continuous notation

$$\mathring{e}(x) = \int_x^\infty \frac{l(x)\,\mathrm{d}x}{l(x)},$$

and since

$$l(x) = \exp\left[-\int_0^x \mu(u)\,\mathrm{d}(u)\right],$$

it can be seen that life expectancy at age **x** reflects both the **cumulative hazard** from birth to age **x** (through l_x), and the cumulative hazard from **x** to the oldest age (through T_x, itself an integral of l_x).

In **actuarial** analysis it is normal to distinguish between the complete (exact) expectation of life and the curtate or whole year expectation, but in **demography** and epidemiology the complete expectation is universally employed.

In most populations $\mathring{e}(x)$ tends to rise between birth and age 1, and to decline linearly thereafter, although in very low mortality countries the decline is virtually linear throughout the age range.

The most common life expectancy encountered is $\mathring{e}(0)$, the expectation of life at birth. Because $\mathring{e}(0)$ incorporates the entire mortality experience of the cohort or life table population, it may be considered as an age standardized (*see* **Standardization Methods**) measure of mortality, where the standard age distribution is derived from the age pattern of mortality itself.

Life expectancy at birth has increased substantially with modernization, rising from a preindustrial level of perhaps 40 years to current levels of over 80 in countries like Japan. Because of its cumulative impact throughout the age range, improved survival in infancy has made the greatest contribution to this increase.

In recent years there have been unexpected gains in expectation of life at older ages in some very low mortality countries, leading to predictions that expectation of life could rise to 100 years, with significant effects on social security and pension systems. However, 85 seems a more likely upper limit [2].

Traditionally, life table theory has not had a strong statistical component: the focus has primarily been on the average expectation of life, rather than on its distribution. However, Chiang [1] has addressed the **sampling** theory of the life table, and more recently the homogeneity/heterogeneity of life expectancy has received renewed attention, particularly in the context of expectation of life at advanced ages.

Life expectancy is also used as a powerful tool in association with multistate or multilevel life tables. Expectations of working life, of a healthy life, or of a life free of disability are examples of this. Unlike death, individuals may move in and out of these states, requiring modifications to the logic of the life table to incorporate nonabsorbing states.

Life Table

A life table is a tabular representation of central features of the distribution of a positive **random variable**, say T, with an absolutely continuous distribution. It may represent the lifetime of an individual, the failure time of a physical component, the remission time of an illness, or some other duration variable. In general, T is the time of occurrence of some event that ends individual survival in a given status. Let its cumulative distribution function (cdf) be $F(t) = \Pr(T \leq t)$ and let the corresponding survival function be $S(t) = 1 - F(t)$, where $F(0) = 0$. If $F(\cdot)$ has the probability density function (pdf) $f(\cdot)$, then the risk of event occurrence is measured by the **hazard** $\mu(t) = f(t)/S(t)$, for t where $S(t) > 0$. Because of its sensitivity to changes over time and to risk differentials between population subgroups, $\mu(t)$ is a centerpiece of interest in empirical investigations.

In applications to human mortality, which is where life tables originated, the time variable normally is a person's attained age and is denoted x. The function $\mu(x)$ is then called the *force of mortality* or *death intensity* (*see* **Hazard Rate**). The life-table function $l_x = 100\,000\ S(x)$ is called the *decrement function* and is tabulated for integer x in *complete life tables*; in *abridged life tables* it is tabulated for sparser values of x, most often for five-year intervals of age. The *radix* l_0 is selected to minimize the need for decimals in the l_x table; a value different from 100 000 is sometimes chosen. Other life-table functions are the expected number of deaths $d_x = l_x - l_{x+1}$ at age x (i.e. between age x and age $x + 1$), the single-year death probability $q_x = \Pr(T \leq x + 1 | T > x) = d_x/l_x$, and the corresponding survival probability $p_x = 1 - q_x$. Simple integration gives

$$q_x = 1 - \exp\left[-\int_x^{x+1} \mu(s)\,\mathrm{d}s\right]. \qquad (1)$$

Life-table construction consists in the estimation and tabulation of functions of this nature from empirical data. If ungrouped individual-level data are available, then the **Kaplan–Meier estimator** can be used to estimate l_x for all relevant x and estimators of the other life-table functions can then be computed subsequently. Alternatively, a segment of the **Nelson–Aalen estimator** can be used to estimate $\int_x^{x+1} \mu(s)\,\mathrm{d}s$; (1) can then be used to estimate q_x for each x, and the rest of the computations follow suit. From any given schedule of death probabilities $q_0, q_1, q_2, \ldots$, the l_x table is easily computed sequentially by the relation $l_{x+1} = l_x(1 - q_x)$ for $x = 0, 1, 2, \ldots$. Much of the effort in life-table construction therefore is concentrated on providing such a schedule $\{q_x\}$.

More conventional methods of life-table construction use **grouped survival times**. Suppose for simplicity that the range of the lifetime T is subdivided into intervals of unit length and that the number of failures observed during interval x is D_x. Let the corresponding total person-time recorded under risk of failure in the same interval be R_x. Then, if $\mu(t)$ is constant over interval x (the assumption of *piecewise constancy*), then the *death rate* $\hat{\mu}_x = D_x/R_x$ is the **maximum likelihood** estimator of this constant. Relation (1) can again be used to provide an estimator

$$\hat{q}_x = 1 - \exp(-\hat{\mu}_x), \qquad (2)$$

and the crucial first step in the life-table computation has been achieved. Instead of (2), $\hat{\mu}_x \big/ \left(1 + \frac{1}{2}\hat{\mu}_x\right)$ is often used to estimate q_x. This solution is of older vintage and may be regarded as an approximation to (2).

Two kinds of problems may arise: (i) the exact value of R_x may not be known, and (ii) the constancy assumption for the hazard may be violated.

When the exact risk time R_x is not known, some approximation is often used. An Anglo-Saxon tradition is to use the midyear population in the age interval. Alternatively, suppose that the number N_x of survivors to exact age x and the number W_x of withdrawals (losses to follow-up) in the age interval are known. What has become known as the **actuarial method** then consists in approximating R_x by $N_x - \frac{1}{2}(D_x + W_x)$. If there are no withdrawals and N_x is known, then D_x/N_x is the maximum likelihood estimator of q_x, and this provides a suitable starting point for the life-table computations.

For the case where only grouped data are available and the piecewise-constancy assumption for the intensity function is implausible, various methods have been developed to improve on (2). For an overview, see Keyfitz [12]. Even if single-year age groups are used, mortality drops too fast in the first year of life to merit an assumption of constancy over this interval. Demographers often use $\hat{\mu}_0/[1 + (1 - a_0)\hat{\mu}_0]$ to estimate q_0, where a_0 is some small figure, say between 0.1 and 0.15 [2]. If it is

possible to partition the first year of life into subintervals in each of which mortality *can* be taken as constant, then it is statistically more efficient essentially to build up a life table for this year. This leads to an estimate like $\hat{q}_0 = 1 - \exp(-\sum_i \hat{\mu}_i)$, where the sum is taken over the first-year intervals. See Dublin et al. [5, p. 24] for an example.

The force of mortality is sometimes represented by a function $h(x;\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a vector of parameters. Actuaries most often use the classical Gompertz–Makeham function $h(x;a,b,c) = a + bc^x$ for the force of mortality in their life tables (*see* **Parametric Models in Survival Analysis**). When individual-level data are available, it would be statistically most efficient to estimate the parameters by the maximum likelihood method, but most often they are estimated by fitting $h(\cdot;\boldsymbol{\theta})$ to a schedule of death rates $\{\hat{\mu}_x\}$, perhaps by **least squares**, minimum chi-square (*see* **Ban Estimates**), or some **method of moments**. This approach is called *analytic graduation*; for its statistical theory, see [11]. One of many alternatives to modeling the force of mortality is to let [10]

$$\frac{q_x}{p_x} = A^{(x+B)^C} + D\exp[-E(\ln x - \ln F)^2] + GH^x.$$

So far we have tacitly assumed that the data come from a group of independent individuals who have all been observed in parallel and whose lifetimes have the same cdf. **Staggered** (delayed) **entries** into the study population and voluntary exits (withdrawals) from it are permitted provided they contain no information about the risk in question, be it death, recurrence of a disease, or something else. Nevertheless, the basic idea is that of a connected cohort of individuals that is followed from some significant starting point (like birth or the onset of some disease) and which is diminished over time due to *decrements (attrition)* caused by the risk's operation. In demography, this corresponds to following a **birth cohort** through life or a marriage cohort while their marriages last, and the ensuing tables are called *cohort life tables*.

Because such tables can only be terminated at the end of a cohort's life, it is more common to compute age-specific attrition rates $\hat{\mu}_x$ from data collected for the members of a population during a limited period and to use the mechanics of life-table construction to produce a *period life table* for the population from such rates. If mortality patterns are tied to cohorts, then individuals who live at widely differing ages in the period of observation cannot be expected to have the same risk structure, and the period table is said to reflect the patterns of a *synthetic* (fictitious) cohort exposed to the risk of the period at the various ages.

Multiple-decrement Tables

When two or more mutually exclusive risks operate on the study population (*see* **Competing Risks**), one may correspondingly compute a *multiple-decrement table* to reflect this. For instance, a period of sickness can end in death or, alternatively, in recovery. Suppose that an integer random variable K represents the *cause of decrement* and define $F_k(t) = \Pr(T \le t, K = k)$, $f_k(t) = \mathrm{d}F_k(t)/\mathrm{d}t$, and $\mu_k(t) = f_k(t)/S(t)$, assuming that all $F_k(\cdot)$ are absolutely continuous. Then $\mu_k(\cdot)$ is the cause-specific hazard (intensity) for risk cause k and $\mu(t) = \sum_k \mu_k(t)$ is the total risk of decrement at time t. For the multiple-decrement table, we define the decrement probability

$$\begin{aligned} q_x^{(k)} &= \Pr(T \le x+1, K = k | T > x) \\ &= \int_0^1 \exp\left[-\int_0^t \mu(x+s)\,\mathrm{d}s\right] \mu_k(x+t)\,\mathrm{d}t. \end{aligned} \tag{3}$$

For given risk intensities, $q_x^{(k)}$ can be computed by numerical integration in (3). The expected number of decrements at age x as a result of cause k is $d_x^{(k)} = l_x q_x^{(k)}$. When estimates are available for the cause-specific risk intensities, one or two columns can therefore be added to the life table for each cause to include estimates of $d_x^{(k)}$ and possibly $q_x^{(k)}$.

Several further life-table functions can be defined by formal reduction or elimination of one or more of the intensity functions in formulas like those above. In this manner, a *single-decrement life table* can be computed for each cause k, depicting what the normal life table would look like *if* cause k were the only one that operated in the study population and *if* it did so with the risk function estimated from the data. The purpose is to see the effect of the risk cause in question without interference from other causes. Some demographers call this abstraction the risk's *pure* effect. No assumption is made that in practice the total attrition risk can actually be reduced to the level of the one which is in focus or that this cause operates independently of other causes. For instance, a single-decrement life table of recovery from an

illness reflects the pure timing effect of the duration structure of the intensity of recovery even though the elimination of mortality is unattainable.

A single-decrement life table is at an extreme end of a class of tables produced by deleting one (or more) of the cause intensities in formulas like those above. To obtain a *cause-deleted life table*, where only cause k has been eliminated, one may introduce $\mu_{-k}(t) = \mu(t) - \mu_k(t)$,

$$q_x^{(-k)} = \int_0^1 \exp\left[-\int_0^t \mu_{-k}(x+s)\,\mathrm{d}s\right]\mu_{-k}(x+t)\,\mathrm{d}t$$
$$= 1 - \exp\left[\int_x^{x+1} \mu_{-k}(s)\,\mathrm{d}s\right], \qquad (4)$$

and so on, and a "normal" life table may be computed with $\mu(t)$ replaced by $\mu_{-k}(t)$ everywhere. A corresponding cause-deleted multiple-decrement life table may be based on reduced cause-specific decrement probabilities like

$$\int_0^1 \exp\left[-\int_0^t \mu_{-k}(x+s)\,\mathrm{d}s\right]\mu_j(x+t)\,\mathrm{d}t,$$
$$\text{for } j \neq k.$$

Such a table would show what a normal table would look like *if* it were possible to eliminate cause k without changing the risk of any other cause. Again no assumption needs to be made about the feasibility of such elimination in real life nor about cause independence. The computations are based on a pure abstraction. The interpretation for real-life applications must be based on substantive considerations and is a different matter.

Life Expectancy

An individual's **life expectancy** (at birth) is the expected value

$$\mathring{e}_0 = \mathrm{E}(T) = \int_0^\infty [1 - F(x)]\,\mathrm{d}x = \int_0^\infty \frac{l_x}{l_0}\,\mathrm{d}x$$

of his or her lifetime T, computed for the probability distribution $F(\cdot)$ operating at the time of birth. When the individual has survived to (exact) age x, his or her remaining lifetime, $U = T - x$, is positive and has the survival function $S_x(u) = S(x+u)/S(x) = l_{x+u}/l_x$, and the *residual life expectancy* is

$$\mathring{e}_x = \mathrm{E}(T - x | T > x) = \int_0^\infty S_x(u)\,\mathrm{d}u = \int_0^\infty \frac{l_{x+u}}{l_x}\,\mathrm{d}u.$$

If $L_x = \int_0^1 l_{x+t}\,\mathrm{d}t$, we get $L_x \cong \frac{1}{2}(l_x + l_{x+1})$ by the trapezoidal rule of numerical integration, and

$$\mathring{e}_x = \sum_{t=0}^\infty L_{x+t} \cong \sum_{t=0}^\infty \frac{l_{x+t}}{l_x} - \frac{1}{2}, \qquad (5)$$

which is normally used to compute values for $\mathring{e}_x$.

Equivalent names for the life expectancies are *mean survival time* for $\mathring{e}_0$ and *mean residual survival time at age x* for $\mathring{e}_x$. The *median length of life* is the median in the distribution of T; it used to be called the *probable length of life* (*see* **Median Survival Time**). Correspondingly, the *median residual length of life* at age x used to be called the *probable residual length of life*. If we denote the latter by ξ_x, then it is defined by the relation $l_{x+\xi_x} = \frac{1}{2}l_x$.

The above functions can be computed for cohort life tables and for period life tables. Figure 1 shows plots of the function $\mathring{e}_x$ according to the mortality experience for Swedish women in 1891–1900 and 1990–1994. The life expectancy at birth has increased from 53.6 years in the older table to 80.8 some one hundred years later. Note that in the older table $\mathring{e}_x$ increases with x up to age 2 and remains above $\mathring{e}_0$ up through age 11. When mortality is high at very young ages, surviving the first part of life *increases* your expected remaining lifetime. As a consequence of mortality improvements for very young children, these features have

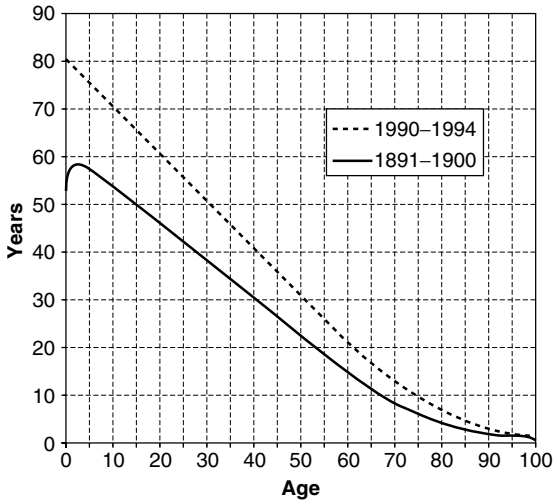

Figure 1 Residual life expectancy for Swedish women, 1891–1900 and 1990–1994

disappeared in the younger table. Note that the expected *total* lifetime, $x + \mathring{e}_x$, always increases with x throughout the human lifespan. (One can show that the derivative of this function is always positive.) The longer you have lived already, the longer you can expect the total length of your life to be.

In a multiple-decrement situation, formula (5) can be used to compute a residual life expectancy $\mathring{e}_x^{(-k)}$ from the decrement series of the cause-deleted life table for risk k. The difference $\mathring{e}_x^{(-k)} - \mathring{e}_x$ is the gain one would get in residual life expectancy at age x *if* it were possible to eliminate risk cause k without changing the risk intensity of any other cause of decrement. Dublin et al. [5, p. 96] note that according to the cause-specific mortality of the US in 1939–1941 the gain would be 9.01 years for white men and 8.80 years for white women at age 0 if one could eliminate the risk of death due to cardiovascular–renal diseases at all ages (and change no other cause-specific mortality risks). The gains from eliminating the risk of death in cancer alone were much less (1.39 years for men and 2.05 years for women).

History and Literature

The first step toward the development of the life table was taken when **Graunt** [9] published his famous *Bills of Mortality*. There were subsequent contributions by **Halley**, Huygens, Leibniz, Euler, and others. Deparcieux [4] clarified the definition of the life expectancy and identified the need for separate tables for men and women. Wargentin [17] was the first to publish real age-specific death rates, and the first to do so for a whole country. Price [14] included most of the columns now associated with the life table, and the tables by Duvillard [7] contained them all. The basic notions of cause-eliminated life tables go back to Bernoulli [1]. Cournot [3] developed the essentials of their mathematics. See Dupâquier [6] and Seal [15] for historical overviews. Smith & Keyfitz [16] have collected extracts from many original texts.

Life-table techniques are described in most introductory textbooks on the methods of actuarial statistics, biostatistics, demography, or epidemiology. See for example, Chiang [2], Elandt-Johnson & Johnson [8], or Manton & Stallard [13].

JAN M. HOEM

Likelihood Principle

All statisticians will agree that many, if not most, modern procedures in all approaches to statistics involve some use of the **likelihood** function. However, they will be much less in agreement about the applicability of some general likelihood principle. Although such principles have generated animated debate in the past, in recent years, fewer statisticians have shown interest in the foundations of their discipline, so discussion has waned (*see* **Inference, Foundations of**).

Suppose that we are interested in obtaining empirical information about a fixed set of completely specified models $P(\boldsymbol{\psi}) \in \mathcal{P}$, indexed by the unknown parameters $\boldsymbol{\psi}$. We observe values $\mathbf{y}$ of the relevant **random variable** $Y \in \mathcal{Y}$, using an appropriate study design. Then, the probability of these specific observations can be calculated for any member of the set $\mathcal{P}$. This is called the *likelihood function* $L(\boldsymbol{\psi}; \mathbf{y})$ for $\boldsymbol{\psi}$ given the set of models $\mathcal{P}$ and the observed data $\mathbf{y}$ [7]. Observed likelihood functions are said to be proportional if the proportionality constant contains only functions of $\mathbf{y}$, but not of $\boldsymbol{\psi}$.

On the basis of the likelihood function, a number of *likelihood principles* have been formulated. These are listed below from the weakest to the strongest.

1. Any model indexed by $\boldsymbol{\psi}_1$ is more plausible or *likely* than another $\boldsymbol{\psi}_2$, in the light of only the given observed data, written $L(\boldsymbol{\psi}_1; \mathbf{y}) > L(\boldsymbol{\psi}_2; \mathbf{y})$ if it makes these data more probable [8].
2. Data sets coming from replications of the same study design, thus having *the same sample space*, and having proportional likelihood functions contain the same information about $\boldsymbol{\psi}$ given $P(\boldsymbol{\psi})$ [6].
3. *Any* data sets with proportional likelihood functions contain the same information about $\boldsymbol{\psi}$ given $P(\boldsymbol{\psi})$ [2, 4].
4. From Principle 3, all inferences must be based on the likelihood function in such a way that proportional likelihoods lead to the same conclusions about $\boldsymbol{\psi}$ given $P(\boldsymbol{\psi})$ [3].

These should all be distinguished from **maximum likelihood** (sometimes also called a principle) that provides only a point estimate, perhaps with an asymptotic interval of precision. **Inferences** using likelihood principles involve the complete likelihood function, not just one value of it.

Principle 1 refers only to the observed data, making no reference to repetitions, to alternative designs, or to prior information not contained in $\mathcal{P}$. Principle 2 has been called the weak likelihood principle and Principle 3, the strong likelihood principle. These principles are closely related to **sufficient statistics** and to *conditioning* on the design used as well as on the observed outcome. At least for discrete data spaces, likelihood principle 3 can be derived from such sufficiency and **conditionality principles** [4], whereas Principle 2 is equivalent to sufficiency.

In contrast to the first two principles, Principles 3 and 4 imply that the same conclusions would be made from samples drawn from different probability spaces, that is, with different sample designs, if the resulting likelihood functions are proportional. Then, inference should not depend on the sample space $\mathcal{Y}$, but only on $\mathcal{P}$ and on the *observed* values $\mathbf{y}$.

The most common simple example used to illustrate the import of the likelihood principle is repeated Bernoulli trials (*see* **Binary Data**). Thus, the family of models $\mathcal{P}$, indexed by the constant unknown probability π, will describe a series of (supposedly) independent Bernoulli trials to be performed. Notice that independence and constant probability are *assumptions* of the models.

1. In a fixed sample size design, a coin is tossed a fixed number of times n and the number of heads y recorded. If the tosses are independent with constant probability of heads, the likelihood function is **binomial**,

$$L(\pi; y, n) = \binom{n}{y} \pi^y (1-\pi)^{n-y} \qquad (1)$$

   and the sample space is $\mathcal{Y} = \{y : 0 \leq y \leq n\}$.
2. In a sequential design (*see* **Sequential Analysis**), the coin will be tossed until a fixed number of tails c has been observed. Thus, y is the number of heads recorded in a random total sample size of $n = c + y$ tosses. With the same conditions of independence and constant probability as in Design 1, the likelihood function is **negative binomial**,

$$L(\pi; y, c) = \binom{c+y-1}{c-1} \pi^y (1-\pi)^c \qquad (2)$$

   and the sample space is $\mathcal{Y} = \{y : y \in \mathbf{N}\}$.

The second design differs in several important ways from the first. Not only is the sample size random, but we must also have available the result of each trial, as it occurs, in order to know whether to stop or not, and, hence, we must necessarily have the time-ordered sequence of results. This will often be the reason why such a design is chosen. However, this information is always lost in the negative binomial likelihood given above so that, in such cases, it would not be the appropriate likelihood function. On the other hand, Design 1 can be performed without this sequential information being available. If it is available, it also is discarded in constructing the above likelihood.

Once the total number of tosses, $n = c + y$, and the number of heads, y, are known, both likelihood functions, for a model of independent events with constant probability, are proportional to

$$\pi^y(1-\pi)^{n-y} = \pi^y(1-\pi)^c \tag{3}$$

and y is the sufficient statistic for π (given n or c fixed). However, in specifying the likelihood for Design 2, and perhaps that for Design 1, we discard relevant information about π. This is only necessarily available in the sequential order of results produced by Design 2. This lost information would allow us to check the assumptions of independence and constant probability π.

The difference between the two designs (fixed versus random sample size) is reflected in the frequentist approach to the problem. With the same null hypothesis and the same observed results, a ***P* value** will generally be different in the two designs because the sample spaces differ. Such inferences violate Principles 3 and 4.

In this sense, a frequentist procedure does not clearly separate testing the **null hypothesis** of a given fixed value for π from checking these more fundamental assumptions of the model. However, application of Principle 3 or 4 in this example clearly involves the assumption that the set of models under consideration, indexed by π, and defining the likelihood function, contains the true model. Dependence or nonconstant probability are excluded by hypothesis and information to check these assumptions is discarded.

Application of the stronger likelihood principles involves a number of strong assumptions that should be made explicit:

1. The set of models $P(\boldsymbol{\psi})$ must be fully specified and it must be assumed that one of them is true.
2. All uncertainty must be included in $\boldsymbol{\psi}$. It must index all unknowns in the problem, such as unknown variables and values to be predicted, and not just parameters in the classical sense.
3. If different designs are involved, $\boldsymbol{\psi}$ must be identical in all of them.
4. Choice among different designs must be noninformative.

In a decision problem, such as testing for treatment effect in a Phase III **clinical trial**, these may all be reasonable assumptions. However, in scientific research, Assumptions 1 and 4 are usually questionable.

- Scientific models are always approximations and can never be "true". The scientist must be able to question *all* assumptions and, as far as possible, check them with the data.
- The choice between two designs is rarely indifferent (made by random selection). One design will be used rather than another because it provides more appropriate information, given its costs.

Discussion of the likelihood principle necessarily involves the importance of the *stopping rule*. This specifies how observation is ended in a study. Stopping rules must only use information available up until the point in time when stopping is to occur. The role of the stopping rule can clearly be seen in the above Bernoulli example. The implication of likelihood principle 3 is that only the likelihood based on the final result of a properly conducted sequential trial should be used in making inferences. It is irrelevant that intermediate checks of the data were made to determine when to stop (perhaps by examining intermediate likelihoods). This contrasts with frequentist analyses involving "spending" the test probability over the course of a sequential trial (*see* **Interim Analysis of Censored Data**). Here, the final test depends on what happened throughout the trial and not just on the final outcome.

The way to handle **censoring** and **missing data** such as dropouts is closely related to the stopping rule. According to the stronger likelihood principles, if the censoring or missing data mechanism is noninformative about the process of interest, it need not explicitly appear in the likelihood function. Planned censoring will generally be of this form but missing

data, by definition, are generally unplanned and hence more difficult. Empirically, missingness, if not completely independent of the process under study (the broken test tube), will invariably be closely implicated with that process and must be modeled and included in the likelihood function no matter what approach is used.

Different approaches to inference necessarily imply differing appreciation of the various likelihood principles. The likelihood school maintains that Principle 1 is adequate to draw many scientific conclusions. However, the relative plausibilities of a set of models must be tempered by their complexity using a penalty, such as is done with information criteria (AIC [1], BIC [9], or their modifications; *see* **Akaike's Criteria**).

The frequentist school holds that Principle 1 is inadequate because indication of performance in repeated application of inferences is necessary. However, its techniques involve the use of the sample space, that is, what might have been observed, thus excluding Principles 3 and 4. If obeyed to the letter, this has drastic consequences. Although a study might have no censoring or missing data, if it could have had some, then the sample space for calculating test and confidence probabilities should include the possibility of censoring or missingness.

The **Bayesian** school upholds Principle 4 and provides strong arguments for the need to use **prior** probabilities in implementing it. Historically, up until about 1990, most debate was centered around this principle [3]. More recently, Principle 1 has received increasing attention, notably in the context of applying model selection criteria [5] such as the AIC or BIC (*see* **Bayesian Methods for Model Comparison**).

The type of design adopted for a given study will depend on the type of information required to be collected, as well as on other factors such as cost. Rarely will different designs provide proportional likelihood functions, as in the example of Bernoulli trials above. Thus, in most applied statistical practice, Principles 3 and 4 will not be of major concern in this context.

A more fundamental issue involves whether or not inferences should be conditioned solely on the observed data. Frequentist tests and confidence intervals involve the probabilities of events that might have been observed, given the design, and not just on what was observed. The Bayesian school argues that these are invalid. However, the latter argument can only be sustained if one is certain that the true model is contained in the set under consideration.

Thus, the strength of likelihood principle that one is prepared to apply, in the classification outlined above, must depend on one's confidence in the validity of the set of models under study. If one is certain about the set of models and only wishes to distinguish among them in the light of new data, a strong likelihood principle can be justified. On the other hand, if all aspects of the models are under scientific scrutiny, choice of inference based on a much weaker likelihood principle will be more prudent. However, restricting inference only to a likelihood principle narrows statistical analysis to routine **decision** problems, making scientific *discovery* impossible.

Likelihood Ratio Tests

Suppose $\mathbf{x}_{\text{obs}}$ is a vector of data that have been collected in order to test a hypothesis. The likelihood ratio test is a hypothesis testing procedure that can be performed in a wide variety of situations. To apply the procedure, we must be able to regard the observed data $\mathbf{x}_{\text{obs}}$ as having been drawn at random from a population whose distribution is described by a joint density function $f(\mathbf{x};\boldsymbol{\theta})$ depending on an unknown parameter vector $\boldsymbol{\theta}$, and we must formulate the hypothesis as a statement about $\boldsymbol{\theta}$. The distribution of the population may be discrete or continuous or may have both discrete and continuous components, such as occurs with some censored data.

The function $L(\boldsymbol{\theta}) = f(\mathbf{x}_{\text{obs}};\boldsymbol{\theta})$ is called the **likelihood** function. Let Θ denote the set of possible parameter vectors and let Θ_0 be a subset of Θ. For testing the null hypothesis H_0: $\boldsymbol{\theta} \in \Theta_0$ vs. the alternative hypothesis H_a: $\boldsymbol{\theta} \notin \Theta_0$, Neyman & Pearson [11] introduced the *likelihood ratio test* (abbreviated as *LR test*; also called the *generalized likelihood ratio test* or *maximum likelihood ratio test*). Let $L(\hat{\boldsymbol{\theta}})$ be the maximum value of the likelihood as $\boldsymbol{\theta}$ varies over Θ, let $L(\hat{\boldsymbol{\theta}}_0)$ be the maximum as $\boldsymbol{\theta}$ varies over Θ_0, and let

$$\lambda = \frac{L(\hat{\boldsymbol{\theta}}_0)}{L(\hat{\boldsymbol{\theta}})}.$$

The maximizing value $\hat{\boldsymbol{\theta}}$ of the parameter vector is called the maximum likelihood estimator (MLE) of $\boldsymbol{\theta}$ (*see* **Maximum Likelihood**), and $\hat{\boldsymbol{\theta}}_0$ is the MLE under the null hypothesis. We can expect the MLE $\hat{\boldsymbol{\theta}}$ to be close to the true parameter vector. If the null hypothesis were true, i.e. if the true parameter vector were in Θ_0, then we would expect both $\hat{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\theta}}_0$ to be close to the true parameter vector, and hence we would expect λ to be close to 1. The likelihood ratio test rejects the null hypothesis if λ is significantly smaller than 1, i.e. if the maximum likelihood under the null hypothesis is significantly smaller than the maximum likelihood under the alternative hypothesis.

In special situations the ***P* value** of a likelihood ratio test can be calculated exactly, but in general it must be approximated. If $f(\mathbf{x};\boldsymbol{\theta})$ satisfies certain regularity conditions (discussed below), then an approximate P value can be obtained as the proportion of a **chi-square distribution** that is larger than $-2\log\lambda$, where the number of **degrees of freedom** is the number of independent conditions that the null hypothesis imposes on the parameter vector $\boldsymbol{\theta}$. This proportion can be calculated by using the chi-square cumulative distribution function that is available in some computer packages, or bounds can be put on it by using a chi-square table.

Example 1

The diastolic blood pressures of 15 patients with moderate essential hypertension were measured immediately before and two hours after taking the drug captopril [4, p. 72]. A common way to analyze such data is to calculate the differences ("after" minus "before") and regard them as a random sample from a normally distributed population with unknown mean, δ, and unknown standard deviation, σ. The null hypothesis that the drug has no effect on blood pressure can be formulated as H_0: $\delta = 0$. The likelihood function is

$$L(\delta,\sigma) = \frac{1}{(2\pi)^{n/2}\sigma^n}\exp\left[-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\delta)^2\right],$$

where n is the sample size and the x_is are the differences. For the observed blood pressure data this becomes

$$L(\delta,\sigma) = \frac{1}{(2\pi)^{15/2}\sigma^{15}} \times \exp\left[-\frac{1}{2\sigma^2}(15\delta^2+278\delta+2327)\right].$$

The likelihood attains its maximum value, $L(\hat{\delta},\hat{\sigma})$, at $\hat{\delta} = -9.27$ and $\hat{\sigma} = 8.32$. Under the null hypothesis, the likelihood attains a maximum value, $L(0,\hat{\sigma}_0)$, at $\hat{\sigma}_0 = 12.46$. Then $-2\log\lambda = 2[\log L(-9.27, 8.32) - \log L(0, 12.46)] = 12.10$. Since the null hypothesis imposes only one condition on the parameters, the number of degrees of freedom is 1. From a chi-square table we see that the approximate P value is less than 0.001, and we conclude that the drug has an effect.

Example 1 is simple enough that there are explicit formulas for the MLEs: $\hat{\delta} = \overline{x}$, where $\overline{x}$ is the sample mean; $\hat{\sigma} = [(n-1)/n]^{1/2}s$, where s is the sample standard deviation; and $\hat{\sigma}_0 = (\sum x_i^2/n)^{1/2}$. Therefore there are explicit formulas for $L(\hat{\delta},\hat{\sigma})$ and $L(0,\hat{\sigma}_0)$ and hence for λ, namely $\lambda = (\hat{\sigma}/\hat{\sigma}_0)^n$. In general, however, $L(\hat{\boldsymbol{\theta}})$ and $L(\hat{\boldsymbol{\theta}}_0)$ must be calculated by

numerical optimization methods (*see* **Optimization and Nonlinear Equations**).

In Example 1 the LR test is equivalent to the usual t test. In fact, if $x_1, \ldots, x_n$ is a random sample from a normally distributed population with unknown mean μ and unknown standard deviation σ, then the LR test statistic, $-2\log\lambda$, for testing H_0: $\mu = \mu_0$, is an increasing function of the **Student's *t* statistic** $|t| = |\overline{x} - \mu_0|/(s/\sqrt{n})$. Therefore, in this situation it is possible to obtain the exact P value of the LR test. (But of course it is exact only if the population is exactly normally distributed.) From a t table it is seen that the exact P value also is less than 0.001.

Example 2

For the data in Example 1, the assumption that the blood pressure differences come from a normally distributed population can be justified by arguing that the data contain no outliers and that the t test is robust against nonnormality. But if one felt uncomfortable about assuming normality, a different test of the null hypothesis of no drug effect could be performed by regarding the differences as a random sample from a continuous population with an unknown proportion π of positive values. Here we are assuming nothing about the population other than that it is continuous. The null hypothesis can be formulated as H_0: $\pi = 0.5$. Let x denote the number of patients whose blood pressure differences were positive. The likelihood function is

$$L(\pi) = \frac{n!}{x!(n-x)!}\pi^x(1-\pi)^{n-x}.$$

This is another simple example in which the MLE has an explicit formula: $\hat{\pi} = x/n$. For the blood pressure data, $-2\log\lambda = 2[\log L(2/15) - \log L(0.5)] = 9.01$. The number of degrees of freedom is 1. From a chi-square table we see that the approximate P value is between 0.01 and 0.001, and we again conclude that the drug has an effect. The exact P value is also available in this example. By using the fact that, under our assumptions, the exact distribution of x is **binomial**, one obtains $P = 0.007$.

Example 3

One half of a group of 42 leukemia patients were treated with the drug 6-mercaptopurine and the other half were given a placebo [3]. Their remission times, in weeks, were recorded during a period of one year. At the end of the year some patients still had had no remission, and so these observations were censored. Let us assume that the patients were selected and treated independently of one another. A reasonable model for these data is that they are two independent **censored** random samples from two **Weibull** distributions. The likelihood function is

$$L(\kappa_1, \rho_1, \kappa_2, \rho_2) = L_1(\kappa_1, \rho_1)L_2(\kappa_2, \rho_2),$$

where

$$L_i(\kappa_i, \rho_i) = \kappa_i^{d_i}\rho_i^{d_i\kappa_i} \times \exp\left[(\kappa_i - 1)\sum_{\text{unc}}\log x_{ij} - \rho_i^{\kappa_i}\sum_{\text{all}} x_{ij}^{\kappa_i}\right],$$

in which x_{ij} is the jth observation in the ith subgroup ($i = 1, 2$, $j = 1, \ldots, 21$), d_i is the number of uncensored observations in the ith subgroup, "unc" indicates summation over the uncensored observations, and "all" indicates summation over all the observations, including the censored ones. The null hypothesis of no treatment effect can be expressed as H_0: $\kappa_1 = \kappa_2$ and $\rho_1 = \rho_2$.

No explicit expression for λ is available in this example. However, there is an explicit expression for the MLE $\hat{\rho}_i$ as a function of κ_i, namely $\hat{\rho}_i = (d_i/\sum_{\text{all}} x_{ij}^{\kappa_i})^{1/\kappa_i}$. Substitute this into $L_i(\kappa_i, \hat{\rho}_i)$ to obtain the **profile likelihood** $L_{\text{P}i}(\kappa_i)$. A numerical procedure must be used to maximize the profile likelihood, yielding the MLE $\hat{\kappa}_i$, from which we obtain $L(\hat{\kappa}_1, \hat{\rho}_1, \hat{\kappa}_2, \hat{\rho}_2) = L_{\text{P}1}(\hat{\kappa}_1)L_{\text{P}2}(\hat{\kappa}_2)$. Similarly, combining the two subgroups into a single sample under the assumption that H_0 is true, we can obtain $L_{\text{P}0}(\hat{\kappa}_0)$ and then $-2\log\lambda = 2[\log L_{\text{P}1}(\hat{\kappa}_1) + \log L_{\text{P}2}(\hat{\kappa}_2) - \log L_{\text{P}0}(\hat{\kappa}_0)] = 66.17$. The number of degrees of freedom is 2. From a chi-square table we see that the approximate P value is less than 0.001, and we conclude that the treatment has an effect.

Likelihood ratio tests are commonly used in a number of different statistical areas. In **multiple linear regression** and **analysis of variance** for models with independent and identically normally distributed errors, the usual ***F* tests** are equivalent to LR tests. In **multivariate analysis**, tests using the Wilks lambda criterion (*see* **Discriminant Analysis, Linear**) are equivalent to LR tests. In the analysis of **generalized linear models**, the reduction in deviance between a

model and an extended model is equal to the LR test statistic $-2\log\lambda$ for testing whether the two models are significantly different. To test hypotheses about **contingency tables**, one typically uses either the Pearson **chi-square test** or the LR test.

Likelihood ratio tests have been proposed in many other areas too. For any parametric statistical model that satisfies certain, fairly general, regularity conditions, the null distribution of $-2\log\lambda$ is well approximated by a chi-square distribution, and so it is straightforward, at least in theory, to apply the LR test to test the parameters of the model. In practice, calculation of the likelihood ratio often requires numerical optimization, which can involve substantial computation; but computation is becoming less of a concern as computer capabilities increase. The regularity conditions mentioned above assume that the support $\{\mathbf{x} : f(\mathbf{x};\boldsymbol{\theta}) > 0\}$ does not depend on $\boldsymbol{\theta}$, that $f(\mathbf{x};\boldsymbol{\theta})$ is differentiable with respect to $\boldsymbol{\theta}$, and a few other requirements that are mathematically technical but often satisfied. Under such conditions the null distribution of the LR test statistic can be approximated by a chi-square distribution with d degrees of freedom, where d is the difference in the dimensions of Θ and Θ_0. By the dimension of Θ is meant the number of "freely varying" components in the vector $\boldsymbol{\theta}$. More precisely, the dimension of Θ is k if it contains a solid k-dimensional cube and does not contain a solid $(k+1)$-dimensional cube. The degrees of freedom d can also be described as the number of independent conditions that the null hypothesis imposes on the parameter vector $\boldsymbol{\theta}$.

The chi-square approximation for the null distribution of the LR test statistic is based on asymptotic theory (*see* **Large-sample Theory**) and so it may not work well if the sample size is small. For example, for small categorical data sets the chi-square approximation is usually poor [1] and produces inaccurate P values. The approximation may also be inadequate if the number of parameters is large, such as when testing the goodness of fit of a **generalized linear model** against a saturated model [5], or if the null parameters are on the boundary of the parameter set, such as when testing whether a variance component is zero [9, p. 501].

In situations where the chi-square distribution poorly approximates the null distribution of the likelihood ratio test statistic it is sometimes possible to obtain a better approximation, or even the exact distribution. For example, for the Wilks lambda criterion, its null distribution is better approximated by using an F distribution rather than a chi-square distribution [12], and there are numerical procedures for calculating its exact critical values to any desired precision. Higher-order asymptotic methods, such as Bartlett adjustment [10] (*see* **Bartlett's Test**) or modified profile likelihood [8, 13], can be used to adjust a likelihood ratio so that its null distribution can be well approximated.

In the simple case of testing H_0: $\boldsymbol{\theta} = \boldsymbol{\theta}_0$ vs. H_a: $\boldsymbol{\theta} = \boldsymbol{\theta}_1$, the **Neyman–Pearson lemma** states that the likelihood ratio test is the **most powerful** test for any given level. In a one-parameter **exponential family** the LR test of a one-sided hypothesis is a uniformly most powerful test. Under certain more general conditions, LR tests have been shown to be optimal in several senses: asymptotically most stringent [15], asymptotically locally most powerful unbiased [2], and Bahudur efficient [14]. However, LR tests may not be robust to violations of the model assumptions [6, 7].

The likelihood ratio test has wide applicability and has given reasonable results in a large number of cases in which its performance has been studied.

D. BIRKES

Likelihood Ratio

Let $\mathbf{x}_{\text{obs}}$ be a vector of observed data. To analyze the data, one often assumes that $\mathbf{x}_{\text{obs}}$ has been randomly drawn from a population whose distribution is described by a joint density function $f(\mathbf{x};\boldsymbol{\theta})$ depending on an unknown parameter vector $\boldsymbol{\theta}$. The distribution may be discrete or continuous or may have both discrete and continuous components, such as occurs with some censored data. The **likelihood** of the parameter vector $\boldsymbol{\theta}$ based on the data vector $\mathbf{x}_{\text{obs}}$ is defined to be $L(\boldsymbol{\theta}) = f(\mathbf{x}_{\text{obs}};\boldsymbol{\theta})$. Given two possible values of the parameter vector, the one with the greater likelihood is regarded as being more likely to be the true parameter value. That is to say, the value $\boldsymbol{\theta}_1$ is more likely than the value $\boldsymbol{\theta}_2$ if the *likelihood ratio* $L(\boldsymbol{\theta}_1)/L(\boldsymbol{\theta}_2)$ is greater than 1. In fact, the likelihood ratio can be used as a quantitative measure of the strength of support that the data provide for $\boldsymbol{\theta}_1$ in comparison with $\boldsymbol{\theta}_2$ [1, 4, 5].

For example, consider an urn containing 10 balls, θ of which are red and $10-\theta$ are green. Suppose we draw two balls at random without replacement from the urn and both balls are red. The probability of such an outcome is $f(2;\theta) = (\theta/10)[(\theta-1)/9] = \theta(\theta-1)/90$. To compare the possibility that $\theta = 6$ with the possibility that $\theta = 5$, we can calculate the likelihood ratio $L(6)/L(5) = f(2;6)/f(2;5) = 1.5$ and state that $\theta = 6$ is 1.5 times as likely as $\theta = 5$.

The likelihood ratio $L(\boldsymbol{\theta}_0)/L(\boldsymbol{\theta}_1)$ is a sensible test statistic for testing the simple null hypothesis $\mathrm{H}_0\colon \boldsymbol{\theta} = \boldsymbol{\theta}_0$ vs. the simple alternative hypothesis $\mathrm{H}_1\colon \boldsymbol{\theta} = \boldsymbol{\theta}_1$ (*see* **Hypothesis Testing**). If the ratio is small, then the likelihood of $\boldsymbol{\theta}_0$ is small in comparison with the likelihood of $\boldsymbol{\theta}_1$, and so it makes sense that we should reject H_0. Moreover, Neyman & Pearson [3] showed that this test is the most powerful one among all tests having the same level (*see* **Neyman–Pearson Lemma**). For testing a general null hypothesis $\mathrm{H}_0\colon \boldsymbol{\theta} \in \boldsymbol{\theta}_0$ vs. a general alternative hypothesis $\mathrm{H}_1\colon \boldsymbol{\theta} \in \boldsymbol{\theta}_1$, Neyman & Pearson [2] proposed the test statistic $\lambda = L(\hat{\boldsymbol{\theta}}_0)/L(\hat{\boldsymbol{\theta}})$, where $L(\hat{\boldsymbol{\theta}}_0)$ is the maximum value of the likelihood as $\boldsymbol{\theta}$ varies over $\boldsymbol{\theta}_0$ and $L(\hat{\boldsymbol{\theta}})$ is the maximum value of the likelihood as $\boldsymbol{\theta}$ varies over $\boldsymbol{\theta}_0$ and $\boldsymbol{\theta}_1$ (*see* **Likelihood Ratio Tests**). The null hypothesis is rejected if λ is small. Some authors call λ a *likelihood ratio* but it is also called a *likelihood ratio criterion* or *generalized likelihood ratio* or *maximum likelihood ratio* or *likelihood ratio test statistic*. The quantity $-2\log\lambda$ is also sometimes called a *likelihood ratio test statistic*.

Other Interpretations of the Likelihood Ratio

Although the concept of likelihood is distinct from the concept of probability, it is possible to give the likelihood ratio $L(\boldsymbol{\theta}_1)/L(\boldsymbol{\theta}_2)$ a direct probability interpretation if we take a **Bayesian** viewpoint. Suppose that, on the basis of past experience, it can be assumed that the true parameter is either $\boldsymbol{\theta}_1$ or $\boldsymbol{\theta}_2$ and that both are equally probable. Then our **prior distribution** is given by $\Pr(\boldsymbol{\theta}_1) = \Pr(\boldsymbol{\theta}_2) = 0.5$. The likelihood ratio coincides with the ratio $\Pr(\boldsymbol{\theta}_1|\mathbf{x}_{\text{obs}})/\Pr(\boldsymbol{\theta}_2|\mathbf{x}_{\text{obs}})$ of the posterior probabilities of the two parameters.

If the likelihood ratio is viewed as a random function, in the manner indicated below, then it is a minimal sufficient statistic (*see* **Sufficient Statistic**). Choose a fixed parameter vector $\boldsymbol{\theta}_0$ and, for each fixed value of $\mathbf{x}$, regard the likelihood ratio $R(\mathbf{x})(\boldsymbol{\theta}) = L(\boldsymbol{\theta};\mathbf{x})/L(\boldsymbol{\theta}_0;\mathbf{x}) = f(\mathbf{x};\boldsymbol{\theta})/f(\mathbf{x};\boldsymbol{\theta}_0)$ as a real-valued function of $\boldsymbol{\theta}$. Let $\mathbf{X}$ be a random vector with density $f(\mathbf{x};\boldsymbol{\theta})$. It is a consequence of the factorization theorem for sufficient statistics that $R(\mathbf{X})$ is a minimal sufficient statistic.

Likelihood

In general use the word *likelihood* is a synonym for **probability** but in statistics it has a more specific meaning; it is the probability (or probability density) of the observed data given the probability model which gave rise to the data. Likelihood is used to compare different possible candidate values for the *parameters* of the model, and for this purpose it needs to be defined only up to a constant of proportionality: any constant multiple of the likelihood serves equally well. When comparing two candidate values for a parameter, the one with the greater likelihood is said to be *more likely*, and parameter values for which the probability of the observed data is greatest are known as *most likely* values, or **maximum likelihood** estimates. The concept of likelihood is central to both the *frequency* and the **Bayesian** theory of **inference**. In addition there have been many attempts to found a theory of inference on likelihood alone.

A Simple Example

Let 10 subjects be followed for five years, and a record made of whether they die (fail) or survive. A simple probability model is that the outcome for each subject is independently random with probability π for failure and $1-\pi$ for survival. The probability π is the *parameter* of the model. When four subjects fail, and six survive, the probability of the observed data is found from the **binomial distribution** to be

$$L(\pi) = 210\pi^4(1-\pi)^6.$$

Suppose we wish to compare $\pi = 0.1$ with $\pi = 0.5$ as possible values for the true value which gave rise to the data. The two likelihoods are $L(0.1) = 0.0112$ and $L(0.5) = 0.2051$, so $\pi = 0.5$ is more likely than $\pi = 0.1$. The most likely value is $\pi = 0.4$, which has likelihood 0.2508. Since the likelihood can be scaled by any constant without altering such comparisons it is often convenient to scale it to take the value 1 when π takes its most likely value. The scaled likelihood for π is then the **likelihood ratio** $L(\pi)/L(\hat{\pi})$, where $\hat{\pi}$ is the most likely value for π.

Part (a) of Figure 1 shows the likelihood ratio for a range of possible values for π. Values of π corresponding to a high likelihood ratio are said to be *supported* by the data; those with a low likelihood ratio are not supported. The distinction between supported and not supported depends on where the cut-point is placed on the likelihood ratio scale. A convenient summary of the information about π in the data is provided by the most likely value of π and

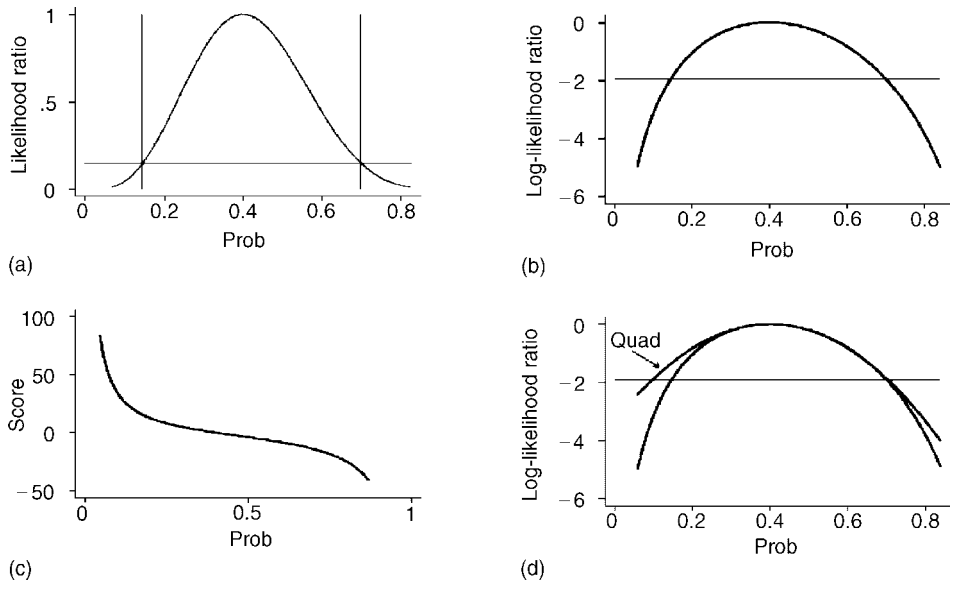

Figure 1 (a) Likelihood, (b) log likelihood, (c) score, and (d) quadratic approximation

a range of values which are supported at a given cut-point. The choice of cut-point can be regarded as a matter of convention; for example, we might all agree that parameter values with likelihood ratios above 0.15 are supported, while those with values below are not supported. Another approach is to choose the cut-point in terms of how well the supported range works when evaluated for repeated samples from the probability model assumed to have given rise to the data. This is called the *frequency* approach to statistics.

For any particular value of π the cut-point 0.1465 produces a supported range which includes the value of π in approximately 95% of repeated samples, provided the likelihood curve has roughly a *normal* bell shape. For this cut-point, then, the range of supported values corresponds to a 95% **confidence interval**. The supported range may also be thought of as a Bayesian *plausibility* interval based on a uniform *prior* belief about the true value of π. With a cut-point 0.1465 the area under the curve in part (a) of Figure 1, between the two verticals, is approximately 95% of the total area, so the *posterior* probability that π lies between the two limits is approximately 0.95. For all but very small studies the likelihood will have a normal bell shape (this is called the **central limit theorem**), and the three approaches (given likelihood ratio, given confidence level, and given posterior probability) will lead to almost the same range of values for the parameter.

Likelihood ratios are most easily studied as differences in log likelihoods. In this example the log likelihood is

$$l(\pi) = 4\log(\pi) + 6\log(1-\pi),$$

and the log of the likelihood ratio is $l(\pi) - l(\hat{\pi})$. This log-likelihood function is shown in part (b) of Figure 1; the cut point for the supported range is now $\log(0.1465) = -1.921$ and the shape of the log-likelihood ratio curve is quadratic rather than a bell. The shape can be further explored by examining the gradient at each value of the parameter, given by

$$l'(\pi) = \frac{4}{\pi} - \frac{6}{(1-\pi)}.$$

This is called the *score* function and it is usually written as $u(\pi)$. The graph of the score function is shown in part (c) of Figure 1; note that the score is zero when π takes its most likely value of 0.4.

Some General Definitions

Let the data consist of observations $x_1, x_2, \ldots, x_N$, with probability model $f(x;\theta)$, which depends on a parameter θ. When there are only a limited number of possible values for x the function $f(x;\theta)$ specifies the probability of each outcome, and when there are infinitely many outcomes $f(x;\theta)$ specifies the probability density. The log likelihood for θ is

$$l(\theta) = \sum_{i=1}^{N} \log f(x_i;\theta),$$

and the score function is

$$u(\theta) = l'(\theta) = \sum_{i=1}^{N} \frac{f'(x_i;\theta)}{f(x_i;\theta)}.$$

The most likely value of θ is $\hat{\theta}$, satisfying $u(\hat{\theta}) = 0$.

In the neighborhood of $\theta = \hat{\theta}$ the score function is approximately linear [see part (c) of Figure 1], and using Taylor's expansion

$$u(\theta) \approx u(\hat{\theta}) + (\theta - \hat{\theta})u'(\hat{\theta}).$$

The quantity $u'(\hat{\theta}) = l''(\hat{\theta})$ is negative, and its numerical value, namely $-l''(\hat{\theta})$, is called the observed **information** and is referred to as $j(\hat{\theta})$, or j for short. Since $u(\hat{\theta}) = 0$ the linear approximation can be written as

$$u(\theta) \approx -j(\theta - \hat{\theta}).$$

In part (c) of Figure 1 j is the numerical value of the gradient of the score function at $\pi = 0.4$. The steeper this gradient the more precise $\hat{\theta}$ is as an estimate of θ.

When considering the frequency properties of $\hat{\theta}$ as an estimate of θ it is best to write the function $l(\theta)$ as $l(\theta;x)$, stressing that it is a function of both the parameter values and the data. In a strictly likelihood approach the data are fixed and θ varies, which is why we write the function as $l(\theta)$. In the frequency approach it is x (the data) which varies and θ which is fixed, so that $l(\theta;x)$ is a **random variable**. The value of θ should be thought of as fixed at its true value, i.e. the value which gave rise to the data. The score $u(\theta;x)$ is now also a random variable, and is particularly important in frequency theory because its mean is zero and its variance can be calculated from the log likelihood. In fact

$$\mathrm{var}(u) = -\mathrm{E}[l''(\theta;x)].$$

The quantity $-\mathrm{E}\{l''(\theta; x)\}$ is called the *expected* or *Fisher information* and referred to as $i(\theta)$. When evaluated at $\theta = \hat{\theta}$ the expected information usually reduces to the same thing as the observed information, i.e. $i(\hat{\theta}) = j(\hat{\theta})$. Using the approximation $u(\theta) \approx -j(\theta - \hat{\theta})$, it follows that

$$\hat{\theta} - \theta \approx j^{-1}u(\theta),$$

and

$$\mathrm{var}(\hat{\theta}) \approx j^{-1}\mathrm{var}(u)j^{-1}.$$

Since $\mathrm{var}(u) \approx j$, the right-hand side of this equation becomes $j^{-1}jj^{-1} = j^{-1}$, so the variance of $\hat{\theta}$ in repeated samples is approximately j^{-1}, the inverse of the observed information.

The expression $\mathrm{var}(\hat{\theta}) \approx j^{-1}\mathrm{var}(u)j^{-1}$ is called the *information sandwich*. There are situations when it is unwise to assume that $\mathrm{var}(u) = j$, and better to replace $\mathrm{var}(u)$ by an empirically based estimate, using the individual values $u(\hat{\theta}; x_i)$. In this case the sandwich does not reduce to j^{-1} but provides instead a more robust estimate of the variance of $\hat{\theta}$.

When combining data from several sources, about the same parameter, the total log likelihood is obtained by adding the log likelihoods from the different sources. Since the score is the first derivative of the log likelihood, the total score is also found by adding the scores from the different sources, and since the information is the second derivative of the log likelihood it too is found by adding over sources. This additive property of the log likelihood and its derivatives makes the combining of data from different sources straightforward.

Approximate Log Likelihoods

The function $l(\theta)$ can be expanded around $\theta = \hat{\theta}$ using Taylor's expansion:

$$l(\theta) \approx l(\hat{\theta}) + (\theta - \hat{\theta})l'(\hat{\theta}) + \tfrac{1}{2}(\theta - \hat{\theta})^2 l''(\hat{\theta}).$$

Since $l'(\hat{\theta}) = 0$ and $j = -l''(\hat{\theta})$, it follows that

$$l(\theta) - l(\hat{\theta}) \approx -\tfrac{1}{2}j(\theta - \hat{\theta})^2.$$

This may also be written as

$$l(\theta) - l(\hat{\theta}) \approx -\frac{1}{2}\left(\frac{\theta - \hat{\theta}}{S}\right)^2,$$

where $S^2 = j^{-1}$ is the variance of $\hat{\theta}$. The fact that the log likelihood is approximately quadratic shows that the frequency distribution of $\hat{\theta}$ is approximately normal. A 95% confidence interval for θ is therefore given by $\hat{\theta} \pm 1.960S$. Alternatively, solving

$$-\frac{1}{2}\left(\frac{\theta - \hat{\theta}}{S}\right)^2 = \log(0.1465) = -1.921$$

for θ leads to the same expression.

Two or More Parameters

Extending the results from one parameter to two or more parameters is largely a question of notation. For simplicity we concentrate on two parameters $\boldsymbol{\theta} = (\theta_1, \theta_2)$. The log likelihood $l(\theta)$ is now a function of both parameters, and there are two score functions $\mathbf{u} = (u_1, u_2)$, where u_1 is the derivative of $l(\theta_1, \theta_2)$ with respect to θ_1, and u_2 is the derivative of $l(\theta_1, \theta_2)$ with respect to θ_2. Similarly, there are two most likely values $\hat{\boldsymbol{\theta}} = (\hat{\theta}_1, \hat{\theta}_2)$ which together maximize the value of $l(\theta)$. The observed information becomes

$$j_{11}(\hat{\boldsymbol{\theta}}) = \frac{-\partial^2 l(\boldsymbol{\theta})}{\partial\theta_1^2},$$

$$j_{22}(\hat{\boldsymbol{\theta}}) = \frac{-\partial^2 l(\boldsymbol{\theta})}{\partial\theta_2^2},$$

$$j_{12}(\hat{\boldsymbol{\theta}}) = j_{21}(\hat{\boldsymbol{\theta}}) = \frac{-\partial^2 l(\boldsymbol{\theta})}{\partial\theta_1\partial\theta_2},$$

where all the derivatives are evaluated at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$. These quantities are often written as a 2×2 information matrix $\mathbf{j}(\hat{\boldsymbol{\theta}})$ with elements $j_{rs}(\hat{\boldsymbol{\theta}})$, where $r = 1, 2$ and $s = 1, 2$. Similarly, the expected information becomes a 2×2 matrix $\mathbf{i}(\boldsymbol{\theta})$ with elements

$$i_{rs}(\theta) = -\mathrm{E}\left[\frac{\partial^2 l(\boldsymbol{\theta})}{\partial\theta_r\partial\theta_s}\right].$$

All the results for one parameter extend in a fairly straightforward way to two or more parameters. In particular, the distribution of $\mathbf{u} = (u_1, u_2)$ has zero mean (0, 0), and covariance matrix equal to $\mathbf{i}(\boldsymbol{\theta})$, the expected information matrix. When evaluated at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$ this becomes equal to $\mathbf{j}(\hat{\boldsymbol{\theta}})$, the observed

information matrix. The linear approximation to the score functions becomes

$$u_1 \approx -j_{11}(\theta_1 - \hat{\theta}_1) - j_{12}(\theta_2 - \hat{\theta}_2),$$
$$u_2 \approx -j_{12}(\theta_1 - \hat{\theta}_1) - j_{22}(\theta_2 - \hat{\theta}_2),$$

which may be written in matrix terms as

$$\mathbf{u} \approx -\mathbf{j}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}), \qquad \hat{\boldsymbol{\theta}} - \boldsymbol{\theta} = \mathbf{j}^{-1}\mathbf{u}.$$

The mean of the distribution of $\hat{\boldsymbol{\theta}}$ is approximately (0, 0) and the covariance matrix is approximately

$$\mathbf{j}^{-1}\mathrm{var}(\mathbf{u})\mathbf{j}^{-1},$$

which reduces to $\mathbf{j}^{-1}$ when var($\mathbf{u}$) is replaced by $\mathbf{j}$.

Finally, the quadratic approximation to the log likelihood in the neighborhood of $(\hat{\theta}_1, \hat{\theta}_2)$ is

$$l(\theta_1, \theta_2) - l(\hat{\theta}_1, \hat{\theta}_2) \approx -\tfrac{1}{2} j_{11}(\theta_1 - \hat{\theta}_1)^2 - \tfrac{1}{2} j_{22}(\theta_2 - \hat{\theta}_2)^2 - j_{12}(\theta_1 - \hat{\theta}_1)(\theta_2 - \hat{\theta}_2),$$

which shows that the joint distribution of $(\hat{\theta}_1, \hat{\theta}_2)$ is approximately bivariate normal with mean (0, 0) and covariance matrix $\mathbf{j}^{-1}$.

Nuisance Parameters

A supported *region* for (θ_1, θ_2) can be found by solving $l(\theta_1, \theta_2) = -1.921$, but in most practical applications one of the two parameters (say θ_1) is of interest and the other is a *nuisance*; so one wants a supported range for θ_1. It is straightforward to find a supported range for θ_1 for a given value θ_2^0 for θ_2, by solving $l(\theta_1, \theta_2^0) = -1.921$ for θ_1, but the answer will in general depend on θ_2^0. Only rarely will the supported range be independent of the value chosen for θ_2^0.

There are two possible ways of obtaining a supported range for θ_1 which is not dependent on choosing a particular value of θ_2. The first way is to find some aspect of the data which, when held fixed, leads to a *conditional* log likelihood which depends only on θ_1. Provided the aspects of the data which are held fixed are uninformative about θ_1, no information is lost by using the conditional log likelihood.

The second way is to replace the nuisance parameter θ_2 by its most likely value given θ_1, that is by $\hat{\theta}_2(\theta_1)$. The resulting log likelihood, $l_p(\theta_1) = l(\theta_1, \hat{\theta}_2(\theta_1))$, is called the *profile* log likelihood for θ_1, and can be used to find a confidence interval for θ_1 by solving $l_p(\theta_1) = -1.921$, as before. The idea of profile log likelihood extends to more than one nuisance parameter, but should not be used when there are many nuisance parameters to be eliminated, but not very much data. This is because each $\hat{\theta}_2(\theta_1)$ is too poorly estimated for the resulting profile log likelihood to be useful. A well-known example where this happens is a matched case–control study where there is a nuisance parameter for each new matched set. In this situation it is necessary to use a conditional log likelihood, and indeed this is generally the best thing to do provided one is available. Unfortunately there are many situations where it is not possible to find a conditional likelihood which depends only on the parameter of interest.

A quadratic approximation to the **profile likelihood** for θ_1 is found by starting from the quadratic approximation to $l(\theta_1, \theta_2)$, in the neighborhood of $(\hat{\theta}_1, \hat{\theta}_2)$, and then obtaining the profile likelihood for θ_1. This gives a quadratic approximation to $l_p(\theta_1)$, the profile likelihood for θ_1, of the form

$$l_p(\theta_1) \approx -\frac{1}{2}\left(\frac{\theta_1 - \hat{\theta}_1}{S}\right)^2,$$

where S is given by

$$S^2 = \frac{j_{22}}{j_{11}j_{22} - j_{12}^2}.$$

This is the first diagonal element in the inverse of $\boldsymbol{j}$, the observed information matrix, so the quadratic approximation to the profile likelihood for θ_1 coincides with the normal approximation to $\hat{\theta}_1$.

Hypothesis Testing

From a strictly likelihood point of view, support for a specific *null* value of a parameter, say θ^0, is measured by the likelihood ratio for this value in the same way as for any other value of θ. The likelihood ratio is a measure of how different θ^0 is from $\hat{\theta}$. Cut-points on the likelihood ratio scale are a matter of convention; some useful ones are shown in Table 1.

From a frequency point of view we measure how far θ^0 is from $\hat{\theta}$ in terms of how often the value of some statistic in repeated samples exceeds the value observed. To do this requires a statistic whose distribution when $\theta = \theta^0$ is known, and a natural one

Table 1

Likelihood ratio	Evidence against the null value
>0.25	None
0.15–0.25	Slight
0.05–0.15	Strong
<0.05	Very strong

to choose is the score $u(\theta^0; x)$. When the true value of θ is θ^0, the score has mean zero and variance $i(\theta^0)$, so the distribution of

$$z = \frac{u(\theta^0) - 0}{[i(\theta^0)]^{1/2}}$$

is approximately N(0, 1), a normal distribution with unit variance, and the probability of observing a value greater than $|z|$ is obtained by looking z^2 up in a χ^2 distribution with one degree of freedom (df). This probability is called the ***P* value**, and the test is called a *score test*.

Another candidate for the choice of statistic is $\hat{\theta}$, the most likely value of θ. When the true value of θ is θ^0, this statistic has an approximately normal distribution with mean θ^0 and variance j^{-1}. The probability of observing a value greater than $|z|$, where z is now

$$z = \frac{\hat{\theta} - \theta_0}{j^{-1/2}},$$

is obtained by looking z^2 up in a χ^2 distribution with one df. The test is now called a *Wald test*.

The last and generally the best statistic which is used is the log-likelihood ratio itself. Provided the log-likelihood curve is reasonably close to a quadratic shape, the distribution of

$$d = 2[l(\hat{\theta}) - l(\theta^0)]$$

is approximately χ^2 with one df. The probability of observing a value of d which is greater than the one actually observed is found by looking up d in tables of the **chi-square distribution** on 1 df. The test is now called the (log) **likelihood ratio test**.

All three tests extend to null hypotheses in which several parameters take their null values; for example the distribution of

$$2[l(\hat{\theta}_1, \hat{\theta}_2) - l(\theta_1^0, \theta_2^0)]$$

is approximately χ^2 on two df.

Further Reading

The concept of likelihood was introduced to statistics by Fisher in 1925, but the first book to discuss statistical inference from an exclusively likelihood point of view is Edwards [4]. More recent accounts which stress the central role of likelihood in statistical inference are given by Lindsey [5] at an elementary level, Azzalini [1] at an intermediate level, and Barndorff-Nielson & Cox [2] at an advanced level. An elementary account of the use of likelihood in the context of epidemiology is given by Clayton & Hills [3].

Likert Scale

A Likert scale, or summated rating scale, is computed by summing responses over several items hypothesized to measure the same latent variable or construct [1]. Likert scales are often used to measure opinions, beliefs, or attitudes regarding a particular underlying construct. Items that comprise Likert scales are often measured on Likert response formats, which represent degrees of endorsement of those items [2]. For example, consider the following item measured on a five-point Likert response format:

Item:	Diet is an important part of a healthy lifestyle				
Response options:	Strongly agree	Agree	Neither	Dis-agree	Strongly disagree
	1	2	3	4	5

Items measured on Likert response formats are generally presented as declarative statements. For respondents to discriminate among response options, it is recommended that the items be presented as strong declarative statements.

Likert response formats may have three, four, five or more response options. An example of a six-point Likert response format which could have been used for the sample item above is: Strongly agree, Moderately Agree, Mildly agree, Mildly Disagree, Moderately disagree, and Strongly disagree. The five-point Likert response format is widely used. The number of response options for a given item depend upon the item being measured and subjects' abilities to discriminate between response options. Investigators should try to provide respondents with response options that are approximately equally spaced across the continuum of endorsement.

Many applications involve the measurement of a single underlying construct using multiple items, since in many cases single items are not adequate to measure the construct with sufficient precision. A Likert scale is constructed by summing or averaging responses over the set of all items to produce an overall score. In constructing the Likert scale, usually each item is equally weighted. If an investigation involves k such items, each measured on the same r-point Likert response format (responses coded as $1, 2, \ldots, r$, with higher scores reflecting more endorsement of each item), then the theoretic range of the Likert scale is k to kr.

Assumptions underlying the construction of multiple-item Likert scales are that each item is linearly related to the overall scale score, and that each item comprising the scale has approximately the same distribution (e.g. similar means and standard deviations). As an aside, when investigators present a set of items related to a single construct to respondents, some of the items should be reverse coded so as to reduce the likelihood that respondents consistently select the same response (e.g. strongly agree) for each item.

There are a number of techniques used to evaluate the **reliability** and validity (*see* **Validation Study**) of multiple-item Likert scales. These include, for example, the internal consistency reliability of the Likert scale, which is generally assessed using the **Cronbach's alpha** coefficient, and construct validity, which is assessed through **factor analysis**.

KIMBERLY A. DUKES

Limit Theorems

The earliest results in mathematical probability (dating from 1654) involved computations for finite sample spaces having equally likely outcomes, and thus could be regarded merely a branch of elementary combinatorics. The subject took a major step forward, however, both in the depth of its results and the sophistication of its methods after the discovery of its first limit theorems: James Bernoulli's **law of large numbers** (*c*. 1685, published posthumously in his *Ars conjectandi* of 1713) and Abraham De Moivre's **central limit theorem** [5] for sequences of dichotomous **binary** trials. These results extracted order from chaos by demonstrating that random phenomenon in the small (a limited number of observations) can exhibit regularities and deterministic behavior in the large.

Such results were often motivated by, and provided a theoretical basis for, the process of statistical **estimation**; in modern terminology, the law of large numbers amounts to nothing other than a statement that the sample mean is a **consistent** estimator of the population mean. If, for example, S_n denotes the number of successes in n dichotomous trials having probability of success p, then Bernoulli proved that $\lim_{n\to\infty} S_n/n = p$; using Stirling's approximation (including correction terms) to estimate the individual terms in the **binomial distribution** and then summing, De Moivre dramatically refined Bernoulli's result to discover the remarkable fact that

$$\lim_{n\to\infty} \Pr\left[a \le \frac{S_n - np}{[np(1-p)]^{1/2}} \le b\right] = \frac{1}{(2\pi)^{1/2}} \int_a^b \exp\left(-\frac{1}{2}x^2\right) \mathrm{d}x.$$

During the nineteenth and twentieth centuries, this result was extended far beyond the simple coin-tossing setup considered by De Moivre, important contributions being made by the French school of **Laplace** and **Poisson**, the Russian school of Chebyshev, Markov, Liapunov, Bemstein, Khinchin, and **Kolmogorov**, and the varied contributions of von Mises, Cantelli, Lindeberg, Lévy, and Feller in the period between the two world wars. Fueling these advances were the use of increasingly sophisticated methods such as the introduction of **characteristic functions** (by Laplace) and the **method of moments** (by Markov). The introduction of measure theory by Lebesgue and its use in the axiomatization of mathematical probability by Kolmogorov (*see* **Probability Theory**) led in turn to a sharp distinction between different forms of limit theorem, corresponding to different concepts of convergence: most commonly, **convergence in distribution**, probability, almost sure, and in L^p.

It is useful to regard a sequence of random variables as a single function $X(n, \omega)$, n being an integer and ω an element of a sample space. If one first fixes n, the result is a **random variable** $X_n(\cdot)$ (a function on the sample space), and one can then investigate the behavior of the distribution of X_n as $n \to \infty$; limiting behavior in this case corresponds to convergence in distribution. If, on the other hand, one first fixes ω, the result is a sequence $\omega(\cdot)$ (a function on the set of integers), and one can investigate the behavior of this *sample path* for typical values of ω; this corresponds to the case of almost sure convergence provided that the sequence converges except on a set of ω having probability 0.

The two behaviors can be very different. If, for example, the sequence represents an aperiodic finite **Markov chain**, then the distribution of X_n converges to the stationary distribution of the chain, but the sample paths $\omega(\cdot)$ cycle endlessly among the finite states of the chain; thus, in one sense, the chain exhibits ordered behavior over time, but in another it remains chaotic. (This phenomenon was first pointed out by Paul Ehrenfest, who introduced his celebrated urn model to illustrate that the Zermelo *recurrence paradox* does not contradict Boltzmann's demonstration that in statistical mechanics the entropy of a system, properly understood, is an increasing function of time. One can, in fact, prove some limit theorems in probability by first showing that an associated entropy function for a sequence of random variables increases with time.)

Thus, the law of large numbers has two versions, weak and strong, corresponding to convergence in probability and almost sure convergence. Just as the central limit theorem can be regarded as a refinement of the weak law of large numbers, the *law of the iterated logarithm* may be regarded as a refinement of the strong law of large numbers (almost sure convergence of the sequence of sample means to the population mean). This result (due in increasing generality to Khinchin, Kolmogorov, and Hartmann–Wintner),

one of the three pearls of the classical limit theorems, states that the sample path behavior for a sum of independent and identically distributed random variables, properly normalized, is at once both simple and unexpected: if $X_1, X_2, X_3, \ldots$ are independent and identically distributed random variables, such that $\mathrm{E}[X_k] = 0$, $\mathrm{var}[X_k] = 1$ and $S_n = X_1 + \cdots + X_n$, then

$$\Pr\left[\limsup_{n\to\infty} \frac{S_n}{(2n \log\log n)^{1/2}} = 1\right] = 1.$$

(It is simple to deduce from this that the set of limit points for the normalized sequence is almost surely the closed interval $[-1, 1]$.) Other such "zero–one" laws include the celebrated Borel–Cantelli lemmas used to prove the strong law.

This classical theory was subsequently extended to the study of sums and triangular arrays of sequences of random variables not having two **moments**, and using forms of normalization other than the mean and standard deviation. The stable and infinitely divisible distributions then arise as possible limiting distributions; the entire edifice is summarized in spare and elegant fashion in the classic and beautiful book of Gnedenko & Kolmogorov [8]. Lamperti [9] provides an attractive and accessible account of many of the key features of this classical theory.

Other generalizations of the classical theorems include the Birkhoff *ergodic theorem* and the *martingale convergence theorem*. The ergodic theorem (a direct descendant of Ehrenfest's attempts to explain and justify Boltzmann's theories) extended convergence of sample means from the domain of independence to that of stationary sequences (sequences invariant under shift); the martingale convergence theorem extracts a key property of centered sums (that one's expected future gain in a sequence of fair games is the same as one's present fortune) to derive other limiting forms of behavior. In the hands of Doob [6] and his successors, the martingale concept and its use became a fundamental and pervasive aspect of modern probability theory.

Two important modern advances in limit theorems after this classical period were the concepts of invariance principles and functional limit theorems. *Invariance principles* establish that if one sequence in a class of possible sequences converges to a limit, then all sequences in that class must converge to the same limit. Thus, one proof of the central limit theorem demonstrates that if the normalized sum of a sequence of independent and identically distributed random variables having a second moment (such as Bernoulli trials) converges to the standard normal distribution, then all sequences in this class must also converge to this limit (see [4]). *Functional central limit theorems* generalize the central limit theorem by considering functionals of sample paths (such as the maximum) and determining their limiting distribution by computing the distribution of that functional applied to the limiting distribution of sample paths: **Brownian motion**. The abstraction of these two theories led to the creation of the subject of *weak convergence* (see [2]).

There is a simple hierarchy that applies to the most common modes of convergence for a sequence of random variables: convergence almost surely $\Rightarrow$ convergence in probability $\Rightarrow$ convergence in distribution. These implications admit of limited reversal: if a sequence of random variables converges in probability, then every subsequence contains a further subsequence converging almost surely; if a sequence of random variables converges in distribution, then one can find a sequence of random variables having the same one-dimensional distributions that converges almost surely (*Skorokhod's theorem*).

This last result is related to a distinctively modern element in the proof of limit theorems: the use of *coupling methods* to construct versions of the random elements in question that live on the same probability space. Due originally to the gifted French probabilist Doeblin (who died tragically at the beginning of the Second World War), the method only gained currency decades later. Its use provides perhaps the most elegant derivation of the limiting behavior for countable Markov chains (see, for example, [3]).

The increasing use of the **bootstrap** [7], **Markov chain Monte Carlo**, simulated annealing, and other **computer-intensive methods** only recently possible, points to an emerging post-modern period of limit theorems in mathematical probability, the outlines of which are only just beginning to be clear. For a number of interesting applications of modern limit theorems to the biological sciences, see Waterman [10]. Such applications include methods as diverse as the Aldous [1] Poisson clumping heuristic, the Erdös–Renyi law of large numbers, and the theory of large deviations.

S.L. ZABELL

Linder, Forrest E.

Born: November 21, 1906, in Waltham, Massachusetts.
Died: August 18, 1988, in Washington, DC.

Forrest E. Linder devoted a lifetime of service to the worldwide development of vital and health statistics (*see* **Vital Statistics, Overview**). Although born in Massachusetts, he grew up in Iowa where, at Iowa State University, he received a doctorate in mathematics and statistics. Following a brief assignment with a foundation in Massachusetts, he moved to Washington, DC, in 1935, where he served until 1944 as a statistician with the US Bureau of the Census. In 1939 he spent a year in Montevideo assisting the Uruguayan government in establishing a vital statistics system. This was the beginning of Linder's interest in international vital statistics. He subsequently established an international vital statistics program at the Bureau of the Census, which provided training in civil registration and vital statistics to foreign national officials as well as an on-site consulting program for Latin American countries.

During World War II he served as Assistant Chief of the Medical Statistics Division of the US Navy, where he was responsible for establishing a morbidity reporting system, including the necessary data-processing support to provide current estimates of morbidity and mortality for the personnel of a greatly expanded wartime navy. After the war, Linder joined the United Nations where he became the first Chief of the Demographic and Social Statistics Branch of the UN Statistical Office. There, his contributions to the improvement of the **demographic** statistics of developing countries included projects he conceived and inspired, such as the world **censuses** of population and housing of 1950 and 1960 and a series of regional seminars on vital and health statistics. He was instrumental in designing and producing the first *United Nations Demographic Yearbook, Principles for a Vital Statistics System*, and the *Handbook of Vital Statistics Methods*.

In 1957, Linder returned to the federal civil service in Washington, DC, to become the director of the newly established National Health Survey, a program of the US Public Health Service. When the National Office of Vital Statistics was merged with the National Health Survey in 1960 to form the **National Center for Health Statistics (NCHS)**, Linder was named as its first director, a post he held until his retirement in 1967.

Upon leaving the Public Health Service, he joined the faculty at the University of North Carolina where he was both professor of biostatistics and the first director of the International Program of Laboratories for Population Statistics, popularly known as POPLAB [3]. While at POPLAB, he began to lay the groundwork for an international organization that would address the professional interests and needs of national officials responsible for civil registration. Recognizing that these officials were a diverse group, often working in isolation and without an international focus for information exchange and guidance, he founded the International Institute for Vital Registration in 1974, an organization to encourage and promote the improvement of civil registration throughout the world with special attention to lesser developed countries. When he retired from the university he served as President and Executive Director of the Institute until his death in 1988.

During a career that spanned half a century, Forrest Linder had an impressive list of important technical publications; these covered a wide range of topics in demography and health, such as fertility measurement, morbidity and mortality analysis, and survey methodology applied to public health (*see* **Surveys, Health and Morbidity**) [1, 2, 4–7]. He served on international and national advisory committees, such as the World Fertility Survey Steering Committee, US Agency for International Development Research Advisory Committee, **World Health Organization** Expert Committees on Health Statistics, and the US National Committee on Vital and Health Statistics; and he received the Distinguished Service Award from the US Department of Health, Education and Welfare and the Bronfman Prize from the **American Public Health Association**.

In each of his professional endeavors Forrest Linder exhibited a strong pioneering spirit at the highest technical level. Throughout his career he continued his abiding interest in the improvement of national and international vital and health statistics and he had an unfailing belief in the importance of his undertakings. His work has had a positive influence not only on civil registration and vital statistics programs

throughout the world, but also on the many statisticians, demographers and others with whom he came in contact.

Lindley's Paradox

A sharp **null hypothesis** may be strongly rejected by a standard sampling theory test of significance (*see* **Hypothesis Testing**) and yet be awarded high odds by a **Bayesian** analysis based on a small **prior probability** for the null hypothesis and a diffuse distribution of one's remaining probability over the **alternative hypothesis**. This disagreement between sampling theory and Bayesian methods was first studied by Jeffreys [2], and it was first called a paradox by Lindley [3].

The paradox can be exhibited in the simple case where we are testing $\theta = 0$ using a single observation Y from a **normal distribution** with variance one and mean θ. If we observe a large value y for Y ($y = 3$, for example), then standard sampling theory allows us to reject confidently the null hypothesis. But the Bayesian approach advocated by Jeffreys can give quite a different result. Jeffreys advised that we assign a nonzero prior probability π_0 to the null hypothesis and distribute the rest of our probability over the real line according to a fairly flat probability density, $\pi_1(\theta)$. If the range of possible values for θ is very wide, then the set of values within a few units of y will be very unlikely under $\pi_1(\theta)$, and consequently the overall **likelihood** of the alternative hypothesis,

$$L_1 = \int_{-\infty}^{\infty} \frac{1}{(2\pi)^{1/2}} \exp\left[-\frac{1}{2}(y-\theta)^2\right] \pi_1(\theta)\, \mathrm{d}\theta,$$

will be very small. It may even be so much smaller than the likelihood of the null hypothesis,

$$L_0 = \frac{1}{(2\pi)^{1/2}} \exp\left(\frac{-y^2}{2}\right),$$

that the odds in favor of the null hypothesis,

$$\frac{\Pr(\theta = 0 | Y = y)}{\Pr(\theta \neq 0 | Y = y)} = \frac{\pi_0}{1-\pi_0} \frac{L_0}{L_1}, \qquad (1)$$

are substantial.

We can think of (1) as a way of balancing arguments for and against the null hypothesis. *Against* the null hypothesis is its small initial probability (small π_0) and the unlikeliness of the observation under the null hypothesis (small L_0). *For* the null hypothesis is the unlikeliness of alternative values of θ near y [small $\pi_1(\theta)$, leading to small L_1]. There is no strong constraint between the arguments for and against. No matter how small π_0 and L_0 are, a sufficiently diffuse $\pi_1(\theta)$ can make L_1 small enough to counterbalance them.

If we are confident of the specified prior distribution – if, for example, we are working with a series of problems involving θs that are zero about π_0 of the time and distributed roughly according to $\pi_1(\theta)$ the rest of the time – then the Bayesian analysis is unassailable, and hence we must reject the standard sampling theory. An observation three standard deviations from the null hypothesis is not adequate to reject the null hypothesis if that observation is even more unlikely under the alternative hypothesis. This has led many authors to suggest that we make tests increasingly stringent as measurements become more precise relative to the range of possible values for what is being measured. We should, for example, lower the significance level (*see* **Level of a Test**) as the sample size grows. More sophisticated suggestions are made by Berger & Delampady [1].

However, if diffuseness of $\pi_1(\theta)$ reflects merely a wide uncertainty about θ rather than a positive prior confidence that values of θ near y are likely to occur, then the conflict seems to constitute a criticism of the Bayesian analysis. If we have no idea how θ arises, then our mere ignorance cannot justify a skepticism about values close to y so strong as to outweigh real evidence against the value of zero. This has motivated non-Bayesian approaches discussed by Shafer [4].

Linear Mixed Effects Models for Longitudinal Data

Introduction

Linear mixed-effects (LME) models [9] have become a popular tool for analyzing **longitudinal data** that arise in areas as diverse as **clinical trials**, **epidemiology**, agriculture, economics, and geophysics. The increasing popularity of these models is explained by the flexibility they offer in modeling the within-subject **correlation** often present in longitudinal data, by the handling of both balanced and unbalanced data, and by the availability of reliable and efficient **software** for fitting them [16, 20].

As a motivating example to illustrate the key ideas behind LME models, we consider data from a longitudinal study on the heights of a sample of 26 boys from Oxford, England, described and analyzed in [8] and presented in Figure 1.

As typically occurs with longitudinal data, the **growth** curves show a similar pattern across subjects (a linear trend, in this case), but important individual differences, both in intercept and in slope, are also observed.

Different approaches can, in principle, be used to model longitudinal data: (a) ignore the between-subject differences, concentrating on the estimation of the overall trend; (b) use a separate model for each subject, thus accounting for between-subject differences; and, (c) use a mixed-effects model. In the case of the Oxford data, the first approach consists of assuming the *population average* model

$$y_{ij} = \beta_0 + \beta_1 x_{ij} + \varepsilon_{ij} \tag{1}$$

to represent the height measurement y_{ij} on subject i at time x_{ij}. The within-subject errors ε_{ij} are assumed independently distributed as $\mathcal{N}(0, \sigma^2)$. The parameters of interest, the population intercept β_0, the population slope β_1, and the error variance σ^2, are estimated via ordinary **least squares** (OLS) [7]. The between-subject differences in growth pattern, which are not accounted for in the model, lead to incorrect **standard errors** for the OLS estimates $\widehat{\beta}_0$ and $\widehat{\beta}_1$ and this is the main drawback of this approach.

The model associated with the second approach uses *subject-specific* coefficients β_{0i} and β_{1i} to accommodate differences between subjects

$$y_{ij} = \beta_{0i} + \beta_{1i} x_{ij} + \varepsilon_{ij}. \tag{2}$$

However, it fails to take into account the common growth pattern observed across subjects, requires a large number of estimates (53 in this case), and does not scale-up with the number of subjects. Population inferences require a second-stage analysis, in which the individual estimates are treated as data. This is fairly inefficient and can lead to poor population estimates, especially when the data are unbalanced.

The linear mixed-effects approach strikes a balance between the population average model (1) and the subject-specific model (2), being expressed as

$$y_{ij} = (\beta_0 + b_{0i}) + (\beta_1 + b_{1i}) x_{ij} + \varepsilon_{ij}. \tag{3}$$

It accommodates between-subject variation in growth pattern via **random effects** $\mathbf{b}_i = [b_{0i}, b_{1i}]'$, while capturing the population average behavior through **fixed effects** $\boldsymbol{\beta} = [\beta_0, \beta_1]'$. The random effects are assumed to be independently distributed as $\mathcal{N}(\mathbf{0}, \boldsymbol{\Psi})$ vectors (*see* **Multivariate Normal Distribution**) and this common distribution ties together the observations from different subjects. A total of six parameters (the two fixed effects, the within-subject variance, and the three unique parameters in $\boldsymbol{\Psi}$) need to be estimated, irrespective of the number of subjects observed, so that the model is scalable in the number of subjects. The LME fit provides, in a single step, information about the population behavior as well as the between-subject variation in growth pattern.

In the next section, we describe the general linear mixed-effects model for Gaussian longitudinal data, its assumptions and estimation methods. Software for fitting the LME model is mentioned in the section "Software" and extensions to other mixed-effects models are briefly discussed in the section "Extensions".

Model Definition and Assumptions

The linear mixed-effects model for a Gaussian response measured longitudinally on a set of M subjects, proposed by [13], is a generalization of (3) that is expressed as

$$\mathbf{y}_i = \mathbf{X}_i \boldsymbol{\beta} + \mathbf{Z}_i \mathbf{b}_i + \boldsymbol{\varepsilon}_i \tag{4}$$

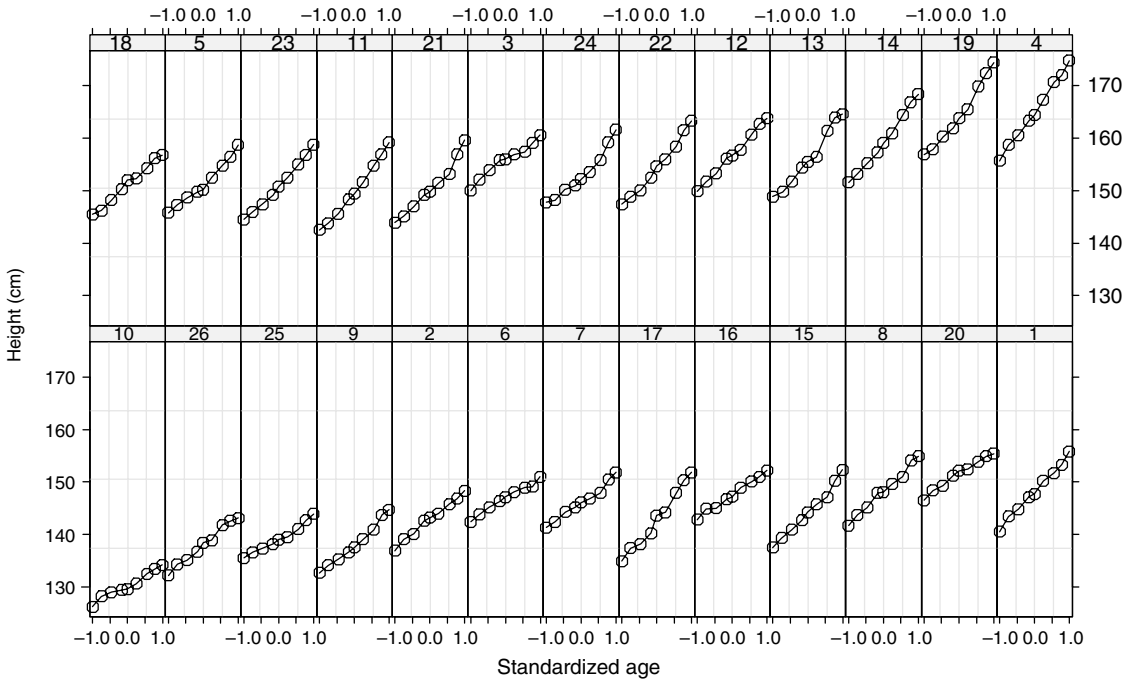

Figure 1 Heights of 26 boys from Oxford, England, each measured on nine occasions. The ages have been standardized to allow an easier comparison of the individual growth curves

where i is the subject index, $\mathbf{y}_i$ is an n_i-dimensional vector of observed responses, $\mathbf{X}_i$ and $\mathbf{Z}_i$ are known $n_i \times p$ and $n_i \times q$ regression **matrices** corresponding to the p-dimensional fixed-effects vector $\boldsymbol{\beta}$ and the q-dimensional random-effects vector respectively, and $\boldsymbol{\varepsilon}_i$ is an n_i-dimensional vector of within-subject errors. Note that the number of observations n_i, as well as the regression matrices $\mathbf{X}_i$ and $\mathbf{Z}_i$ are allowed to vary with subjects, so that unbalanced data are naturally handled. In the case of the Oxford data, the LME model formulation (4) would use $\mathbf{X}_i = \mathbf{Z}_i = [\mathbf{1} \ \mathbf{x}_i]$, with $\mathbf{1}$ representing a column vector of ones and $\mathbf{x}_i$ a column vector with the standardized times corresponding to subject i.

The $\mathbf{b}_i$ are assumed to be independent with distribution $\mathcal{N}(\mathbf{0}, \boldsymbol{\Psi})$ and the $\boldsymbol{\varepsilon}_i$ are assumed to be independent with distribution $\mathcal{N}(\mathbf{0}, \boldsymbol{\Lambda}_i)$, independent of the $\mathbf{b}_i$. The $\boldsymbol{\Psi}$ **covariance matrix** may be unstructured or structured – for example, diagonal [12], being parameterized by a set of parameters $\boldsymbol{\theta}$. The $\boldsymbol{\Lambda}_i$ matrices are typically assumed to depend on i only through their dimensions, being parameterized by a fixed, generally small, set of parameters $\boldsymbol{\lambda}$ – for example, an AR(1) structure [1] (*see* **ARMA and ARIMA Models**).

Even though the random effects are useful and intuitive quantities to represent between-subject differences in the coefficients, they are not observable in practice. Therefore, estimation and inference generally rely on the *marginal* distribution of the observed response vectors $\mathbf{y}_i$. Because of the linearity of the random effects in the LME model (4), the assumptions on the random effects and the within-group errors, and the properties of the multivariate normal distribution, it can be shown that the $\mathbf{y}_i$ are marginally distributed as independent $\mathcal{N}(\mathbf{X}_i\boldsymbol{\beta}, \boldsymbol{\Sigma}_i)$ random vectors, where the marginal covariance matrix is given by $\boldsymbol{\Sigma}_i = \mathbf{Z}_i\boldsymbol{\Psi}\mathbf{Z}_i' + \boldsymbol{\Lambda}_i$.

There are two ways in which the LME model (4) can account for within-subject correlation and heteroscedasticity (nonconstant variance) (*see* **Scedasticity**): through the random effects $\mathbf{b}_i$, and through the within-subject errors $\boldsymbol{\varepsilon}_i$. Because the random effects $\mathbf{b}_i$ are fixed by subject, and do not vary with time, the within-subject observations share the same random effects and are, therefore, correlated. This is represented by the $\mathbf{Z}_i\boldsymbol{\Psi}\mathbf{Z}_i'$ component of $\boldsymbol{\Sigma}_i$. Note, also, that the diagonal elements of $\mathbf{Z}_i\boldsymbol{\Psi}\mathbf{Z}_i'$ need not be constant, so that it can also accommodate

heteroscedasticity. The within-subject error contribution to the marginal covariance matrix is given directly by $\mathbf{\Lambda}_i$, which can be nondiagonal (correlation) and have different diagonal elements (heteroscedasticity). These two-model components may actually compete for explaining the marginal covariance structure of the response vectors and some care should be exercised when specifying their structure to avoid numerical problems in the **optimization** algorithm used to estimate the model parameters [20].

Estimation

Several methods of parameter **estimation** have been proposed for linear mixed-effects models. We concentrate here on two general methods: **maximum likelihood** (ML), and **restricted maximum likelihood** (REML). Descriptions and comparisons of the various estimation methods used for LME models can be found, for example, in [21] and [24]. For a **Bayesian** perspective, see [25].

The log-**likelihood** function corresponding to the LME model (4), based on the marginal distribution of the $\mathbf{y}_i$ (*see* **Marginal Likelihood**), is given by

$$\ell(\boldsymbol{\beta}, \boldsymbol{\theta}, \boldsymbol{\lambda}|\mathbf{y}) = -\frac{1}{2}\left\{N\log(2\pi) + \sum_{i=1}^{M}\left[\log|\mathbf{\Sigma}_i| + (\mathbf{y}_i - \mathbf{X}_i\boldsymbol{\beta})'\,\mathbf{\Sigma}_i^{-1}\,(\mathbf{y}_i - \mathbf{X}_i\boldsymbol{\beta})\right]\right\}, \tag{5}$$

where $\mathbf{y}$ denotes the entire response vector, and N the total number of observations. Conditional on $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$, it is easy to show to that the maximum likelihood estimate (MLE) of the fixed effects is given by

$$\widehat{\boldsymbol{\beta}} = \widehat{\boldsymbol{\beta}}(\boldsymbol{\theta}, \boldsymbol{\lambda}) = \left(\sum_{i=1}^{M}\mathbf{X}_i'\mathbf{\Sigma}_i^{-1}\mathbf{X}_i\right)^{-1}\sum_{i=1}^{M}\mathbf{X}_i'\mathbf{\Sigma}_i^{-1}\mathbf{y}_i. \tag{6}$$

The MLEs of $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ cannot be expressed in closed form, except in trivial cases, and numerical optimization of the loglikelihood function (5) must be employed. The MLE of $\boldsymbol{\beta}$ is then obtained by replacing $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ in (6) with their corresponding MLEs.

The most popular optimization methods for likelihood estimation in LME models are the **EM algorithm** [5] and Newton–Raphson or quasi-Newton methods [23] (*see* **Optimization and Nonlinear Equations**). A detailed discussion of numerical optimization in LME models, including efficient methods for calculating the loglikelihood (5) on the basis of orthogonal-triangular decompositions, is given in [15].

Maximum likelihood estimates of **variance components** tend to underestimate these parameters [10]. Restricted (or residual) maximum likelihood (REML) methods [10, 19] were developed to circumvent this problem. The REML loglikelihood is defined as the loglikelihood of a set of ordinary least-squares **residual** contrasts of the response vector $\mathbf{y}$ with respect to the fixed-effects regression matrix $\mathbf{X}$. By the definition of the LME model, this loglikelihood does not contain any information about the fixed effects and can be expressed as [10]

$$\ell_R(\boldsymbol{\theta}, \boldsymbol{\lambda}|\mathbf{y}) = \ell(\widehat{\boldsymbol{\beta}}(\boldsymbol{\theta}, \boldsymbol{\lambda}), \boldsymbol{\theta}, \boldsymbol{\lambda}|\mathbf{y}) - \tfrac{1}{2}\log\left|\sum_{i=1}^{M}\mathbf{X}_i'\mathbf{\Sigma}_i^{-1}\mathbf{X}_i\right|. \tag{7}$$

REML estimates of $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ are obtained via numerical optimization of (7) using similar algorithms as in the ML case. Although the REML loglikelihood does not have information on the fixed effects, REML estimates of $\boldsymbol{\beta}$ are obtained by plugging the REML estimates of $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ into (6). Table 1 presents the ML and REML estimates for the Oxford example, model (3). The random-effects parameters $\boldsymbol{\theta}$ are represented by the standard deviations σ_0 and σ_1 corresponding, respectively, to b_{0i} and b_{1i}, and their correlation coefficient ρ. The within-subject parameters $\boldsymbol{\lambda}$ include only the within-subject standard deviation σ.

In this example, because of the balanced structure of the data, the only differences between ML and REML estimation is in the standard deviations of the random effects, with REML giving larger estimates, as expected.

Table 1 ML and REML estimates for the Oxford data LME model

Method	β_0	β_1	σ_0	σ_1	ρ	σ
ML	149.37	6.53	7.92	1.65	0.64	0.66
REML	149.37	6.53	8.08	1.68	0.64	0.66

Even though the random effects are not regarded as parameters in the LME model, it is also of interest in practice to obtain predicted values for them. The best linear **unbiased predictors** (BLUPs) of the random effects, given $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$, are the conditional means of the $\mathbf{b}_i$ given the responses $\mathbf{y}_i$:

$$\widehat{\mathbf{b}}_i = \widehat{\mathbf{b}}_i(\boldsymbol{\theta}, \boldsymbol{\lambda}) = \boldsymbol{\Psi}\mathbf{Z}_i'\boldsymbol{\Sigma}_i^{-1}\left[\mathbf{y}_i - \mathbf{X}_i\widehat{\boldsymbol{\beta}}(\boldsymbol{\theta}, \boldsymbol{\lambda})\right]. \quad (8)$$

Estimated BLUPs are obtained, in practice, by replacing $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ in (8) with their corresponding (RE)ML estimates.

Inference

As a consequence of the estimates of $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ not being expressible in closed-form, inference on the LME model parameters usually relies on approximate distributions for the (RE)ML estimates, derived from asymptotic results. Under certain regularity conditions, generally satisfied in practice, the MLEs in the LME model (4) are **consistent** and asymptotically normal [11, 18] (*see* **Large-sample Theory**). Furthermore, the MLEs $\widehat{\boldsymbol{\beta}}$ are asymptotically uncorrelated with the MLEs $\widehat{\boldsymbol{\theta}}$ and $\widehat{\boldsymbol{\lambda}}$. The approximate distributions for the MLEs in the LME model are

$$\widehat{\boldsymbol{\beta}} \dot{\sim} \mathcal{N}\left(\boldsymbol{\beta},\ \left(\sum_{i=1}^{M}\mathbf{X}_i'\boldsymbol{\Sigma}_i^{-1}\mathbf{X}_i\right)^{-1}\right),$$

$$\begin{bmatrix}\widehat{\boldsymbol{\theta}}\\ \widehat{\boldsymbol{\lambda}}\end{bmatrix} \dot{\sim} \mathcal{N}\left(\begin{bmatrix}\boldsymbol{\theta}\\ \boldsymbol{\lambda}\end{bmatrix},\ \mathbf{I}^{-1}(\boldsymbol{\theta}, \boldsymbol{\lambda})\right), \quad (9)$$

where $\mathbf{I}(\boldsymbol{\theta}, \boldsymbol{\lambda})$ denotes the **information matrix** [3] corresponding to $(\boldsymbol{\theta}, \boldsymbol{\lambda})$, that is, minus the expected value of the second-order derivative of the loglikelihood function (5) with respect to $(\boldsymbol{\theta}, \boldsymbol{\lambda})$ (which does not depend on $\boldsymbol{\beta}$).

The REML estimates in the LME model are also consistent and asymptotically normal [11], with the same approximate distributions as in (9), but with the information matrix $\mathbf{I}(\boldsymbol{\theta}, \boldsymbol{\lambda})$ calculated using the REML loglikelihood ℓ_R defined in (7).

In practice, the unknown parameters $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ are replaced by their respective (RE)ML estimates in the approximate distributions (9). These approximate distributions are then used to produce **hypothesis tests** and **confidence intervals** in the model parameters.

Likelihood-ratio tests [14] are generally used to test hypothesis about $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ in *nested* models with the same fixed effects. Corrections on the number of **degrees of freedom** are needed in the case of tests involving boundary conditions [22]. Likelihood-ratio tests are less frequently used to compare nested models with different fixed-effects because (a) they cannot be used under REML estimation (the REML loglikelihoods of models with different $\mathbf{X}_i$ matrices are not comparable); and (b) they tend to produce tests that are too liberal, in the sense that the actual significance **levels** tend to be considerably higher than their nominal values. For these reasons, Wald tests (*see* **Chi-square Tests**) are preferred to test hypothesis on the fixed effects, with different approximations being used for the denominator degrees of freedom in the corresponding **Student's *t*-** and ***F***-tests [16].

Software

The availability of reliable and efficient software for fitting linear mixed-effects models in commercial packages is one of the main reasons for their increasingly widespread use.

The SAS system includes several procedures and macros for fitting mixed-effects models, with `PROC MIXED` [16] being solely devoted to the linear mixed-effects model. It implements both ML and REML estimation and allows separate specifications of the fixed-effects model ($\mathbf{X}_i$), the random-effects model ($\mathbf{Z}_i$ and $\boldsymbol{\Psi}$), and the within-subject error model ($\boldsymbol{\Lambda}_i$). Similar capabilities are available in the **S-PLUS** and **R** languages, implemented in the `lme` function, which is part of the more comprehensive `NLME` library for mixed-effects models [20]. Both `PROC MIXED` and `lme` have the advantage of being part of general purpose statistical packages, so they can be used in conjunction with other features in the system, such as graphics and programming language capabilities.

Stand-alone, commercial software for fitting linear mixed-effects models is also available, including MLwiN [26], HLM [27], Mplus [28], and AS Reml [29]. All of these include capabilities for fitting and analyzing linear mixed-effects models for longitudinal data, plus varying additional features and capabilities. See the corresponding URLs in the References section for more information on each software.

Extensions

The linear mixed-effects model described in the section "Model Definition and Assumptions" can be

extended in a variety of ways. The LME model (4) is intended for longitudinal data collected on subjects, characterizing a single level of grouping. **Multilevel** linear mixed-effects models [2, 8] handle the case of multiple nested levels of grouping, which often occurs in education and sociology, for example. The generalization of model (4) to the multilevel case is straightforward, with the same estimation methods and similar optimization algorithms being used for estimation [20].

Nonlinear mixed-effects (NLME) models [4, 20, 24] extend linear mixed-effects models by allowing the regression function to depend nonlinearly on fixed and random effects. Because of its greater flexibility, an NLME model is generally more interpretable and **parsimonious** than a competitor empirical LME model based, say, on a **polynomial** or **spline function**. The greater flexibility of NLME models does not come without cost, however. Because the random effects are allowed to enter the model nonlinearly, the marginal likelihood function, obtained by integrating the joint density of the response and the random effects with respect to the random effects, does not have a closed-form expression, as in the LME model. As a consequence, an approximate likelihood function needs to be used for the estimation of parameters, leading to more **computer-intensive** estimation algorithms and to less reliable inference results.

Generalized linear mixed-effects models (GLMMs) [6, 17] have been developed for grouped data with non-Gaussian response variables, like **binary** and count data. As with NLME models, the marginal loglikelihood of GLMMs generally does not have a closed-form expression because of model nonlinearity with respect to the random effects. Estimation methods use different approximations to the loglikelihood, resulting in more computationally intensive algorithms and less reliable estimation results than in LME models.

Linear Programming

Linear programming (LP) is a decision model (*see* **Decision Theory**) that was developed early in the history of **operations research** and has wide applicability. It is a technique for finding optimal solutions, i.e. solutions to a decision problem that optimize some objective (maximize profit, minimize cost, etc.) subject to a set of constraints. In health care, LP has been applied both to management decision making and to decisions regarding clinical care. A few examples of LP are: (i) to improve breast cancer diagnosis on the basis of cell characteristics from a fine needle biopsy and to model the likelihood of recurrence in surgically treated patients [10]; (ii) to optimize scheduling nurses to meet coverage needs at the lowest cost [7]; (iii) to develop a model of costs and revenues based on patient diagnostic groups for strategic planning at a major university medical center [1]; (iv) to identify underutilized resources and inefficient production of services at the Department of Veterans Affairs medical centers [14]; (v) to develop a severity index for emergency medicine patients with cardiac problems [11]; (vi) to determine a treatment plan for radiation therapy that optimizes tumor exposure while reducing the exposure of healthy tissue [12]; and (vii) to compare alternative methods to develop a state rate-setting formula for nursing homes [2]. Greenberg [3–6] provides a tutorial with an overview of LP methodology and applications, while Hillier & Lieberman [8] is an excellent basic reference.

Although LP is the decision model most widely used by corporations, health care applications have been limited in the past by inaccessible software, unavailable data and low demand. Charge based fee-for-service clinical practice and cost-plus reimbursement for hospitals coupled with less competition in the past produced a low perceived need to optimize. The growth of managed care with its emphasis on global budgets and capitation for the care of populations is changing this situation; consequently, LP is likely to become more important in health care management and in **health services research** (*see* **Health Services Organization in the US**).

Model

An LP model has three main components: (i) a set of *decision variables* which represent quantities over which management has control; (ii) an *objective function*, defined on the decision variables, representing the quantity that the decision maker wishes to optimize; and (iii) a set of *constraints* representing the limitations imposed on the decision choices. The word *linear* refers to the form of the functions of the decision variables appearing in the objective function and in the constraints. The form of these functions is a summation of terms, each term being a single decision variable multiplied by a coefficient. Thus, linear programming, strictly defined, does not permit forms that have variables raised to powers or multiplied by other variables. There are techniques for nonlinear programming, but they involve different algorithms. The term *programming* refers to the iterative nature of solution techniques, not to computer programming.

Solving an LP problem involves finding a set of values to assign to the decision variables that will maximize (or minimize) the objective function without violating any of the constraints. Constraints may reflect limitations on resources, policy requirements, proportional relationships that must be maintained, or other requirements of the situation. There are three types of functional constraints: requirements – "greater than or equal to", limitations – "less than or equal to", and strict equality. Sign constraints are requirements that a variable be nonnegative.

There are three stages in LP analysis: formulation, solution, and interpretation. Formulation involves expressing the decision problem as an LP model in *standard form*. In standard form the constraints have the variables on the left-hand side of the operator and a constant on the right-side (known as RHS or right-hand-side quantities). Next, the "optimal solution" is found and its general properties are determined, including sensitivity to parameter variations (*see* **Sensitivity Analysis**) and shadow prices for all constraints. Then, interpretation involves translating the numbers produced by the solution technique into their meaning in the context of the decision to be made.

Solution Techniques

Once an LP model has been formulated, a solution is sought. Some LP models do not have solutions. Actually, with any LP model exactly one of the following will be the case: (i) it will have at least one optimal solution; (ii) it will be infeasible; or (iii) it will

be unbounded. An *infeasible model* is one in which there is no solution that satisfies all of the constraints. An *unbounded model* is one in which the objective function can move infinitely far in the desired direction. In the latter case, it is likely that the model was formulated incorrectly, or does not represent a real-life situation. There are three widely known *techniques for solving* LP problems: the Graphical Solution Technique, the **Simplex** Method, and the Interior Point Method (also known as "Karmarkar's Algorithm").

Graphical Solution Technique

This technique is generally used only for problems that contain two variables; its value is more as a teaching tool than as a practical problem-solving technique. Coordinate axes represent the decision variables and constraints are plotted, often resulting in an enclosed area; assuming that a feasible solution does exist, the set of all feasible solutions in this enclosed area is called the *feasible region* (Figure 1). Each corner of this enclosed area is known as a *corner-point feasible* (CPF) solution; the importance of CPF solutions is that the optimal value of the objective function will come from this set. The objective function is then set to an arbitrary constant, yielding an equation which is plotted as a line (called a contour line or isoquant). Another arbitrary constant is then used to generate a parallel line with the same slope and in the direction of improving the objective function. The last CPF solution to intersect an isoquant line as it leaves the feasible region in the direction of optimization is the optimal solution. The optimal solution(s) will become apparent from this analysis. If there is an optimal solution, then there will be at least one corner point optimal solution; if two corner points are optimal, then all of the points in between them are also optimal.

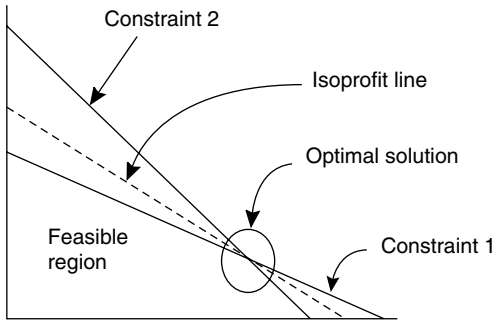

Figure 1 Graphical method for solving linear programming problems

If constraints do not stop the contour lines from moving infinitely far in the desired direction, then the problem is *unbounded*. An unbounded problem has failed to include or appropriately value at least one relevant constraint.

If there is no simultaneous optimal solution to all of the constraints in the problem as formulated, then the model may be infeasible, also known as *inconsistent*, or misspecified. Infeasible LP problems result from the constraint equations, not the objective function, and they should be reviewed if the model is infeasible. In practice, constructing large LP models may involve constraint inputs from many different individuals or teams, so initial infeasibility of a model is not uncommon.

As mentioned above, this technique is applied to two variable problems. LP models with only one decision variable are not of practical significance. With three decision variables, the feasible region would typically be a three-dimensional figure with flat surfaces, and the objective function would be represented by contour planes finding the best corners of this figure. With more than three variables, visual representation becomes impracticable.

Example

A simplified problem that could be solved by the graphical technique is the decision for assigning the mix of appointment slots for two types of patients in a fee-for-service Nurse Practitioner clinic to produce the optimal amount of revenue. Assume that the revenue from a hypertensive patient visit (H) is \$10 and for a patient with diabetes (D) \$18, that Nurse Practitioners (NP) see the former on average for six minutes and the latter for 15 minutes while Nursing Assistants (NA) are with both types of patients for 18 minutes, and that total available Nurse Practitioner hours equals 7000 while those for Nursing Assistants equals 14 000. The objective function is then $10H + 18D$, the first constraint is $0.1H + 0.25D \leq 7000$, and the second constraint is $0.3H + 0.3D \leq 14\,000$. The optimal solution is to schedule 31 111 hypertension patients and 15 555 diabetes patients.

The Simplex Method

George Dantzig developed the Simplex Method in the 1940s and it has proven to be both robust and versatile. This method produces successive outputs, known as tableaus, as part of its iterative search for an optimal solution. To establish an initial tableau, remove inequalities and satisfy the nonnegativity constraints of the model, additional variables are introduced: *slack* variables for constraint equations ("$\leq$") and *surplus* variables for requirements ("$\geq$"). In the optimal solution to the LP, slack or surplus variables will be zero for active constraints and positive for inactive constraints.

The standard equation constraint form of the LP in matrix notation is then

$$\begin{aligned} \text{optimize } Z &= c\mathbf{x} \\ \text{subject to } A\mathbf{x} + \mathbf{s} &= \mathbf{b} \\ \mathbf{x}, \mathbf{s} &\geq 0. \end{aligned}$$

Continuing with the graphical analogy, the Simplex Method first identifies a corner point; if there is none, then the problem is said to be *inconsistent*, or infeasible. Once a corner point is identified, then the **algorithm** moves from corner point to adjacent corner point of the feasible region, with each successive iteration produced by the Gaussian elimination equaling or improving the value of the objective function. The algorithm terminates when an optimal CPF solution is identified; the resulting basic feasible solution consists of the nonnegative variables in the set.

Example

In an article on hospital financial planning [1] linear programming is used at a leading academic medical center to evaluate the resource and revenue implications of changes in patient acuity level and primary insurer. The goal in this formulation is to maximize net revenue after variable expenses:

$$\max \sum_j (r_j - vc_j)^* x_j,$$

where r_j = total revenue from patient type j, vc_j = total variable cost from patient type j, and x_j = number of patients of type j. Here, the decision variables can be optimized for a given situation or varied to explore the financial impact under differing scenarios, for example, in contract negotiations, in considering major capital renovations, or in considering a shift in patient mix based on marketing emphases or regulations. Examples of constraints in this model include the number of beds in each clinical service, ancillary services, requirements that the institution meet at least minimum levels of demand for admission by populations it has traditionally served, and limits on patient demand by various groups – based on the output from a separate forecasting study.

For an LP (the *primal*) there also exists an alternate formulation of the problem, called the *dual*, in which the number of decision variables in the primal equals the number of constraints in the dual and the number of constraints in the primal equals the number of decision variables in the dual. Optimization of the primal also results in optimization of the dual; however, if the primal is a maximization model, then the dual will be a minimization model and vice versa. When the optimal solution contains fewer positive variables than constraints, it is said to be *degenerate*. One result of degeneracy is that there is restricted ability to do postoptimality analyses.

Most problems of practical significance are too large to be solved manually, so specialized software has been written to perform this function. The time to solve an LP is essentially determined by the number of constraints in the problem rather than the number of decision variables; therefore, using the relationship between the primal and dual specifications, solving the formulation with the smaller number of constraints will be faster. Although computing speed and power continue to increase, this is a useful observation since the sizes of the problems to be solved are also increasing.

Beyond computational efficiency there is economic information contained in the correspondence between the primal and dual. Much of the value of an LP solution comes from post-optimality, or sensitivity, analysis. The typical computer output for an optimized LP model will contain values for the objective function, for basic structural variables (those having nonzero values), shadow prices for the constraints and change vectors for Right-Hand-Side and objective ranging or sensitivity analyses. These *change vectors* report how much the basic variables change when the Right-Hand-Side constraints are increased or decreased; *shadow prices* show how much the

value of the objective function will change as the values of the RHS change. Taken together, these results answer the questions of how much of which resources should be purchased, if any, and at what price.

The range of values over which these sensitivity analyses are valid is restricted: information on the lower and upper bounds of these ranges for each variable will be included in the printout under sensitivity analysis. If the quantities being considered in the sensitivity analyses lie outside these ranges, then the model must be rerun with different inputs since the original optimal solution would no longer be valid. Finally, sensitivity results are only correct when the values reported lie within the upper and lower bounds, and only when one variable is changed at a time. If the analyst is interested in simultaneous changes to more than one variable, again the model must be rerun with these changes in the input.

Interior Point Method

An alternative to the Simplex Method was reported by Narendra Karmarkar in 1984. Karmarkar's approach and similar barrier algorithms are based on progressing along successive points interior to the feasible region toward an optimal solution. Since the algorithm does not move from corner to corner as the Simplex does, it is potentially much faster for very large problems and may be the only option for extremely large problems. Research continues on interior point algorithms for LP; however, they are currently inferior to the Simplex Method in supporting sensitivity analysis [8, 9].

Software

Few problems of practical significance can be solved manually; fortunately, developments in hardware and software have moved the ability to solve large linear programming problems to the desktop. Depending on the operating system, size of the problem, price, data input source(s), and other features desired, many options exist to support a knowledgeable user; however, online support for a novice is infrequently provided [15].

Perhaps the most immediately useful of the LP software to a broad audience are the **spreadsheet** packages that include optimization routines or have transparent "add-ins" for this function. These functions, coupled with stored models and report writer capability, allow users easy import of data into widely used applications packages to produce outputs clearly on the basis of an array of scenarios or assumptions. Some commercial packages, e.g. SAS OR [13] (*see* **Software, Biostatistical**) employ enhancements that allow the user greater flexibility of features than the Simplex Method alone would permit.

Quantitative management courses, such as those typically taught in masters programs in business or health administration, increasingly rely on spreadsheet applications to teach these methods – increasing the likelihood that the techniques may be applied more often than in the past.

Internet

Typical LP resources on the **internet** include web sites for professional associations, university courses on LP, computer routines that permit LP problems to be solved over the internet, and other areas of specialization. Although the internet is dynamic, a useful overview of resources and potential uses is provided by Sodhi [16].

Summary

Until recent advances in data availability, hardware, software, and trained users, the trade-off between the time and cost of modeling, obtaining the data, and the likely payoff for what might be one-time efforts, discouraged widespread use of LP in health care. As the expectations for efficient, quality health care increase and integrated financing and delivery systems look for ways to address simultaneously demands for lower cost and higher quality, the opportunities for the application of LP should increase.

Linear Rank Tests in Survival Analysis

Linear rank tests for survival data are generalized **nonparametric methods** for testing the null hypothesis of equal **survival distributions** among groups.

A number of approaches to generalizing rank tests to censored data have appeared in the literature – approaches which are often quite different from one another. The earliest statistic to reach widespread use was that of Gehan [13], who generalized the **Wilcoxon–Mann–Whitney** scores for the two-group problem. Mantel [24] used arguments based on the construction of the **Mantel–Haenszel** test for stratified $2 \times K$ contingency tables to propose a test that later became known as the **logrank test**. Efron [8] then proposed a statistic based on combining the values of the estimated survival distributions of two groups across time. In 1970 Breslow [5] provided a generalization of the Kruskal–Wallis statistic that reduced to the Gehan–Wilcoxon statistic in two samples. The work of Peto & Peto [25] made important progress in studying the properties of these and other tests. In 1972, the **proportional hazards** model of Cox [6] (*see* **Cox Regression Model**) provided a setting in which the logrank test could be derived as a **partial likelihood** score test from a regression model. Prentice [26] showed in 1978 that many of these tests were asymptotically equivalent to tests that were natural generalizations of the classical linear rank tests for uncensored data described in Hájek & Šidák [17]. In his seminal doctoral thesis and later published work, Aalen [1, 2] showed that the theory of **counting processes** and martingales could be used to recast two-sample tests with right-censored data in the multiplicative intensity model and to study their asymptotic theory. Gill [14] extended this work to a complete study of the operating characteristics of two-sample tests with censored data, and Andersen et al. [3] illustrated the use of this methodology for tests used to compare more than two groups. Remarkably, all these approaches point to essentially the same tests.

Censored data rank tests are most well-developed for right-censored failure time data. Data are right-censored if, for each subject in a study, the underlying data consist of the time, T, to some event and a censoring time, U, while the observable data are $X = \min(T, U)$ and $\delta = I(T \leq U)$, where $I(A)$ is the usual indicator random variable of the event A. The variable T is commonly called a failure time or a survival time. The underlying survival function, $\Pr(T > t)$, is usually denoted by $S(t)$, the cumulative hazard, $-\log S(t)$, by $\Lambda(t)$ for continuous T, and the hazard function for absolutely continuous T by $\lambda(t)$ (*see* **Survival Distributions and Their Characteristics**). If S has discontinuities or is otherwise not differentiable, the cumulative hazard function is given more generally by $\Lambda(t) = -\int_0^t [S(u-)]^{-1}\, \mathrm{d}S(u)$. We let $\pi(t) = \Pr(X \geq t)$, the probability that a subject is at risk at time t.

Linear rank tests are most commonly used when making comparisons among K groups, $K \geq 2$, or when comparing a single group with a known or hypothesized population. For the K-group problem, the observable data consist of the pairs (X_{ij}, δ_{ij}), $1 \leq j \leq n_i$, $i = 1, \ldots, K$; that is, there are n_i observations in the ith of K groups, with underlying survival distribution $S_i(t)$ and probability $\pi_i(t)$ of being at risk. The validity of all the tests discussed below depends centrally on the assumption that the observed failure rate among cases at risk of failure is the same rate that would be observed if censoring were not present. This is satisfied if T_{ij} and U_{ij} are independent random variables for all pairs i, j, and we assume this condition throughout.

We use the counting process setting here. That methodology is not only the most recent and the most successful in studying the asymptotic theory of these tests, but it also provides a surprisingly useful framework for a less formal exploration of their properties. The theory for these tests is best understood for the two-sample problem, and, since the two-group comparison problem is the most prevalent testing problem with censored data, we discuss that case in greater detail.

Gill [15] provides an accessible and intuitive introduction to the martingale approach to survival analysis in the context of the proportional hazards model.

The Counting Process Approach

Counting process methods are now widely used for survival data, and these methods have a particularly simple form when used to study rank tests. Generally, a **stochastic process** $N = [N(t) : t \geq 0]$ is a counting

process if $N(0) = 0$ and it has increasing, right-continuous step functions for paths, with jumps of size 1 at each discontinuity. The process

$$N_{ij} = [N_{ij}(t) = I(X_{ij} \le t, \delta_{ij} = 1); t \ge 0]$$

has simple right-continuous step functions for paths, beginning at 0 at $t = 0$ and taking a single jump to 1 at time t if and only if $T_{ij} = t$ and $T_{ij} \le U_{ij}$. The information in the pair (X_{ij}, δ_{ij}) is equivalent to that in the complete path of N_{ij} as well as in the path of the process $N_{ij}^{\mathrm{U}}(t) = I(X_{ij} \le t, \delta_{ij} = 0)$. Formally, the information up to time t in the pair N_{ij}, N_{ij}^{U} is represented as the σ-algebra $\mathcal{F}_t^{ij}$ generated by the set of variables $[N_{ij}(u), N_{ij}^{\mathrm{U}}(u); 0 \le u \le t]$. The **information** in all K groups up to time t is the product σ-algebra $\mathcal{F}_t = \otimes_{ij} \mathcal{F}_t^{ij}$. Since that information increases with time, the collection of σ-algebras $\mathcal{F} = (\mathcal{F}_t; t \ge 0)$ forms a filtration, i.e. an increasing sequence (in t) of σ-algebras.

The counting process approach uses the stochastic calculus of martingales in its representation of test statistics and the martingale **central limit theorems** [29] for the asymptotic theory (*see* **Large-sample Theory**). A process $M = [M(t); t \le 0]$ is a martingale with respect to a filtration $(\mathcal{G}_t; t \ge 0)$ if

1. $M(t)$ is adapted to $\mathcal{G}_t$ for each t
2. $\mathrm{E}|M(t)| < \infty$ for all $t < \infty$, and
3. $\mathrm{E}[M(t+s)|\mathcal{G}_t] = M(t)$ a.s. for all $s \ge 0, t \ge 0$.

Condition 3 implies that $\mathrm{E}[M(t) - M(u)|\mathcal{G}_u] = 0$ for all $u \le t$, and this is sometimes written informally as $\mathrm{E}[\,\mathrm{d}M(t)|\mathcal{G}_{t-}] = 0$. A process M is called a submartingale if the equation for the conditional expectation in condition 3 above is replaced by the inequality $\mathrm{E}[M(t+s)|\mathcal{G}_t] \ge M(t)$. Because the martingale property depends on the underlying filtration, we sometimes say that M is a $\mathcal{G}_t$-martingale. The martingale definition implies that a linear combination of processes which are martingales with respect to a common filtration $\mathcal{G}$ will itself be a $\mathcal{G}_t$-martingale.

It is possible to show that, when T_{ij} and U_{ij} are independent for all pairs i, j, the process

$$M_{ij}(t) = N_{ij}(t) - \int_0^t Y_{ij}(u)\,\mathrm{d}\Lambda_i(u) \qquad (1)$$

is a martingale with respect to the filtration $\mathcal{F}$ defined above, where $Y_{ij}(u) = I(X_{ij} \ge u)$ is the process denoting whether or not subject i, j has failed or been censored before time t (cf. Theorems 1.3.1 and 1.3.2 in Fleming & Harrington [10]). The integral on the right-hand side of (1) is called the compensator for the process N_{ij}. For simplicity of notation we usually write (1), and others like it, as

$$M_{ij} = N_{ij} - \int Y_{ij}\,\mathrm{d}\Lambda_i.$$

It is not surprising that M_{ij} is an $\mathcal{F}_t$-martingale. Conditional on the history of the failure and censoring processes before time t, the conditional probability of a jump in N_{ij} at t is approximately $Y_{ij}(t)\,\mathrm{d}\Lambda_i(t)$, so that $E(\mathrm{d}N_{ij} - Y_{ij}\,\mathrm{d}\Lambda_i|\mathcal{F}_{t-}) = 0$. This result is an example of the more general Doob–Meyer decomposition for submartingales (cf. [9]), which states that for any submartingale Z (subject to boundedness conditions) there exists a predictable process A, called the compensator for Z, such that $Z - A$ is a martingale.

Nearly all commonly used linear rank statistics for survival data can, under H_0, be represented, or at least approximately so, as $\sum_{ij} \int H_{ij}\,\mathrm{d}M_{ij}$, or as sums of stochastic integrals of "predictable" processes with respect to the fundamental martingale processes. This construction allows the use of the stochastic calculus for martingales outlined below. More detail may be found in Fleming & Harrington [10] and Andersen et al. [4]. To keep the technical material to a minimum, we have not given the most general versions of these results.

There are several definitions of a predictable process; the following is one of the more accessible.

Definition. A stochastic process $H = [H(t); t \ge 0]$ defined on a probability space $(\Omega, \mathcal{A}, P)$ is predictable with respect to a filtration $\mathcal{F} = (\mathcal{F}_t; t \ge 0)$ on that space if H is measurable with respect to the smallest σ-algebra on $[0, \infty) \times \Omega$ generated by the adapted left-continuous processes.

This definition implies that any left-continuous $\mathcal{F}_t$-adapted process will be $\mathcal{F}_t$-predictable; operationally, that is how predictability is checked.

Slightly more general versions of the following theorems appear in Fleming & Harrington [10, cf. Theorem 2.4.1].

Theorem 1. Suppose H is a bounded, $\mathcal{F}_t$-predictable process and M an $\mathcal{F}_t$-martingale with

$M(0+) - M(0) = 0$. Then the process

$$\int H \, dM = \left[\int_0^t H(u) \, dM(u); t \geq 0 \right]$$

is an $\mathcal{F}_t$-martingale.

Theorem 2. Suppose M_1 and M_2 are square integrable $\mathcal{F}_t$-martingales (i.e. $\sup_{t \geq 0} EM_i^2(t) < \infty, i = 1, 2$). Then there exists a unique $\mathcal{F}_t$-predictable process $\langle M_1, M_2 \rangle$ such that $M_1 M_2 - \langle M_1, M_2 \rangle$ is an $\mathcal{F}_t$-martingale.

The process $\langle M_1, M_2 \rangle$ is called the predictable covariation process for the martingales M_1 and M_2. When M_1 and M_2 are the same process M, $\langle M, M \rangle$ is called the predictable quadratic variation process, and is often denoted by $\langle M \rangle$. Since martingales have constant expected value, $EM_1(t)M_2(t) = E\langle M_1, M_2 \rangle(t)$ whenever $M_1(0)M_2(0) - \langle M_1, M_2 \rangle(0) = 0$. This formula is particularly valuable for computing second **moments** when the quadratic variation process takes a simple form, as it does for the counting process martingales arising in survival analysis.

It is possible to show that

$$\left\langle \int H_1 \, dM_1, \int H_2 \, dM_2 \right\rangle = \int H_1 H_2 \, d\langle M_1, M_2 \rangle$$

(cf. Fleming & Harrington [10, Theorem 2.4.2]).

The following summarizes results on quadratic variation processes for counting process martingales.

Definition 1. A k-dimensional counting process $(N_1, N_2, \ldots, N_k)$ is called a multivariate counting process if each component N_j is a counting process and no two component processes jump at the same time.

Theorem 3. Let $(N_1, N_2, \ldots, N_k)$ be a multivariate counting process, and let A_j be the compensator of N_j. Then $\langle M_j, M_j \rangle = \int (1 - \Delta A_j) \, dA_j$ and $\langle M_i, M_j \rangle = -\int \Delta A_i \, dA_j$ for $i \neq j$.

When a survival distribution is continuous, $\Delta A = 0$, and these formulas are particularly simple. In that case $\langle M_i, M_j \rangle = 0$ and the martingales M_i and M_j are called orthogonal. The more general formula is useful, however, in estimating second moments when there are **ties** in observed failure times, even when the underlying model is continuous, as will be seen below.

Common Linear Rank Tests

Despite its demanding technical foundation, the martingale approach to rank tests is a useful setting for formulating tests. This is most easily seen for two-sample tests. Suppose two groups have survival functions S_1 and S_2 and cumulative hazard functions Λ_1 and Λ_2. Let $\overline{N}_i = \sum_j N_{ij}$, $\overline{Y}_i = \sum_j Y_{ij}$, and $\overline{M}_i = \overline{N}_i - \int \overline{Y}_i \, d\Lambda_i$, $i = 1, 2$. The observed number of failures at time t in group 1 is $dN_1(t)$; with independent censoring and under H_0: $\Lambda_1 = \Lambda_2$, the conditionally expected number of failures in group 1 at t, given that a failure has been observed at t, is

$$\frac{\overline{Y}_1(t)\{ d[\overline{N}_1(t) + \overline{N}_2(t)]\}}{[\overline{Y}_1(t) + \overline{Y}_2(t)]}.$$

A simple test of H_0 can be constructed by comparing

$$\int_0^\infty d\overline{N}_1 - \overline{Y}_1 \frac{d(\overline{N}_1 + \overline{N}_2)}{\overline{Y}_1 + \overline{Y}_2} \tag{2}$$

with 0. This statistic is the numerator of the logrank statistic. Simple algebra shows that under H_0 the above expression is equal to

$$\begin{aligned}
\int_0^\infty \frac{\overline{Y}_1 \overline{Y}_2}{\overline{Y}_1 + \overline{Y}_2} \left(\frac{d\overline{N}_1}{\overline{Y}_1} - \frac{d\overline{N}_2}{\overline{Y}_2} \right) &= \int_0^\infty \frac{\overline{Y}_1 \overline{Y}_2}{\overline{Y}_1 + \overline{Y}_2} \\
&\quad \times \left[\left(\frac{d\overline{N}_1}{\overline{Y}_1} - d\Lambda_1 \right) - \left(\frac{d\overline{N}_2}{\overline{Y}_2} - d\Lambda_2 \right) \right] \\
&= \int_0^\infty \frac{\overline{Y}_2}{\overline{Y}_1 + \overline{Y}_2} \, d\overline{M}_1 - \int_0^\infty \frac{\overline{Y}_1}{\overline{Y}_1 + \overline{Y}_2} \, d\overline{M}_2 \\
&= \sum_{j=1}^{n_1} \int_0^\infty \frac{\overline{Y}_2}{\overline{Y}_1 + \overline{Y}_2} \, dM_{1j} \\
&\quad - \sum_{j=1}^{n_2} \int_0^\infty \frac{\overline{Y}_1}{\overline{Y}_1 + \overline{Y}_2} \, dM_{2j}.
\end{aligned} \tag{3}$$

Gill [14] used an expression similar to (3) as a foundation for a generalized class of statistics that includes many previously discussed in the literature.

Definition. Suppose one has two samples of right-censored observations (X_{ij}, δ_{ij}), $1 \leq j \leq n_i$, $i = 1, 2$, giving rise to the counting and at risk processes $\overline{N}_i, \overline{Y}_i$, $i = 1, 2$, and let $(\mathcal{F}_t; t \geq 0)$ be the filtration generated by $[N_{ij}(u), Y_{ij}(u); 0 \leq u \leq t, 1 \leq j \leq$

$n_i, i = 1, 2]$. Let K be a bounded nonnegative $\mathcal{F}_t$-predictable process satisfying $K(t) = 0$ whenever $\overline{Y}_1(t)\overline{Y}_2(t) = 0$. Then

$$G_K = \int_0^\infty K\left(\frac{\mathrm{d}\overline{N}_1}{\overline{Y}_1} - \frac{\mathrm{d}\overline{N}_2}{\overline{Y}_2}\right)$$

is called a statistic of the class $\mathcal{K}^+$. When

$$K = \left(\frac{n_1 + n_2}{n_1 n_2}\right)^{1/2} W\left(\frac{\overline{Y}_1\overline{Y}_2}{\overline{Y}_1 + \overline{Y}_2}\right)$$
$$= \left(\frac{n_1 n_2}{n_1 + n_2}\right)^{1/2} W\frac{\overline{Y}_1}{n_1}\frac{\overline{Y}_2}{n_2}\frac{n_1 + n_2}{\overline{Y}_1 + \overline{Y}_2},$$

the statistic is called a weighted logrank statistic. The fraction $\overline{Y}_1\overline{Y}_2/(\overline{Y}_1 + \overline{Y}_2)$ appears in the usual logrank statistic; as will be seen later, the terms involving sample sizes ensure **convergence** under null and alternative hypotheses. The function W reweights the observed minus expected increments in (2). Although weighted logrank statistics are a subset of the statistics of class $\mathcal{K}^+$, they are the most common in applications, and we give those somewhat more attention here. Since the function W is the important part of the weight function in these statistics, we denote weighted logrank statistics by G_W.

The upper limit of integration in the integral representation for statistics of class $\mathcal{K}^+$ occasionally causes confusion. Because the weight function in the two-sample statistic takes value 0 as soon as at least one of the **risk sets** is empty, the integral as written denotes a statistic computed for the portion of the time axis over which there are cases at risk in both groups. Contributions to the statistic stop when all cases in either one of the groups have failed or have been censored; that is the most natural way for the practitioner to think of these nonparametric statistics. In the asymptotic theory for some of these statistics, the integral may be computed only over a prespecified time interval for which the probability of a subject being at risk at the right end point is bounded away from zero. That is not necessary for most of the statistics discussed here. Finally, the upper limit of integration may be thought of as a variable t when the statistic is considered a process with changing values as time increases. This last perspective is used in the martingale calculus.

If W is a predictable process, a weighted logrank statistic can, under H_0, be represented as sums of stochastic integrals of predictable processes with respect to martingales, so that G_W is itself a martingale. This representation and its quadratic variation process can be used to derive formulas for the first two moments of these test statistics. The following summarizes Theorems 3.3.1 and 3.3.2 in Fleming & Harrington [10]; except for some regularity conditions and tedious algebra, it follows directly from Theorems 1 and 2.

Theorem 4. Let G_K be a statistic of the class $\mathcal{K}$. When $\Lambda_1 = \Lambda_2 = \Lambda, \mathrm{E}G_K = 0$ and

$$\mathrm{E}G_K^2 = \mathrm{E}\sum_{i=1}^{2}\int_0^\infty \frac{K^2}{\overline{Y}_i}(1 - \Delta\Lambda)\,\mathrm{d}\Lambda.$$

The variance estimator

$$\hat{\sigma}^2 = \int_0^\infty \sum_{i=1}^{2}\frac{K^2}{\overline{Y}_i}\left(1 - \frac{\Delta\overline{N}_1 + \Delta\overline{N}_2 - 1}{\overline{Y}_1 + \overline{Y}_2 - 1}\right)$$
$$\times \frac{\mathrm{d}(\overline{N}_1 + \overline{N}_2)}{\overline{Y}_1 + \overline{Y}_2} \tag{4}$$

is an **unbiased** estimate of $\mathrm{E}G_K^2$.

When Λ is continuous, $\Delta\Lambda = 0$ in the expression for $\mathrm{E}G_K^2$, and the second term in the sum comprising the integrand in $\hat{\sigma}^2$ would seem unnecessary. That term is present only when two or more observed failure times are equal, however, and seems to improve the small-sample behavior of the estimator in tied data.

When $W = 1$, the statistic is the logrank statistic originally proposed by Mantel [24]. The same statistic arises as a partial likelihood score statistic in a proportional hazards regression model with a single binary covariate, although that approach leads to the variance estimate which assumes $\Delta\Lambda$ is identically 0. When $W(t)$ is a function of the proportion of cases at risk at time t, $[\overline{Y}_1(t) + \overline{Y}_2(t)]/(n_1 + n_2)$, the statistic is a member of the family proposed by Tarone & Ware [32]. If W is exactly the proportion of cases at risk, then G_W is the Gehan [13] generalization of the Wilcoxon statistic. If $W = \hat{S}^-$, the left-continuous version of the **Kaplan–Meier** [19] estimator computed with the two groups combined, then the statistic is asymptotically equivalent to the Wilcoxon generalization proposed by Prentice [26] and to a similar statistic proposed by Peto & Peto [25]. When $W = (\hat{S}^-)^\rho, \rho > 0$, the resulting family of statistics is that proposed by Harrington &

Fleming [18]. In this family, the logrank statistic corresponds to $\rho = 0$ and the Prentice–Wilcoxon to $\rho = 1$. Gray & Tsiatis [16] have shown that this family may be extended to allow $\rho < 0$. The statistic proposed by Efron [8] is equivalent to one with weight

$$W = \frac{(\overline{Y}_1 + \overline{Y}_2)\hat{S}_1^- \hat{S}_2^- I(\overline{Y}_1 \overline{Y}_2 > 0)}{(\overline{Y}_1 \overline{Y}_2)}.$$

Since both $\overline{Y}_1$ and $\overline{Y}_2$ are $\mathcal{F}_t$-adapted and left-continuous, the use of the left-continuous version of the Kaplan–Meier estimator in these statistics ensures predictability of the integrand K.

The counting process representation of these statistics provides insight into the term "linear rank tests". In uncensored data, where $X_{ij} = T_{ij}$ for all pairs i, j, a classical linear rank statistic as discussed in Hájek & Šidák [17] has the form $\sum_{i,j} a(R_{ij})$, where R_{ij} is the rank of T_{ij} in the combined sample and a is function assigning scores to the ranks. When the weight function W in a weighted logrank statistic depends only on the order of the possibly censored observations in the combined sample, as in all the statistics discussed above, then the Stieltjes integral representation of the statistic consists of a linear combination of scores assigned to observed failures according to the ordering of the observations X_{ij}.

The counting process representation also sheds light into the operating characteristics of these two-sample tests. The weighted logrank statistics can be written as

$$c \int_0^\infty W \left[\mathrm{d}\overline{N}_1 - \overline{Y}_1 \frac{\mathrm{d}(\overline{N}_1 + \overline{N}_2)}{\overline{Y}_1 + \overline{Y}_2} \right],$$

where c is a constant depending only on sample size. When W is constant, the observed minus expected failures are weighted equally, so that deviations from 0 in these terms in the right tail of the observations, where the risk sets are small, have as much influence on the value of the statistic as early deviations at times with large risk sets. If S_1 and S_2 are absolutely continuous and $\lambda_1 - \lambda_2$ changes sign at some time t, i.e. the underlying distributions have crossing hazard functions, then the logrank statistic may have a value that is not significantly different from zero, regardless of sample size (cf. Fleming et al. [11] for an example from a clinical study and Prentice & Marek [27] for an extended discussion). If W decreases when the observations increase, as in the Harrington–Fleming family when $\rho > 0$, then earlier differences in the observed minus expected failures will be emphasized. Gill [14] shows that statistics of the class $\mathcal{K}^+$ are consistent as long as $\Lambda_1(t) \geq \Lambda_2(t)$ for all t or vice versa, with strict inequality on at least one interval containing nonzero mass for the two distributions. Formal results about asymptotic operating characteristics under alternative hypotheses are summarized later.

The K-sample, $K > 2$, statistics are natural generalizations of the two-sample tests. Let $\overline{N}_i, \overline{Y}_i, i = 1, \ldots, K$, be defined as with two groups, and let $\overline{N} = \sum_i \overline{N}_i$ and $\overline{Y} = \sum_i \overline{Y}_i$. Under H_0: $\Lambda_1 = \Lambda_2 = \cdots = \Lambda_K$, the K-dimensional statistic with the ith component given by

$$G_{W,i} = \int_0^\infty W \left(\mathrm{d}\overline{N}_i - \overline{Y}_i \frac{\mathrm{d}\overline{N}}{\overline{Y}} \right)$$

is, for each group, a weighted sum of observed minus conditionally expected number of failures. It is not difficult to show that $\sum_i G_{W,i} = 0$, so that there are only $K - 1$ linearly independent components in the statistic. More detailed information about the covariance of the components of the statistic comes from the equivalent (under H_0) martingale representation

$$G_{W,i} = \sum_{l=1}^K \int_0^\infty W \left(r_{il} - \frac{\overline{Y}_i}{\overline{Y}} \right) \mathrm{d}\overline{M}_l,$$

where $r_{il} = 1$ when $i = l$ and 0 otherwise. If we assume that the underlying cumulative hazard functions are continuous and that there are no ties in the observed data, the components of the statistic can be written as a sum of integrals with respect to orthogonal martingales. The simpler formulas for quadratic variation and covariation can be used to show that, under the hypothesis that all groups have a common cumulative hazard Λ,

$$\langle G_{W,i} \rangle = \sum_{l=1}^K \int_0^\infty W^2 \left(r_{il} - \frac{\overline{Y}_i}{\overline{Y}} \right)^2 \overline{Y}_l \, \mathrm{d}\Lambda$$

and

$$\langle G_{W,i}, G_{W,k} \rangle = \sum_{l=1}^K \int_0^\infty W^2 \left(r_{il} - \frac{\overline{Y}_i}{\overline{Y}} \right)$$

$$\times \left(r_{kl} - \frac{\overline{Y}_k}{\overline{Y}} \right) \overline{Y}_l \, \mathrm{d}\Lambda$$

$$= \int_0^\infty W^2 \frac{\overline{Y}_i}{\overline{Y}} \left(r_{ik} - \frac{\overline{Y}_i}{\overline{Y}} \right) \overline{Y} \, \mathrm{d}\Lambda.$$

The last expression leads to a natural estimator $\hat{\Sigma}$ of the **covariance matrix** of the statistic, with elements $\hat{\sigma}_{ik}$ given by

$$\hat{\sigma}_{ik} = \int_0^\infty W^2 \frac{\overline{Y}_i}{\overline{Y}} \left(r_{ik} - \frac{\overline{Y}_k}{\overline{Y}} \right) \mathrm{d}\overline{N}. \qquad (5)$$

As with the two-sample statistic, it is possible to show that $\mathrm{E}(\hat{\sigma}_{ik}) = \mathrm{cov}(G_{W,i}, G_{W,k})$.

The basic martingale may also be used to construct a statistic for comparing a single sample with a known or hypothesized population distribution with failure rate $\mathrm{d}\Lambda_0$. The natural analog of the weighted logrank statistic is

$$c \int_0^\infty W(\, \mathrm{d}\overline{N}_1 - \overline{Y}_1 \, \mathrm{d}\Lambda_0 \, \mathrm{d}u).$$

These statistics are discussed in detail in Andersen et al. [4] and Woolson [33].

Asymptotic Distribution Theory

Large-sample normality for the K-sample statistics under both null and alternative distributions has been established by a number of authors. The original derivations of these tests by Gehan, Mantel, and others contained strong plausibility arguments for asymptotic distributions, and Schoenfeld [31] may have been one of the first to establish formally the asymptotic **efficiency** of the logrank test under proportional hazards alternatives. Using the original martingale formulation of Aalen and the martingale central limit theorem of Rebolledo [29], Gill provided a thorough study of the large-sample operating characteristics of the two-sample tests under both null and alternative hypotheses (*see* **Power**). Andersen et al. [3] used the same methodology to study the large-sample behavior of tests for more than two samples. The theorems below summarize the major results in this area. The first results provide asymptotic distributions under the null hypothesis, first for the two-sample case, and then for the general K-sample statistics.

The most general theorems about the convergence of these statistics require more regularity conditions than might at first be expected. Beyond the usual conditions needed for central limit theorems, the asymptotic normality in these statistics can be disturbed if the weight function W becomes too large or if the cumulative hazard approaches infinity too quickly. The following theorem for the two-sample case covers nearly all the statistics used in practice and, because of the form of the weight function, does not require many conditions. This theorem appears as Theorem 7.2.1 in Fleming & Harrington [10], and relies for its proof on the more general result of Corollary 4.3.1 in Gill [14].

Theorem 5. In the two-sample testing problem with right-censored data (as described above), let $\hat{S}(t)$ denote the Kaplan–Meier estimator computed from the combined samples. Let $\hat{\pi}(t)$ denote the pooled sample estimator of the probability that a subject is alive and uncensored at time t, i.e. $\hat{\pi}(t) = [\overline{Y}_1(t) + \overline{Y}_2(t)]/(n_1 + n_2)$. Let f be a nonnegative bounded continuous function of bounded variation on [0, 1]. Suppose the weighted logrank statistic G_W has weight function of the form

$$\left(\frac{n_1 n_2}{n_1 + n_2} \right)^{1/2} W(t) \frac{\overline{Y}_1(t)}{n_1} \frac{\overline{Y}_2(t)}{n_2} \frac{n_1 + n_2}{\overline{Y}_1 + \overline{Y}_2},$$

where $W(t) = f[\hat{S}(t-)]$ or $W(t) = f[\hat{\pi}(t)]$. Suppose that $\lim_n n_i/n = a_i$ exists and lies in (0, 1), and let $\hat{\sigma}$ be as in (4). Then under H_0: $\Lambda_1 = \Lambda_2$, $G_W/\hat{\sigma}$ converges in distribution, as $n \to \infty$, to a normally distributed random variable with mean 0 and variance 1.

Theorem 6 follows from Theorem V.2.1 and Example V.2.10 in Andersen et al. [4]. Because of the linear dependence of the terms in the K-dimensional statistic, the last component is usually dropped when computing the quadratic form for a Wald test (*see* **Likelihood**).

Theorem 6. In the K-sample testing problem with right-censored data (as described above), let $\hat{S}(t)$ denote the Kaplan–Meier estimator computed from the combined samples. Let $\hat{\pi}(t)$ denote the pooled sample estimator of the probability that a subject is at risk at time t, i.e.

$$\hat{\pi}(t) = [\overline{Y}_1(t) + \cdots + \overline{Y}_K(t)]/(n_1 + \cdots + n_K).$$

Let f be a nonnegative bounded continuous function of bounded variation on [0, 1]. Suppose the weight function W in the K-sample weighted logrank statistic is of the form $W(t) = f[\hat{S}(t-)]$ or $W(t) = f[\hat{\pi}(t)]$, and let the ith component of the standardized statistic be given by

$$G_{W,i} = \left[\frac{n}{n_i(n-n_i)}\right]^{1/2} \int_0^\infty W\left(\mathrm{d}\overline{N}_i - \overline{Y}_i \frac{\mathrm{d}\overline{N}}{\overline{Y}}\right),$$

where $n = \sum_i n_i$. Let the column vector $\mathbf{G}$ be given by $\mathbf{G}' = (G_{W,1}, \ldots, G_{W,K-1})$, and let the estimated covariance matrix for this $(K-1)$ dimensional vector be denoted by $\hat{\mathbf{\Sigma}}_{K-1}$ with elements given in (5). Suppose that $\lim_n n_i/n$ exists and lies in (0, 1) for each i. Then, under H_0: $\Lambda_1 = \cdots = \Lambda_k$, and as $n \to \infty$, the quadratic form $\mathbf{G}'\hat{\mathbf{\Sigma}}_{K-1}^{-1}\mathbf{G}$ converges in distribution to a χ^2 random variable with $K-1$ **degrees of freedom** (*see* **Chi-square Distribution**).

When all K components of the statistic are used in the quadratic form, a generalized inverse of the complete, singular covariance matrix may be used (*see* **Matrix Algebra**).

Asymptotic distributions under alternative hypotheses provide information about the power of the statistics. Gill [14] has shown that all two-sample tests of class $\mathcal{K}^+$ have asymptotic power 1, i.e. are consistent, under ordered hazards alternatives. Consequently, asymptotic power comparisons must be made under sequences of alternatives approaching the null hypothesis. Results with the counting process formulation are again simplest in the two-sample case. If a test statistic is asymptotically normal under a sequence of alternative hypotheses converging to the null hypothesis as the sample size increases, then the ratio of the square of the asymptotic mean to the asymptotic variance is called the (asymptotic) *efficacy*. The efficacy will be the noncentrality parameter in the χ^2 distribution for the square of the statistic, and the ratio of efficacies for two statistics, computed under the same sequence of alternatives, has the same value as the asymptotic ratio of the sample sizes needed for the two tests to have equal power. To avoid technical details, we will argue only heuristically here. Generally, much more care must be taken when establishing limiting distributions under sequences of alternative distributions. Gill [14] contains detailed results for the two-sample problem; the results for the K-sample problem may be found in Andersen et al. [3, 4]. The asymptotic theory of testing, especially for rank-based methods, may be found in Randles & Wolfe [28] and Hájek & Šidák [17].

For simplicity, we assume that the underlying survival distributions are absolutely continuous. We let $n = n_1 + n_2$ index the underlying survival and hazard functions in the sequence of alternative distributions. When the two hazard functions λ_1^n and λ_2^n are not equal, a two-sample statistic of the class $\mathcal{K}^+$ can be written

$$\begin{aligned} G_K &= \int_0^\infty K\left(\frac{\mathrm{d}\overline{N}_1}{\overline{Y}_1} - \frac{\mathrm{d}\overline{N}_2}{\overline{Y}_2}\right) = \int_0^\infty K\left(\frac{\mathrm{d}\overline{N}_1}{\overline{Y}_1} - \lambda_1^n\right) \\ &\quad - \int_0^\infty K\left(\frac{\mathrm{d}\overline{N}_2}{\overline{Y}_2} - \lambda_2^n\right) + \int_0^\infty K(\lambda_1^n - \lambda_2^n) \\ &= \int_0^\infty \frac{K}{\overline{Y}_1}\,\mathrm{d}\overline{M}_1 - \int_0^\infty \frac{K}{\overline{Y}_2}\,\mathrm{d}\overline{M}_2 \\ &\quad + \int_0^\infty K\left(\frac{\lambda_1^n}{\lambda_0} - \frac{\lambda_2^n}{\lambda_0}\right)\lambda_0, \end{aligned} \tag{6}$$

where λ_0 is the hypothetical common hazard function under the null hypothesis. For the weighted logrank statistics,

$$K = \left(\frac{n_1 n_2}{n_1 + n_2}\right)^{1/2} W \frac{\overline{Y}_1}{n_1}\frac{\overline{Y}_2}{n_2}\frac{n_1 + n_2}{\overline{Y}_1 + \overline{Y}_2},$$

where W is usually a function converging to some deterministic function w. The martingale central limit theorem implies that the first two terms in (6) converge to a mean zero Gaussian **(normal)** random variable, and the strong **law of large numbers** implies that the last two terms in the equation for K above converge collectively to $\pi_1\pi_2/(a_1\pi_1 + a_2\pi_2)$. Loosely speaking, the convergence of the statistic to a Gaussian variable under a sequence of alternatives will depend on the convergence of

$$\int_0^\infty \frac{\pi_1\pi_2}{a_1\pi_1 + a_2\pi_2} w \left(\frac{n_1 n_2}{n_1 + n_2}\right)^{1/2} \left(\frac{\lambda_1^n}{\lambda_0} - \frac{\lambda_2^n}{\lambda_0}\right)\lambda_0.$$

The last three terms in the integrand above may be written as

$$\left(\frac{n_1 n_2}{n_1 + n_2}\right)^{1/2} \left[\left(\frac{\lambda_1^n}{\lambda_0} - 1\right) - \left(\frac{\lambda_2^n}{\lambda_0} - 1\right)\right]\lambda_0.$$

Convergence under the sequence of alternative distributions will thus depend on convergence of

$$\left[\frac{n_1 n_2}{(n_1+n_2)}\right]^{1/2}\left[\left(\frac{\lambda_i^n}{\lambda_0}\right)-1\right]$$

to a function $g_i, i=1,2$. This implies when $i=1$, for instance, that the ratio of functions λ_1^n/λ_0 must converge to 1 at rate $n_1^{1/2}$, and that λ_1^n/λ_2^n must also converge to 1 at the same rate. If $g=g_1-g_2$, then the asymptotic mean of the statistic under this sequence of alternatives will be

$$\mu=\int_0^\infty \frac{\pi_1\pi_2}{a_1\pi_1+a_2\pi_2} w g \lambda_0.$$

The asymptotic variance of the statistic will be determined by the first two integrals in (6), and turns out to equal the asymptotic variance under the null hypothesis,

$$\sigma^2=\int_0^\infty \frac{\pi_1\pi_2}{a_1\pi_1+a_2\pi_2} w^2 \lambda_0.$$

The asymptotically best weighted logrank test statistic is the member of that class that maximizes this efficacy with respect to the asymptotic weight function w. Gill [14] uses a Lagrange multiplier argument to show that, in fact, the asymptotic efficacy is maximized over all of $\mathcal{K}^+$ when a statistic is a weighted logrank statistic with weight function W converging to an asymptotic weight function w proportional to g. This result can be used to calculate the best test from $\mathcal{K}^+$ against particular types of alternatives.

Suppose that $\lambda_i^n=\lambda_{\theta_i^n}$. Then,

$$\left(\frac{n_1 n_2}{n_1+n_2}\right)^{1/2}\left(\frac{\lambda_1^n}{\lambda_0}-1\right) = \frac{\lambda_{\theta_i^n}-\lambda_{\theta_0}}{\theta_i^n-\theta_0}\times\left(\frac{n_1 n_2}{n_1+n_2}\right)^{1/2}\frac{\theta_i^n-\theta_0}{\lambda_{\theta_0}}. \qquad (7)$$

If $\theta_i^n\to\theta_0$ such that

$$\lim_{n\to\infty}\left(\frac{n_1 n_2}{n_1+n_2}\right)^{1/2}(\theta_i^n-\theta_0)=c_i^*,$$

then both sides in (7) will approach $c_i^*\partial/\partial\theta\log\lambda_\theta$, where the derivative with respect to θ is evaluated at θ_0. Consequently, the function g appearing in the asymptotic mean and efficacy under a sequence of alternatives will be proportional to

$$\left.\frac{\partial}{\partial\theta}\right|_{\theta=\theta_0}\log\lambda_\theta.$$

This result confirms that, for instance, when $\lambda_{\theta_i^n}(t)=\lambda_0(t)\exp(\theta_i^n), i=1,2$ (i.e. proportional hazards alternatives), the most efficient statistic of class $\mathcal{K}^+$ has a constant weight function W (i.e. is the logrank statistic).

Computing asymptotic relative efficiencies against optimal tests for parametric models is more difficult, but uses the same approach. Gill [14] shows that, when the hazard function in the two-sample problem is known up to a single parameter $\theta_i^n, i=1,2$, satisfying

$$\theta_i^n-\theta_0=(-1)^{i+1}c\left[\frac{n_{i'}}{n_i(n_1+n_2)}\right]^{1/2},\quad i\neq i',$$

then the asymptotic efficacy of the **likelihood ratio test** of equality of the two hazard functions is given by

$$\int_0^\infty\left(\frac{\partial}{\partial\theta}\log\lambda_\theta\big|_{\theta=\theta_0}\right)^2(a_2\pi_1+a_1\pi_2)\lambda_{\theta_0}.$$

Gill also shows that the ratio of the asymptotic efficacies comparing an optimal test of class $\mathcal{K}^+$ to the likelihood ratio test is bounded above by 1, as expected, but that the ratio may equal 1 when $\pi_1=\pi_2$. Under random censoring, $\pi_i(t)=\Pr(T_{ij}\geq t)\Pr(U_{ij}\geq t)$. Since in the limit $\Pr(T_{1j}\geq t)=\Pr(T_{2j}\geq t)$, fully efficient tests of the class $\mathcal{K}^+$ can be found when asymptotic censoring distributions are equal.

The study of asymptotic operating characteristics of general K-sample tests uses similar tools; the interested reader can find a detailed treatment in Andersen et al. [4].

The counting process and martingale framework provides methods for a rigorous study of the operating characteristics of linear rank tests for censored data, but a variety of other approaches have been used in special cases. As mentioned in the introduction, Gehan [13] originally generalized the two-sample Wilcoxon test by extending the notion of the scores used in the Mann–Whitney version of the Wilcoxon statistic. Gehan then used a permutation argument

to compute a distribution under the null hypothesis, conditional on the observed pattern of censorship (*see* **Randomization Tests**), and argued that the permutation distribution would approach normality in large samples. Since the Gehan–Wilcoxon statistic corresponds to a weighted logrank statistic with weight function $W(t) = [\overline{Y}_1(t) + \overline{Y}_2(t)]/(n_1 + n_2)$, which asymptotically depends on both the underlying survival and censoring distributions in the groups, Gill's results show that this version of the Wilcoxon statistic has operating characteristics that depend on the censoring distribution. Leurgans [22, 23] also provides extensive applied and theoretical discussions of the asymptotic operating characteristics of rank statistics for censored data.

Mantel's [24] original derivation of the two-sample logrank statistic treated the observations as a series of **2 × 2 contingency tables**, with one table at each observed failure time. The marginal classifications of the tables denoted the number of subjects at risk in each group just prior to the observed failure time, and the numbers of subjects failing or not failing at the observed time. Mantel argued that, conditional on the risk sets in the two groups at the observed failure times, the set of observed minus conditionally expected number of failures in group 1 were independent, and that standard central limit theorems could be used to justify asymptotic normality. Mantel's arguments were heuristic, but the differences between observed and conditionally expected failures in the tables are exactly the increments in the integral representation, (2). The martingale representation shows that these increments are uncorrelated and consequently asymptotically independent. Mantel also argued that, since the Mantel–Haenszel statistic on which the logrank test is based is efficient at detecting a constant **odds ratio** different from 1 in stratified 2×2 tables, the logrank should have good power against proportional hazards alternatives.

Prentice [26] generalized the theory of linear rank tests, as described in Hájek & Šidák [17], to censored observations by suggesting a modification to the efficient score. This approach outlined a general context for linear rank tests for censored data, and showed that many of the statistics finding widespread use could be thought of as special cases of this general approach. Prentice was the first to show that Gehan's generalization of the Wilcoxon statistic was not the only natural way to create a Wilcoxon-type statistic for censored data. The Wilcoxon statistic in uncensored data arises from the optimal scoring function for shift alternatives in the **logistic distribution** [17], and Prentice's generalized scoring function for censored data led to a statistic that was approximately the weighted logrank statistic with weight function $\hat{S}(t-)$. Cuzick [7] later showed that many of the asymptotic results on linear rank tests for uncensored data could be extended to test statistics using the Prentice scoring function.

Because of space constraints, many important contributions to this field have necessarily been omitted. First, in the interest of simplicity, we have suppressed much of the generality that results from the use of martingale theory. The more complete treatments in [4], [14], and elsewhere discuss the use of local martingales, which relax some of the implicit boundedness conditions in the martingale definition. Local martingales allow more general weight functions in $\mathcal{K}^+$ statistics and also are used, sometimes in subtle ways, in the proofs of many of the results stated here. The asymptotic theory for these tests has been described only briefly (with mathematical details kept to a minimum) and small-sample properties not at all. It is possible to derive a permutation distribution for tests such as the logrank under the null hypothesis and the assumption of equal censoring in both groups, but most small-sample studies have relied on **simulation** (cf. Lee et al. [21] and Latta [20]). Alternative variance estimators to those given here are discussed in Andersen et al. [4]. Stratified tests are available for situations when differences among groups within strata are constant but baseline failure rates across strata differ (cf. [4]) (*see* **Stratification**). Gastwirth [12] and others have discussed the problem of how to combine linear rank tests for censored data when it is difficult to specify clearly the form of an alternative hypothesis. Robins & Rotnitzky [30] have proposed tests that relax the independent censoring assumption so prominently used here. Many authors have studied nonparametric estimates of survival distributions with left- or interval-censored data, and these estimates often lead to test statistics. Several nonlinear rank tests based on the sample path behavior of statistics from $\mathcal{K}^+$ have been proposed; some generalize the classical **Kolmogorov–Smirnov test**. There is an extensive literature on **sequential** methods that can be used with censored data linear rank tests in clinical trials and other prospective studies (*see* **Interim Analysis of Censored Data**). Finally,

many more linear rank tests have been proposed than just those discussed in this article.

DAVID HARRINGTON

Linear Regression, Simple

Historically, the term "regression" was introduced by **Galton** [3, p. 246] to describe the tendency for the offspring of seeds "to be always more mediocre [i.e. more average] than their parent seeds . . .. The experiments showed further that the mean filial regression towards mediocrity was directly proportional to the parental deviation from it". Pearson & Lee [4] subsequently collected data on the heights of 1078 father–son pairs in order to study Galton's "law of universal regression" which they summarized as "Each peculiarity in a man is shared by his kinsmen, but on the average in a less degree" (*see* **Regression to the Mean**).

Modern applications rarely involve the element of "regression" as Galton meant it; however, the word is now too established to change. Consequently, regression now describes any relationship between a **response** (dependent, outcome) variable, Y, and a **covariate** or **explanatory** (independent, predictor) variable, X. Strictly speaking, only the response, Y, is assumed to vary randomly; however, in many applications the observed values of X are not known or fixed. We assume that any inherent variation in the measurement of X can be ignored. If this is not the case, we strongly advise resorting to methods that are appropriate when there is measurement error in an explanatory variable (*see* **Errors in Variables**). Simple linear regression involves finding the best-fitting curve that relates $\mathrm{E}(Y|X)$, the mean value of Y given X, and X, using an equation with a suitable functional form, such as $\mathrm{E}(Y|X) = \beta_0 + \beta_1 X$. This regression equation is called linear because $\mathrm{E}(Y|X)$ is a linear (straight-line) function with respect to the unknown model parameters, β_0 and β_1. It is not essential that $\mathrm{E}(Y|X)$ also depend linearly on X, although this is frequently the case in applications. For example, the model $\mathrm{E}(Y|X) = \beta_0 + \beta_1 X^2$ describes a linear regression model that is a straight-line function of β_0 and β_1, but is quadratic in X (*see* **Polynomial Regression**). Whatever the model form, the goals of regression modeling are

1. to determine whether Y and X are associated in some systematic way; and/or
2. to estimate or **predict** the value of Y, or its mean, corresponding to a known value of X.

The unknown parameters, β_0 and β_1, are estimated from data – ordered pairs $(X_1, Y_1), \ldots, (X_n, Y_n)$ – using the method of **least squares**, which was discovered independently by **Gauss** and Legendre; see Plackett [5].

Estimating β_0 and β_1

Before fitting a linear regression model to data, it is wise to examine a scatterplot of Y vs. X in order to ensure that the proposed relationship is a sensible one (*see* **Graphical Displays**). Such a scatterplot is shown in Figure 1 for measurements of systolic blood pressure and age obtained from 21 males between the ages of 25 and 80. For these data, the notion that average systolic blood pressure increases systematically, in a roughly linear manner, with age seems plausible.

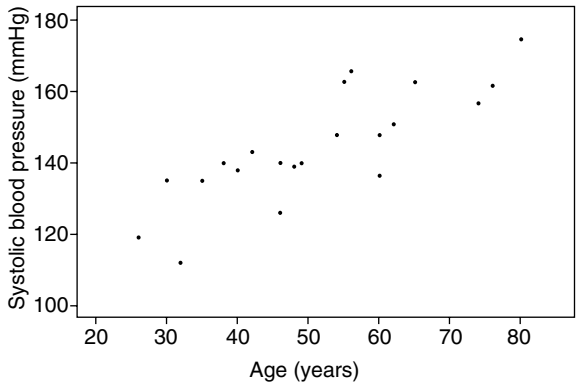

Figure 1 A scatterplot of systolic blood pressure (Y) vs. age (X) for a sample of 21 males between 25 and 80 years old

All linear regression models consist of a systematic component – the model equation, $E(Y|X) = \beta_0 + \beta_1 X$ – and a residual (random, error) component, ε; the sum, $\beta_0 + \beta_1 X + \varepsilon$, constitutes the regression model for Y. The **residual**, $\varepsilon = Y - \beta_0 - \beta_1 X$, represents the amount by which an observed value of Y deviates from the predicted mean, $\beta_0 + \beta_1 X$. Not all (X_j, Y_j) pairs for a given set of data will lie on the predicted line (curve). The method of least squares identifies the unique values of β_0 and β_1 that minimize the average of the squared residuals. Specifically, $\hat{\beta}_1 = S_{xy}/S_{xx}$ and $\hat{\beta}_0 = \overline{y} - \hat{\beta}_1 \overline{x}$, where $\overline{x} = \sum_{i=1}^{n} x_i/n$, $\overline{y} = \sum_{i=1}^{n} y_i/n$, $S_{xy} = \sum_{i=1}^{n}(x_i - \overline{x})(y_i - \overline{y})$, and $S_{xx} = \sum_{i=1}^{n}(x_i - \overline{x})^2$. The equation of the estimated regression of Y on X is

$$\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 X = \overline{y} + \hat{\beta}_1 (X - \overline{x}).$$

Least squares estimates can be derived based only on the assumptions that the residuals, $\varepsilon_1, \ldots, \varepsilon_n$, are uncorrelated and have a mean value of zero and constant variance, σ^2. We use the estimated residuals $\hat{\varepsilon}_i = Y_i - \hat{Y}_i = Y_i - \hat{\beta}_0 - \hat{\beta}_1 X_i, i = 1, \ldots, n$, to estimate σ^2. The formula

$$\hat{\sigma}^2 = \frac{1}{n-2} \sum_{i=1}^{n} \hat{\varepsilon}_i^2,$$

which involves $\sum_{i=1}^{n} \hat{\varepsilon}_i^2$, the estimated residual sum of squares, emphasizes that two parameters, β_0 and β_1, are estimated; hence the divisor $n - 2$. Adopting the additional assumption that the residuals are **normally distributed** gives rise to various statistical procedures that we will discuss subsequently. First, however, we examine linear regression as an explanation for the observed variability in the response, Y.

Partitioning the Variability in Y

To account for the variability in Y, we can always resort to the simplest explanation, namely that Y varies about a fixed mean, μ. The corresponding linear regression model is $Y_i = \beta_0 + \varepsilon_i$, where $\beta_0 = \mu$. In this case, the residuals, i.e. $\varepsilon_i = Y_i - \beta_0 = Y_i - \mu$, are usually large, and result in a substantial estimate of σ^2. For the data concerning blood pressure and age, these estimated residuals are shown in Figure 2(a). In the absence of additional information, this is the only explanation we can devise for the observed variability in Y.

However, when Y appears to depend systematically on X, we can use the known values of X that were measured concurrently with Y to estimate $E(Y|X)$. Using $\hat{Y} = E(Y|X)$, we can partition the observed variability in Y into two components – the change in $E(Y|X)$ accounted for by the change in X, and the residual variability of Y values that have the same value of X, and hence the same value of $E(Y|X)$. These two components of variability correspond to the systematic component, $\beta_0 + \beta_1 X$, and the residual component, ε, respectively, in the linear regression model $Y = \beta_0 + \beta_1 X + \varepsilon$. By estimating $E(Y|X) = \beta_0 + \beta_1 X$, we can reduce the estimated residuals and hence the estimate of σ^2, the residual variation. Clearly, the estimated residual sum of squares in Figure 2(b) will be much less than the corresponding value based on the estimated residuals in Figure 2(a). Equivalently, knowing a subject's age provides important information about what his blood pressure is likely to be.

This partition of the variability in Y is usually summarized in an **analysis of variance** (ANOVA) table, such as the one corresponding to the example shown in Table 1. This partitioning is represented by the equation

$$\sum_{i=1}^{n}(Y_i - \overline{Y})^2 = \sum_{i=1}^{n}(\hat{Y}_i - \overline{Y})^2 + \sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2,$$

which is alternatively described by the relationship

$$\text{total sum of squares} = \text{model sum of squares} + \text{residual sum of squares.}$$

The ratio of the model sum of squares to the total sum of squares is called R^2, and represents the proportion of the observed variability in Y that is accounted for by modeling the mean response for Y as the function, $\beta_0 + \beta_1 X$, of X.

Table 1 An ANOVA table summarizing the partition of observed variability in blood pressure measurements into the systematic (model) component represented by the estimated regression model, $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 X$, and the residual component. The value of R^2 for these data is 0.69

Source	SS	df	MS
Model	3453.5	1	3453.5
Residual	1545.8	19	81.36
Total	4999.3	20	

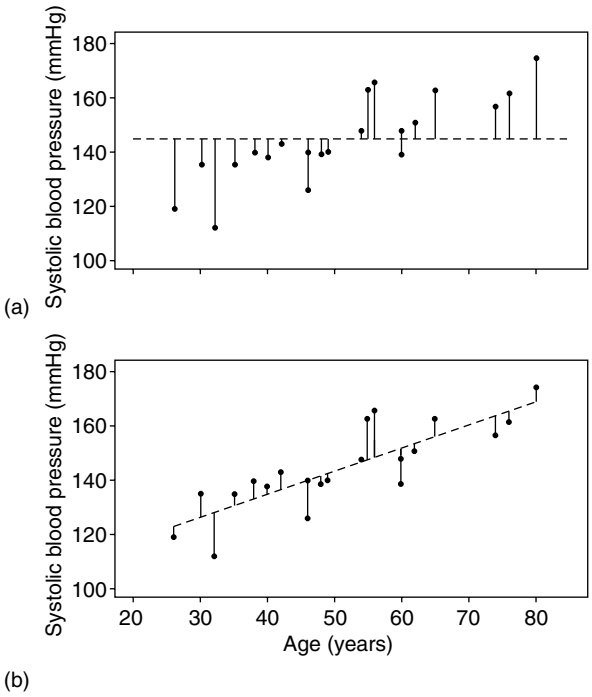

Figure 2 Estimated residuals (solid lines) for systolic blood pressure measurements (Y) in a sample of 21 males between 25 and 80 years old. (a) Based on the simple model, $Y = \mu + \varepsilon$; the dashed line indicates $\hat{\mu} = 144.7$. (b) Based on the linear regression model, $Y = \beta_0 + \beta_1 X + \varepsilon$, relating Y and age (X); the dashed line indicates the least squares estimated regression equation $\hat{Y} = 100.6 + 0.86X$

Interpreting the Regression Estimates

If two values of the explanatory variable differ by one unit, the corresponding values of the model equation differ by β_1. Therefore, $\hat{\beta}_1$ represents the estimated change in the mean response associated with a unit increase in the explanatory variable. Of course, this estimate and its interpretation are only valid within the range of X values used in fitting the linear regression model.

The value β_0 represents the mean response when $X = 0$. Frequently, this mean response may be of no interest, or may not belong to the range of X values used in fitting the model to data. A more useful parameter in many situations is $\gamma = \beta_0 + \beta_1 \overline{x}$, which represents the mean response when $X = \overline{x}$, the observed average of the explanatory variable. The estimated value is $\hat{\gamma} = \hat{\beta}_0 + \hat{\beta}_1 \overline{x} = \overline{y}$, the sample mean of Y.

The estimates of β_0 and β_1 for the example are 100.6 and 0.86, respectively. From these data we conclude that 0.86 mmHg is the estimated increase in mean systolic blood pressure associated with each additional year of age for men 25–80 years old. At an age of $\overline{x} = 51.1$ years, the estimated mean value is $\hat{\gamma} = \overline{y} = 145$ mmHg.

Statistical Inference in Linear Regression

Under the additional assumption that the residuals, $\varepsilon_1, \ldots, \varepsilon_n$, are normally distributed, the estimators of β_0 and β_1 have normal sampling distributions. Estimated **standard errors** (est. se) for $\hat{\beta}_0$ and $\hat{\beta}_1$ are routinely produced by most computing packages (*see* **Software, Biostatistical**). The ratio of each difference, $\hat{\beta}_0 - \beta_0 \hat{\beta}_1 - \beta_0$, to its corresponding estimated standard error follows a **Student's *t* distribution** with $n - 2$ **degrees of freedom** (df). From these results, **hypothesis tests** and/or **confidence intervals** for β_0 and β_1 can be evaluated. Likewise, the **sampling distribution** of $\hat{\gamma} = \overline{Y}$ is

normal, and the corresponding estimated standard error is $s/\sqrt{n}$, where $s^2 = \hat{\sigma}^2$.

A test of the null hypothesis, $H_0 : \beta_1 = 0$, is routinely used to assess the significance of the regression; that is, to determine whether the data constitute statistical evidence of an association between Y and X. This test can be based either on the ratio $\hat{\beta}_1$/est. se$(\hat{\beta}_1)$, which has a Student's t distribution with $n - 2$ df, or on $[\hat{\beta}_1/\text{est. se}(\hat{\beta}_1)]^2$, which has an ***F* distribution** with 1 and $n - 2$ df. The latter test statistic is equal to the ratio of the model mean square to the residual mean square in the corresponding ANOVA table for the regression analysis, and usually appears in an additional column labelled F ratio.

For the blood pressure vs. age example, the estimated standard errors for $\hat{\beta}_0, \hat{\beta}_1$ are 7.05 and 0.13, respectively. The 95% confidence interval for β_1 is (0.58, 1.14), and for γ the interval is (136, 153).

Model Diagnostics

A fitted regression model and associated statistical inferences are based on various assumptions concerning the functional form of the model for $\mathrm{E}(Y|X)$ and distributional properties of the residuals. Violations of these assumptions may invalidate conclusions based on the regression analysis. Therefore, it is essential to check these assumptions, using various types of **diagnostic** plots.

The estimated residuals, $\hat{\varepsilon}_i = Y_i - \hat{\beta}_0 - \hat{\beta}_1 X_i$, $i = 1, \ldots, n$, play an essential role in model diagnostics. Many computer packages offer the option of using these ordinary residuals or the corresponding standardized or studentized residuals, which have a common variance. Use of either of the latter two is preferable, since the $\hat{\varepsilon}_i$s do not all have the same variance.

The following diagnostic plots furnish graphical evidence that one or more of the model assumptions may be contradicted by the data:

1. Residuals vs. the fitted values, $\hat{Y}_i$. An unsuitable functional form is usually revealed by the systematic appearance of this plot, as is nonconstant variance.
2. Residuals vs. the explanatory variable, X_i. Systematic patterns in this plot can indicate violations of the mean 0, constant variance assumptions, or inappropriate model form.
3. Normal probability plot of the residuals. This plot checks the normal distribution assumption from which all the statistical inference procedures arise (*see* **Normal Scores**).
4. Residuals vs. the temporal/spatial order of data collection. Unexpected regularity in this plot suggests that the Y_is may be correlated. To prepare this diagnostic check, it is essential to record the temporal/spatial ordering when data are first collected.
5. Index plots (plot against the case number, i.e. the observation label) of the leverages and Cook's distance (*see* **Normal Scores**). The former are a measure of the amount of influence exerted on $\hat{Y}_i$ by the corresponding observed response, Y_i. Cook's distance is a summary measure of the influence that each case exerts on the estimated regression coefficients. These two diagnostic plots can reveal outliers (values of Y that are anomalous with respect to the rest of the data) or influential points (values of (X_j, Y_j) that strongly influence the estimated values of $\hat{\beta}_0, \hat{\beta}_1$ and s^2).

Deviations from the expected (null) pattern in any of these plots may indicate problems that require further investigation or remedial action. For additional details concerning model diagnostics, see Belsley et al. [1] or Cook & Weisberg [2]. Further details concerning examination of the adequacy of a fitted regression model are found in the article on **Goodness of Fit**.

DAVID E. MATTHEWS

Linearization Methods of Variance Estimation

The **variance** of a linear function of variables is a linear function of variables. An approximation by a linear function of a nonlinear function enables one to derive an approximate variance of a complex nonlinear function. The most common approach consists of taking linear terms of Taylor series expansion of the nonlinear function of the observations around their expected values. The approach has been widely used for approximating large-sample variances (*see* **Large-sample Theory**), and is referred to as Taylor Series Linearization or the **Delta method**. Another linearization approach was suggested by Quenouille [6] and made well known by Tukey [10] as **jackknife**. A good review of the jackknife and other methods appears in [7].

Tepping [9] suggested the use of Taylor series linearization for estimating variances in complex sample surveys. Applications to **mean** and **linear regression** coefficients for complex surveys were presented by Kish & Frankel [4] and Folsom [3]. Some **simulation** results were presented by Shah et al. [8]. Woodruff [11] presented a general application of the linearization method to explicit functions of observed data. Binder [1] extended the results to parameters defined as implicit functions or estimating equations. Binder also proved the asymptotic **normality** of the estimates. Binder [2] presented an application of Taylor series linearization to the estimation of parameters for Cox's **proportional hazard** model for the survival data collected from a complex sample survey. We present here a brief summary of the results by Woodruff [11] and Binder [1].

The Taylor series linearization method is illustrated here for statistics that can be defined explicitly as functions of linear statistics estimated from a survey sample. Means, totals, proportions, general ratios of the form $\sum wx / \sum wy$, and linear regression coefficients all fall into this category of functions. A linearized variable, Z_i, is defined on the basis of the Taylor series expansion of the function, and then substituted into the variance formula appropriate under the specified design for any linear statistic estimated from the sample.

The technique will be illustrated for a statistic which is a function of two linear statistics, although it extends to any number of linear statistics and to statistics that are vectors. Let $\hat{\theta}$ be an estimate of the population parameter θ, with $\hat{\theta} = F(X, Y)$ where X and Y are two linear sample statistics. Let $\mu_x = \mathrm{E}(X)$ and $\mu_y = \mathrm{E}(Y)$, where the **expectation** operator E denotes averaging over repeated sampling from the **target population**. θ can be expanded in a Taylor series about μ_x and μ_y, so that

$$\begin{aligned}\hat{\theta} = {} & F(\mu_x, \mu_y) + \partial F_x(\mu_x, \mu_y)(X - \mu_x) \\ & + \partial F_y(\mu_x, \mu_y)(Y - \mu_y) \\ & + \text{higher order terms},\end{aligned}$$

where the $\partial F_x(\mu_x, \mu_y)$ and $\partial F_y(\mu_x, \mu_y)$ functions are first-order partial derivatives of F with respect to X and Y evaluated at their respective expectations, μ_x and μ_x. If the higher order terms are negligible, then

$$\begin{aligned}\mathrm{var}[\hat{\theta}] &\doteq \mathrm{E}[\hat{\theta} - F(\mu_x, \mu_y)]^2 \\ &= \{(\partial F_x)^2 \mathrm{E}(X - \mu_x)^2 + (\partial F_y)^2 \mathrm{E}(Y - \mu_y)^2 \\ &\quad + 2(\partial F_x)(\partial F_y) \\ &\quad \times \mathrm{E}[(X - \mu_x)(Y - \mu_y)](Y - \mu_y)\} \\ &\quad \times \{(\partial F_x)^2 \mathrm{var}(X) + (\partial F_y)^2 \mathrm{var}(Y) \\ &\quad + 2(\partial F_x)(\partial F_y)\mathrm{cov}(X, Y)\},\end{aligned}$$

where $\partial F_x = \partial F_x(\mu_x, \mu_y)$ and $\partial F_y = \partial F_y(\mu_x, \mu_y)$.

An equivalent computational procedure for producing the Taylor series variance estimate suggested by Woodruff [11] recognizes that the variable portion of the linearization in his Eq. (3.2) is

$$Z = (\partial F_x)X + (\partial F_y)Y,$$

and therefore

$$\begin{aligned}\mathrm{var}[\hat{\theta}] &\doteq \mathrm{var}[(\partial F_x)X + (\partial F_y)Y] \\ &= \mathrm{var}(Z).\end{aligned}$$

Noting that X and Y are linear statistics formed from the corresponding response variates x_i and y_i, measured on the ith sample unit, the variance approximation can be produced by substituting the linearized variable

$$Z_i = (\partial F_x)X_i + (\partial F_y)Y_i$$

for x_i or y_i in the variance formula appropriate for computing var(X) or var(Y) under the specified sample design. To obtain a sample estimate for the Taylor series variance approximation, one replaces the population-evaluated derivative functions in Z_i with the corresponding sample analog, i.e.

$$Z_i = [\partial F_x(X, Y)]x_i + [\partial F_y(X, Y)]y_i.$$

Binder [1, 2] proposed and justified using an implicit differentiation method for estimating the variance for a vector of survey statistics. Binder's results are particularly useful when the parameters are implicitly defined, but the results also cover the explicit case.

Logistic regression coefficients and survival models (*see* **Survival Analysis, Overview**) fall into this category of parameters that are implicitly defined.

Let $\theta = (\theta_1, \ldots, \theta_p)'$ be the finite population parameter vector which is defined by

$$W(\theta) = \sum_{k=1}^{N} U(Z_k; \theta) - v(\theta) = 0,$$

where $Z_k = (z_{1k}, \ldots, z_{qk})$ are the data values for the kth unit, and $W(\theta)$ is a vector with the ith element:

$$W_i(\theta) = \sum_{k=1}^{N} V_i(Z_k; \theta) - v_i(\theta) = 0.$$

Let $U(\theta) = \sum_{k=1}^{N} U(Z_k; \theta)$ be estimated from the sample by $\hat{U}(\theta)$. $\hat{U}(\theta)$ is the estimator of the total based on the functions of data values $U(Z_1; \theta), \ldots, U(Z_n; \theta)$, for example $\hat{U}(\theta) = \sum_{i \in S} w_i U(Z_i; \theta)$. Then, $\hat{W}(\theta) = \hat{U}(\theta) - v(\theta)$. Assuming that a unique solution exists, $\hat{\theta}$, the estimate of θ, is defined as the solution to

$$\hat{W}(\hat{\theta}) = 0.$$

To approximate the variance of $\hat{\theta}$, Binder expands $\hat{W}(\hat{\theta})$ in a Taylor series about the point $\hat{\theta} = \theta$, where θ is the true unknown parameter. Defining $\hat{J}(\theta) = \partial \hat{W}(\theta)/\partial\theta$ as the $p \times p$ matrix whose ij element is the partial derivative $\partial \hat{W}_i(\theta)/\partial\theta_j$, and expanding $\hat{W}(\hat{\theta})$ about $\hat{\theta} = \theta$, gives

$$0 = \hat{W}(\hat{\theta}) \approx \hat{W}(\theta) + \hat{J}(\theta)(\hat{\theta} - \theta),$$

or, if $\hat{J}^{-1}(\theta)$ exists,

$$\hat{\theta} - \theta \doteq \hat{J}^{-1}(\theta)\hat{W}(\theta).$$

This leads to the approximation of the variance matrix of $\hat{\theta}$:

$$V(\hat{\theta}) \doteq [\hat{J}^{-1}(\theta)][V(\hat{W}(\theta))][\hat{J}^{-1}(\theta)]',$$

where $V(\hat{W}(\theta))$ is the **covariance matrix** of $\hat{W}(\theta)$. Finally, θ is replaced by its estimator $\hat{\theta}$, in both $\hat{J}^{-1}(\theta)$ and $V(\hat{W}(\theta))$ to obtain the estimator of the covariance matrix of $\hat{\theta}$:

$$\hat{V}(\hat{\theta}) = [\hat{J}^{-1}(\hat{\theta})][\hat{V}(\hat{W}(\hat{\theta}))][\hat{J}^{-1}(\hat{\theta})]'.$$

Binder [1] gives regularity conditions that are needed to ensure the asymptotic normality of the parameters $W_i(\hat{\theta})$ and the consistency of $\hat{V}(\hat{\theta})$. These conditions include:

1. the existence of a parameter space that contains a neighborhood of the parameter θ;
2. the existence of a sequence of sample designs and populations which admits asymptotically normal estimators for certain population totals and consistent estimators for the variance of the estimate of the totals: in particular, $\hat{W}(\theta)$ is approximately normally distributed for fixed θ;
3. some continuity and limiting conditions on $W(\theta)$ and its partial derivatives, and a continuity condition on the variance of the estimated total.

Furthermore, Binder [1, Corollary 2] shows that the asymptotic distribution of $\sqrt{n}(\hat{\theta} - \theta)$ is the same as the asymptotic distribution of a **random variable** that is **multivariate normal** with mean zero and variance–covariance matrix $n[\hat{J}^{-1}(\hat{\theta})][\hat{V}\hat{W}(\hat{\theta})][\hat{J}^{-1}(\hat{\theta})]'$.

The question is often raised as to how good the linearization method is compared with other alternatives. There are basically three major competing methods: balanced repeated replication (BRR), jackknife, and **bootstrap** methods.

The drawbacks of the linearization methods are:

1. Linearization methods require computation of derivatives, and hence are more difficult to program than BRR or jackknife. Linearization methods are also limited to smooth functions of observations.
2. The impact of weight adjustments, such as **post-stratification** or **nonresponse**, on variance estimation is difficult to account for, and is often ignored in most implementations.

The advantages for the linearization method are:

1. They require substantially less computational resources than jackknife and BRR and are most suitable for large datasets.
2. They are applicable to a large number of situations, and can be applied to **multistage** designs with or without replacements. BRR and jackknife are somewhat limited in this respect.

Krewski & Rao [5], and Rao & Wu [7] have compared the three methods. Linearization methods are less **biased** and more stable than BRR or jackknife methods. Asymptotically, all of the methods provide **consistent estimators** of the variances, and hence the differences between them get smaller as the sample size increases. Overall there are no compelling reasons to choose one method over the others, and the decision to select a method should be based on convenience and available software. Currently, three software packages have implemented variance estimation using the linearization method. These are: SUDAAN, by Research Triangle Institute; PCCARP, by Iowa State University; and STATA, by Stata Corporation (*see* **Software, Biostatistical**).

Linkage Analysis, Model-based

In the field of **human genetics**, the main goal has been to identify the **genes** that are responsible for various phenotypes (*see* **Genotype**) – typically diseases. The primary method for doing so has been through looking at phenotypically silent marker loci that are randomly distributed in the genome (*see* **Polymorphism**), and trying to determine which such loci have alleles that tend to cosegregate in families with the trait of interest. In linkage analysis one tries to estimate the frequency with which the marker and disease gene segregate together in families. When we talk of model-based linkage analysis, it is assumed that one can fully describe the mode of action of the disease gene, i.e. its allele frequency (*see* **Gene Frequency Estimation**) and the **penetrances** for each disease locus genotype (*see* **Gene**). When one does not know these quantities accurately, one often applies model-free linkage analysis methods (*see* **Linkage Analysis, Model-free**), which effectively correspond to special cases of model-based linkage analysis. Similarly, it can be shown that other methods for detecting correlations between a marker locus and disease gene on a population level through **linkage disequilibrium** analysis can also be considered as special cases of model-based linkage analysis. For this reason, it is important to understand the principles of model-based linkage analysis, because their principles are behind all statistical gene mapping techniques (*see* **Genetic Map Functions**).

Biological Basis of Linkage

The human genetic material is composed of large linear units of deoxyribonucleic acid (DNA) called chromosomes, each of which contains a long linear sequence of genes. These genes are **DNA sequences** that tell the cell how to construct a specific protein, and thus these genes provide the blueprint from which a person is assembled. There are 22 pairs of chromosomes in each human cell, plus a pair of sex chromosomes (X and Y) which determine the sex of an individual (XX individuals are female, and XY individuals are male). Each person receives one copy of each chromosome from his mother and one copy from his father, and thus each person has 50% of his DNA inherited from each parent. Since 50% of one's genes come from each parent, there is a **correlation** between related individuals at the phenotypic level, and thus the common observation that certain diseases "run in families". The male sperm cell and the female egg cell each contain one copy of each chromosome (haploid state) from the father and mother, respectively, instead of two copies of each chromosome as in a normal somatic cell (diploid state). When the sperm and egg combine to form a new child, this infant again has two copies of each chromosome. The important step in determining the genetic makeup of the new child is to look at how the single copy of each chromosome is selected for each gamete. The process by which these haploid gametes are generated is called meiosis. If we label the two copies of chromosome N that a given parent has as N_a and N_b (where this individual received chromosome N_a from his father and chromosome N_b from his mother), then **Mendel's laws** dictate that which copy of each chromosome is transmitted to any given gamete is determined at random, and that each chromosome is inherited independently of every other. Thus, the probability that a gamete receives chromosome 1_b equals the probability that it receives 1_a, and the same holds for chromosomes 2,3, and so on. In this simplified model of inheritance, if an allele located somewhere on chromosome 1_a was received by a given gamete, then the probability of another allele on chromosome 1_a also being inherited would be 1, while the probability of an allele located on chromosome 2_a being inherited would be 0.5. If life were this simple, then we could easily test whether or not two genes were on the same chromosome (syntenic) by checking whether any gamete ever received the a allele at one gene and the b allele at the other. Under the **null hypothesis** that two genes are on different chromosomes, 50% of gametes would receive the a allele at one gene and the b allele at the other, and it would thus be very easy to test for synteny.

In human meiosis, however, it is not as simple as this. There is an additional source of variation in the genetic material. During meiosis the two copies of each chromosome line up next to each other and undergo a random process called recombination in which the two copies of each chromosome can exchange their genetic material with each other (as illustrated in Figure 1). In fact, there may be many

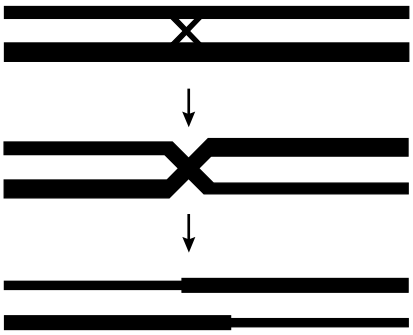

Figure 1 Pictorial representation of recombination. The (thick and thin) lines represent homologous chromosomes during meiosis; the black X in the top of the figure represents a recombination event, one outcome of which is indicated in the figure

such crossover events per chromosome in each meiotic event, and thus there is a great deal of variation between even the most tightly related people. When an odd number of crossover events occur between two genes, the alleles from different ancestral chromosome are received (i.e. allele a at one locus and allele b at the other) – in this situation we say that a recombination of the genetic material has occurred between these two loci – the combination of alleles a at one locus and b at the other is a new combination that was not present on either parental chromosome. If an even number of crossovers occurs between two genes, then the same combination of alleles as in the parents is present in the gamete – this is termed a nonrecombination. If two loci are on different chromosome, they recombine with probability 50% (since, as was indicated earlier, given allele a was inherited at a given point on chromosome 1, the probability of an allele on chromosome 2 being present in the gamete in its b form is 50%). Similarly, if two loci are very far apart on the same chromosome (and we assume an absence of chromatid interference) they also recombine with probability 50%, but when two loci are very close together on the same chromosome, the probability of a recombination between them tends toward 0 as the distance between them decreases. Thus it becomes possible to devise a means of testing for linkage between two loci by looking at whether they recombine with probability 50% or less.

There are a large number of loci spread randomly throughout the human genome called marker loci that have no known function, but that are very variable from person to person, and whose positions in the genome are well known. It is straightforward to determine the genotype of any individual at these polymorphic DNA sequence variations, and thus we can look for genes with unknown position in the genome by testing whether the gene of interest recombines with a marker locus with probability less than 50%. Since there are marker loci spread throughout the genome, at least one of them should be linked to any new gene we wish to isolate. The goal of linkage analysis is to identify marker loci that recombine with our trait locus with low probability, such that we may significantly narrow down the portion of the total genome where this gene can be found by subsequent labor-intensive molecular analysis. The closer we can get to the gene through the simple process of linkage analysis, the easier it will be to identify, though typically it is impossible to get within less than 2 cM – approximately 2 000 000 base pairs – through linkage analysis with a disease having a known mode of inheritance, while for complex traits with an unknown mode of inheritance, it may be difficult to get within less than 10 cM (10 000 000 base pairs), further complicating the subsequent molecular analyses required. The next Sections introduce the mathematical techniques employed in the testing and estimation of linkage in humans, starting from the simplest situations and continuing through to the general case.

Lod Score Analysis

The most commonly employed statistic in human genetic linkage analysis is based on the principle of **maximum likelihood**. In this, we compute the probability of the observed data under different assumptions about the unknown parameter – here the recombination fraction (typically denoted as θ). The null hypothesis is that $\theta = 0.5$, and the alternative is that $\theta < 0.5$, so the test statistic is based on the maximum of the **likelihood ratio** $\Lambda(\theta) = L(\theta)/L(\theta = \frac{1}{2})$. For purely historical reasons, the lod score function commonly used is $Z(\theta) = \log_{10}[\Lambda(\theta)]$; however, the quantity $2 \ln \Lambda$ is much more theoretically pleasing since, asymptotically, $\max_\theta[2 \ln \Lambda(\theta)](= \Lambda_{\max})$ is distributed as a mixture of a 50% point mass at 0 and 50% $\chi^2_{(1)}$ – the 50% point mass at zero because of the one-sided alternative, $\theta < 0.5$ (if $\hat{\theta} = 0.5$, $\Lambda_{\max} = 0$) and other arguments (cf. [15], [20], and [7]). The

conventional critical value used in linkage analysis for calling a test significant is $Z \geq 3$, which corresponds to a ***P* value** of 0.0001 if we assume the distribution given above. The reason for insisting on such a small P value is due to the multiple testing employed (*see* **Multiple Comparisons**) if one were to conduct a full genome scan with many markers, and the low prior probability of linkage to a randomly selected marker locus (see [6], [11], [16], and [21] for more details).

Counting Recombinants and Nonrecombinants – Phase-known Pedigrees

In some situations it is possible to directly observe whether a recombination occurred or not between two loci in a given meiosis. This is commonly the case in animal crosses, where you can breed animals to the point where you know which of their offspring are the results of recombinant meioses and which are nonrecombinant. Let us assume that our data are in the form of genotypes, so we can write the pedigree **likelihood** as

$$L(\theta) = \Pr(\text{genotypes}_{\text{parents}}) \times \Pr(\text{genotypes}_{\text{offspring}}|\text{genotypes}_{\text{parents}}),$$

and the lod score can then be written as

$$\log_{10}\frac{L(\theta)}{L\left(\theta=\frac{1}{2}\right)} \log_{10} = \frac{\Pr(\text{genotypes}_{\text{parents}}) \times \Pr(\text{genotypes}_{\text{offspring}}|\text{genotypes}_{\text{parents}};\theta)}{\Pr(\text{genotypes}_{\text{parents}}) \times \Pr\left(\text{genotypes}_{\text{offspring}}|\text{genotypes}_{\text{parents}};\theta=\frac{1}{2}\right)}.$$

Note that in the ratio we can factor out Pr(genotypes$_{\text{parents}}$), since this factor is independent of the recombination fraction, as the genotypes are known and identical in numerator and denominator. Therefore, assuming we can count the number, k, of recombinants out of n meioses (leaving $n-k$ nonrecombinants), the likelihood is simply $L(\theta) = \theta^k(1-\theta)^{n-k}$. The maximum likelihood estimate of the recombination fraction in this case is trivial to compute as $\hat{\theta} = k/n$ if $k < n/2$; $\hat{\theta} = 0.5$ if $k \geq n/2$ (since values of $\theta > 0.5$ are inadmissible). While this estimate of θ is biased (because of the inadmissibility of estimates of $\theta > 0.5$), it can be shown to be asymptotically unbiased (cf. [16]). It is possible to count recombinants and nonrecombinants in situations when the phase is known. When we say the phase is known we mean that it is possible to tell which alleles were inherited from each grandparent. Consider the pedigree shown in Figure 2; in that pedigree it is apparent that allele A at the first locus and allele B at the second locus in the father were inherited together from the grandfather; and similarly alleles a and b were inherited together from the grandmother. If the two loci are syntenic, it would mean they are on the same chromosome in the father. In this case, among the children all A B or a b haplotypes are nonrecombinants (parental types), while all children who received haplotypes A b or a B are recombinants (or nonparental types). In this example, there are four nonrecombinant children and two recombinants, so our lod score is computed as

$$Z(\theta) = \log_{10}\frac{\theta^2(1-\theta)^4}{(0.5)^2(0.5)^4} = \log_{10} 2^6\theta^2(1-\theta)^4.$$

In this pedigree, the maximum likelihood estimate of θ is $2/6 = 1/3$, so the maximum lod score is $Z(1/3) = 0.1475$. Note that the information coming

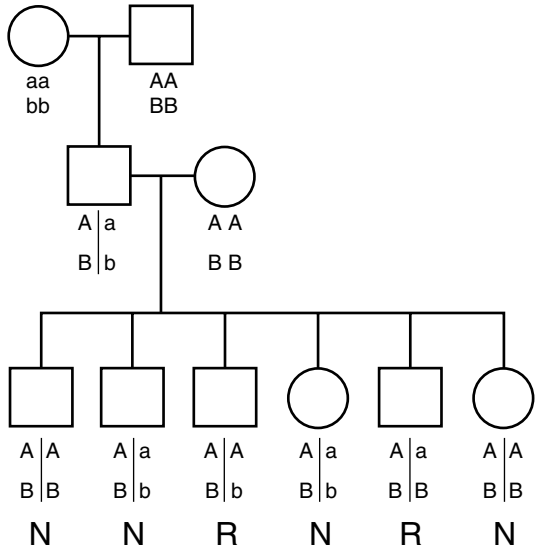

Figure 2 Sample phase-known pedigree with two codominant loci indicated–the first locus has two alleles (A and a) and the second locus has alleles B and b. Nonrecombinant meioses are indicated by "N" and recombinant meioses by "R"

from alleles inherited from the mother by the offspring was not included in this computation. This is because there is no linkage information coming from the mother as she is homozygous (*see* **Heterozygosity**) at both loci, and thus she transmits alleles A and B to all children with probability 1, independently of the recombination fraction. In fact, a parent has to be heterozygous at both loci to be informative for linkage. If the mother were Aa at the first locus and BB at the second, then every child would receive a B allele with probability 1, and at the other locus A is inherited with probability 0.5, independently of the recombination fraction (since the inheritance of the B allele is ubiquitous).

Lod Scores in Phase-unknown Pedigrees

Often there is some ambiguity about the parental phase – for example, if the grandparents were unavailable for genotyping. Consider the same pedigree without the grandparents having been typed (as shown in Figure 3). In this situation, there are two possible phases for the father – either he could have phase A B/a b or he could have phase A b/a B. A priori these two phases are equally likely (assuming an absence of linkage disequilibrium), so we either have four recombinants and two nonrecombinants or we have four nonrecombinants and two recombinants. Early human geneticists would throw these pedigrees away because it was thought that they contained no useful information about linkage. However, there is information in these families. The likelihood is computed as

$$\begin{aligned} L(\theta) &= \Pr(\text{parents})\,\Pr(\text{off}|\text{parents};\theta) \\ &= \sum_{\text{phases}} \Pr(\text{phase}_{\text{father}}) \\ &\quad \times \Pr(\text{genotypes}_{\text{off}}|\text{phase}_{\text{father}};\theta), \end{aligned}$$

since the only ambiguity in the parental genotypes is in the paternal phase. In this example, each phase has probability 0.5, so

$$\begin{aligned} L(\theta) &= \tfrac{1}{2}\theta^4(1-\theta)^2 + \tfrac{1}{2}\theta^2(1-\theta)^4 \\ &= \tfrac{1}{2}\theta^2(1-\theta)^2[\theta^2 + (1-\theta)^2]. \end{aligned}$$

Note that the maximum likelihood estimate (MLE) of θ is not trivial to compute by hand, although it can be estimated using numerical maximization techniques; using the ILINK program of the LINKAGE package [13] (*see* **Software for Genetic Epidemiology**), the MLE is found to be 0.5. Even though there are not 50% of meioses in this case showing evidence of recombination, as analyzed in detail by Nordheim et al. [15], there are an enormous number of potential phase-unknown pedigrees that all yield an estimate of $\theta = 0.5$. That is not to say that phase-unknown pedigrees do not provide information about linkage in general. Consider a phase-unknown pedigree with N children all of whom received the identical alleles at both loci – this would either represent N recombinants or N nonrecombinants. The likelihood would then be equal to $L(\theta) = \frac{1}{2}\theta^N + \frac{1}{2}(1-\theta)^N$, which can be shown to be maximized when $\theta = 0$, giving a lod score of

$$\begin{aligned} Z_{\text{PU}}(\theta = 0) &= \log_{10} \frac{\frac{1}{2}(0)^N + \frac{1}{2}(1)^N}{\frac{1}{2}\left(\frac{1}{2}\right)^N + \frac{1}{2}\left(\frac{1}{2}\right)^N} \\ &= \log_{10} \frac{\frac{1}{2}}{\left(\frac{1}{2}\right)^N} = (N-1)\log_{10}(2), \end{aligned}$$

where the subscript PU stands for phase-unknown. If the pedigree were phase-known with six nonrecombinants, then the likelihood would be $L(\theta) = (1 -$

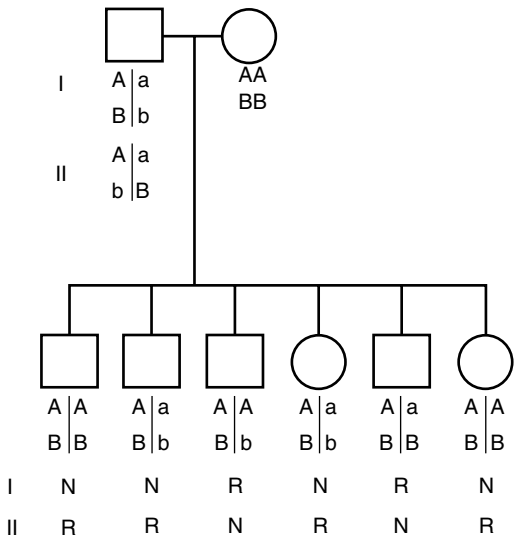

Figure 3 Sample phase-unknown pedigree with two possible phases for the father – indicated as I and II – under each of his offspring is an indication of whether the individual had a recombination or not between these two loci under each possible phase for the father

$\theta)^N$, which is also maximized when $\theta = 0$, but giving a lod score of $Z_{\mathrm{PK}}(\theta = 0) = \log_{10}(1)^N/\left(\frac{1}{2}\right)^N = N\log_{10}(2)$, where the subscript PK indicates phase-known. So, in each pedigree there is a cost of one meiosis when the phase is unknown if there is no recombination – when there is recombination in the pedigree the cost is even higher, as was illustrated by the previous example. It may seem like a small cost initially, but if you consider that the average sibship size is between two and three, the cost can be huge in a large set of pedigrees. The lod score in each phase-unknown pedigree is $Z_{\mathrm{PU}}(\theta = 0) = [(N-1)/N]Z_{\mathrm{PK}}(\theta = 0)$ when all sibs are nonrecombinant. Note that this is an upper bound on the phase-unknown lod score as a function of the phase-known lod score. In general, $Z_{\mathrm{PU}}(\hat{\theta}) \leq [(N-1)/N]Z_{\mathrm{PK}}(\tilde{\theta})$, where θ is estimated separately in the phase-known and phase-unknown cases, and there is linkage. In the US, most sibships are of size two or three, so that the lod scores in each pedigree are at least 1.5–2 times higher for phase-known pedigrees than for phase-unknown pedigrees, when there is linkage between the two loci. Since lod scores can be added across pedigrees at the same recombination fraction values (since all pedigrees are independent, and independent likelihoods can be multiplied), the sum over a large set of pedigrees will also be 1.5–2 times larger or more if there is linkage and the phase can be established unequivocally.

Genotypes Unknown

We are often confronted with the complication that not all individuals' genotypes are known. Remember that, when we know the genotypes of the parents, the pedigree likelihood for a phase-known nuclear pedigree is

$$L(\theta; \text{data}) = \Pr(g_{pa})\Pr(g_{ma}) \prod_{\text{offspring}} \times \Pr(g_{offs}|g_{ma}, g_{pa}; \theta),$$

where g_{ma} is the genotype of the mother, etc.; and in the case of unknown phase it is just

$$L(\text{data}) = \sum_{\text{phase}} \Pr(g_{ma}, \text{Phase}_{ma})\Pr(g_{pa}, \text{Phase}_{pa}) \times \prod_{\text{offspring}} P(g_{offs}|g_{pa}, g_{ma}, \text{Phase}_{pa}, \text{Phase}_{ma}; \theta).$$

If we were interested in the actual probability of the data, then we would have to use the allele frequencies at each marker locus in order to compute $\Pr(g_{pa})$ from the allele frequencies for the two loci. For example, if g_{ma} were AA at one locus and BB at the other, then $\Pr(g_{ma})$ would be Pr(A) Pr(A) Pr(B) Pr(B) if we assume **Hardy–Weinberg equilibrium** and absence of linkage disequilibrium. Note that, in the phase-known situation, the lod score is

$$Z(\theta) = \log_{10} \frac{\Pr(g_{ma})\Pr(g_{pa}) \times \prod_{\text{offspring}} \Pr(g_{offs}|g_{ma}, g_{pa}; \theta)}{\Pr(g_{ma})\Pr(g_{pa}) \times \prod_{\text{offspring}} \Pr\left(g_{offs}|g_{ma}, g_{pa}; \theta = \frac{1}{2}\right)},$$

and we do not need to worry about the exact values of the probability of the parental genotypes, since they can be factored out of this ratio and have no effect on the lod score – this makes sense because the parental genotypes tell us nothing in and of themselves about the recombination fraction. Similarly, in the phase-unknown case, we also know the genotypes of the parents, so we can factor the independent genotype and phase probabilities as $\Pr(g_{ma}, \text{Phase}_{ma}) = \Pr(g_{ma})\Pr(\text{Phase}_{ma})$, assuming absence of linkage disequilibrium, and so

$$\begin{aligned} Z(\theta) = \log_{10} \Bigg(& \Pr(g_{ma})\Pr(g_{pa}) \sum_{\text{phase}_{ma}} \Pr(\text{Phase}_{ma}) \\ & \times \sum_{\text{phase}_{pa}} \Pr(\text{Phase}_{pa}) \prod_{\text{offspring}} \Pr(g_{offs}|g_{ma}, g_{pa}, \\ & \frac{\text{Phase}_{ma}, \text{Phase}_{pa}; \theta)}{\Pr(g_{ma})\Pr(g_{pa})} \\ & \times \sum_{\text{phase}_{ma}} \Pr(\text{Phase}_{ma}) \sum_{\text{phase}_{pa}} \Pr(\text{Phase}_{pa}) \\ & \times \prod_{\text{offspring}} \Pr\left(g_{offs}|g_{ma}, g_{pa}, \text{Phase}_{ma}, \right. \\ & \left. \text{Phase}_{pa}; \theta = \tfrac{1}{2}\right) \Bigg). \end{aligned}$$

Again, the parental genotype probabilities factor out of this equation, but the phase probabilities do not.

In fact, it is possible to consider the phase as an integral part of the parental genotype, and in that

case we see that we are effectively taking the sum over all possible parental genotypes (with phase), and weighting them by their probabilities. This argument can be easily extended to cover situations in which we known nothing about the genotype of the parents. In that case, the likelihood can be written as

$$L(\theta; \text{data}) = \sum_{G_{\text{ma}}} \sum_{G_{\text{pa}}} \Pr(G_{\text{ma}}) \Pr(G_{\text{pa}}) \times \prod_{\text{offspring}} \Pr(\text{g}_{\text{offs}} | G_{\text{ma}}, G_{\text{pa}}; \theta),$$

where G_i is the genotype with the phase of individual i; note that for the offspring we do not know the phase. If we wished to express this formula in terms of each offspring's genotype with phase, then it would be

$$L(\theta; \text{data}) = \sum_{G_{\text{ma}}} \Pr(G_{\text{ma}}) \sum_{G_{\text{pa}}} \Pr(G_{\text{pa}}) \times \prod_{\text{offspring}} \sum_{G_{\text{offs}}} \Pr(G_{\text{offs}} | G_{\text{ma}}, G_{\text{pa}}; \theta).$$

In this way we can also include offspring whose genotype is unknown, or who have some ambiguity in their genotypes. Only the parental genotypes are functions of the allele frequencies, while the genotypes of their children are dependent solely on the parental genotypes and the recombination fraction in each case.

Genotype Unknown – Phenotype Known

It is important to note that thus far we have been dealing only with genotypes, and we have assumed that we can either identify the genotype or else we know nothing. In reality we are usually somewhere in the middle; the most important way linkage analysis is used is to identify genes which affect the expression of some trait, typically by increasing the probability of becoming affected with some disease. In this situation, there are additional parameters needed to perform the linkage analysis – we need to quantify the probability of the phenotype conditional on each of the possible genotypes at the locus in question. For example, if we have a dominant disease with full penetrance, then this means that we have a disease-predisposing locus with, typically, two alleles, D and +, where $\Pr(\text{disease}|\text{DD}) = \Pr(\text{disease}|\text{D}+) = 1$; $\Pr(\text{disease}|++) = 0$. Note that this also uniquely determines the penetrances for the phenotype "unaffected" as well, because $\Pr(\text{disease}|\text{DD}) + \Pr(\text{unaffected}|\text{DD}) = 1$. In this case $\Pr(\text{unaffected}|\text{DD}) = \Pr(\text{unaffected}|\text{D}+) = 0$, and $\Pr(\text{unaffected}|++) = 1$. For a fully penetrant recessive disease, $\Pr(\text{disease}|\text{DD}) = 1$, and $\Pr(\text{disease}|\text{D}+) = \Pr(\text{disease}|++) = 0$. These are the two most classical situations in which the genotypes are not uniquely determined by the phenotypes. These penetrances can be factored into the likelihood in a straightforward manner as

$$L(\theta; \text{data}) = \Pr(\text{Ph}_{\text{ma}}) \Pr(\text{Ph}_{\text{pa}}) \times \prod_{\text{offspring}} \Pr(\text{Ph}_{\text{offs}} | \text{Ph}_{\text{ma}}, \text{Ph}_{\text{pa}}; \theta),$$

where Ph_i is the observed phenotype for individual i at all loci. If we allow for the penetrances as described above, we know that $\Pr(\text{Ph}) = \sum_G \Pr(G) \Pr(\text{Ph}|G)$. For parents, $\Pr(G)$ can be computed from the allele frequencies at each locus, and $\Pr(\text{Ph}|G)$ is the penetrance that must be specified for each locus. The sum is taken over all possible genotypes at all loci. If the individual is an offspring in the pedigree, then $\Pr(G)$ is replaced by $\Pr(G|G_{\text{ma}}, G_{\text{pa}}; \theta)$, and the penetrance remains unchanged, since this is considered to depend only on the individual's genotype. In this way we can take into account any possible relationships between genotype and phenotype. Note that many genotypes will not be possible, as they are incompatible with Mendelian laws – for example, you cannot have parents who are AA and AA having a child who has genotype aa. For this reason, many terms will have zero probability. Complicated computer programs have been written to perform these calculations for any set of penetrances and general pedigree structures. For further details about the technical aspects of likelihood calculations in linkage analysis the reader is referred to [1] and [16]. The important thing here is to see why it is necessary to specify all the parameters, and how they affect the analysis.

Fully Penetrant Recessive Traits

The simplest mode of inheritance to consider for a disease is one with full penetrance and no phenocopies. Let us start by considering a simple recessive trait, which means that $\Pr(\text{affected}|\text{DD}) = 1$ and $\Pr(\text{affected}|\text{D}+ \text{ or } ++) = 0$. Look at the

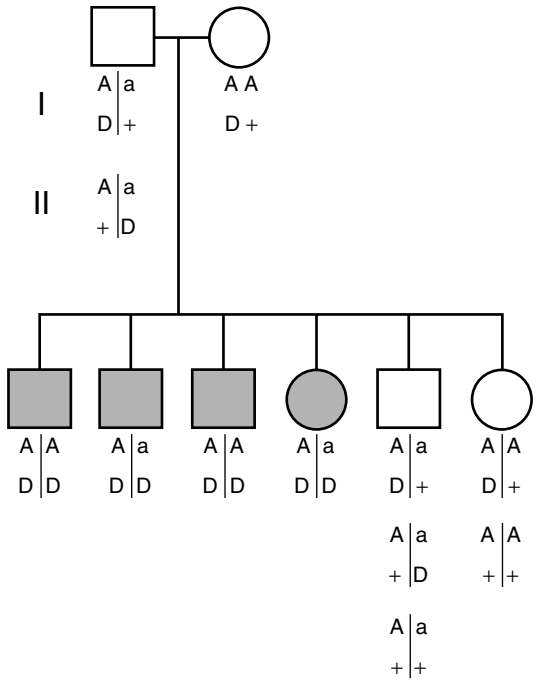

Figure 4 Sample pedigree with a fully penetrant autosomal recessive disease segregating. Solid shapes indicate affected individuals with this trait, and open figures are unaffected

pedigree in Figure 4. In this pedigree, the possible genotypes (with phase) for each individual are indicated – the probabilities of all other genotypes can be shown to be 0. Because the trait is fully penetrant recessive, all affected individuals must have genotype DD, and all unaffected individuals are either D+ or ++. Because the parents have affected children, they must each have at least one D allele, and because they are unaffected, they cannot have two – therefore, they are D|+. The only ambiguous cases are the two unaffected children, who could be either ++ or D+, since both of these are compatible with the parental genotypes and the phenotype unaffected. Because the mother is not heterozygous at both loci, we cannot tell whether recombination occurred between the trait and marker loci (since all children must receive the A allele from her with probability 1, irrespective of what disease allele they received). Because there is no ambiguity in the genotype of the affected individuals, it is clear that they provide most of the information about linkage. The ambiguity of the other sibs' disease locus genotypes adds noise to the analysis. Because disease alleles are typically rare, and recessive diseases are quite often lethal, it is rare for parents to be affected themselves, and thus the majority of pedigrees which one will ascertain (*see* **Ascertainment**) are either nuclear pedigrees, as in Figure 4, or inbred (*see* **Inbreeding**) pedigrees, where the disease alleles in the affected kids are identical by descent from some common ancestor.

In the case of inbred pedigrees, most affected children would be homozygous at a marker locus tightly linked to the recessive trait locus [19] (this is also the fundamental cause of linkage disequilibrium if one thinks of populations as large extended inbred pedigrees). Smith [19] proposed that an efficient strategy for detecting linkage with rare recessive traits in inbred pedigrees would be to look for marker loci at which affected individuals are more frequently homozygous than expected – a technique that has come to be known as homozygosity mapping. It is critical to point out that homozygosity mapping is not a different statistical technique to analyze data – in fact, one normally applies standard model-based linkage analysis to the pedigree in question. It is merely an efficient technique for minimizing the amount of genotyping one needs to detect linkage, by only typing one affected child from a consanguineous marriage segregating a recessive disease in the initial genome screen – later, of course, one should go back and genotype the parents and other family members to make sure that the individual has received the marker alleles identical by descent (IBD) from one common ancestor.

Fully Penetrant Dominant Disease

The second classical model for trait inheritance is fully penetrant dominant, in which $\Pr(\text{affected}|\text{DD or D+}) = 1$ and $\Pr(\text{affected}|{+}{+}) = 0$. The majority of affected individuals in such a disease are going to have genotype D+, because the disease allele is typically very rare, and all affected children have at least one affected parent. As a result of this, pedigrees segregating fully penetrant dominant diseases are typically large and extend over multiple generations, with smaller sibships than in recessive disease pedigrees. This is because, in recessive diseases, when we ascertain pedigrees to have more than one affected child, we are biased toward

large sibships, whereas for dominant diseases there are typically affected individuals in many generations. For this reason, dominant traits are often transmitted in phase-known meioses, whereas most meioses in recessive pedigrees are phase-unknown (typically only the bottom generation has affected individuals).

Complex Disease

A complex disease is one for which either the mode of inheritance is unknown, there are multiple genes involved, diagnosis is uncertain, or environmental factors are the entire cause of the disease, and no genes are involved at all [12]. Typically, the penetrances are not 0 and 1, but somewhere in the middle, even for single gene disorders. It may be that a disease has a late age of onset, which is variable from individual to individual, or it may be that certain environmental factors are necessary in combination with the genes to produce a phenotype, etc. (*see* **Penetrance**).

When such complexities are present, it becomes difficult to do a good model-based linkage analysis, because the linkage analysis is based on specified parameters, as indicated above. When these parameters are incorrectly specified, the recombination fraction is usually overestimated, and the lod scores may be smaller than if the model was correct. That is not to say the power is always highest when analysis is done under the correct model – power to detect linkage often tends to be higher when the genetic effect of a locus on the trait is overestimated, especially if the mode of inheritance is actually very weak – hence the high power of **"model-free" linkage methods**, which are in many cases mathematically equivalent to lod score analyses under models with very strong genetic effects, as shown later in this article. However, when the mode of inheritance is incorrectly specified, it is impossible to get accurate estimates of the location of a disease gene from the recombination fraction estimates, and the test statistic itself is the only means of determining the location of the disease gene. For this and other reasons it is very difficult to fine-map a disease gene for a complex trait in an equivalently sized dataset, and the accuracy will be orders of magnitude less with complex traits. As an extension of this argument, it will also probably be very difficult to find linkage disequilibrium with complex trait predisposing genes, as those genes are often very common, thus leading to extreme allelic and nonallelic heterogeneity in the population-as-pedigree.

Testing for Linkage – Positive and Negative

Originally, the lod score method was proposed as a sequential procedure in which one would continue to add more and more families until the lod score at some predetermined recombination fraction either exceeded 3, in which case linkage was accepted, or fell below -2, in which case linkage was said to be excluded [14]. However, the common practice changed such that people now maximize the lod score over the recombination fraction to prove linkage with greater **power**, while to exclude linkage they simply look at all values of θ for which the lod score remains below -2 (all points to the left of the upward pointing arrow in Figure 5). The example shown in Figure 5 would allow for the conclusion that there is linkage with MLE of a recombination fraction equal to $\hat{\theta}$, as indicated in the figure, and yet linkage is also excluded at small recombination fractions in the same pedigree. Since it is known, for linkage analysis under an incorrect mode of inheritance assumption, that the recombination fraction MLEs are biased in an upward direction [17], such decision rules for "exclusion" mapping are not very useful when the mode of inheritance is not well characterized and correctly modeled.

In modern human genetic linkage studies a large number of markers are tested in a fixed set of pedigrees. In this context, the spirit of lod score analysis has changed dramatically since the days of Morton [14]. We are no longer testing one specific marker, but an entire genome-wide set of markers, typically spaced at intervals from 5–10 cM, in which case there would be about 600 such markers in a full genomic scan. In analyzing this situation, there is a multiple testing problem to be taken into account. If there is a single gene disorder, it has been argued that the gene must be somewhere, and thus as more markers are shown to be unlinked, the prior probability that one of the remaining markers is linked is increased, and this would theoretically compensate for the large number of tests. However, this argument does not hold if we are using linkage analysis to prove there is a gene. For certain complex diseases we have no proof of a genetic component at

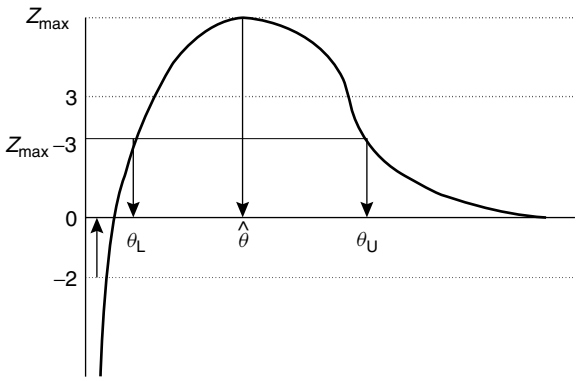

Figure 5 Sample graph of two-point lod scores as a function of the recombination fraction, with: indicators of the maximum lod score, Z_{max}; the maximum likelihood estimate of the recombination fraction, $\hat{\theta}$; the upper and lower limits of its 3-unit support interval, (θ_U and θ_L); and the exclusion region (to the right of the upwardly pointing arrow)

all, despite the best efforts of **segregation analysis**. If there is no gene, the prior probabilities of linkage are not increased after many markers are all found to be unlinked to the trait.

The current theoretical arguments about critical values are based on the null hypothesis distribution of the lod score maximized over all markers in the genome. If there is no linkage, different analyses have predicted the probability of a lod score of 3 arising by chance for some marker to be between 0.005 and 1, depending on the pedigree structure, marker informativeness, and other assumptions (e.g. [9] and [22]). For example, for a fixed critical value, with more informative markers, there is a lower rate of **false** (and true) **positives** over the whole genome. There is thus a small but nontrivial chance of getting at least one false positive in a genome screen with a large number of markers. In practice, one might consider how their best lod scores compare with the lod scores at other markers throughout the genome – obviously the highest lod scores are the most promising, and the lower ones are less so (cf. [22]). There are no hard and fast rules, because molecular technology has progressed to the point where one can feasibly obtain genotypes for as many markers as one wants. Ideally, one should consider the lod scores for all markers in a completed genome scan jointly before interpreting borderline results, in contrast to the old days (i.e. 3–4 years ago) of linkage analysis where typing small numbers of markers was a huge chore. For complex diseases, a lod score of 3 is not so convincing today, unless it is with a **candidate gene**, or it is interpreted in the context of a full genome scan.

Estimation of the Recombination Fraction

When the mode of inheritance is known, it is possible to compute the exact likelihood for the data, and the maximum likelihood estimates of the recombination fraction, while typically biased, are consistent. To demonstrate the **bias** in a very simple example, let us consider a phase-known pedigree with four informative meioses, and let us assume that the recombination fraction is 0.50. Then we compute the expectation of the MLE. The possible outcomes are given in Table 1. Because $E(\hat{\theta}) = \sum_{Data} \hat{\theta} Pr(data)$, where the sum is taken over all possible outcomes, in this case, while $\theta = 0.5, E(\hat{\theta}) = 0.40625$, which shows a considerable downward bias. However, asymptotically, as the number of informative meioses approaches infinity, the **expectation** of the estimate approaches its true value, and therefore the MLE of θ is **consistent**.

That the MLE of the recombination is consistent is valuable to researchers in human genetics, as it gives a means not only to detect linkage through use of the lod score as a test statistic, but also to estimate the distance between the marker locus and the disease-predisposing gene. Normally, because these estimates are not very accurate in small samples, we construct support intervals around the MLE, and say that the true recombination lies somewhere in that interval with reasonable certainty. The k-lod-unit support interval for the MLE of the recombination

Table 1 Sample demonstration of the bias in estimates of the recombination fraction in small samples

Pedigree	Outcome			
Recombinants	Nonrecombinants	Pr(data)	$\hat{\theta}$	Pr(data)*$\hat{\theta}$
0	4	(0.5)	0	0
1	3	4(0.5)	0.25	0.0625
2	2	6(0.5)	0.50	0.1875
3	1	4(0.5)	0.50	0.1250
4	0	(0.5)	0.50	0.03125
Total		1		0.40625

fraction consists of all values of θ for which $Z(\theta) \geq Z(\hat{\theta}) - k$. Historically, researchers used $k = 1$ to construct a support interval which asymptotically was approximately equivalent to a 95% confidence interval. However, an inconsistency arises when the maximum lod score is greater than 1 and less than 3, because in that case a 1-unit support interval would exclude the null hypothesis $\theta = 0.5$, even though the null hypothesis has not been rejected. Two possible solutions to this problem are in common practice. The original recommendation was to think of linkage analysis as a two-step procedure, i.e. first one tests the null hypothesis of no linkage, and if this null hypothesis is rejected, then and only then do you consider the estimates of the recombination fraction and its 1-unit support interval [3]. Another argument suggests that, since testing and estimation are based on the same statistic, it is impossible to separate the two logically, and for this reason, a 3-lod-unit support interval should be constructed (because the test is typically performed with the critical value of $Z > 3$) [21]. Fundamentally, either argument works, and it all depends on what the end-user wants to believe – the latter procedure will allow support intervals to be constructed even without significant test results, while the former does not; however, the latter procedure gives much wider support intervals, and thus does not narrow down the region in which the investigators would have to look for the gene as much as a 1-unit support interval would. The counter argument is that 1 in 20 times (approximately) the gene would be outside the 1-unit support interval, while only 1 in 10 000 times would the gene fall outside the 3-unit support interval. The choice of support criteria is dependent largely on the desires of the investigator and whether one thinks a 5% chance of missing the gene is a gamble worth taking.

The caveat of all this discussion about estimating recombination fractions is that it is dependent on the accuracy of the parametric model for the disease *and* the marker locus. It presumes that the allele frequencies are all accurately estimated and that the penetrances are correct as well. For complex diseases, this is never the case, especially at the trait locus. In many cases, it is impossible to do this correctly when we are restricted to the confines of a single-locus parametric model of disease with no environmental cofactors. There have been attempts made to extend linkage analysis methods to multiple gene traits, and to mixed environmental/genetic models, but they are computationally intensive, and do not tend to increase the power of the test statistic greatly. The only gain from these complications, for most cases studied thus far, is an increase in the accuracy of the recombination fraction estimates. However, in practice, if one is using a single gene model which is known with certainty to be incorrect, one will find that the recombination fraction is always overestimated, and loses all of its meaning; in those situations, the value of the test statistic itself is all we have to use in fine-mapping the trait locus.

Relationships Between "Model-free" and "Model-based" Methods

In linkage analysis, **nonparametric methods** have been employed to "increase robustness" [9] and to make the calculations fast and simple [2]. Initially it was impossible to do likelihood-based analysis on complex pedigrees, as for general pedigrees the likelihoods could not be computed in the absence of recent technological and theoretical innovations, while most sib-pair and relative pair analyses could be performed on the back of an envelope. However, as soon as there were additional affected relatives beyond the initial affected relative pair, the analyses become problematic, as there are higher-order correlations among the marker genotypes of multiple affected individuals within a single pedigree. In special situations the multiple relative pairs may be asymptotically pairwise-independent [2], but it is still an approximation to looking at the entire set of affected individuals jointly, as in likelihood-based pedigree analysis.

Recent theoretical studies have demonstrated that one can often use model-based likelihood methods

to compute statistics with equivalent properties to the pairs-based statistics, in which the entire set of affected individuals in a pedigree are analyzed jointly, e.g. [8]. Below, the simplest cases are examined in detail for sib-pair analysis and extended-pedigree identity-by-descent (IBD) analyses (*see* **Linkage Analysis, Model-free**).

Sib-pair Analysis

It has recently been demonstrated [7, 8] that there is an algebraic equivalence between the sib-pair mean test [2] and parametric linkage analysis under a recessive model. More accurately, it has the same statistical properties as a likelihood-based linkage analysis between the marker locus of interest and a "pseudo-marker", which has genotype 1–2 in the mother, 3–4 in the father, and 2–3 in each affected child. If one sets $\theta = 1/2$ between these two loci, then from each parent the children share one allele at the marker locus IBD with probability $p = \theta^2 + (1-\theta)^2 = 0.5$, which is the null hypothesis of the sib-pair mean test statistic. When θ is allowed to take on all values between 0 and 0.5, there is a 1:1 mapping of the interval $[\theta : 0, 0.5] \rightarrow [p : 0.5, 1]$, and the lod score between the marker locus and this "pseudo-marker" is a simple transformation of the sib-pair mean test statistic, $R = (x-y)^2/(x+y)$, where $Z_{\max} = R/2\ln(10)$, x is the number of alleles shared IBD over all sib-pairs, and y is the number of alleles not shared IBD across all sib-pairs). In light of this equivalence when one is analyzing only sibling pairs, the analogy can be extended to multiplex sibships [10, 18] by computing the lod scores between a marker locus and such a "pseudo-marker" where all affected siblings in a sibship have genotype 2/3. The statistic $R = 2\ln[L(\hat{\theta})/L(\theta = 0.5)]$ has a well-defined distribution which converges rapidly, in as few as 20 sibpairs, to a 50–50 mixture of $\chi^2_{(1)}$ and a point mass at $R = 0$. The traditional mean test, no matter what weighting function is assumed for multiplex sibships [2], has a skewed distribution when larger sibships are analyzed. Analysis of the power of this likelihood-based extension has been shown to be consistently robust and powerful over a wide variety of modes of inheritance [4].

Other Affected Relative Pairs

In other "model-free" methods based on extended pedigrees, it is customary to select a set of pairs of relatives and see if they share more alleles IBD than would be expected if there were no linkage. Traditionally, this has been most frequently done by breaking multiplex pedigrees into all possible pairs of affected relatives, and pretending they are independent of each other, when really there is a complicated set of interdependencies which only go away asymptotically (i.e. in unrealistically large datasets). Ultimately, one is interested in testing whether or not a given marker locus segregates independently of the trait in the entire pedigree. Following the aforementioned logic, in pedigrees without consanguinities, any pair of individuals who are not sibs can share at most one allele IBD. If we have a simple pedigree with only two affected individuals, an artificial "pseudo-marker" locus can be created in which they share the one marker allele IBD that is the most they could possibly share, i.e. they each are assigned a pseudo-marker genotype 1/2, where all founder individuals who are not ancestors of all affected individuals are given genotype 1/1. Performing a likelihood-based analysis of this locus (setting the allele frequency of the 2 allele to be very small) against a marker would represent a test equivalent to an IBD test on this relative pair because the recombination fraction again is a 1:1 transformation of the probability that the two relatives share an allele IBD. The model of the trait "pseudo-marker" genotypes is essentially a rare dominant mode of inheritance in the likelihood calculations. In this way it is possible to develop statistics with properties analogous to various nonparametric IBD methods within the unified context of likelihood-based lod score analysis, giving us a common currency and a feel for the underlying symmetries between conceptually different methods of linkage analysis.

Linkage Disequilibrium

Ultimately, linkage disequilibrium analysis is very similar to the extended pedigree analysis described above. In linkage disequilibrium analyses, the population under study is thought of as one giant pedigree, in which the disease predisposing allele is assumed to have entered a population once, or very few times (*see* **Linkage Disequilibrium**). Then, many generations later, at tightly linked marker loci, the allele which was on the founder chromosome would still be present with a higher frequency among affected individuals. In essence, the null hypothesis is that

the marker locus genotypes are independent of the disease, i.e. the disease and marker alleles have segregated independently in this population. Under the alternative hypothesis, however, the assumption is that the affected individuals would share more alleles IBD from this common ancestor than any two randomly selected individuals from the population. Again, an analogy can be made to likelihood-based linkage analysis in the population, following the paradigm from the previous section, assuming each individual had received 2 alleles IBD (i.e. we typically have to look at genotypes in **case–control** disequilibrium studies). However, in a population, we assume that the individuals under study are so distantly related that we can approximate the linkage analysis by simply comparing the genotype frequencies in affecteds and unaffecteds. If there are known to be closer relationships between certain sets of individuals in the population, it would behoove the analyst to take these correlations into account where relationships can be identified, to avoid erroneous assumptions that all genotypes within case and control samples are really iid.

Algebraic Equivalence ≠ Identical Assumptions

It is, of course, erroneous to say that IBD analysis in sib-pairs "assumes" the mode of inheritance to be recessive – rather, it is more appropriate to say that the sib-pair mean test statistic is algebraically equivalent to lod score analysis under a recessive model (with additional assumptions). The subtle difference between these two statements is critical to appreciate, for the null hypothesis properties of likelihood-based lod score analyses do not depend in any way on the true mode of inheritance, and are valid irrespective of the true state of nature. This same statement holds for nonparametric tests as well: under the null hypothesis, the marker is assumed to segregate randomly and independently of the trait, and thus the true mode of inheritance is irrelevant to the validity of any of these tests.

Conclusion

Likelihood-based parametric linkage analysis is the **gold standard** for detecting disease genes through reverse genetics in pedigree data. There are a number of other procedures (*see* **Linkage Analysis, Model-free**) which provide simple and rapid approximations to this type of analysis, but ultimately it remains the standard which the nonparametric methods attempt to emulate. Bearing in mind the **Neyman–Pearson lemma**, which states that if there is a best test of a given hypothesis it will be in the form of a likelihood ratio, and also the manner in which full likelihood analysis can use all of the data and not just a small subset thereof, it remains the method of choice. It has been very successful in mapping hundreds of disease-predisposing genes, and while there are no easy answers to the questions of the future – involving common complex diseases – it seems likely that it will be the best unified framework at our disposal to build upon in answering these more complicated but very important problems.

Linkage Analysis, Multipoint

Multipoint linkage analysis is the analysis of linkage data involving three or more linked loci (*see* **Linkage Analysis, Model-based**). Such analyses are carried out to order or map a set of loci, to position a new locus in relation to a mapped set of loci, or perhaps to exclude a locus from a region containing two or more loci.

Until the mid-1980s, most linkage mapping was two-point; that is, it involved the estimation or testing of a single recombination fraction. Although inefficient from the statistical viewpoint, three or more loci can be mapped using only two-point data, since linear maps are determined by pairwise distances. When there are plenty of data, such as with *Drosophila*, multipoint analyses may be unnecessary. However, in most contexts, data are scarce. In such cases, multipoint linkage analysis can be viewed as an attempt to make more efficient use of recombination data to further the aims of **linkage analysis** [15, 17, 28]. By making fuller use of available data, greater precision or **power** is achievable; at times the differences can be large.

Multipoint linkage analyses are more complex than two-point analyses in several important ways. First, they require the specification of an order for the loci: if we have n linked loci, there are $\frac{1}{2}n!$ potentially distinguishable orders. Secondly, they require the specification of a joint distribution for all possible recombination patterns: for n loci, there are 2^{n-1} such patterns (including the parental one). Thirdly, from the perspective of parametric statistical inference, joint distributions over recombination patterns corresponding to distinct orderings of the loci define noncomparable statistical models. Most of the difficulties of multipoint linkage analysis stem from these facts, particularly the rate of increase of the number of orders or patterns with the number of loci. When linkage analysis is being done using pedigree data, the size (number of individuals) and complexity (presence of one or more loops) of the pedigrees are additional limiting factors.

As with two-point linkage analyses, a major complication in multipoint linkage analyses can be the incompleteness of data. For example, there may be missing data due to some individuals not being typed. All data may be available, but phenotype may not determine genotype, as with dominant traits and other types of incomplete penetrance. **Genotypes** may be known, but haplotypes may not. That is, phase – which allelic combinations across loci are together on the same chromosome – may be unknown (*see* **Haplotype Analysis**). With known genotypes at n loci, there are 2^{n-1} possible haplotypes. While these incompleteness problems can slow down two-point analyses, they can quickly make exact multipoint analyses impossible. However, multipoint analyses can make use of data that cannot be used in two-point analyses; for example, when only uninformative data are available at a locus intermediate between two fully informative loci [18, 24]. In multipoint linkage analysis using pedigree data, the feasibility of an exact analysis will depend on the number of loci, the size and complexity of the pedigrees involved, and the nature and extent of incompleteness in the data.

To explore the topics in a little more detail, it is necessary to introduce some notation. Suppose that we are discussing data from n loci, written $A-B-\cdots-C$ in an arbitrary, but fixed, order. Then the joint recombination probabilities may be denoted by $\mathbf{p} = (p_{i_1 i_2 i_3, \ldots, i_{n-1}})$, where the subscript $i_k = 1$ corresponds to recombination across the kth interval, and $i_k = 0$ corresponds to no recombination across the same interval. For example, if $n = 3$, and the loci are ordered $A-B-C$, then we have four probabilities $\mathbf{p} = (p_{00}, p_{01}, p_{10}, p_{11})$, corresponding to the four patterns of recombination or not across $A-B$ and $B-C$. The order with respect to which these probabilities are defined does not need to be the true one, and if we change it, the probabilities need only be relabeled. For example, if we go from the order O: $A-B-C$ with probabilities $\mathbf{p}$, to O': $A-C-B$ with probabilities $\mathbf{p'}$, then $\mathbf{p'}$ is related to $\mathbf{p}$ as follows:

$$p'_{00} = p_{00}, \qquad p'_{10} = p_{10},$$
$$p'_{01} = p_{11}, \qquad p'_{11} = p_{01}.$$

Our first remark is that three-point phase known crosses have been used for decades to order loci in experimental organisms without any explicit model assumptions. This works because, under very general conditions, the smallest of the four probabilities $(p_{i_1 i_2})$ corresponds to the event of double recombination across two consecutive intervals when the loci are correctly ordered. For example, if the correct order is O: $A-B-C$, then (assuming no chromatid

interference (*see* **Genetic Map Functions**):

$$p_{11} \leq p_{10}, \qquad p_{01} \leq p_{00}.$$

If, however, O': $A-C-B$ is the correct order, but we have written our probabilities relative to O, then $p'_{11} = p_{01}$ will be the smallest probability. It follows that with sufficiently large samples of data, any set of loci can be ordered by inspection, with only a small chance of error. Naturally, this is also possible using only the pairwise recombination fractions, but that would take more data to achieve the same level of confidence in the ordering. More generally, it is possible to show that under the assumption of no chromatid interference, a multipoint recombination probability decreases, or at least does not increase, when any nonrecombinant interval is changed to recombinant status [26]. Lathrop et al. [16] discuss three-point mapping from the point of view of hypothesis testing.

Historically, the first formal linkage analysis involving more than two loci was given by Fisher [4]. There, he showed how to combine data from a number of two-point analyses in order to get **efficient** estimates of a set of recombination fractions. Although the data were all two-point, Fisher needed to express the recombination fraction across the union $A-C$ of two adjacent intervals $A-B$ and $B-C$ in terms of their individual recombination fractions. He did so by making the assumption of *complete interference*; that is, by assuming that, at most, one recombination could occur across any pair of adjacent intervals. This is equivalent to the following joint distribution:

$$p_{00} = 1 - r_1 - r_2, \quad p_{01} = r_2,$$
$$p_{10} = r_1, \qquad\qquad p_{11} = 0,$$

where r_1 and r_2 are the recombination fractions across $A-B$ and $B-C$, respectively. This model would not be appropriate for the analysis of three-point data in which double recombinants are observed, but it has been used in modern times with very short intervals, see, for example [24], section 6.7. The first satisfactory class of recombination models were the χ^2 **renewal process** models discussed by Fisher and his students and colleagues [5]; Bailey [1] gives a good overview of this research. The simplest of these joint probabilities is too complex to be given here, and this is probably the reason that this class of models has not been used with human data until recently [20]. In human linkage analysis one finds almost exclusive use made of the extremely tractable **Poisson** or *no interference* model, whose joint probabilities for three loci take the form:

$$p_{i_1 i_2} = r_1^{i_1}(1-r_1)^{1-i_1} r_2^{i_2}(1-r_2)^{1-i_2},$$

where, for $i = 1, 2$, the recombination fractions r_i may be expressed in terms of map distances d_i by

$$r_i = \tfrac{1}{2}(1 - \exp(-2d_i)).$$

It seems that although this model and its extension to more than three loci fail to fit most data sets of any size, the recombination fractions and locus orderings obtained are generally satisfactory [26]. However, the map distances estimated under this model may be seriously in error, and so use is typically made of a suitable map function at the end of the analysis. We refer to **Genetic Map Functions** for more on this point, and for further details concerning probability models for recombination, within which multipoint recombination probabilities must be calculated. The major alternatives to the χ^2 renewal models introduced by Fisher et al. are due to Karlin & Liberman [10] and Risch & Lange [25] (independently), called count-location or generalized no interference models, and the model of Goldgar & Fain [6].

Ordering More Than Three Loci

Many strategies exist for ordering a set of loci on the basis of multipoint recombination data concerning those loci. Some of these are mentioned in [24], and for others we refer to [29]. There is no evidence to suggest that a method exists that is generally better than choosing that order that maximizes the **likelihood** of the data using a suitable recombination model, at least not when the calculation of the likelihoods corresponding to each of the $\frac{1}{2}n!$ distinct orders is possible. The Poisson or no interference model is the one typically used in this context. Although there does not appear to be a systematic study of this issue, the available evidence suggests that only small gains in the efficiency of ordering loci are to be found by using a more suitable model when interference exists (see [2], [6], [7], [18], and [26] for related results).

It is not possible to examine all of the different orders when the number of loci grows beyond 15–20.

At that point it becomes necessary to adopt some deterministic or stochastic search strategy, which concludes with an order that may be suboptimal. In this respect, the locus ordering problem resembles the traveling salesman problem widely discussed in the field of combinatorial optimization [9]. However, the programs that are currently widely used to order loci on the basis of human or other pedigree data make little or no use of recent research from that field.

Location Scores

The idea behind the use of location scores [17] is that we wish to compare two simple hypotheses concerning the location of an unmapped locus. One states that it is at a specific position, B, in the interior of the chromosomal interval subtended by two known loci A and C; the other asserts that it is elsewhere, unlinked to either A or C. This comparison will be carried out using the log-likelihood ratio based on data concerning the known loci A and C, and the unmapped locus. For the present illustration we will suppose that we have complete information, including phase, concerning the three loci, and the question of interest is whether these data provide more support for the hypothesis that the locus is at a specific position, B, in the interval $A-C$, than the alternative that it is elsewhere, unlinked to both. In practice, there may be further loci to the left of A and to the right of C, as well as incomplete data, but we will ignore these possibilities here.

The probabilities ($p_{i_1 i_2}$) under the first hypothesis must be specified using a suitable model, and we suppose that after this is done, the likelihood for the data is $L(ABC)$. However, if the locus is unlinked to both A and C, then we will have

$$p_{00} = p_{11} = \tfrac{1}{2}(1-r), \qquad p_{01} = p_{10} = \tfrac{1}{2}r,$$

where r is the recombination fraction between A and C, assumed known. This assignment will lead to a likelihood for the data that we denote $L(AC)$. A **likelihood ratio test** of the null hypothesis that the locus is unlinked to either A or C, against the alternative that it is at B, will then be based on the quantity

$$L = \log\left[\frac{L(ABC)}{L(AC)}\right],$$

and the null hypothesis will be rejected if L is sufficiently large. If we regard B as a variable point in the interval $A-C$, this quantity can be viewed as a function $L = L(B)$ of the position B along the interval, and this is called a *location score*. A significant peak in the function at some point may then be interpreted as suggesting that the unmapped locus is at that point. Of course, the threshold determining significance must be decided upon taking into account the model and the length of the interval.

In practice, this calculation may be repeated in each of a series of adjacent intervals, and the global maximum, or all maxima *above* some threshold, noted. As long as there are recombinations in a given data set in every such interval, the resulting plot will go to $-\infty$ as the endpoints of each interval are approached, and be roughly parabolic in between, although the shape can be somewhat different with certain patterns of incomplete data. Further details and graphs can be found in [27].

An alternative use of these location scores leads to what is known as *exclusion mapping*. The idea here is that if the location score stays *below* a suitable threshold throughout an interval, then this may be interpreted as suggesting that the unmapped locus lies nowhere in the interval. As with the direct use of location scores, care needs to be taken with thresholds. Practices differ, and we refer to [24] for more details on this matter.

Algorithms and Programs for Multipoint Linkage Mapping

I will refer mainly to human linkage analysis using qualitative data on one or more pedigrees. Multipoint linkage analysis with quantitative traits is a specialized subarea that I cannot discuss here, although some of the references given below cover that topic as well. Programs for carrying out multipoint linkage analysis for crosses of experimental organisms are much more straightforward to write, but no such general purpose programs seem to have gained widespread use. However, particular programs do circulate among communities of scientists studying the same or similar organisms.

Overviews of available computer programs for multipoint linkage mapping in humans can be found in Ott [24] and Terwilliger & Ott [27]. These also contain excellent bibliographies.

Algorithms for carrying out multipoint linkage analysis with human (and other) pedigree data are of two kinds: those based upon the **Elston–Stewart** [3] approach, using what is known as peeling, and those based upon the Lander & Green [14] hidden Markov model formulation. Each of these classes of algorithms has its strengths and weaknesses, and there are problems that cannot be solved exactly with either of them. The Elston–Stewart approach underlies most of the algorithms discussed in [24] and [27], and we refer to these for further details. For a recent improvement of the implementation of these algorithms, see [23]. One new package that has become available since the publication of [24] and [27] uses the basic Lander & Green algorithm in a number of different human linkage problems [13]. These include analyses with sib-pairs [11], the analysis of recessive traits with nuclear families [12], and multipoint linkage with many markers for general pedigrees of moderate size [13]. Another recent program assists with map construction [22].

When exact linkage analysis methods fail because of time or space constraints, **Monte Carlo methods** may be used. At present, these are more research tools than approaches suitable for routine use, but they are developing rapidly, and should become more widely used in the near future. Lin [19] is a recent review, discussing both the sequential imputation approach of Irwin et al. [8] and **Markov chain Monte Carlo** methods [21].

TERRY P. SPEED

Linkage Analysis, Multivariate

For correlated traits, such as those predicting cardiovascular disease risk, multivariate approaches for genetic **linkage** can increase the **power** and precision of estimators for genetic effects [13, 29]. For traits influenced by several genetic factors, the specific genetic loci may induce distinct correlation structures among the measures, so that one can separate the effects of each genetic locus by **multivariate analysis**, even though this might not be possible with simple univariate analyses. Finally, multivariate analysis provides a statistically efficient mechanism for controlling the analysis-wise significance level, when there are multiple trait observations for each subject (*see* **Multiple Comparisons**). In multivariate analysis of quantitative traits, it is not always apparent whether a variable should be treated as a **covariate** or as an outcome. For example, in analysis of blood pressure, body-mass index (BMI), which is a measure of obesity, is often treated as a covariate. However, if a genetic factor influences both BMI and blood pressure, then adjusting blood pressure for BMI would reduce the effects from the major-genetic locus. Therefore, using methods that can analyze several traits jointly is essential. Genetic model-free methods [5, 10, 25, 30] are more easily applied than full **likelihood** methods, which require modeling the **prevalences** of genetic factors along with the parameters to describe the **genotype** specific phenotype distributions.

De Andrade et al. [18] and Almasy et al. [4] developed and applied models for performing multivariate linkage analysis using **variance components** (VC) procedures. Eaves et al. [20] developed **structural equations models** for partitioning multivariate sources of variation among major-genetic, polygenic, and nongenetic sources of variation. Vogler et al. [35] used VC analysis to jointly perform a multivariate analysis of five traits that were simulated as a part of the Genetic Analysis Workshop. Multivariate VC analysis was primarily used as a descriptive tool, without detailed discussion of issues related to **hypothesis testing** or **estimation**. Todorov et al. [34] recently constructed a very general framework extending VC analysis as a general aspect of structural equations modeling. The framework that they provided can incorporate arbitrarily large families, but the optimization procedures are simplified for data from sibpairs. Iturria and Blangero [26] proposed an **EM algorithm** for obtaining **maximum likelihood** estimates in a multivariate VC linkage model parallel to the commonly used scoring algorithm. Programs to perform multivariate VC analysis are currently available as components of the **software** packages ACT [17], SEGPATH [28], SOLAR [3], and EMVC [26].

The Multivariate Model

The multivariate variance components (MVC) approach is an extension of the univariate approach described by

$$\mathbf{Y}_j|\mathbf{X}_j = \boldsymbol{\mu} + \mathbf{X}_j\boldsymbol{\beta} + \mathbf{a}_j + \mathbf{g}_j + \mathbf{e}_j, \qquad (1)$$

where $\mathbf{Y}_j$ is a vector of dimension N_j of trait values for the family j, $\boldsymbol{\mu}$ is the overall mean vector of dimension N_j for family j, $\mathbf{X}_j$ is an $N_j \times p$ matrix of covariates, $\boldsymbol{\beta}$ is a p-vector of **regression** coefficients, $\mathbf{g}_j$ is a N_j-vector of genetic effects by which the major locus affects the trait values for family j, $\mathbf{a}_j$ is a $1 \times N_j$ vector expressing how the additive polygenic factor affects the trait values for family j, and $\mathbf{e}_j$ is residual variation (or environmental effects) from the model; for more details, see [5, 15]. The MVC approach is also a model-free approach, and it has advantages over model-dependent approaches. To simply describe these models, we use the vec transformation [4, 6, 18] to string out the observations as a single vector and then allow elements of this vector to be correlated, according to the model proposed by equation (1). Let $\mathbf{Y}_j = (Y_{11}, \ldots, Y_{1N_j}, \ldots, Y_{mN_j})'$ be a vector of m multivariate trait values for N_j members of the jth family. Let N be the total number of families, $\boldsymbol{\beta}$ a vector of dimension mp of the regression coefficients for the p covariates (including a vector of 1's corresponding to the overall mean), $\mathbf{X}_j = \mathbf{I}_m \otimes \mathbf{X}_{N_j,p}$ an $mN_j \times mp$ known matrix of covariate values for the jth family, where $\otimes$ is the Kronecker product. Then, the variance–covariance matrix of the m traits, $\mathbf{V}_j$, with dimension $mN_j \times mN_j$ is

$$\mathbf{V}_j = \mathbf{A} \otimes \mathbf{R}_j + \mathbf{B} \otimes \boldsymbol{\pi}_j + \mathbf{C} \otimes \mathbf{I}_j, \qquad (2)$$

where, $\mathbf{R}_j$ is the $N_j \times N_j$ matrix of the coefficients of relationship for the jth family; $\boldsymbol{\pi}_j$ an $N_j \times N_j$

matrix of estimated proportion of alleles identical by descent (IBD) for pairs of related individuals for the jth family; $\mathbf{I}_j$ is the $N_j \times N_j$ identity matrix; and **A**, **B**, and **C** are, respectively, polygenic, major-gene, and residual variance–covariance matrices each of dimension $m \times m$. A fourth term to measure dominance components can be added. Because the dominance component of variance (*see* **Population Genetics**) is usually much smaller than the additive component, it is ignored here, but can be modeled by including increased covariance among pairs sharing two alleles IBD. Similarly, additional terms to model-shared environment can be added. When longitudinal data are considered, the error variance structure can be modified to take account of **serial correlation** among the observations [16]. A special approach can be taken for discrete/quantitative traits. In this approach, a decomposition is effected in which the quantitative trait is first conditioned on the discrete trait [38].

Hypothesis Tests for Multivariate Analysis

The Multivariate Haseman–Elston (MH–E) Test

Amos et al. [7] developed a multivariate analog of the Haseman–Elston test [24]. To test for linkage, the procedure evaluates the regression expression

$$E\left[\sum_{k=1}^{m}\left(c_k\left(Y_{ik}-Y_{lk}\right)\right)^2 \mid \pi_{il}\right] = \alpha + \beta\pi_{il} \qquad (3)$$

subject to the constraints $\left(\sum_{k=1}^{m} c_k^4 + \sum_{l<k<3}^{m} 4\, c_l^2\, c_k^2\right) = 1$, to ensure that the variance of this linear function remains constant during the optimization. MAXFUN [33] was used to optimize the coefficients, c. The union–intersection approach can be used to develop a hypothesis test for **multivariate regression**, and results in the evaluation of a ratio of quadratic forms. This ratio would be expected to follow an **F-distribution** with m and $\eta - m - 1$ degrees of freedom for a test that includes a single regression coefficient (and hence effects from a single linked major gene) and η independent sibpairs except that the constraint on c that one imposes has a slightly different form from typical multivariate regression. Allison et al. [2] used the direct search option of MAXFUN to evaluate a grid of values, subject to the constraint that $\sum_{i=1}^{m} c_i^2 = 1$ to find the values c that maximize equation (3). However, they did not provide a limiting distribution for their test statistic and therefore one must depend upon empirical critical values to assess significance. Amos et al. [6] found that the critical values were similar to those provided by the F-distribution, suggesting that an F-distribution can be used to obtain significance levels. However, for smaller samples, the distribution of the test statistic was slightly wider than predicted by an F-distribution. Elston et al. [21] developed a regression approach in which the centered cross product of sibpairs are regressed upon IBD and showed that this method can be more powerful than the older H–E test. They also showed that a simple multivariate test could be constructed by first obtaining the **principal components** (PC) and then combining the ***P* values** from testing each of the separate analysis for each PC. Gorlova et al. [22] studied the statistical properties of these PC analysis and found the PC analysis to have slightly higher power than the MH–E test.

The Multivariate Variance Components Test

To test for genetic linkage, we construct a **likelihood ratio test**. Under the **null hypothesis**, the major-gene parameter(s) **B** of equation (2) are constrained to **0**. For simplicity, let us consider bivariate traits. For bivariate linkage analysis of an additive genetic effect, the parameters are σ^2_{a1}, σ^2_{a2}, and $\sigma_{a1,a2}$ where the first two components measure the major-genetic variance of the traits and the third component measures the major-gene covariance for the traits. We also usually constrain the major-gene variances to be positive so that they fall in the admissible part of the parameter space. As a result, the distribution of the bivariate test that the major-gene components and covariance are zero, is a mixture of 1/4 χ^2_0, 1/2 χ^2_1, and 1/4 χ^2_3 as suggested by Self and Liang [31]. This follows because for one-quarter of the parameter space, both genetic variance parameters are estimated to be positive and hence lead to a **chi-squared test** having three degrees of freedom; for one-half of the parameter space, one of the genetic variances is constrained to be 0 and hence the major-gene covariance is 0 so that the **chi-squared distribution** has one degree of freedom, while for the remaining one-quarter of the parameter space, both genetic variances are constrained to be zero, resulting in a degenerate distribution of a point mass at 0.

Because the same major-gene alleles are assumed to be determining the two traits, it is logical to consider imposing the constraint $\sigma_{a1,a2} = \pm\sigma_{a1}\sigma_{a2}$, which is always satisfied whenever there is a single genetic factor in a region and the dominance components of variance affecting each trait is 0. As discussed by Almasy et al. [4], the observed correlation attributable to a locus may not be one if there are multiple loci affecting both traits in a region. Therefore, they proposed testing the hypotheses of pleiotropy, which presumes that the trait(s) are influenced by the same gene versus coincident linkage, which presumes that there are two or more linked loci that separately influence the traits. If the covariance is constrained to be the product of the square root of the variances, then the hypothesis test of linkage for either of the traits becomes a mixture of 1/4 χ_0^2, 1/2 χ_1^2, and 1/4 χ_2^2. In this case, the covariance is no longer a parameter to be estimated. Amos et al. [6] compared the efficacy of fitting data either with or without this constraint on the covariance. They found rather similar power for either the unconstrained or constrained tests when the empirically derived critical values were used.

Power of Tests

Theoretical studies have evaluated the power of multivariate procedures for genetic studies of crosses between inbred animal lines and the general conclusions are relevant to studies of outbred animals and humans. Jiang and Zeng [27] provided analytical forms describing the distribution of bivariate likelihood ratio and regression-based tests. These forms can be used for comparing the asymptotic performance of tests for linkage using bivariate or univariate data. To allow for the possibility that observations may not be **normal** and tests may not converge rapidly to limiting distributional forms, Churchill and Doerge [14] advocated a permutation based approach for hypothesis testing. Under this approach data are resampled, allowing the investigator to compare test statistics constructed from data to the empirical null distribution of a regression-based test statistic, generated using the same set of data. Deterministic studies indicated that when there is a genetic correlation between traits being studied, multivariate approaches are more powerful than univariate approaches [29]. However, the relative gain in power was highly dependent upon the strength of the correlation as well as its direction relative to residual familial (or polygenic) components, as was also noted for animal models [27]. The greatest gain in power occurs when the polygene and major-gene correlations between traits have opposite signs. VC are usually implemented under an assumption of **multivariate normality**, as this ensures computational simplicity in obtaining estimates. However, recent studies [1, 36] have shown lack of convergence of the test for linkage to a limiting chi-squared distribution when the data are not normally distributed and there is a strong residual correlation among sibs, after allowing for the major-gene effect. Methods to allow the construction of accurate tests for nonnormal data include data **trimming** [37], application of **generalized estimating equations** or robust variance estimation [9], construction of hypothesis tests that allow for **kurtosis** in the data [11] or the construction of permutation tests (*see* **Randomization Tests**) [23]. Application of each of these approaches for multivariate data could be rather complex, and tests using either permutation tests or generalized estimating equations are computationally intensive. Sham et al. [32], following some earlier work by Dudoit and Speed [19], have proposed regressing the IBD sharing of relatives onto the trait values. This approach has the advantage of being relatively insensitive to distributional assumptions while maintaining power, compared with variance-components procedures here discussed. This approach requires some further development for application to multivariate traits.

Comparison of multivariate tests have been presented recently in the literature by Allison et al. [2] and Amos et al.[6]. Allison et al. presented results from a large **simulation** study to assess the effectiveness of a bivariate H–E test for linkage versus the univariate H–E test. Their results showed that bivariate analyses can improve the power to detect linkage, with a greater gain in power when the genetic covariance due to a major locus linked to the marker studied is negative and the residual covariance among the traits is positive. They applied slightly different test statistic that was earlier proposed by Amos et al. [7], although the general form is similar. Their alternative test did not follow any well-characterized distributional form. Therefore, they used a **Monte Carlo method** to develop hypothesis tests. Amos et al. [6] performed extensive simulation studies to

compare the power of VC and the multivariate H–E tests proposed by Amos et al. [7]. They also validated the use of software for use in multivariate analysis of quantitative traits, and provided empirical power results for the study of bivariate traits. Amos et al. [6] showed that bivariate VC procedures provided more power than the bivariate Haseman–Elston test at a higher computational cost. Although the MH–E test had lower power than bivariate VC procedures, this procedure still holds promise as a tool for rapidly studying combinations of three or more traits. Because by using simple correlation methods the investigator cannot easily decide which traits to study in multivariate linkage analysis, two approaches can be taken. First, biologically relevant attributes of the traits may allow the investigator to choose combinations of traits for study. Second, the MH–E procedure or newer modifications of it [21, 22] could be used to screen for combinations of variables to be studied. The PC approach suggested by Elston et al. [21] and further studied by Gorlova et al. [22] provides a rapid and efficient method for screening traits using either regression or ML variance components methods. However, full multivariate variance components linkage analysis is suggested where linkages are noted since it provides more meaningful and interpretable results. For sufficiently large sample sizes, the formulation of the MH–E test appeared to be approximately distributed as an F-distribution [6]. Thus, results from analysis using this method should be easily interpretable. A step-up or step-down procedure can be used to decide among traits to be included in analysis [8]. When a set of traits has been identified for further analysis by using the MH–E procedure, VC analysis can be implemented. Ultimately, as combinations of traits are studied, multivariate applications of fully parametric linkage models might be implemented to characterize the specific effects of each allele at a locus.

Model-dependent approaches for genetic linkage fit parameters to model the prevalence of each allele influencing a trait along with a model to describe the distribution of trait values, conditional upon the genotypes and covariates. Because a large number of parameters must be fitted, model-dependent multivariate methods have not been widely used in linkage analysis [12]. As a result, no model-dependent genetic linkage studies of more than two genetically influenced risk factors have been published.

Linkage Disequilibrium

Linkage disequilibrium, more appropriately termed allelic association or allelic disequilibrium, refers to the nonrandom association between the alleles at two or more genetic loci in a natural breeding population (*see* **Gene**). The concept of linkage disequilibrium was postulated by population geneticists in theoretical studies of the consequences of random mating on the distribution of alleles and allelic combinations (**genotypes**) at multiple loci. Further theoretical studies have shown that in most instances this nonrandom association declines rapidly with evolutionary time, and as a function of the recombination frequency between the loci. However, with natural selection, allelic associations may persist in a population for long evolutionary time periods. With the availability of high-resolution genetic maps in the human and many other species, empirical studies of linkage disequilibrium in different genomic segments have been initiated. These studies have not only shed light on the distribution of alleles and allelic combinations in the genome, but also on the **population genetic** mechanisms that are likely to lead to the observed distribution of linkage disequilibrium across loci. In particular, these studies suggest that in certain circumstances, linkage disequilibrium can be used to infer the location of a disease-causing gene by studying **disease–marker associations**.

Hardy–Weinberg Law

The rediscovery of Mendelism (*see* **Mendel's Laws**) coincided with the identification of hundreds of phenotypes, in diverse species, whose inheritance could be explained by a dominant or recessive allele. In crosses, the familiar $3:1$ segregation ratio (*see* **Segregation Analysis, Classical**) was consistently observed for these phenotypes, leading to the suggestion that the population frequency of dominant to recessive genotypes should also be in the 3:1 ratio. This suggestion was, however, easily refuted by observations in natural populations. This dilemma was resolved by Hardy and Weinberg who showed by theoretical analysis that the frequency of genotypes in populations, under the simplifying assumptions of random mating in a population of infinite size and the absence of mutation, migration and selection, was solely determined by the frequencies of the constituent alleles [7] (*see* **Hardy–Weinberg Equilibrium**). Thus, if the allele frequencies of the dominant, D, and recessive, d, alleles at an autosomal locus were p and q, respectively, then the frequencies of the genotypes DD, Dd, and dd are $p^2, 2pq$, and q^2, respectively. The same results apply to females at an X-linked locus, with males having alleles in proportion to their population frequencies. In the presence of dominance, the dominant and recessive phenotypes have population frequencies of $p^2 + 2pq = 1 - q^2$ and q^2, respectively. Under these assumptions, Hardy and Weinberg also showed that, irrespective of the initial genotype frequency distributions, one generation of random mating generates the above genotype frequencies and that these allele and genotype frequencies do not change further over time, i.e. the frequencies are at an equilibrium state.

Shortly after, in the 1910s, with the discovery of genetic linkage, theoretical studies were initiated to investigate the consequences of random mating when two linked loci were considered, and under the same simplifying assumptions used by Hardy [7]. Jennings [10] and Robbins [18] showed that with two linked genes, the population, once again, approached an equilibrium state in which the alleles at the two loci associated at random; Geiringer [6] solved the problem with three linked factors. If two loci, one with alleles D and d with frequencies p and q, respectively, and a second with alleles E and e with frequencies r and s, respectively, are linked with recombination frequency θ ($0 \leq \theta \leq 1/2$), then, at equilibrium, the frequency of homozygotes such as DDEE is p^2r^2, the frequency of single **heterozygotes** such as DdEE is $2pqr^2$, and the frequency of the double heterozygote DdEe is $4pqrs$. In random mating populations, the equilibrium population frequency of any genotype, at one or more loci, is determined solely by the constituent allele frequencies at individual loci.

Linkage Disequilibrium

Jennings [10], Robbins [18], and Geiringer [6] also determined the rate of approach to equilibrium when more than one locus is involved and gave the genotypic distributions after any finite number of generations. These authors showed that, under random mating, the frequency of any multilocus genotype, g generations from an initial condition, is determined

by the products of frequencies of the four haplotypes (allele combinations) DE, De, dE, and de, and that the haplotype frequencies change over time. After g generations, the haplotype frequencies are:

$$\mathrm{DE}: h_1 = pr + \varepsilon,$$
$$\mathrm{De}: h_2 = ps - \varepsilon,$$
$$\mathrm{dE}: h_3 = qr - \varepsilon,$$
$$\mathrm{de}: h_4 = qs + \varepsilon.$$

In each generation there is a specific departure of the haplotype frequencies from the equilibrium values; this excess or deficiency is denoted as ε and termed the coefficient of allelic association or linkage disequilibrium. Note that the numerical value of ε is bounded, since each haplotype frequency is nonnegative, less than unity, and the four haplotype frequencies add to 1, as follows:

$$-\min(pr, qs) \leq \varepsilon \leq \min(ps, qr).$$

With genetic recombination between the D and E locus, the coefficient of allelic association declines every generation so that in successive generations they are related as:

$$\varepsilon' = (1 - \theta)\varepsilon.$$

Thus, in g generations, the total decline is,

$$\varepsilon_g = (1 - \theta)^g \varepsilon_0,$$

where ε_0 is the coefficient of allelic association at generation zero (initial condition). Note that in any generation, $\varepsilon = h_1 h_4 - h_2 h_3$.

The above equations suggest that linkage disequilibrium occurs only as a nonequilibrium phenomenon since it always declines to zero. However, the rate of decline is determined by the recombination value with a half-life of $-\ln 2/\ln(1 - \theta)$; the inverse relationship with the recombination value suggests that, for very close linkage, disequilibrium may persist for long evolutionary time periods.

Causes of Linkage Disequilibrium

An extensive body of population genetics literature shows how various forms of natural selection acting on individual genes can lead to permanent, equilibrium association of the alleles at two loci, even in the absence of linkage [15]. Additionally, when two loci are linked, natural selection at one locus can lead to the apparent selection at a linked locus ("hitchhiking") and permanent linkage disequilibrium. However, and as stated earlier, in the absence of natural selection no permanent associations are expected at two linked loci. Thus, the term linkage disequilibrium is a misnomer since linkage is neither necessary nor sufficient for permanent associations to occur; the descriptive term allelic (nonrandom) association is more appropriate. Other circumstances under which allelic associations can occur, although not permanently, are population admixture and population subdivision (*see* **Admixture in Human Populations**). In the latter case, a population with hidden subpopulations, each of which differs in allele frequencies and/or allelic associations, but treated as a single population, can also create allelic disequilibrium. Further details on these and other theoretical models are provided in [14–16].

In many large, random mating populations allelic associations are nevertheless observed. In humans, such observations, restricted to very closely linked **blood group** genes, such as those within the Rhesus (C, D, and E loci) and MNS (M and S loci), or within the **HLA system** of genes, have been known for a long time [1]. More recently, with the availability of multiple DNA **polymorphisms** in a small genomic region, these studies have gained in popularity. In fact, polymorphic alleles at multiple sites all within 20–30 kilobases of DNA demonstrate allelic associations [3]. These observations are best explained by the nonequilibrium state of the human population and the expectation of a slow decay of linkage disequilibrium when the maximal recombination rate within a region is less than 0.0005 per generation [3]. These observations have found multiple uses such as for associating specific mutations with a molecular haplotype in a genomic region [12] and for mapping the location of a mutation to a small genetic interval [13].

Parameterization and Estimation

Allelic associations, parameterized as the coefficient of linkage disequilibrium ε, are most easily and efficiently estimated from haplotype data. However, for most diploid organisms it is not possible to derive haplotypes from diploid two-locus genotypes unless family data (i.e. parents, offspring, and other relatives are sampled and studied) are also available (*see*

Haplotype Analysis). Then, haplotype frequencies are estimated from the relative frequencies of haplotypes in a sample of independent families and by counting only independent haplotypes within each family. Tests of allelic associations ($H_0: \varepsilon = 0$) are based on the significance of a chi-squared statistic with 1 df comparing the observed and expected (under equilibrium) haplotype frequencies. In a sample of n haplotypes studied, if allelic associations are present, the expected value of this **chi-square** statistic is $\chi^2 = n\rho^2$, where,

$$\rho = \frac{\varepsilon}{(pqrs)^{1/2}}.$$

Thus, the **correlation** in the chi-square **contingency table** of observations is another measure of linkage disequilibrium, one that is a natural measure based on the test of association. In many investigations, this latter measure has been used since ρ appears to be less dependent on the allele frequencies than ε. A measure that is not dependent on allele frequencies and finding more popular use in these studies is Yule's measure of association [13]:

$$A = \frac{h_1h_4 - h_2h_3}{h_1h_4 + h_2h_3}.$$

The above results are for loci with two alleles per locus, whereas many polymorphic markers have multiple alleles. Then, coefficients for allelic association have to be defined for each allele pair at two loci, allele triples for three loci, and so on. A discussion of these multiple disequilibria and tests of hypotheses on them is discussed in [19].

When family data are unavailable, linkage disequilibrium parameters can be efficiently estimated from population samples using iterative methods such as the **EM algorithm**. In the genetic context, this was first proposed by Hill [9] for two loci; additional methods and calculations of sample size for predefined statistical **power** was studied by Brown [2]. In addition, Brown [2] considers the appropriate parameterization of disequilibria for multiple loci taken together (i.e. the nonrandom association of alleles at multiple loci) once the pairwise disequilibria have been considered. Tests of significance (*see* **Hypothesis Testing**) are performed by appropriate modifications of the chi-square test alluded to above. Of greater importance, particularly with DNA polymorphism data, is the existence of multiple alleles at each locus studied. In this circumstance there are several possible tests of disequilibrium, such as an omnibus test or conditional tests on specific collection of alleles. Weir & Cockerham [19] have provided a theoretical and statistical account of this situation.

It is clear that accurate estimates of allelic associations require very large sample sizes when the allele frequencies, at one of the two loci studied, are close to 0 or 1. This occurs whenever **disease–marker associations** are evaluated. In these circumstances a conditional sampling strategy, in which marker genotypes are evaluated within classes of affected and unaffected individuals, is very efficient. Chakravarti et al. [4] have provided a **maximum likelihood** method for estimation of linkage disequilibrium statistics from conditional marker genotype data. These methods are useful for mapping disease genes with respect to a map of DNA markers (*see* **Genetic Map Functions**) [11, 13].

Current Applications

Studies of allelic associations across the genome and in various natural populations are now beginning, with the availability of high-resolution genetic maps in a number of species. So far, the primary purpose of these studies has been to probe the population structure of natural populations. Since in large randomly mating populations no allelic associations are expected, the finding of widespread associations will suggest that these populations are either not in equilibrium or that they have been recently established from a small number of founders. The fitting of specific population genetic models can then elucidate whether the nonequilibrium nature of these populations is due to genetic drift, natural selection, subdivision, or migration. In the human, these types of studies all suggest that modern humans have descended from a limited pool of founders ($\sim$10 000) approximately 200 000 years or so before the present.

In the human, the greatest application of studies of allelic association is to find the location of a disease gene with respect to a map of DNA markers, once the gene has been genetically localized to a DNA segment under 1000 kilobases. This was first demonstrated with the molecular cloning of the gene for cystic fibrosis [13]. A theoretical basis for disease–marker associations owing to common descent of a specific mutation from an ancestor, such as for cystic fibrosis, has been given by Hastbacka et al.

[8] and Puffenberger et al. [17]. The prospects for such disease mapping, as an aid to the molecular cloning of the mutant gene, has also been discussed by Jorde [11]. Recent studies of variation patterns of the human genome suggests that nonrandom associations between the most common type of sequence variant, the single nucleotide polymorphism (SNP), is highly clustered. Gabriel et al. [5] have shown that nonrandom associations in several human populations occur as blocks of high association with apparent random association between blocks. This highly punctuate pattern seems to be more prominent in non-African than African samples. An international project, the HapMap project, to decipher these patterns in multiple samples from across the world is currently underway and promises to uncover a wide variety of statistical problems that beg for a solution.

ARAVINDA CHAKRAVARTI

Linkage Information Content

Several authors have studied the measurement of **marker polymorphism**. Chakraborty et al. [2] proposed a criterion to evaluate whether a mating pair randomly drawn from a population is potentially informative for **linkage** studies. They defined a mating pair to be potentially informative if it is capable of producing offspring of at least two different phenotypes. Botstein et al. [1] proposed a similar measure, called the **polymorphism information content** (PIC) value. The PIC value is defined as the probability that the marker **genotype** of a given offspring will allow one to deduce which of the two marker alleles (*see* **Gene**) it received from the affected parent (in the absence of crossing-over) (*see* **Linkage Analysis, Model-based**), assuming one of the parents is affected with a rare dominant disease. Guo & Elston [3] introduced the concept of transmission informativeness, the probability of being able to deduce which of the two marker alleles a parent has transmitted given the marker genotypes of the offspring and both parents, and showed that the PIC value is equal to the average transmission informativeness over all possible parent–offspring trios. They hence proved that the PIC value is in fact a general measure of how informative a marker is regardless of the mode of inheritance of the trait being studied.

The use of model-free linkage analysis (*see* **Linkage Analysis, Model-free**) on samples of relative pairs has become common practice in genetic studies of **complex diseases**. This is based on identity-by-descent (ibd) probabilities; hence, a marker's usefulness for detecting linkage by such a method depends on the probability of being able to determine the ibd probabilities for each particular type of relative pair. Because the informativeness measures discussed above are not adequate for such a purpose, the linkage information content (LIC) value was developed [3, 6] to measure the informativeness of a marker for determining the ibd-sharing status of particular types of relative pairs. In the following section, the concept and the calculation of LIC are introduced for five types of relative pairs: full sib, half-sib, grandparent–grandchild, first cousin, and avuncular pairs.

Linkage Information Content Value for Specific Types of Relative Pairs

For a particular marker and a particular pair of relatives A and B, $\mathrm{LIC_{AB}}$ is defined as the probability of knowing how many alleles A and B share ibd at that marker. For a particular type of relative pair R, $\mathrm{LIC_R}$ is the average value of $\mathrm{LIC_{AB}}$ over all AB pairs in the population, i.e.

$$\mathrm{LIC_R} = \sum_{\substack{\text{all possible} \\ \text{AB pairs}}} \Pr(\mathrm{AB})\Pr(\text{knowing ibd status} \mid \text{AB pair}).$$

In what follows the alleles at a marker locus are represented by A_i, A_j, A_k and A_l, and it is understood that different subscripts indicate different alleles.

Full Sib

To be able to determine whether a sib pair shares the same allele from a parent, that parent has to be heterozygous. If one parent is heterozygous and the other is homozygous (mating types: $\mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_i\mathrm{A}_j$ or $\mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_j\mathrm{A}_k$), then the ibd status for the sib pair can be determined for only one (the heterozygous) parent. In the case when both parents are heterozygous (either the same heterozygous genotype, i.e. mating type: $\mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_i\mathrm{A}_j$; or different heterozygous genotype, i.e. $\mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_i\mathrm{A}_k$ or $\mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_k\mathrm{A}_l$) and we know which allele each parent has transmitted to at least one of the sibs, then the ibd status for the sib pair from both parents is determined [6]. The LIC value of a marker for sib pairs is defined to be the sum of the probability of being able to determine the sharing status from both parents and half of the probability of being able to determine the sharing status from only one parent, i.e. $\mathrm{LIC_S} = \mathrm{LIC_{S2}} + \frac{1}{2}\mathrm{LIC_{S1}}$, where

$$\begin{aligned}\mathrm{LIC_{S2}} = {} & \Pr(\mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_i\mathrm{A}_j \text{ parents})\Pr(\text{knowing sib pair sharing status} \mid \mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_i\mathrm{A}_j \text{ parents}) \\ & + \Pr(\mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_i\mathrm{A}_k \text{ parents})\Pr(\text{knowing sib pair sharing status} \mid \mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_i\mathrm{A}_k \text{ parents}) \\ & + \Pr(\mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_k\mathrm{A}_l \text{ parents})\Pr(\text{knowing sib pair sharing status} \mid \mathrm{A}_i\mathrm{A}_j \times \mathrm{A}_k\mathrm{A}_l \text{ parents}),\end{aligned}$$

and

$$\begin{aligned}\mathrm{LIC_{S1}} = {} & \Pr(\mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_i\mathrm{A}_j \text{ parents})\Pr(\text{knowing sib pair sharing status} \mid \mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_i\mathrm{A}_j \text{ parents}) \\ & + \Pr(\mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_j\mathrm{A}_k \text{ parents})\Pr(\text{knowing sib pair sharing status} \mid \mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_j\mathrm{A}_k \text{ parents})\end{aligned}$$

The overall LIC for sib pairs, on simplification, is given for a marker with allele frequencies p_{i} by

$$\mathrm{LIC_S} = 1 - \sum_i p_i^2 + \frac{1}{2}\sum_i p_i^4 - \frac{1}{2}\left(\sum_i p_i^2\right)^2.$$

Half-sib

The LIC value for half-sib pairs is the probability of being able to deduce which marker allele the common parent has transmitted to each child in the half-sib pair. To be informative, the common parent of a half-sib pair has to be heterozygous, and neither the child nor the spouse can have the same heterozygous genotype in each of the two nuclear families [3]. Therefore, the LIC value for half-sibs is given by

$$\begin{aligned}\mathrm{LIC_H} &= \sum_{i=1}^{n-1}\sum_{j=i+1}^{n} 2p_i p_j (1 - p_i p_j)^2 \\ &= 1 - \sum_i p_i^2 - 2\left(\sum_i p_i^2\right)^2 + 2\sum_i p_i^4 \\ &\quad + \left(\sum_i p_i^3\right)^2 - \sum_i p_i^6.\end{aligned}$$

Grandparent–Grandchild, First Cousin, and Avuncular Pairs

The LIC value for grandparent–grandchild, first cousin, and avuncular pairs can be calculated by

$$\begin{aligned}\mathrm{LIC_R} = \sum {} & \Pr(\text{grandparental mating type}) \\ & \Pr(\text{middle generation genotypes} \mid \text{grandparental mating type}) \\ & \Pr(\text{knowing ibd status} \mid \text{grandparental mating type and middle generation genotypes})\end{aligned}$$

for type R relative pairs. The mating type probabilities are determined assuming random mating. The calculation of the probability of the middle generation genotype(s) given the grandparental mating type is straightforward. The conditional probability of knowing ibd status for a particular type of relative pair can be obtained for a given mating type and middle generation genotypes (see Table 1 of [6] for details). For example, if the mating type is $\mathrm{A}_i\mathrm{A}_i \times \mathrm{A}_j\mathrm{A}_j$, then all the children will have genotype $\mathrm{A}_i\mathrm{A}_j$ with probability 1. In the case of grandparent–grandchild pairs, we know whether the grandchild has inherited an allele from a grandparent if and only if we know which allele the parent ($\mathrm{A}_i\mathrm{A}_j$) transmitted to the grandchild, which has a probability of $1 - p_i p_j$. That is, the conditional probability of knowing the ibd status for the grandparent–grandchild pair is $1 - p_i p_j$. In the case of avuncular pairs, the conditional probability of knowing ibd status is 0 because we have no

Table 1 The maximum LIC value for full sib, half-sib, grandparent–grandchild, first cousin, and avuncular pairs, for a marker with n alleles

Type of relative pair	Maximum LIC value
Full sib	$\dfrac{(n-1)(2n^2-1)}{2n^3}$
Half-sib	$\dfrac{(n+1)^2(n-1)^3}{n^5}$
Grandparent–grandchild	$\mathrm{LIC_G} = \dfrac{(n+1)^2(n-1)^3}{n^5}$
First cousin	$\mathrm{LIC_C} = \dfrac{(n-1)(4n^6-n^5-7n^4+2n^3+5n^2-2n-2)}{4n^7}$
Avuncular	$\mathrm{LIC_A} = \dfrac{(n-1)(2n^4-n^3-3n^2+1)}{2n^5}$

way to identify whether the A_i and/or A_j alleles are identical by descent for the two siblings in the middle generation. The LIC value for each of the three types of relative pairs can thus be obtained by summing up the products of the probabilities of mating type, the middle generation genotype(s), and the conditional probabilities of knowing ibd status. Specifically, the LIC value for grandparent–grandchild pair is

$$\begin{aligned}\mathrm{LIC_G} &= \sum_i \sum_{j\neq i} p_i^2 p_j^2 (1-p_i p_j) + \sum_i \sum_{j\neq i} 4p_i^3 p_j \\ &\times \left(\frac{1}{2}\right)(1-p_i p_j) + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} 2p_i^2 p_j p_k \left(\frac{1}{2}\right) \\ &\times [(1-p_i p_j) + (1-p_i p_k)] \\ &+ \sum_i \sum_{j\neq i} \sum_{k\neq i,j} 4p_i^2 p_j p_k \left(\frac{1}{4}\right)[(1-p_i p_j) \\ &+ (1-p_i p_k) + (1-p_j p_k)].\end{aligned}$$

The LIC value for first cousin pairs is given by

$$\begin{aligned}\mathrm{LIC_C} &= \sum_i \sum_{j\neq i} p_i^2 p_j^2 \left(\frac{1}{2}\right)(1-p_i p_j)^2 + \sum_i \sum_{j\neq i} 4p_i^3 \\ &\times p_j \left(\frac{1}{4}\right)\left[\frac{1}{2}(1-p_i p_j) + \frac{1}{2}(1-p_i p_j)\right. \\ &\left. + \frac{3}{4}(1-p_i p_j)^2\right] + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} 2p_i^2 p_j p_k \left(\frac{1}{4}\right) \\ &\times \left[\frac{3}{4}(1-p_i p_j)^2 + \frac{3}{4}(1-p_i p_j)(1-p_i p_k)\right. \\ &\left. + \frac{3}{4}(1-p_i p_j)(1-p_i p_k) + \frac{3}{4}(1-p_i p_k)^2\right] \\ &+ \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} 4p_i^2 p_j^2 \left(\frac{1}{16}\right)[(1-p_i p_j) + 1 \\ &+ (1-p_i p_j) + 2(1-p_i p_j)^2 + (1-p_i p_j) \\ &+ 1 + (1-p_i p_j)] + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} 4p_i^2 p_j p_k \\ &\times \left(\frac{1}{16}\right)\left[\frac{1}{2}(1-p_i p_j) + \frac{1}{2}(1-p_i p_k) + 1\right. \\ &\left. + \frac{1}{2}(1-p_i p_j) + (1-p_i p_j)^2 + 1 + (1-p_i p_j)\right. \\ &\left. \times (1-p_j p_k) + \frac{1}{2}(1-p_i p_k) + 1 + (1-p_i p_k)^2\right. \\ &\left. + (1-p_i p_k)(1-p_j p_k) + 1 + (1-p_i p_j)\right. \\ &\left. \times (1-p_j p_k) + (1-p_i p_k)(1-p_j p_k)\right. \\ &\left. + (1-p_j p_k)^2\right] + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} \sum_{l\neq i,j,k} p_i p_j p_k p_l \\ &\times \left(\frac{1}{16}\right)[(1-p_i p_k)^2 + (1-p_i p_k)(1-p_i p_l) \\ &+ (1-p_i p_k)(1-p_j p_k) + 1 + (1-p_i p_l) \\ &\times (1-p_i p_k) + (1-p_i p_l)^2 + 1 + (1-p_i p_l) \\ &\times (1-p_j p_l) + (1-p_j p_k)(1-p_i p_k) + 1 \\ &+ (1-p_j p_k)^2 + (1-p_j p_k)(1-p_j p_l) + 1 \\ &+ (1-p_j p_l)(1-p_i p_l) + (1-p_j p_l) \\ &\times (1-p_j p_k) + (1-p_j p_l)^2].\end{aligned}$$

The LIC value for avuncular pairs is

$$\begin{aligned}\mathrm{LIC_A} &= \sum_i \sum_{j\neq i} 4p_i^3 p_j \left(\frac{1}{4}\right)\left[\frac{1}{2}(1-p_i p_j)\right. \\ &\left. + \frac{1}{2}(1-p_i p_j)\right] + \sum_i \sum_{j\neq i} \sum_{k\neq i,j} 2p_i^2 p_j p_k \left(\frac{1}{4}\right) \\ &\times \left[\frac{1}{2}(1-p_i p_j) + \frac{1}{2}(1-p_i p_k) + \frac{1}{2}(1-p_i p_j)\right. \\ &\left. + \frac{1}{2}(1-p_i p_k)\right] + \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} 4p_i^2 p_j^2 \left(\frac{1}{16}\right) \\ &\times [1 + 2(1-p_i p_j) + 1 + 1 + 2(1-p_i p_j) + 1] \\ &+ \sum_i \sum_{j\neq i} \sum_{k\neq i,j} 4p_i^2 p_j p_k \left(\frac{1}{16}\right)[1 + (1-p_i p_j) \\ &+ (1-p_i p_k) + 3 + (1-p_j p_k) + 2 \\ &+ (1-p_j p_k) + 1 + (1-p_i p_j) + (1-p_i p_k) + 1] \\ &+ \sum_i \sum_{j\neq i} \sum_{k\neq i,j} \sum_{l\neq i,j,k} p_i p_j p_k p_l \left(\frac{1}{16}\right) \\ &\times [1 + (1-p_i p_l) + (1-p_j p_k) + 1 + (1-p_i p_k) \\ &+ 1 + 1 + (1-p_j p_l) + (1-p_i p_k) + 1 + 1 \\ &+ (1-p_j p_l) + 1 + (1-p_i p_l) + (1-p_j p_k) + 1].\end{aligned}$$

The maximum value of LIC is attained when a marker has n equally frequent alleles and is summarized in Table 1 for the five types of relative pairs.

Conclusion

The success of linkage analysis in studying complex diseases is significantly dependent on the informativeness of the markers used. We often assume that markers are fully informative, which is usually not true in practice. LIC values measure how informative a marker is for ibd sharing for each type of relative pair, and so provide an appropriate measure for a model-free linkage analysis, especially in the design of linkage studies that use relative pairs [4, 5]. Niu et al. [7] developed a software package called POLYMORPHISM that calculates LIC values for each of these five types of relative pairs. The LIC values calculated by POLYMORPHISM may be used to determine the average informativeness of markers for IBD sharing status and can be entered into DESPAIR, a program in the software package S.A.G.E. [8], to obtain the optimal two-stage global search design for linkage studies.

Linkage Analysis, Model-free

Model-free linkage methods, in contrast to **model-based linkage methods**, do not depend on prior specification of a model of inheritance for the disease or trait of interest. In other words, the frequencies and **penetrances** of disease **genotypes** need not be known in advance, and functions of these quantities may in fact be estimated in conjunction with linkage parameters. It is important to recognize, however, that many of the methods do rely on assumptions about the underlying genetic model and some methods are in fact parametric and semiparametric in nature. In this Section, two general types of model-free linkage methods will be distinguished – those designed for qualitative traits and those designed for quantitative traits – although both theory and applications of these two groups of methods overlap. Model-free linkage methods typically evaluate marker locus identity-by-descent (IBD) relationships among family members, often pairs of siblings, and thus are often referred to as relative-pair, or sib-pair, methods.

Identity by Descent

A pair of related individuals shares an allele IBD if that allele has a common ancestral source, i.e. the same chromosome of the same ancestor. In the context of linkage analysis, the common ancestor is taken to be a recent ancestor – one within the sampled pedigree. For example, if the pair are siblings, the common ancestors are their parents, and the sibs may have inherited the same paternal allele and/or maternal allele. Let f_i, $i = 0, 1, 2$, be the prior (unconditional) probability that a relative pair shares i alleles IBD at a single marker locus, and $\hat{f}_i$ the estimate of f_i conditional on available marker data (*see* **Genetic Markers**). Now, let π be the proportion of alleles a relative pair shares IBD at a single locus, and $\hat{\pi} = \frac{1}{2}\hat{f}_1 + \hat{f}_2$ the estimate of π conditional on available marker data. Table 1 gives the prior (unconditional) distribution of π for different types of relative pairs.

Computation of the $\hat{f}_i$ for a single marker locus, using available pedigree marker data, was first proposed by Haseman & Elston [24] for nuclear families, and later by Amos et al. [3] for extended pedigrees.

Table 1 Prior distribution of π for relative pairs

Type of relative pair	π			
	0	$\frac{1}{2}$	1	E(π)
Sibling	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{2}$
Second degree	$\frac{1}{2}$	$\frac{1}{2}$	0	$\frac{1}{4}$
Third degree	$\frac{3}{4}$	$\frac{1}{4}$	0	$\frac{1}{8}$

Let I_{m} represent the available family marker data. Then

$$\hat{f}_i = \frac{\Pr(\pi = i/2, I_{\mathrm{m}})}{\Pr(I_{\mathrm{m}})}$$

is a general form for estimating $\hat{f}_i$. The denominator is the probability, or likelihood, of the pedigree marker data, and may be computed using an **Elston–Stewart** ("peeling") **algorithm**; the numerator can be written as a sum of the terms of the denominator consistent with sharing i alleles IBD, each term representing a phase-known pedigree genotype. More detailed algorithms for computing $\hat{f}_i$ for different types of relative pairs were given by Amos et al. [3]. Whittemore & Halpern [52] also presented a peeling algorithm for computing the probabilities of IBD relationships among the genes of pedigree members, and then showed how to use these probabilities to calculate the probability of any combination of genotypes or phenotypes for the pedigree members.

Estimation of multipoint IBD probabilities has also been explored. Let d represent the **genetic distance** from an arbitrary origin on a marker map with known intermarker distances. To compute the $\hat{f}_{di}$, the estimated allele-sharing distribution at location d, Kruglyak & Lander [29] employed a hidden **Markov chain** model that assumes that the π at consecutive loci behave in a first-order Markov manner; i.e. $\Pr(\pi_k|\pi_1, \pi_2, \ldots, \pi_{k-1}) = \Pr(\pi_k|\pi_{k-1})$, for loci ordered 1 through k on a chromosome. Inheritance at each location d is represented by an inheritance vector $V(d)$, in which each component corresponds to a particular meiosis in the pedigree and the component takes a value of 0 or 1 according to whether the paternal or maternal allele is transmitted. Computation of the probability distribution for $V(d)$ conditional on the marker data can be accomplished by considering pairs of loci successively. Additional computational speed is achieved by taking advantage of the fact that phase differences in the founders

are equivalent and have equal probabilities [31]. An even faster algorithm uses a divide-and-conquer method and allows for meiosis-specific recombination fractions at virtually no additional cost [27]. These algorithms are all modifications of the Lander–Green algorithm [30, 32]. Sobel & Lange [46] developed a **Markov chain Monte Carlo** algorithm to approximate multipoint IBD-sharing estimates in larger pedigrees.

Given multipoint IBD-sharing estimates at marker locus locations, **regression** models can also be used to obtain IBD-sharing estimates at points between two markers. Let f_{ij} be the prior (unconditional) joint probability that a sib-pair shares i alleles IBD at one marker locus and j alleles IBD at a second, usually linked, marker locus, and let $\hat{f}_{ij}$ be estimates, conditional on the available marker data, that account for the recombination fraction, assumed to be known, between the two markers. Let $\hat{f}_{i.} = \sum_j \hat{f}_{ij}$, $\hat{f}_{.j} = \sum_i \hat{f}_{ij}$, $\hat{\pi}_1 = \hat{f}_{1.}/2 + \hat{f}_{2.}$, $\hat{\pi}_2 = \hat{f}_{.1}/2 + \hat{f}_{.2}$, and $\widehat{\pi_1\pi_2} = \hat{f}_{11}/4 + (\hat{f}_{12} + \hat{f}_{21})/2 + \hat{f}_{22}$. Given these multipoint estimates of IBD-sharing at two adjacent loci and assuming no crossover interference (*see* **Genetic Map Functions**), IBD-sharing at a point d between the two loci can be obtained using the regression equations

$$\hat{\pi}_d = \rho_0 + \rho_1\hat{\pi}_1 + \rho_2\hat{\pi}_2$$

and

$$\hat{f}_{1d} = \omega_0 + \omega_1(\hat{\pi}_1 + \hat{\pi}_2 - 2\widehat{\pi_1\pi_2}) + \omega_2\hat{f}_{1.} + \omega_3\hat{f}_{.1} + \omega_4\hat{f}_{11},$$

where expressions for the regression parameters in terms of the recombination fractions between the two loci (θ_{m}), between the first marker and $d(\theta_1)$, and between the second marker and $d(\theta_2)$ are given in Table 2 [34].

Linkage Between Marker and Qualitative Trait

Model-free linkage methods designed for qualitative traits often consider samples of affected sib-pairs or sibships with at least two affected members. If a trait and marker are linked, affected sib-pairs should share more alleles IBD than expected by chance. Under the **null hypothesis** of no linkage, sib-pairs are expected to share exactly 0, 1, or 2 alleles IBD at a single marker locus with respective probabilities $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$. Early test statistics generally assumed that the marker IBD state can be determined with certainty, so that a sample of n pairs can be partitioned into n_0, n_1, and n_2 pairs corresponding to sharing 0, 1, or 2 alleles IBD. Day & Simons [14] and Suarez et al. [48], assuming such a fully informative marker locus, proposed a one-sided (*see* **Alternative Hypothesis**) **nonparametric** test statistic (T_2) that compares the observed proportion of sib-pairs that share exactly two marker alleles IBD to its null value of $\frac{1}{4}$:

$$T_2 = \frac{n_2/n - 1/4}{[3/(16n)]^{1/2}}.$$

Green & Woodrow [22] proposed a one-sided nonparametric test statistic (T_{m}) that compares the observed mean proportion of marker alleles shared IBD to its null value of $\frac{1}{2}$:

$$T_{\mathrm{m}} = \frac{n_2 + n_1/2 - 1/2}{[1/(8n)]^{1/2}}.$$

Extensions for use with larger sibships were proposed by Green & Woodrow [22] and deVries et al. [15]. These more general test statistics can substitute $\bar{\hat{\pi}} = \sum_{j=1}^{n}\hat{\pi}_j/n$ for $n_2 + n_1/2$ and an empirical variance estimate for the denominator when IBD sharing cannot be determined with certainty.

A **goodness-of-fit** statistic that compares the observed IBD distribution to that expected by chance was proposed by Weitkamp et al. [50]. Blackwelder

& Elston [5] compared the **power** of this test statistic, T_2, and T_m and found that T_m has greater power for most one-locus genetic models; T_2 has more power for some recessive models. Schaid & Nick [44] studied the asymptotically most powerful linear combination of the $\hat{f}_i$ and determined that T_m has power close to optimal for a broad range of single-locus models. Knapp et al. [28] determined that, provided $\delta_1^2 = \delta_0\delta_2$, where $\delta_s = \Pr(\text{affected}|\text{trait genotype with } s \text{ susceptibility alleles})$, T_m is uniformly most powerful in θ, the recombination fraction between trait and marker loci.

Suarez et al. [48] characterized the distribution of sib-pair IBD sharing in terms of the population trait prevalence K, additive genetic variance σ_a^2, dominance genetic variance σ_d^2, and θ, the recombination fraction between trait and marker loci. Suarez et al. [44] determined the boundaries of this parameter space under a one-locus model. Risch [38–41] developed a parametric strategy for detecting linkage to complex diseases using affected sib-pairs and extended the methodology to multilocus trait models and to other types of relative pairs. Let z_{ri} be parameters defined as the probability that an affected relative pair of type r shares i marker alleles IBD. Then the lod score [the log base 10 of the ratio of the likelihoods under the alternative and the null hypothesis of no linkage (*see* **Likelihood Ratio**)] for the pedigree marker data I_m given **ascertainment** of an affected relative pair of type r (arp_r) can be written

$$Z(I_m|\text{arp}_r) = \log_{10} \sum_{i=0,1,2} \frac{\hat{f}_i z_{ri}}{f_{ri}}. \qquad (1)$$

Under the null hypothesis $\theta = \frac{1}{2}$, $z_{ri} = f_{ri}$, for $i = 0, 1, 2$, and $Z(I_m|\text{arp}_r) = 0$. The lod score (1) is maximized over the z_{ri} at regular (e.g. 1 cM) intervals in a chromosomal region containing the typed markers. Alternatively, Hauser et al. [25] maximized the lod score over both the z_{ri} and the recombination fraction between one of two flanking markers and a disease locus assumed to lie between them.

Now define K_r to be the probability that a relative of type r of an affected individual is also affected, and let $\lambda_r = K_r/K$ be the **relative risk** of disease to a relative of type r. Let the subscripts s, o, and m denote sibling, parent/offspring, and monozygotic twins (*see* **Heterozygosity**), respectively. Under the assumption that a single locus confers susceptibility to disease, the z_{ri} are related to the relative risks and the recombination fraction as shown in Table 3 [39]. For affected sib-pairs, when $\theta = 0$, $z_{s0} = 1/(4\lambda_s)$, $z_{s1} = \lambda_0/(2\lambda_s)$, and $z_{s2} = \lambda_m/(4\lambda_s)$. Constraints on the z_{si} consistent with a one-locus genetic model are: $z_{s0} \geq 0$, $z_{s2} + z_{s0} \geq z_{s1}$, and $z_{s1} \geq 2z_{s0}$. Holmans [26] determined the asymptotic distribution of the maximum lod score under these constraints to be a mixture of χ_1^2 and χ_2^2 random variables; a lod score of 2.3 corresponds to a significance level of 10^{-3}. For various types of relative pairs, Lander & Kruglyak [33] proposed that pointwise significance levels (*see* **Hypothesis Testing**) and lod scores corresponding to a genome-wide significance of 0.05 be considered "significant" evidence in favor of linkage, assuming a single disease locus and an infinitely dense marker map. Davis et al. [13] developed **simulation**-based nonparametric statistics that condition on the marker genotypes of the unaffected family members.

Table 3 Parameters of z_{ri} for relative pairs[a]

Type of relative pair	z_{r0}	z_{r1}	z_{r2}
Full sibling	$\frac{1}{4} - \frac{1}{4\lambda_s}(2\psi - 1)[(\lambda_s - 1) + 2(1 - \psi)(\lambda_s - \lambda_o)]$	$\frac{1}{2} - \frac{1}{2\lambda_s}(2\psi - 1)^2(\lambda_s - \lambda_o)$	$\frac{1}{4} + \frac{1}{4\lambda_s}(2\psi - 1)[(\lambda_s - 1) + 2\psi(\lambda_s - \lambda_o)]$
Grandparental	$\frac{1}{2} - \frac{1}{2\lambda_g}(1 - 2\theta)(\lambda_g - 1)$	$\frac{1}{2} + \frac{1}{2\lambda_g}(1 - 2\theta)(\lambda_g - 1)$	–
Avuncular	$\frac{1}{2} - \frac{1}{2\lambda_a}(1 - \theta)(1 - 2\theta)^2(\lambda_a - 1)$	$\frac{1}{2} + \frac{1}{2\lambda_a}(1 - \theta)(1 - 2\theta)^2(\lambda_a - 1)$	–
Half-sibling	$\frac{1}{2} - \frac{1}{2\lambda_h}(2\psi - 1)(\lambda_h - 1)$	$\frac{1}{2} + \frac{1}{2\lambda_h}(2\psi - 1)(\lambda_h - 1)$	–
First cousin	$\frac{3}{4} - \frac{1}{2\lambda_c}[(1 - \theta)^4 + \theta^2(1 - \theta)^2 + \frac{\theta^2}{2} - \frac{1}{4}](\lambda_c - 1)$	$\frac{1}{4} + \frac{1}{2\lambda_c}[(1 - \theta)^4 + \theta^2(1 - \theta)^2 + \frac{\theta^2}{2} - \frac{1}{4}](\lambda_c - 1)$	–

[a]From Risch [39], reproduced by permission of the publisher; $\psi = \theta^2 + (1 - \theta)^2$; s = full sibling, g = grandparental, a = avuncular, h = half-sibling, c = first cousin, o = parent/offspring.

For samples of affected sib-pairs, a test statistic with more power than the lod score for some recessive models is

$$\frac{T_{z_2} = \left(\hat{z}_{s2} - \frac{1}{4}\right)}{\text{var}(\hat{z}_{s2})},$$

where $\text{var}(\hat{z}_2)$ is obtained from the observed **information matrix** [35].

Affected sib-pair methods are particularly useful in detecting linkage to complex diseases, which are expected to be oligogenic. The single-locus lod score provides a valid test of linkage even if other loci contribute to a disease. Multilocus models are also of interest. A general two-locus lod score with eight free parameters may be written as

$$Z(I_m|\text{arp}_s) = \log_{10} \sum_{i=0,1,2} \sum_{j=0,1,2} \frac{z_{ij} \hat{f}_{i1} \hat{f}_{j2}}{f_{i1} f_{j2}},$$

where the subscripts 1 and 2 refer to the two loci, and z_{ij} are parameters representing the probability that an affected sib-pair shares i alleles IBD and the first locus and j at the second locus. The two disease loci are assumed to be unlinked. If the two loci interact in a multiplicative fashion, then $z_{ij} = z_i z_j$ by definition, and four free parameters are required. Let λ_{ki} be the relative risk to a relative that shares i alleles IBD with an affected individual at disease locus k, and let K_k and λ_{ks} be the contributions to the overall prevalence and sibling relative risk due to locus k. If the two loci interact in an additive fashion, then

$$\frac{z_{ij}}{f_{1i} f_{2j}} - 1 = \frac{1}{\lambda_s} \left(\frac{K_1}{K}\right)^2 (\lambda_{1i} - \lambda_{1s}) + \frac{1}{\lambda_s} \left(\frac{K_2}{K}\right)^2 (\lambda_{2j} - \lambda_{2s}),$$

an additive property [39]; this formulation also requires four free parameters.

The lod score (1) may also be written as

$$Z(I_m|\text{arp}_s) = \log_{10} \left[1 + \beta \left(\hat{\pi} - \tfrac{1}{2}\right) + \gamma \left(\hat{f}_1 - \tfrac{1}{2}\right)\right],$$

where $\beta = (\sigma_a^2 + \sigma_d^2)/(K K_s) = 4(z_2 - z_0)$ and $\gamma = -\sigma_d^2/(2K K_s) = 2(z_1 - z_0 - z_2)$. The general two-locus model may similarly be parameterized in terms of **variance components** $\sigma^2_{a_j}, \sigma^2_{d_j}, \sigma^2_{a_1 a_2}, \sigma^2_{d_1 d_2}$, and $\sigma^2_{a_j d_{3-j}}$ – the contribution to the total genetic variance due to the **interaction** between the additive (a) or dominance (d) component of the jth locus, $j = 1, 2$ [11, 16, 23, 35]. One such model [35] is

$$\begin{aligned} Z(I_m|\text{arp}_s) = \log_{10} \Big\{ 1 + (K K_s)^{-1} \Big[& B_1 \left(\hat{\pi}_1 - \tfrac{1}{2}\right) \\ & + C_1 \left(\hat{f}_{11} - \tfrac{1}{2}\right) + B_2 \left(\hat{\pi}_2 - \tfrac{1}{2}\right) \\ & + C_2 \left(\hat{f}_{12} - \tfrac{1}{2}\right) + D \left(\hat{\pi}_1 \hat{\pi}_2 - \tfrac{1}{4}\right) \\ & + F_1 \left(\hat{\pi}_1 \hat{f}_{12} - \tfrac{1}{4}\right) + F_2 \left(\hat{\pi}_2 \hat{f}_{11} - \tfrac{1}{4}\right) \\ & + G \left(\hat{f}_{11} \hat{f}_{12} - \tfrac{1}{4}\right) \Big] \Big\}, \end{aligned}$$

where

$$\begin{aligned} B_j &= \sigma^2_{a_j} + \sigma^2_{d_j}, \quad j = 1, 2, \\ C_j &= \frac{-\sigma^2_{d_j}}{2}, \quad j = 1, 2, \\ D &= \sigma^2_{a_1 a_2} + \sigma^2_{a_1 d_2} + \sigma^2_{a_2 d_1} + \sigma^2_{d_1 d_2}, \\ F_j &= \frac{-\sigma^2_{a_j d_{3-j}} + \sigma^2_{d_1 d_2}}{2}, \quad j = 1, 2, \end{aligned}$$

and

$$G = \frac{\sigma^2_{d_1 d_2}}{4}.$$

When K and K_s are known, the variance components may be estimated directly; otherwise, the model can be fitted by reparameterizing so that $B_1^* = B_1/(K K_s)$, and similarly for the remaining parameters. **Additive** and **multiplicative models** can also be fitted using variance components parameterizations [35].

For linkage analysis using small pedigrees, Kruglyak et al. [31] proposed calculating a scoring function $S(v, \Psi)$ (*see* **Scores**) that depends on an inheritance vector v and the observed disease phenotypes Ψ in the pedigree. When the inheritance vector is unknown, one computes its conditional expectation

$$\overline{S}(\Psi) = \sum_v S(v, \Psi) P(v),$$

where $P(v)$ is estimated using available marker data. The authors further discuss a model-free scoring function that considers IBD-sharing among sets of affected family members; this scoring function was first proposed by Whittemore & Halpern [51]. Let a denote the number of affected individuals in a

pedigree, let h be a collection of alleles obtained by choosing one allele from each of these individuals, and let $b_i(h)$ denote the number of times that the ith founder allele appears in h. The scoring function is defined as

$$S_{\text{all}}(v) = 2^{-a} \sum_h \left[\prod_i b_i(h)! \right],$$

where the sum is over the 2^a possible ways to choose h. Kruglyak et al. then standardize the score to obtain $Z(v) = [S(v) - \mu]/\sigma$, where μ and σ are the mean and standard deviation of S under the **uniform distribution** of inheritance vectors. A global score is obtaining by taking a weighted average of standardized scores; weights depend on pedigree size.

The affected-pedigree-member (APM) method of Weeks & Lange [49] can also be used to analyze extended pedigrees, and uses identity-by-state sharing to incorporate information from multiple markers; this method is less powerful than methods based on IBD sharing [21]. Curtis & Sham [12] proposed comparing observed and expected numbers of alleles shared IBD between all affected relative pairs in a pedigree. Guo [23] proposed plotting $\hat{\pi}$ over each chromosomal interval and examining further regions for which $\hat{\pi}$ is substantially larger than $\frac{1}{2}$.

Elston [17] and Elston et al. [18] developed and studied two-stage global search designs for linkage analysis to complex diseases using pairs of affected relatives. In the first of the two stages, a genome scan is performed on n affected pairs using m equally spaced marker loci. For each marker with a pointwise ***P* value** less than α^*, k additional markers in the region are typed and a more stringent significance level α applied. Given the relative risk λ_r for a particular trait locus, the desired power of the study, and the ratio of the cost of recruiting one person into the study to the cost of performing one marker assay, n, m, k, and α may be chosen to minimize the total cost of the study. Typically, an optimal two-stage procedure halves the cost of a study, compared to a procedure involving only the first stage and the criterion α.

Linkage analysis may also be done using discordant pairs, i.e. pairs in which one member is affected and the other unaffected. Such pairs provide good power for linkage if the disease is rare and dominant, or if the disease is common. The lod score takes the same form as (1), except that the z_{ri} are now the probabilities that a discordant pair of type r share i alleles IBD. For discordant sib-pairs, genetic constraints are obtained by reversing the roles of z_{s0} and z_{s2} in the inequalities given above for affected sib-pairs.

Linkage Between Marker and Quantitative Trait

The problem of detecting linkage between a marker locus and a locus underlying a quantitative trait using sib-pair data was first considered by Penrose [37], who proposed comparing the covariance of the sib-pair trait and marker differences with that expected when the trait and marker are not linked. Haseman & Elston [24] and Blackwelder [4] expanded this idea and included available marker information from the parents.

Assume that a single locus with alleles T and t underlies a quantitative trait. For an observation X from the trait distribution, the genetic model may be written

$$X = \mu + g + e,$$

where μ is an overall mean, g is a major gene effect such that $g = a, d$, or $-a$ for trait genotypes TT, Tt, or tt, respectively, and e is a residual effect with an unspecified distribution. Putting $p = \Pr(\text{T})$ and $q = 1 - p$,

$$\sigma_{\text{a}}^2 = 2pq[a - d(p - q)]^2,$$
$$\sigma_{\text{d}}^2 = 4p^2q^2d^2,$$

and $\sigma_{\text{g}}^2 = \sigma_{\text{a}}^2 + \sigma_{\text{d}}^2$. Also, let $\sigma_\varepsilon^2 = \text{E}(e_1 - e_2)^2$, for a pair of sibs indexed 1 and 2, and let $\psi = \theta^2 + (1 - \theta)^2$, where θ is the recombination fraction between trait and marker loci.

The squared difference $Y = (X_1 - X_2)^2$ between the measurements of a quantitative trait for a randomly sampled pair of siblings is a linear function of the **Bayesian** estimate of the proportion of marker alleles shared IBD between the members of the pair ($\hat{\pi}$) and the estimated probability that the pair share exactly one marker allele IBD ($\hat{f}_1$), i.e.

$$\text{E}(Y|I_{\text{m}}) = \alpha_{\text{s}} + \beta_{\text{s}}\hat{\pi} + \gamma_{\text{s}}\hat{f}_1,$$

where

$$\alpha_{\text{s}} = \sigma_\varepsilon^2 + 2\sigma_{\text{g}}^2\psi + 2\sigma_{\text{d}}^2\psi(1 - \psi),$$
$$\beta_{\text{s}} = 2\sigma_{\text{g}}^2(1 - 2\psi),$$

and

$$\gamma_s = \sigma_d^2(1-2\psi)^2.$$

If $\theta = \frac{1}{2}$ or $\sigma_g^2 = 0$, then $\beta = 0$; otherwise, $\beta < 0$. After fitting the regression model using **least squares**, an asymptotically normal one-sided test of linkage may be constructed.

Similar regression relationships have been developed for other types of relative pairs, specifically half-sib, grandparental, avuncular, and cousin pairs [2]; all take the form

$$E(Y|I_m) = \alpha_r + \beta_r\hat{\pi},$$

where α_r and β_r are functions of $\sigma_a^2, \sigma_d^2, \sigma_\varepsilon^2$, and θ that are specific to relative pair type r (Table 4). Olson & Wijsman [36] used **generalized estimating equations** to combine information from different types of relative pairs in a set of pedigree data. Assume that p types of relative pairs are of interest and that the data set consists of N pedigrees, each with n_i relative pairs. Under a working independence model, α_r and β_r are estimated separately for each type of relative pair; the robust **covariance matrix** of these estimates is given by

$$\text{var}(\alpha, \beta) = \left(\sum_{i=1}^{N} \mathbf{D}_i'\mathbf{D}_i\right)^{-1} \left(\sum_{i=1}^{N} \mathbf{D}_i'\hat{\mathbf{S}}_i\hat{\mathbf{S}}_i'\mathbf{D}_i\right) \times \left(\sum_{i=1}^{N} \mathbf{D}_i'\mathbf{D}_i\right)^{-1},$$

where $\mathbf{D}_i$ is an $n_i \times 2p$ matrix containing the $\hat{\pi}_r$ and $\hat{f}_1$ (analogous to the design matrix in a linear regression model), and $\mathbf{S}_i$ is a vector of length n_i with elements $y - \alpha_r - \beta_r\hat{\pi}_r$. A one-sided, asymptotically normal, test of linkage takes the form

$$\frac{T = N^{1/2}\mathbf{c}^T\hat{\boldsymbol{\beta}}}{[\mathbf{c}^T\text{var}(\hat{\boldsymbol{\beta}})\mathbf{c}]^{1/2}},$$

where $\mathbf{c}$ is a p-dimensional vector of weights, chosen a priori, with elements $\text{var}(\pi_r)n_r$, n_r is the total number of pairs of type r, and $\hat{\boldsymbol{\beta}}$ is a vector of the regression estimates $\hat{\beta}_r$. In a multipoint setting, or when a candidate locus is being tested, the model with common slope

$$E(Y|I_m) = \alpha_r + \boldsymbol{\beta}\hat{\pi}$$

may be fitted; $\mathbf{D}_i$ becomes an $n_i \times p + 1$ matrix and no a priori weights are required to test linkage. Because $\beta_s = \beta_h$ for all values of the recombination fraction, sib-pairs and half-sib-pairs may be combined in a similar manner for a genome scan using single markers. Schaid et al. [45] combine these two types of pairs into a single test of linkage, using an empirically derived adjustment to the **degrees of freedom** of the t-statistic (*see* **Student's *t* Distribution**) to allow for correlated pairs.

Regression models have been developed for sampling schemes other than random sampling. Assume that probands are sampled from the upper tail of the trait distribution. Let $X_1 > c$ be the proband trait value, and X_2 the trait value for the proband's sibling. **Consistent estimates** of regression coefficients may be obtained by fitting

$$X_2 = A + B_1X_1 + B_2\left(\hat{\pi} - \tfrac{1}{2}\right) + B_3\left(\left|\hat{\pi} - \tfrac{1}{2}\right| - \tfrac{1}{4}\right),$$

[7]. $B_2 = 0$ if $\theta = \frac{1}{2}$; otherwise, $B_2 > 0$. ($B_2 < 0$ if probands are sampled from the lower tail of the

Table 4 Coefficients of the regression of squared pair differences on the proportion of alleles shared IBD for relative pairs[a]

Type of relative pair	α_r	β_r
Half-sibling	$\sigma_\varepsilon^2 + 2\sigma_g^2 - 2\theta(1-\theta)\sigma_a^2$	$-2(1-2\theta)^2\sigma_a^2$
Grandparental	$\sigma_\varepsilon^2 + 2\sigma_g^2 - \theta\sigma_a^2$	$-2(1-2\theta)\sigma_a^2$
Avuncular	$\sigma_\varepsilon^2 + 2\sigma_g^2 - (\frac{5}{2}\theta - 4\theta^2 + 2\theta^3)\sigma_a^2$	$-2(1-2\theta)^2(1-\theta)\sigma_a^2$
First cousin	$\sigma_\varepsilon^2 + 2\sigma_g^2 - (\frac{4}{3}\theta - \frac{5}{2}\theta^2 + 2\theta^3 - \frac{2}{3}\theta^4)\sigma_a^2$	$-2(1-2\theta)^2(1-\frac{4}{3}\theta + 2\theta^2)\sigma_a^2$

[a]From Amos & Elston [2], reproduced by permission of the publisher.

trait distribution.) Conditioning on the ascertainment process, rather than the proband's trait value, gives

$$\mathrm{E}(X_2|I_\mathrm{m}, X_1 > c) = A^* + B_2^*\left(\hat{\pi} - \tfrac{1}{2}\right) + B_3^*\left(\left|\hat{\pi} - \tfrac{1}{2}\right| - \tfrac{1}{4}\right).$$

Use of this sampling scheme greatly increases the power to detect linkage [6, 7], particularly for a rare allele with a large effect.

This "selected sampling" scheme provides excellent power provided that one samples probands from the tail of the distribution with the rarer allele. A second design, which is uniformly powerful in all genetic situations, is sampling of extreme discordant sib-pairs – pairs such that one sib has a trait value from the upper tail and the other from the lower tail. For example, given a large sample of probands with an extreme value in one direction (usually that indicating disease), one might genotype only those pairs for which the sibling has a trait value in the opposite tail. Such extreme discordant pairs provide good power for detecting linkage for additive, dominant, and recessive models [42, 43]. As there may be little trait variation within each tail, it is useful to ignore this variation and model

$$z_i \equiv \Pr(\pi = i/2|\mathrm{edsp}), \quad i = 0, 1, 2,$$

where edsp denotes "extreme discordant sib-pair". The lod score is the same as in the case of sampling sib-pairs discordant for a dichotomous trait, which may be considered a special case of edsp for which the two tails share the same cutpoint, with different constraints on the z_i.

Other approaches to quantitative trait linkage have been proposed. To assess evidence for genetic linkage from pedigrees, Amos [3] modeled the covariance matrix of pedigree trait values in terms of variance components, IBD sharing and the recombination fraction. Let a general model for trait values X be

$$X_i = \mu + g_i + G_i + \boldsymbol{\beta}^\mathrm{T}\mathbf{w}_i + e_i,$$

where μ, g_i, and e_i are the overall mean, major genotype effect, and environmental error, as before, G_i is a random effect of polygenes (*see* **Polygenic Inheritance**), $\mathbf{w}_i$ a vector of fixed covariates, and $\boldsymbol{\beta}$ a set of regression parameters. Without loss of generality, take $\mathrm{E}(g_i) = \mathrm{E}(e_i) = \mathrm{E}(G_i) = 0$. Then

$$\mathrm{E}(X_i) = \mu + \boldsymbol{\beta}^\mathrm{T}\mathbf{w}_i,$$
$$\mathrm{var}(X_i) = \sigma_\mathrm{a}^2 + \sigma_\mathrm{d}^2 + \sigma_\mathrm{G}^2 + \sigma_\mathrm{e}^2,$$

and

$$\mathrm{cov}(X_i, X_j|\pi_{ij}) = f(\theta, \pi_{ij})\sigma_\mathrm{a}^2 + g(\theta, f_{2ij})\sigma_\mathrm{d}^2 + \phi_{ij}\sigma_\mathrm{G}^2 \quad \text{for } i \neq j,$$

where ϕ_{ij} is the coefficient of relationship between family members i and j (*see* **Inbreeding**), $f(\theta, \pi_{ij})$ is given for various relative pairs in Table 5, and $g(\theta, f_{2ij})$ equals 0 for all but sib-pairs, in which case

$$\begin{aligned}\mathrm{cov}(X_i, X_j|\pi_{ij}) = {} & 2\theta(1-\theta)\sigma_\mathrm{g}^2 \\ & + 2(\theta-1)\theta(1-2\theta+2\theta^2)\sigma_\mathrm{d}^2 \\ & + [(1-2\theta)^2\sigma_\mathrm{g}^2 - (1-2\theta)^4\sigma_\mathrm{d}^2]\pi_{ij} \\ & + (1-2\theta)^4\sigma_\mathrm{d}^2 f_{2ij}.\end{aligned}$$

Parameters may be estimated using **maximum likelihood** methods, if **multivariate normality** of errors is assumed, or by estimating-equation approaches.

Another approach, the weighted pairwise correlation (WPC) statistic, was proposed by Commenges [8]. This score test may be applied to sets of large pedigrees with several types of relative pairs. Consider a set of F pedigrees, each with n_f members. For an individual pedigree, a general form for the score statistic is

$$S_\mathrm{L} = \sum_{i<j} W_{ij}U_iU_j,$$

where $W_{ij} = \hat{\pi_{ij}} - \overline{\hat{\pi}}_{rij}$ are centered IBD-sharing estimates for the pair of relatives i and j, and U_i is the residual $x_i - \mathrm{E}(X_i|\text{covariates})$, based on some parametric model for the mean of X. If more **robustness** is desired, the U_i may be replaced by their centered **ranks**, to give

$$S_\mathrm{R} = \sum_{i<j} W_{ij}(R_i - \overline{R})(R_j - \overline{R}),$$

Table 5 Expressions for $f(\theta, \pi_{ij})$[a]

Relative pair	$f(\theta, \pi_{ij})$
Sibling	$\frac{1}{2} + (1-2\theta)^2(\pi_{ij} - \frac{1}{2})$
Half-sibling	$\frac{1}{4} + (1-2\theta)^2(\pi_{ij} - \frac{1}{4})$
Avuncular	$\frac{1}{4} + (1-2\theta)^2(1-\theta)(\pi_{ij} - \frac{1}{4})$
Grandparental	$\frac{1}{4} + (1-2\theta)(\pi_{ij} - \frac{1}{4})$
First cousin	$\frac{1}{8} + (1-2\theta)^2(1 - \frac{4}{3}\theta + \frac{2}{3}\theta^2)(\pi_{ij} - \frac{1}{8})$

[a]From Amos [1], reproduced by permission of the publisher.

where R_i is the rank of the ith residual, and $\overline{R}$ is the mean of the ranks. For a set of F pedigrees, linkage may be tested using

$$S = \frac{\sum_{f=1}^{F}[S_{\mathrm{Rf}} - \mathrm{E}(S_{\mathrm{Rf}})]}{\left(\sum_{f=1}^{F}\mathrm{var}S_{\mathrm{Rf}}\right)^{1/2}},$$

where

$$\mathrm{E}(S_{\mathrm{Rf}}) = -\frac{n_f+1}{12}\sum_{i<j} W_{ijf},$$

$$\mathrm{var}(S_{\mathrm{Rf}}) = A\sum_{i<j} W_{ijf}^2 + B\sum_{i<j}\sum_{r<s;r,s\neq i,j} \times W_{ijf}W_{rsf} - 2C\sum_{i,j\neq i}\sum_{r\neq i,j} W_{irf}W_{jrf},$$

$A=(n_f+1)(n_f-2)(5n_f^2+n_f-8)/720$, $B=(n_f+1)(10n_f+16)/720$, and $C=(n_f+1)(5n_f^2-3n_f-16)/720$. This test is called the weighted pairwise rank correlation (WPRC) test. Simulations show that the WPRC can be more powerful than the Haseman–Elston test for single large pedigrees, or in the presence of genotype-by-environment interaction (*see* **Gene-environment Interaction**) or family-specific residual variance [10]. For larger samples of small pedigrees, the Haseman–Elston test is generally the more powerful, particularly for highly heritable dominant traits. The WPC or WPRC can be applied to dichotomous traits as well as to quantitative traits and can substitute identity-by-state sharing for IBD sharing estimates. Commenges & Abel [9] proposed a **transformation** that yields uncorrelated **residuals** and a more robust test statistic.

Goldgar [19] proposed a multipoint IBD method that assumes that the quantitative trait is due to additive genetic effects and a normally distributed random environmental component. The method is parameterized using the proportion of the total trait variance due to additive genetic effects (h^2) and the proportion (P) of the genetic variance due to loci in the chromosomal interval defined by the marker loci. For each sib-pair, the proportion of the chromosomal region shared IBD, conditional on the marker data, is estimated. A covariance matrix of the sibship trait values is then constructed as a function of the IBD-sharing estimates, h^2, and P. The likelihood for the trait values, conditional on IBD-sharing, is assumed to be multivariate normal; numerical maximum-likelihood techniques are used to estimate P and to test the null hypothesis $P = 0$. Limited simulation suggests that this multipoint method is more powerful than the single-marker Haseman–Elston method. The method also has power comparable to model-based linkage analysis when parental data are unknown, the effect of the major locus is small and there is additional genetic variation, or the parameters of the model-based analysis are misspecified [20].

Software

Estimates of multipoint IBD-sharing may be obtained using MAPMAKER/SIBS (nuclear families) and GENEHUNTER (small pedigrees). These programs also apply a variety of parametric and nonparametric tests of linkage for both quantitative and qualitative data. For single markers, the SAGE program SIBPAL performs nonparametric tests of linkage for affected sib-pairs, and applies the Haseman–Elston regression method for sib and half-sib pairs. The SAGE program RELPAL estimates single-marker allele-sharing probabilities for large pedigrees and applies the Olson–Wijsman test of linkage. The SAGE program DESPAIR provides optimal two-stage designs for genome searches using affected relative pairs. Other software, including APM, ASPEX, ERPA, ESPA, GAS, MFLINK, MIM, NOPAR, and SIMIBD, that perform various aspects of model-free linkage analysis, are available from their respective authors (*see* **Software for Genetic Epidemiology**).

LISREL

The acronym LISREL was coined by Jöreskog [5–7]: it is derived from LInear Structural RELations. Researchers use the term LISREL to refer either to **structural equations models** or to Jöreskog & Sörbom's [8] popular **software** program to estimate such statistical models. The LISREL *model* consists of two primary parts: a latent variable model and a measurement model. The former allows linear relationships between latent (unobserved) variables. This is much like a simultaneous equation model used in econometrics, except that it has latent rather than observed variables. It formulates the relation between the latent variables free of the confounding effects of measurement errors. The measurement model provides the linkages between the latent and observed variables. This model enables a researcher to use multiple indicators of the latent variables and to assess the "quality" of the measures. Many popular linear models (e.g. simultaneous equations, **confirmatory factor analysis**, **multiple regression, analysis of variance**, **analysis of covariance**, etc.) are special cases of Jöreskog's LISREL model.

In the original LISREL model, linear relations were assumed between continuous latent and continuous observed variables. Extensions of the LISREL model (see, for example, [8] and [11]) maintain the assumption of continuous latent variables but allow noncontinuous observed variables; for example, **censored**, ordinal (*see* **Ordered Categorical Data**), or dichotomous variables (*see* **Binary Data**). The relation between the latent variables and the noncontinuous observed variables is nonlinear. Other extensions allow equations that are nonlinear in the latent variables [3, 9, 10]. The article **Structural Equation Models** gives a more complete description of the LISREL model.

The second use of the term LISREL refers to a computer software program. One of the primary reasons for the rise in popularity of structural equation models was the availability of Jöreskog & Sörbom's [8] LISREL software package. For many years, LISREL was the only widely available program capable of estimating and testing these models. It is partly for this reason that both the structural equation model and the software were referred to by the same LISREL term. Since about the mid-1980s, other structural equation software programs have become more common (e.g. [1, 2, 4], and [12]). In addition, Jöreskog & Sörbom have continuously updated the LISREL program. The greater availability of software has contributed both to the further spread of these models as well as to the trend to refer to the statistical models as "structural equation models". The latter term helps to distinguish the model from the software needed to analyze the model.

KENNETH A. BOLLEN

Locally Most Powerful Tests

The classical **Neyman–Pearson Lemma** gives a **most powerful (MP) test** for the problem of testing a simple null hypothesis $\theta = \theta_0$ against a simple alternative hypothesis $\theta = \theta_1$. The Neyman–Pearson tests turn out to be uniformly most powerful (UMP) in some situations, but this is not true in general. For example, when $H_0: \theta \in \Theta_0 \subset \Theta$ and $H_1: \theta \in \Theta_1 \subset \Theta$ are one-sided, then the existence of a UMP test for every level α is essentially equivalent to the requirement that the joint density function has a monotone **likelihood ratio** property [11].

When a UMP test does not exist, one may restrict the class of tests to, say, the class of **unbiased** and/or invariant tests, and then look for a UMP test in this smaller class. Alternatively, one may look for tests that have maximum power against alternatives in a subset of Θ_1. The case when the subset of alternatives is "close" to the null parameter values has received a good deal of attention, presumably because tests that have good power for "local alternatives", which are the hardest to detect, may also retain good power for "nonlocal" alternatives.

Locally Most Powerful Tests

We focus attention to the case when θ is a real parameter, and use the Neyman & Pearson [8, 9] framework. Consider the problem of testing $H_0: \theta \leq \theta_0$ against $H_1: \theta > \theta_0$. Let ϕ_0 be a test function with **power** function $\beta_{\phi_0}(\theta) = E_\theta \phi_0(X)$. Then ϕ_0 is a locally most powerful (LMP) test of size α if there exists a $\Delta > 0$ such that for any other test ϕ with $\alpha = \sup_{\theta \leq \theta_0} \beta_{\phi_0}(\theta) \geq \sup_{\theta \leq \theta_0} \beta_\phi(\theta)$, $\beta_{\phi_0}(\theta_0) \geq \beta_\phi(\theta)$ for every $\theta \in (\theta_0, \theta_0 + \Delta]$. Thus, an LMP test maximizes

$$\frac{\mathrm{d}}{\mathrm{d}\theta}\beta(\theta)\bigg|_{\theta=\theta_0} = \beta'(\theta)\bigg|_{\theta=\theta_0}$$

subject to the size constraint. Under some smoothness conditions one can show that any test of the form $\phi_0(\mathbf{x}) = 1$ if $\partial \log f(\mathbf{x};\theta)/\partial\theta|_{\theta=\theta_0} > k, = 0$ if $\partial \log f(\mathbf{x};\theta)/\partial\theta|_{\theta=\theta_0} < k$ will maximize $\beta'(\theta)|_{\theta=\theta_0}$. Here $f(\mathbf{x};\theta)$ is the joint probability density function (pdf) of a **random sample** $X_1, X_2, \ldots, X_n$ with common pdf $f(\mathbf{x};\theta)$.

Consider for example, the problem of testing $H_0: \theta \leq 0$ against $H_1: \theta > 0$, where θ is the **median** of a **Cauchy** density function $f(x;\theta) = \pi^{-1}[1 + (x-\theta)^2]^{-1}$, $-\infty < x < \infty$. Let $x_1, x_2, \ldots, x_n$ be n observations. It is easy to see that MP size α tests of $\theta = 0$ against $\theta = \theta_1, \theta_1 > 0$, depend on θ_1 and hence a UMP test for testing H_0 against H_1 does not exist. An LMP test of H_0 against H_1 is of form

$$\phi_0(\mathbf{x}) = \begin{cases} 1, & \text{if } \sum_{i=1}^{n} 2x_i/(1+x_i^2) > k, \\ 0, & \text{elsewhere,} \end{cases}$$

where one chooses k so that the size of ϕ_0 is α (*see* **Critical Region**).

This LMP test, although good at detecting small departures from $H_0: \theta \leq 0$, is quite unsatisfactory in detecting values of θ much larger than 0. In fact, $\beta_{\phi_0}(\theta) \to 0$ as $\theta \to \infty$ if $\alpha < 1/2$.

Locally Most Powerful Unbiased Tests

The definition of an LMP test can be extended to the case of two-sided alternatives. In general, there do not exist LMP tests for two-sided alternatives. The LMP test ϕ_0 above is trivially unbiased in some interval $[\theta_0, \theta_0 + \Delta)$. It follows that $\beta'_{\phi_0}(\theta_0) \geq 0$, suggesting that for testing $\theta = \theta_0$ against $\theta \neq \theta_0$ we seek a test ϕ_0 with power function

$$\beta_{\phi_0}(\theta_0) = \alpha, \quad \beta'_{\phi_0}(\theta_0) = 0 \quad \text{and}$$
$$\beta''_{\phi_0}(\theta_0) \text{ maximum.}$$

Such a test is called LMP unbiased of size α for testing $H_0: \theta = \theta_0$ against $H_1: \theta \neq \theta_0$.

An LMP unbiased test is of the form

$$\phi_0(\mathbf{x}) = \begin{cases} 1, & \text{if } \dfrac{\partial^2}{\partial\theta^2} f(\mathbf{x};\theta)\Big|_{\theta=\theta_0} \\ & \quad > k_1 f(\mathbf{x};\theta_0) + k_2 \dfrac{\partial}{\partial\theta} f(\mathbf{x};\theta)\Big|_{\theta=\theta_0}, \\ \boldsymbol{\gamma(\mathbf{x})}, & \text{if } \dfrac{\partial^2}{\partial\theta^2} f(\mathbf{x};\theta)\Big|_{\theta=\theta_0} \\ & \quad = k_1 f(\mathbf{x};\theta_0) + k_2 \dfrac{\partial}{\partial\theta} f(\mathbf{x};\theta)\Big|_{\theta=\theta_0}, \\ 0, & \text{if } \dfrac{\partial^2}{\partial\theta^2} f(\mathbf{x};\theta)\Big|_{\theta=\theta_0} \\ & \quad < k_1 f(\mathbf{x};\theta_0) + k_2 \dfrac{\partial}{\partial\theta} f(\mathbf{x};\theta)\Big|_{\theta=\theta_0}, \end{cases}$$

where k_1, k_2, and $\gamma(\cdot)$ are chosen to satisfy $\beta_{\phi_0}(\theta_0) = \alpha$ and $\beta'_{\phi_0}(\theta_0) = 0$.

For the Cauchy density function in the first section, the critical region of the LMP test is the set of points $\mathbf{x}$ such that

$$2\sum_{i=1}^{n} \frac{x_i^2 - 1}{(1 + x_i^2)^2} + \left[\sum_{i=1}^{n} \frac{2x_i}{1 + x_i^2}\right]^2 > k_1,$$

where k_1 is chosen to satisfy $\beta_{\phi_0}(\theta_0) = \alpha$. This test is not a two-sided version of the LMP test given in the first section.

Locally Most Powerful Invariant Tests

Similar considerations apply when attention is restricted to the class of tests that are invariant under a group of transformations on the sample space. Then it is sufficient to consider test statistics that are functions of the maximal invariant and local optimality criteria may be applied to its density.

Consider, for example, the **nonparametric** two-sample problem. Let $X_1, X_2, \ldots, X_m$ and $Y_1, Y_2, \ldots, Y_n$ be random samples from respective (continuous) distribution functions F and G. Suppose we wish to test $\mathrm{H}_0\colon F(x) \geq G(x)$ for all x against $\mathrm{H}_1\colon F(x) \leq G(x)$ for all x [$F(x) \neq G(x)$ for some x]. Restricting attention to the **sufficient statistics** $X_{(1)} < X_{(2)} < \cdots < X_{(m)}$ and $Y_{(1)} < Y_{(2)} < \cdots < Y_{(n)}$, the problem is invariant under continuous monotone transformations and a maximal invariant is the set of ranks $(R_1, R_2, \ldots, R_m, S_1, S_2, \ldots, S_n)$, where $R_i =$ **rank** of X_i in the combined sample and $S_j =$ rank of Y_j in the combined sample. Invariance considerations lead us to focus attention on tests that depend only on $R_1, R_2, \ldots, R_m$. Again, a UMP rank test of H_0 does not exist, but one can obtain LMP rank tests.

Suppose, for example, that we fix g, the probability density function corresponding to G and consider the location problem of testing $\mathrm{H}_0\colon f(x) = g(x)$ against $\mathrm{H}_1\colon f(x) = g(x - \theta)$ for values of $\theta > 0$. Then the methods of the first section lead to the LMP test: reject $\mathrm{H}_0\colon \theta = 0$ against $\mathrm{H}_1\colon \theta > 0$ for large values of the linear rank statistic $\sum_{i=1}^{m} a(R_i)$, where

$$a(i) = E\left[-\frac{g'(G^{-1}(U_{(i)}))}{g(G^{-1}(U_{(i)}))}\right], \quad i = 1, 2, \ldots, m,$$

and $U_{(1)} < U_{(2)} < \cdots < U_{(N)}$ are the **order statistics** for a random sample of size $N = m + n$ from a **uniform** (0, 1) distribution. The special case when g is normal (0, 1) leads to the well-known Fisher–Yates test (*see* **Normal Scores**), while when g is logistic, the resulting test is the **Wilcoxon–Mann–Whitney test**.

LMP rank tests are especially useful when the data are **censored**. Rank tests with type II censored data have been discussed by Johnson [4] and Mehrotra et al. [6], and by Prentice [12] and Peto & Peto [10] for arbitrarily censored data.

Ferguson [1, Sections 5.5 and 5.7] is an easily accessible source for LMP tests. Both Lehmann [5] and Schmetterer [14, Section III.6], give a more measure-theoretic treatment. Hájek & Šidák [2, Section III.4] give a fairly general treatment of LMP rank tests for various hypotheses of invariance. At a somewhat lower level, one can refer to Randles & Wolfe [13, Section 9.1]. For the multiparameter case, see Isaacson [3], Schmetterer [14], Neyman [7], and Neyman & Pearson [9].

Location–Scale Family

A set of random variables $X_1, \ldots, X_n$ is said to have a location–scale family distribution with parameter (μ, σ) if their joint cumulative distribution function (cdf) can be expressed as

$$F(x_1, \ldots, x_n|\mu, \sigma) = F\left(\frac{x_1 - \mu}{\sigma}, \ldots, \frac{x_n - \mu}{\sigma}\right), \quad \mu \text{ real}, \sigma > 0,$$

for some cdf $F(\cdot)$. Equivalently $(X_1, \ldots, X_n)$ has a location–scale family with parameter (μ, σ) if the joint cdf of $(T_1, \ldots, T_n)$ is $F(t_1, \ldots, t_n)$, where $T_i = (X_i - \mu)/\sigma$, $F(t_1, \ldots, t_n)$ is any n-dimensional cdf, and different $F(\cdot)$s correspond to different location–scale families. The parameter μ is the location parameter and σ is the scale parameter. The parameter (μ, σ) is defined as the location-scale parameter of a random variable X if and only if the distribution of $(x - \mu)/\sigma$ under (μ, σ) is free from μ and σ.

From any location–scale family of distributions, two important subfamilies are obtained; namely, a location family with the parameter μ when σ is fixed (and without loss of generality $\sigma = 1$), and a scale family with the parameter σ when μ is fixed (and without loss of generality $\mu = 0$).

Corresponding to any location–scale family $F(x_1, \ldots, x_n|\mu, \sigma)$, the member of the family with $\mu = 0$ and $\sigma = 1$ has a cdf $F(x_1, \ldots, x_n)$ and is referred to as the "standard" or "generator" of the family, generated through a group of location and scale transformations. If $F(x_1, \ldots, x_n)$ has a probability density function (pdf) $f(x_1, \ldots, x_n)$ with respect to a Lebesgue measure, then the continuous location–scale family has a pdf

$$\frac{1}{\sigma^n} f\left(\frac{x_1 - \mu}{\sigma}, \ldots, \frac{x_n - \mu}{\sigma}\right).$$

Some important examples of location–scale family distributions are **uniform** $(\mu - \sigma, \mu + \sigma)$, **normal** (μ, σ) (here σ is the standard deviation), and **Cauchy** (μ, σ).

Parameter Estimation

Least Squares Estimation

Order statistics play an important role in the estimation of μ and σ. We assume that $X_1, \ldots, X_n$ are independent, identically distributed (iid) with a location scale pdf $(1/\sigma)h[(x - \mu)/\sigma]$, where $h(\cdot)$ is known. From the property of the location–scale family, it follows that $X_i = \mu + \sigma Z_i$, $i = 1, \ldots, n$, where $Z_1, \ldots, Z_n$ are iid with pdf $h(z)$. If $Y_1, \ldots, Y_n$ are the order statistics based on $X_1, \ldots, X_n$, and $Z_{(1)}, \ldots, Z_{(n)}$ are the order statistics based on $Z_1, \ldots, Z_n$, then $Y_i = \mu + \sigma Z_{(i)}$, $i = 1, \ldots, n$. Since $h(\cdot)$ is a known pdf, $\mathrm{E}(Z_{(i)}) = \alpha_i$, and $\mathrm{cov}(Z_{(i)}, Z_{(j)}) = w_{ij}$, $i, j = 1, \ldots, n$, are known [assuming the first two moments of $h(\cdot)$ exist]. Then, we get

$$\mathrm{E}(\mathbf{Y}) = \mu\mathbf{1} + \sigma\boldsymbol{\alpha} = \mathbf{A}\boldsymbol{\theta},$$

where $\mathbf{Y} = (Y_1, \ldots, Y_n)^{\mathrm{T}}$, $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_n)^{\mathrm{T}}$, and $\mathbf{1}$ is a vector with unit elements, $\mathbf{A} = (\mathbf{1}, \boldsymbol{\alpha})$, $\boldsymbol{\theta} = (\mu, \sigma)^{\mathrm{T}}$ and $\mathrm{var}(\mathbf{Y}) = \sigma^2\mathbf{w}$, where $\mathbf{w}$ is the matrix of the elements w_{ij}. Then weighted **least squares** estimates of μ and σ are given by

$$\hat{\mu} = -\boldsymbol{\alpha}^{\mathrm{T}}\boldsymbol{\Gamma}\mathbf{Y}, \quad \hat{\sigma} = \mathbf{1}^{\mathrm{T}}\boldsymbol{\Gamma}\mathbf{Y},$$

where $\boldsymbol{\Gamma} = \boldsymbol{\Omega}(\mathbf{1}\boldsymbol{\alpha}^{\mathrm{T}} - \boldsymbol{\alpha}\mathbf{1}^{\mathrm{T}})\boldsymbol{\Omega}/\Delta$, $\boldsymbol{\Omega} = \mathbf{w}^{-1}$ and $\Delta = |\mathbf{A}^{\mathrm{T}}\boldsymbol{\Omega}\mathbf{A}|$. The variance–**covariance matrix** of these estimates is given by

$$\frac{\sigma^2}{\Delta}\begin{pmatrix} \mathbf{alpha}^{\mathbf{T}}\boldsymbol{\Omega}\boldsymbol{\alpha} & -\mathbf{1}^{\mathrm{T}}\boldsymbol{\Omega}\boldsymbol{\alpha} \\ -\mathbf{1}^{\mathrm{T}}\boldsymbol{\Omega}\boldsymbol{\alpha} & \mathbf{1}^{\mathrm{T}}\boldsymbol{\Omega}\mathbf{1} \end{pmatrix}.$$

For details, see Lloyd [6].

Minimum Risk Equivariant Estimation

Since a location–scale family is a group family (see [4, pp. 19–21]), invariance consideration plays an important role in inference. For a location family of distributions $f(x_1 - \mu, \ldots, x_n - \mu)$ and a group of location transformations, a maximal invariant statistic is given by $(x_1 - x_n, \ldots, x_{n-1} - x_n)$. This is an **ancillary statistic** since its distribution does not depend on μ.

Under a squared error **loss**, the minimum risk equivariant (MRE) estimate (if it exists) of μ is given

by (see, for example, [4, p. 160])

$$\frac{\int \mu f(x_1 - \mu, \ldots, x_n - \mu)\, \mathrm{d}\mu}{\int f(x_1 - \mu, \ldots, x_n - \mu)\, \mathrm{d}\mu}, \tag{1}$$

and is known as the Pitman estimate of μ. If $X_1, \ldots, X_n$ are iid $\mathrm{N}(\mu, \sigma)$ with σ known, then the above estimate reduces to $\overline{x}$. In this case, it is also the uniformly **minimum variance unbiased estimate** (UMVUE) of μ.

Similarly, for a scale family of distributions $(1/\sigma^n) f(x_1/\sigma, \ldots, x_n/\sigma)$ and a group of scale transformations, a maximal invariant statistic is given by $(x_1/x_n, \ldots, x_{n-1}/x_n, x_n/|x_n|)$ (see [4, p. 174]) which is an ancillary statistic. Under the loss function $(a/\sigma^r - 1)^2$, the MRE estimate (if it exists) of σ^r is given by (see, [4, p. 177])

$$\frac{\int_0^\infty \sigma^{n+r-1} f(\sigma x_1, \ldots, \sigma x_n)\, \mathrm{d}\sigma}{\int_0^\infty \sigma^{n+2r-1} f(\sigma x_1, \ldots, \sigma x_n)\, \mathrm{d}\sigma}. \tag{2}$$

For $X_1, \ldots, X_n$ iid $\mathrm{N}(0, \sigma)$ and $r = 2$, the above estimate reduces to $\sum x_i^2/(n+2)$.

For a location–scale family of distributions $(1/\sigma^n) f[(x_1 - \mu)/\sigma, \ldots, (x_n - \mu)/\sigma]$ and a group of location–scale transformations, a maximal invariant statistic is given by (see [4, p. 179])

$$\left(\frac{x_1 - x_n}{x_{n-1} - x_n}, \ldots, \frac{x_{n-2} - x_n}{x_{n-1} - x_n}, \frac{x_{n-1} - x_n}{|x_{n-1} - x_n|} \right).$$

Estimation of $\beta\mu + \gamma\sigma$ for known β and γ is important. (The case $\beta = 1$, $\gamma = 0$, corresponds to the estimation of μ, whereas $\beta = 0$, $\gamma = 1$, corresponds to the estimation of σ, and $\beta = 1$ and given γ corresponds to the estimation of a certain percentile.)

Under an invariant loss function $L(\mu, \sigma, a) = w[(a - \beta\mu - \gamma\sigma)/\sigma]$, the MRE estimator (if it exists) of $\beta\mu + \gamma\sigma$ has been discussed in detail in Datta & Ghosh [2]. For the loss function $w(x) = x^2$, and for $X_1, \ldots, X_n$ iid $\mathrm{N}(\mu, \sigma)$, the MRE estimator of $\beta\mu + \gamma\sigma$ is given by $\beta\overline{X} + \gamma k S$, where

$$k = \frac{(n-1)^{1/2}\Gamma(n/2)}{\sqrt{2}\Gamma[(n+1)/2]},$$

$$S^2 = \frac{1}{n-1}\sum (X_i - \overline{X})^2$$

(see [3, p. 182]). The UMVUE of μ and σ^2 for the $\mathrm{N}(\mu, \sigma)$ problem are $\overline{X}$ and S^2, respectively.

It follows from Berger [1, p. 410] that the MRE estimates for μ in (1), for σ^r in (2), and for $\beta\mu + \gamma\sigma$ are generalized Bayes estimates with respect to the right invariant Haar density for the respective group of location, scale, and location–scale transformations (*see* **Decision Theory**).

Hypothesis Tests

To test for location and scale parameters, the most widely used assumption is that $X_1, \ldots, X_n$ are iid $\mathrm{N}(\mu, \sigma)$. In this setup, to test $\mathrm{H}_0 : \mu = \mu_0$ vs. $\mathrm{H}_1 : \mu \neq \mu_0$, for example, the rejection region for known σ is

$$\left| \frac{n^{1/2}(\overline{X} - \mu_0)}{\sigma} \right| \geq z_{\frac{\alpha}{2}},$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$th percentile point of a **standard normal** distribution. For unknown σ, the corresponding rejection region is obtained by replacing σ and $z_{\alpha/2}$ in the preceding rejection region by S and $t_{\alpha/2}$, the $100(1 - \alpha/2)$th percentile point of **Student's *t* distribution**, with $n - 1$ degrees of freedom, respectively. The above tests can be shown to be uniformly most powerful unbiased (UMPU) tests and can be derived as **likelihood ratio tests**. To test for $\sigma^2, \mathrm{H}_0 : \sigma^2 = \sigma_0^2$ vs. $\mathrm{H}_1 : \sigma^2 \neq \sigma_0^2$, the widely used test which rejects if

$$\frac{(n-1)S^2}{\sigma_0^2} \leq \chi^2_{\frac{1-\alpha}{2}} \quad \text{or} \quad \frac{(n-1)S^2}{\sigma_0^2} \geq \chi^2_{\frac{\alpha}{2}}$$

is an approximate (for large n) UMPU size α test, where $\chi^2_{\alpha/2}$ is the $100(1 - \alpha/2)$th percentile of the χ^2_{n-1} distribution (**chi-square distribution** with $n - 1$ **degrees of freedom**). For details on these tests and other distribution-free tests for the location and scale parameters, the reader is referred to Lehmann [5].

GAURI SANKAR DATTA

Logistic Distribution

The logistic **random variable** X with mean μ and variance σ^2 has a cumulative distribution function

$$F(x, \mu, \sigma) = \left\{1 + \exp\left[\frac{-\pi(x-\mu)}{(\sigma\sqrt{3})}\right]\right\}^{-1}, \quad -\infty < x < \infty, \quad -\infty < \mu < \infty, \quad \sigma > 0, \tag{1}$$

and density function f, which is simply related to its distribution function by

$$f(x, \mu, \sigma) = \frac{\pi}{\sigma\sqrt{3}} F(x, \mu, \sigma)[1 - F(x, \mu, \sigma)]. \tag{2}$$

We denote this distribution by $\mathcal{L}(\mu, \sigma^2)$. These functions may also be expressed as

$$F(x, \mu, \sigma) = \frac{1}{2}\left\{1 + \tan h\left[\frac{\pi}{2}\frac{(x-\mu)}{(\sigma\sqrt{3})}\right]\right\} \tag{3}$$

and

$$f(x, \mu, \sigma) = \frac{\pi}{4\sigma\sqrt{3}} \operatorname{sech}^2\left[\frac{\pi}{2}\frac{(x-\mu)}{(\sigma\sqrt{3})}\right], \tag{4}$$

with the latter expression providing the logistic with the sech-square(d) distribution label. The density f is bell-shaped and symmetrical, with heavier tails than a normal density with the same mean and variance.

To describe some of the basic properties of the logistic distribution, it is simpler to use the "canonical form", $\mathcal{L}(0, \pi^2/3)$, which corresponds to the random variable Z, with mean $\mu = 0$ and variance $\sigma^2 = \pi^2/3$, and has cumulative distribution and density functions

$$G(z) = \frac{1}{1 + \mathrm{e}^{-z}}, \tag{5}$$

$$g(z) = G(z)[1 - G(z)], \tag{6}$$

and a monotonic *hazard* function

$$\lambda(z) = \frac{g(z)}{1 - G(z)} = G(z). \tag{7}$$

Eq. (6), and therefore (2), characterizes the logistic distribution and is equivalent to the linearity of the **transformation**

$$\log\left[\frac{G(z)}{1 - G(z)}\right] = z. \tag{8}$$

This transformation, which is labeled *logit* by Berkson [7], is perhaps the single best known and most popular application of the logistic distribution, especially in the context of modeling **quantal response** data, and performing **logistic regression**.

The distribution function of the standardized random variable $Z/(\pi/\sqrt{3})$, is very close to the **standard normal** distribution, and even closer to the distribution function of a normal random variable with zero mean and standard deviation 15/16 [32]. However, this distribution function is even better approximated by that of a standardized **Student's *t* distribution** with nine **degrees of freedom** [38]. Moreover, unlike the normal distribution, the sum of independent logistic random variables is not a logistic random variable. Goel [23] and George & Mudholkar [19] give closed-form expressions for the distribution function, and the latter authors also propose a simple Student's t approximation.

Characteristic Function

The **characteristic function** of Z may be expressed in the forms

$$\phi_Z(t) = \Gamma(1 - it)\Gamma(1 + it) = \prod_{j=1}^{\infty}\left(1 - \frac{t^2}{j^2}\right)^{-1} \tag{9}$$

and

$$\phi_Z(t) = \sum_{k=1}^{\infty}(-1)^{k-1}\frac{2(2^{2k} - 1)}{(2k)!}B_{2k}(\pi i t)^{2k}, \tag{10}$$

where the B_{2k}s are Bernoulli numbers [54]. The characteristic function (9), or direct integration, may be used to obtain the absolute **moments**

$$\mathrm{E}|Z|^k = 2\Gamma(k+1)\left[1 - \frac{1}{2^{k+1}}\zeta(k)\right], \tag{11}$$

where $\zeta(k) = \sum_{j=1}^{\infty} j^{-k}$, is the zeta function.

From (9), we get the following equalities in distribution [18]:

$$Z \stackrel{\mathcal{D}}{=} \sum_{j=1}^{\infty} W_j$$
$$\stackrel{\mathcal{D}}{=} \sum_{j=1}^{\infty} (E_{1j} - E_{2j}) \stackrel{\mathcal{D}}{=} Y_1 - Y_2, \qquad (12)$$

where the W_js are independent Laplace or double exponential random variables, and the E_{ij}s are independent **exponential** random variables with respective densities $f_{W_j}(w) = (j/2)\exp(-j|w|), -\infty < \omega < \infty$, $f_{E_{ij}}(x) = j\exp(-jx), i = 1, 2; j = 1, 2, \ldots$ and Y_1, Y_2 are iid **extreme value** random variables with density $h(y) = e^{-y}\exp(-e^{-y}), -\infty < y < \infty$. The logistic distribution is also obtained from a mixture of the extreme value distribution and the exponential distribution [13]. From (12) we may conclude immediately that the logistic distribution is infinitely divisible.

Order Statistics

Let $Z_{1:n} \le Z_{2:n} \le \cdots \le Z_{n:n}$ be **order statistics** of a random sample from $\mathcal{L}(0, \pi^2/3)$. Then it can be shown that the characteristic function of $Z_{r:n}$ may be expressed as

$$\phi_{r:n}(t) = \prod_{j=1}^{r-1}\left(1 + \frac{it}{j}\right)\prod_{k=1}^{n-r}\left(1 - \frac{it}{k}\right)\phi_Z(t) \qquad (13)$$

(see [10, 28, 46], and [47]). Consequently,

$$Z_{r:n} + \sum_{k=1}^{n-r} E_{1k} - \sum_{j=1}^{r-1} E_{2j} \stackrel{\mathcal{D}}{=} Z_1, \qquad (14)$$

where the E_{ij}s are independent exponential random variables with densities $f_{E_{ij}}$ given above, $i = 1, 2$, $j = 1, \ldots, n-1$. Gupta & Shah [28] provide percentage points for the rth order statistics, $Z_{r:n}$, for $1 \le n \le 25$. Shah [52] and Gupta & Balakrishnan [27] provide an extensive list of recurrence relations for the moments of order statistics of the logistic distribution. Gupta & Shah [29] and Malik [37] give closed-form expressions for the **range**, $R_n = Z_{n:n} - Z_{1:n}$, and the rth quasi-range, $Z_{n-r:n} - Z_{r+1:n}$. By expressing the distribution of the range in terms of an associated Legendre function, George & Rousseau [22] obtain the recurrence relation

$$nP(R_{n+2} \le x) = (2n+1)\left(\frac{1 + e^{-x}}{1 - e^{-x}}\right) \times \Pr(R_{n+1} \le x) - (n+1) \times \Pr(R_n \le x). \qquad (15)$$

George & Rousseau [21] show that the characteristic function of the midrange $(Z_{n:n} + Z_{1:n})/2$ is a well-poised hypergeometric function, which may be expressed as

$$\varphi_n(t) = \begin{cases} \prod_{j=1}^{p-1}\left(1 + \frac{t^2}{4j^2}\right)[\phi_Z\left(\frac{t}{2}\right)]^2, \\ \qquad \text{if } n = 2p, \\ \prod_{j=1}^{p}\left[1 + \frac{t^2}{(2j-1)^2}\right]\phi_Z(t), \\ \qquad \text{if } n = 2p+1, \end{cases} \qquad (16)$$

and obtain a closed-form expression for its distribution. For a sample of size three, they establish the rather interesting relationship

$$\frac{Z_{1:3} + Z_{3:3}}{2} \stackrel{\mathcal{D}}{=} Z_{2:3}. \qquad (17)$$

Gumbel [24], relating the logistic to extreme value distributions, shows that, for a large family of symmetric distributions satisfying a general set of conditions that are formalized by de Haan [11], the limiting distribution of the midrange is logistic [17]. This result is extended by Gumbel to the "mth midrange", i.e. $(Z_{m:n} + Z_{n-m+1:n})/2$. In this case, the asymptotic distribution is generalized logistic. Gumbel & Keeney [26] show that the logistic is the asymptotic distribution of a family of extremal quotients.

Generalized Logistic

It is easy to see that if U is **uniformly distributed** on the unit interval (0,1), then the logit transform of U, $\log\left[U/(1-U)\right]$, has the logistic distribution function G. In fact, one of the many generalizations of the logistic distribution is obtained by simply replacing the uniform random variable U (which is equal in distribution to a **beta** (1,1) random variable), with a beta

(α, β) random variable, [20, 48]. When $\alpha = \beta$, the symmetric generalized logistic is obtained. Like the logistic distribution, the generalized logistic is used for modeling binary response data [48] and the log of survival times [35]. In the context of application to quantal assay data, Stukel [53] proposes another generalization of the logistic distribution by introducing different shape parameters at the tails of the distribution (*see* **Quantal Response Models**).

Parametric Estimation

The simplicity of the logistic distribution, as expressed by (1)–(6), belies the complexity of the process of estimating its parameters. No closed forms exist for the MLE (**maximum likelihood** estimator), BLUE (best linear **unbiased** estimators), or UMVUE (uniform **minimum variance unbiased estimators**) of the mean μ and variance σ^2. For example, given a random sample $X_1, \ldots, X_n$ from an $\mathcal{L}(\mu, \sigma^2)$ population, the estimating equations for the MLE of μ and σ^2, which must be solved iteratively, may be expressed by

$$\frac{1}{n}\sum_{i=1}^{n}\frac{1}{1+\exp[\pi(X_i-\mu)/(\sigma\sqrt{3})]}=\frac{1}{2} \tag{18}$$

and

$$\frac{1}{n}\sum_{i=1}^{n}\left(\frac{X_i-\mu}{\sigma}\right)\left(\frac{1-\exp\left[\dfrac{\pi(X_i-\mu)}{(\sigma\sqrt{3})}\right]}{1+\exp[\pi(X_i-\mu)/(\sigma\sqrt{3})]}\right)=\frac{\sqrt{3}}{\pi}. \tag{19}$$

From Gupta & Gnanadesikan [28] (in which explicit approximate expressions for the BLUE estimates of μ and σ are given based on selected order statistics $X_{n_1:n} \le X_{n_2:n} \le \cdots \le X_{n_k:n}$), Gupta et al. [30] and Harter & Moore [31] (in which linear estimates are calculated from censored data), a vast literature has evolved on the use of **censored** logistic random variables to estimate μ and σ. Using the large sample variance–**covariance matrix** of the MLEs, Antle et al. [1] construct **confidence intervals** for μ and σ. Bain [4], Eastman [14], Schafer & Sheffield [50], and Bain et al. [5] discuss applications in life-testing using complete and censored data. Other accounts involving the use of linear functions of order statistics for estimating the logistic parameters are given by several authors in Balakrishnan [6, Chapter 4].

Multivariate Distributions

A model for a **bivariate distribution** with logistic marginals first proposed by Gumbel [25] is extended by Malik & Abraham [38] to an m-dimensional multivariate distribution function

$$F_{\mathbf{Z}}(\mathbf{z}) = F_{Z_1,\ldots,Z_m}(z_1,\ldots,z_m) = \left(1+\sum_{i=1}^{m}\exp(-z_i)\right)^{-1}, \tag{20}$$

with density function

$$f_{\mathbf{Z}}(\mathbf{z}) = m!\frac{\exp\left(-\sum_{i=1}^{m}z_i\right)}{\left[1+\sum_{i=1}^{m}\exp(-z_i)\right]^{m+1}}, \tag{21}$$

where $\mathbf{Z} = (Z_1, \ldots, Z_m)$ and $\mathbf{z} = (z_1, \ldots, z_m)$. This distribution, which is sometimes referred to as the Gumbel–Malik–Abraham model, suffers from the restriction that the **correlation** between any pair Z_i, Z_j, is 1/2.

The joint **moment generating function** of $\mathbf{Z}$ is given by

$$M_{\mathbf{Z}}(t_1,\ldots,t_m) = \Gamma\left(1+\sum_{j=1}^{m}t_j\right)\prod_{j=1}^{m}\Gamma(1-t_j). \tag{22}$$

From this generating function, Arnold [3] observes that, analogous to the univariate logistic distribution, the joint distribution of $(Z_1, \ldots, Z_m)$ is the same distribution as $(Y_1 - Y_0, \ldots, Y_m - Y_0)$, where $Y_0, Y_1, \ldots, Y_m$ are independent, identically distributed (iid) extreme value random variables with density given by $h(y) = \mathrm{e}^{-y}\exp(-\mathrm{e}^{-y})$, $-\infty < y < \infty$.

The Gumbel–Malik–Abraham model is one example of a multivariate logistic distribution that can be constructed by using a multivariate analog of a property of the univariate logistic distribution. Others are described by Arnold [3]. These include

a representation in terms of a multivariate survival function:

$$\Pr(\mathbf{Z} \geq \mathbf{z}) = \left[1 + \sum_{j=1}^{m} \exp(z_i) + \sum_{j_1 \neq j_2} c_{j_1 j_2} \exp(z_{j_1} + z_{j_2}) + \cdots + c_{1\ldots m} \exp(z_1 + z_2 + \cdots + z_m) \right]^{-1}, \quad (23)$$

where $\mathbf{Z} \geq \mathbf{z}$ denotes the event $Z_1 \geq z_1, Z_2 \geq z_2, \cdots, Z_m \geq z_m$ and the cs are chosen to satisfy conditions that make (23) a true survival function [2] (*see* **Survival Distributions and Their Characteristics**). This expression can be obtained from a multivariate analog of the following result: if $Z_1, Z_2, \ldots,$ are iid $\mathcal{L}(0, \pi^2/3)$ variables and N is a **geometric** random variable with $\Pr(N = n) = pq^{n-1}$, $q = 1 - p$, then

$$Z_{1;N} - \log p \stackrel{\mathcal{D}}{=} Z_{N;N} + \log p \stackrel{\mathcal{D}}{=} Z_1. \quad (24)$$

Eq. (23) clearly generalizes the Gumbel–Malik–Abraham representation. As an example, the bivariate logistic distribution function obtained from (23) is given by

$$F_{Z_1, Z_2}(z_1, z_2) = [1 + \exp(-z_1) + \exp(-z_2) + \theta \exp(-z_1 - z_2)]^{-1}, \quad (25)$$

where $0 \leq \theta \leq 2$.

Another representation given by Arnold [3] uses the concept of **frailty** from survival analysis to obtain

$$\Pr(\mathbf{Z} \geq \mathbf{z}) = \Lambda_F \left\{ \sum_{j=1}^{m} \Lambda_F^{-1}[1 + \exp(z_j)]^{-1} \right\}, \quad (26)$$

where Λ_F denotes the Laplace transform of a given distribution function F. Using distribution functions instead of survival functions leads to a different, but related, family of multivariate logistic distribution functions

$$\Pr(\mathbf{Z} \leq \mathbf{z}) = \Lambda_F \left\{ \sum_{j=1}^{m} \Lambda_F^{-1}[1 + \exp(-z_j)]^{-1} \right\}. \quad (27)$$

Examples of multivariate logistic distributions from these models are:

$$\Pr(\mathbf{Z} \geq \mathbf{z}) = \left\{ \sum_{j=1}^{m} [1 + \exp(z_j)]^{(1/\alpha)} - m + 1 \right\}^{-\alpha} \quad (28)$$

and

$$\Pr(\mathbf{Z} \leq \mathbf{z}) = \left\{ \sum_{j=1}^{m} [1 + \exp(-z_j)]^{(1/\alpha)} - m + 1 \right\}^{-\alpha}, \quad (29)$$

corresponding to a choice of **gamma** $(\alpha, 1)$ for F and

$$\Pr(\mathbf{Z} \leq \mathbf{z}) = \exp\left[- \left(\sum_{j=1}^{m} \{\log[1 + \exp(-z_j)]\}^{(1/\alpha)} \right)^{\alpha} \right], \quad (30)$$

corresponding to choosing $\Lambda_F(t) = \exp(-t^\alpha)$, $\alpha \leq 1$.

The Farlie–Gumbel–Morgenstern model of a multivariate logistic [3, 33, 34] is yet another representation. This model may be described by

$$\Pr(\mathbf{Z} \leq \mathbf{z}) = \prod_{j=1}^{m} G(z_j) \left\{ 1 + \alpha \prod_{j=1}^{m} [1 - G(z_j)] \right\}, \quad (31)$$

where $|\alpha| < 1$ and $G(z) = (1 + \mathrm{e}^{-z})^{-1}$. This model suffers from a restriction in correlation: $\rho(Z_i, Z_j) = 3\alpha/\pi^2$ for every pair Z_i, Z_j. The correlation structure limits the use of the model. The bivariate version of this model is due to Gumbel [25].

Historical Notes and Applications

The logistic function is one of the oldest models for analyzing **demographic** and organismic growth data. Verhulst [56], Pearl [43, 44], Pearl & Reed [45], Yule [57], and, more recently, Oliver [41, 42] and Leach [36] discuss applications to **population growth**. Other biological applications of the logistic function include the modeling of the growth of yeast cells [40, 45, 51] and the use of the logistic function in analysis of survival data [47].

Reed & Berkson [49], who are usually credited with the logit label, for the inverse transformation of the logistic function, and Berkson [7–9] have championed the use of the logistic distribution function for modeling **dose–response** curves in **bioassay** (see also Finney [15, 16]). Berkson's minimum logit chi-square estimates are easier to compute than maximum likelihood estimates. However, with the availability of sophisticated software, this is no longer a significant advantage over the efficiency of the maximum likelihood estimates. From the limited use of the logistic distribution for quantal bioassay has emerged logistic regression analysis, which is currently a very popular **generalized linear model** procedure for analyzing **binary data**. In the context of applications of logistic regression to health and social sciences, Tsokos & DiCroce [55] give an extensive bibliography. Prentice [48] Stukel [53], Devidas, et al. [12] and others discuss applications of generalizations of the logistic models in low-dose bioassays.

Logistic Regression, Conditional

An important extension of the **logistic regression** model is the analysis of data from stratified samples (*see* **Stratification**). Examples of this application include studies where data are collected from several different sites such as schools, hospitals, or clinics as well as analyses where **covariates** are controlled for by defining *post hoc* stratification variables. The most frequently encountered stratified study design employing the logistic regression model is the matched **case–control study** used in epidemiology (*see* **Matched Analysis**). A discussion of the rationale for these matched studies may be found in epidemiology texts such as Breslow & Day [1], Kleinbaum et al. [5], Schlesselman [8], Kelsey et al. [4], and Rothman [7].

The basic idea is to expand the logistic model by inclusion of stratification variables. Assume the sampled data may be represented as a triple $(y_{kj}, \mathbf{x}_{kj}, \mathbf{z}_k)$, where $j = 1, 2, \ldots, n_k$ represents the particular subject observed within stratum $k = 1, 2, \ldots, K$, $y_{kj} = 0$ or 1 is the observed value of the binary outcome variable for subject j in stratum k, $\mathbf{x}'_{kj} = (x_{kj1}, x_{kj2}, \ldots, x_{kjp})$ is a vector of p nonconstant covariates, and $\mathbf{z}'_k = (z_{k1}, z_{k2}, \ldots, z_{kq})$ is a vector of q covariates defining stratum characteristics. The quantity n_k denotes the number of observations in stratum k. The vector $\mathbf{z}$ may simply contain one variable to indicate the stratum, $z_k = k$, or a set of values of q covariates may be used to define strata. For example, if one defined strata by gender and race coded at three levels, then $\mathbf{z}'_k = (z_{k1}, z_{k2})$ with $z_{k1} = 0$ or 1, $z_{k2} = 1$, 2, or 3, and $k = 1, 2, \ldots, 6$.

A number of different stratified logistic regression models are possible. The simplest logistic regression model has a logit function with one design variable for the stratum specific effect and constant slope across strata for the covariates, namely

$$g(\mathbf{x}_{kj}, z_k) = \beta_0 + \alpha_k + \boldsymbol{\beta}'\mathbf{x}_{kj}. \tag{1}$$

The logit function is discussed in detail in the article on **Logistic Regression**. It is defined in terms of the model conditional probability as $g(\mathbf{x}_{kj}, z_k) = \ln\{\pi(\mathbf{x}_{kj}, z_k)/[1 - \pi(\mathbf{x}_{kj}, z_k)]\}$ and $\pi(\mathbf{x}_{kj}, z_k) = \Pr(Y_{kj} = 1|\mathbf{x}_{kj}, z_k)$. In the parameterization in (1) one may think of the values of α_k as the coefficients for design variables generated by the K levels of the stratum variable. These design variables may be created using any method but the most frequent choice is either referent cell or deviation from means coding. There are $K - 1$ parameters or degrees of freedom associated with the stratification variable. The model in (1) has a stratum-specific intercept and constant slopes. Thus the effect of the covariates is the same for all strata. The covariate vector, $\mathbf{x}$, may contain both main effects as well as higher-order terms such as interactions and squared terms, but may not contain terms that indicate the stratum.

An extension of the model in (1) is possible when the vector $\mathbf{z}$ contains covariates that measure stratum characteristics, e.g. gender and race as noted above. The vector may also contain continuous covariates. Age is often used as a stratification variable. In this setting one may add interactions to (1), which yield a model with stratum-specific slopes. Suppose strata are defined by gender and $z_k = 0$ or $1(1 = \text{male})$ records the gender of the subject. The logit for an extended model is

$$g(\mathbf{x}_{kj}, z_k) = \beta_0 + \alpha_k z_k + \boldsymbol{\beta}'\mathbf{x}_{kj} + z_k \times \boldsymbol{\gamma}'\mathbf{x}_{kj}. \tag{2}$$

The model for females is

$$g(\mathbf{x}_{kj}, z_k = 0) = \beta_0 + \boldsymbol{\beta}'\mathbf{x}_{kj},$$

and the model for males is

$$g(\mathbf{x}_{kj}, z_k = 1) = \beta_0 + \alpha_1 + (\boldsymbol{\beta} + \boldsymbol{\gamma})'\mathbf{x}_{kj}.$$

The model in (2) allows for stratum-specific intercepts as well as stratum-specific slopes. Maximum likelihood estimators of the parameters in (1) or (2) are obtained by extending the likelihood function (*see* **Logistic Regression**) to include a product over strata. The **likelihood** function for the model in (1) is

$$l(\alpha, \beta,) = \prod_{k=1}^{K} \prod_{j=1}^{n_k} \zeta(\mathbf{x}_{kj}, z_k), \tag{3}$$

where $\zeta(\mathbf{x}_{kj}, z_k) = \pi(\mathbf{x}_{kj}, z_k)^{y_{kj}}[1 - \pi(\mathbf{x}_{kj}, z_k)]^{1-y_{kj}}$. Application of the likelihood function in (3) to the model in (2) is accomplished by adding the requisite additional terms to the logit. Estimators of the parameters may be obtained from logistic regression software (*see* **Software, Biostatistical**) by inclusion of the variables recording stratum-specific data into the model.

Thus the model as shown in (1) or (2) does not represent anything particularly new or difficult for the investigator familiar with the logistic regression model. The model-building issues and details are identical to those of the ordinary logistic model, or for that matter any regression model.

Problems begin to arise which require a different approach when the number of strata becomes large and, at the same time, the number of observations within each stratum remains fixed. Application of the logistic regression model to this setting will be described in the remainder of this article.

Logistic Regression with Highly Stratified Data

A convenient setting to illustrate the use of logistic regression with highly stratified data is the matched case–control study design. In this study design subjects are stratified on the basis of covariates believed to be associated with the outcome. Age and gender are examples of commonly used stratification variables. Within each stratum a sample of subjects with the outcome present, called cases ($y = 1$), and a sample of subjects without the outcome, called controls ($y = 0$), is chosen. The number of cases and controls need not be constant across strata, but the most common matched design is one where each stratum includes one case and one control. Study variables are collected on all subjects. We develop the methods for analysis of highly stratified data for the general case. Greater detail is provided for the one-to-one matched design because it can be analyzed using standard logistic regression software.

The methods to be described may be used in settings other than matched case–control studies. For example, suppose that, in a study of student performance, data were collected from 1000 different schools and a fixed number of students was selected from each school. The outcome variable is whether the student "passed" a particular course or standardized test. In this example there are 1000 strata defined by school. The conditional likelihood approach described below is the same for both the case–control study and the general highly stratified design. More stringent sampling assumptions are required in the case–control study, see [3, Chapter 6].

We begin by providing some motivation for the need for special methods for the highly stratified study. We noted in (1) that we could handle the stratified sample by including variables created from the stratification variables in the model. This approach works well when the number of subjects in each stratum is large and strata are few. However, matched studies have few subjects per stratum. For example, in the one-to-one matched design with K case–control pairs we have only two subjects per stratum. A fully stratified analysis of the model in (1) with p covariates would require estimation of $(K + p)$ parameters, the $p + 1$ slope coefficients for the covariates, and the $K - 1$ coefficients for the stratum-specific design variables, using a sample of size $2K$. The optimality properties of the method of maximum likelihood, derived by letting the sample size, K, become large, hold only when the number of parameters remains fixed. In any matched study this is not the case, as the number of parameters increases at the same rate as the sample size. For example, when analyzing a matched one-to-one design via the fully stratified likelihood in (3) using a logistic regression model containing one dichotomous covariate and the $K - 1$ design variables for strata, it can be shown (see [1, p. 250]) that the bias in the estimate of the coefficient is 100%. If we regard the stratum-specific parameters as (nuisance) parameters whose values are neither of great interest to us nor are essential for the inferences required in the study, and we are willing to forgo their estimation, then we can create a conditional likelihood which will yield maximum likelihood estimators of the slope coefficients in the logistic regression model that are consistent and asymptotically normally distributed. The mathematical details of conditional likelihood analysis may be found in [2] (*see* **Likelihood**). We summarize its application to the matched design. Liang [6], in related work, considers a general approach to the analysis of highly stratified data.

The Conditional Logistic Regression Model

Suppose that there are K strata with n_{k1} cases (subjects with $y = 1$) and n_{k0} controls (subjects with $y = 0$) in stratum k, $k = 1, 2, \ldots, K$. The conditional likelihood for the kth stratum is obtained as the probability of the observed data conditional on the stratum total sample size (fixed by the sampling design) and the total number of cases, the **sufficient statistic** for the stratum-specific **nuisance parameter**. This probability is the ratio of the probability of the observed

outcome to the probability for all possible assignments of n_{k1} subjects with $y = 1$ and n_{k0} subjects with $y = 0$ to $n_k = n_{k0} + n_{k1}$ subjects. The number of possible assignments is the n_k choose n_{k1} combinations. Let the subscript j denote any one of these assignments. For any assignment we let subjects 1 to n_{k1} correspond to the subjects with $y = 1$ and subjects $n_{k1} + 1$ to n_k to the subjects with $y = 0$. This will be indexed by i for the observed data and by i_j for the jth possible assignment. The contribution to the conditional likelihood for the kth stratum is

$$l_k(\boldsymbol{\beta}) = \frac{\prod_{i=1}^{n_{k1}} \Pr(y_{ki} = 1|\mathbf{x}_{ki}) \prod_{i=n_{k1}+1}^{n_k} \Pr(y_{ki} = 0|\mathbf{x}_{ki})}{\sum_j \left[\begin{array}{l} \prod_{i_j=1}^{n_{k1}} \Pr(y_{ki_j} = 1|\mathbf{x}_{ki_j}) \\ \times \prod_{i_j=n_{k1}+1}^{n_k} \Pr(y_{ki_j} = 0|\mathbf{x}_{ki_j}) \end{array} \right]}, \quad (4)$$

where the summation over j in the denominator is over the n_k choose n_{k1} combinations. The full conditional likelihood is the product of the $l_k(\boldsymbol{\beta})$ over the K strata,

$$l(\boldsymbol{\beta}) = \prod_{k=1}^{K} l_k(\boldsymbol{\beta}). \quad (5)$$

If we substitute the logistic regression model with the logit defined in (1), $\pi(\mathbf{x}_{ki}) = \Pr(y_{ki} = 1|\mathbf{x}_{ki})$, into (4), then (5) simplifies to

$$l_k(\boldsymbol{\beta}) = \frac{\prod_{i=1}^{n_{k1}} \pi(\mathbf{x}_{ki}) \prod_{i=n_{k1}+1}^{n_k} [1 - \pi(\mathbf{x}_{ki})]}{\sum_j \left\{ \prod_{i_j=1}^{n_{k1}} \pi(\mathbf{x}_{ki_j}) \prod_{i_j=n_{k1}+1}^{n_k} [1 - \pi(\mathbf{x}_{ki_j})] \right\}}. \quad (6)$$

Since the terms of the form $\exp(\beta_0 + \alpha_k)/[1 + \exp(\beta_0 + \alpha_k + \mathbf{x}'_{ki}\boldsymbol{\beta})]$ appear equally in both the numerator and denominator of (6) they cancel out, and (6) simplifies to

$$l_k(\boldsymbol{\beta}) = \frac{\prod_{i=1}^{n_{k1}} \exp(\boldsymbol{\beta}'\mathbf{x}_{ki})}{\sum_j \left(\prod_{i_j=1}^{n_{k1}} \exp(\boldsymbol{\beta}'\mathbf{x}_{ki_j}) \right)}, \quad (7)$$

which depends only on the unknown parameter vector $\boldsymbol{\beta}$. The conditional maximum likelihood estimator for $\boldsymbol{\beta}$ is that value which maximizes (5) when the expression in (7) is used for $l_k(\boldsymbol{\beta})$. Most software packages performing logistic regression have the capability to fit this conditional logistic regression model (*see* **Software, Biostatistical**).

The argument leading to expression (7) is more complicated for a case–control study and requires assumptions about sampling of cases and controls and applications of **Bayes' theorem**. The details will not be presented here but may be found in [3, Chapters 6 and 7].

One must always keep in mind when using the conditional likelihood in (7) that it was obtained by beginning with the usual logistic regression model. Thus, one still interprets the coefficients as "log-odds ratios". The original logistic regression model (1) or (2) tends to become lost in the arithmetic process of re-expressing the likelihood in (7). This point can be especially confusing to those analyzing data from a one-to-one matched case–control study.

The one-to-one matched design is probably the most frequent example of the use of a conditional logistic regression model. We show how one may analyze this design using standard logistic regression software, since not all packages have the capability to perform conditional logistic regression. More general software must be used in other matched designs and in the general highly stratified setting.

Logistic Regression Analysis for the One-to-One Matched Study

In the one-to-one matched study there are two subjects within each stratum. To simplify the notation, let $\mathbf{x}_{k1}$ denote the covariate vector for the case and $\mathbf{x}_{k0}$ the covariate vector for the control in the kth stratum. Using this notation, the conditional likelihood, (7), for the kth stratum is

$$l_k(\beta) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_{k1})}{\exp(\boldsymbol{\beta}'\mathbf{x}_{k1}) + \exp(\boldsymbol{\beta}'\mathbf{x}_{k0})}. \quad (8)$$

Further simplification is obtained by dividing the numerator and denominator of (8) by $\exp(\boldsymbol{\beta}'\mathbf{x}_{k0})$, yielding

$$l_k(\beta) = \frac{\exp[\boldsymbol{\beta}'(\mathbf{x}_{k1} - \mathbf{x}_{k0})]}{1 + \exp[\boldsymbol{\beta}'(\mathbf{x}_{k1} - \mathbf{x}_{k0})]}. \quad (9)$$

The expression on the right-hand side of (9) is identical to a logistic regression model with the constant term set equal to zero, $\beta_0 = 0$, and covariate vector equal to the value of the case minus the value of the control, $\mathbf{x}_k^* = \mathbf{x}_{k1} - \mathbf{x}_{k0}$. This algebraic simplification allows one to use standard logistic regression software to compute the conditional maximum likelihood estimators of the coefficients and their standard errors. To accomplish this, one performs the following data modifications: define the sample size as the number of case–control pairs, compute the difference vector $\mathbf{x}_k^*$, compute a *pseudo*-response variable equal to 1, $y_k^* = 1$, and exclude the constant term from the model, e.g. force its value to be equal to zero. Thus, from a computational point of view, the one-to-one matched design presents no new challenges.

We have found that in the process of creating the differences and setting the "outcome" equal to 1, one can lose sight of the model. It is important to distinguish between the logistic regression model being fit to the data and the computational manipulations required to fit this model with standard logistic regression software. The process is less confusing if one focuses on the logistic regression model first and then considers the computations needed to obtain the parameter estimates. A few examples should help to illustrate this point.

Suppose we have a dichotomous independent variable coded zero or one. This variable is correctly modeled via a single coefficient in the logit, irrespective of whether we enter the variable via a design variable or treat it as continuous. The difference variable which we obtain by subtracting the value of the case from that of the control may take on one of three possible values: (−1, 0 or 1). If we had mistakenly thought of the difference variable as being the actual data, then we would have incorrectly modeled the variable by including two design variables in the model. The correct method is to create a difference variable and treat it as if it were continuous.

As a second example, suppose we have a variable such as race, coded at three levels. To model this variable correctly in the one-to-one matched design, we create, for each case and control in a pair, the values of the two design variables representing race. We compute the difference between these two design variables for the case and control and model each of these differences as if it were continuous. The same process is followed for any categorical scaled covariate. Note that the computer software may not recognize the differences in design variables as being created from the same variable, so one has to be sure that all design variables are included in the model. Another point to keep in mind is that differences between variables used to form strata are equal to zero for all strata and thus will not be useful as main effects. However, one may include interaction terms between stratification variables and other covariates, because differences in these interaction variables will likely not be zero.

In summary, the conceptual process for modeling matched or highly stratified data is identical to that of the usual logistic regression model. If one develops the modeling strategy for highly stratified data as if one had unstratified data, and then uses the conditional likelihood, then one will always be proceeding correctly.

Examples of the Use of the Conditional Logistic Regression Model

For illustrative purposes we use a small one-to-one matched data set obtained from a study of factors associated with the birth of a low birthweight baby (less than 2500 g). These data are in [3, Appendix 3]. These data, as well as the other data sets used in [3], may be obtained in the logistic regression menu at **internet** address `http://www-unix.oit.umass.edu/~statdata`. A one-to-one matched data set was obtained from an unmatched study of 189 births of which 59 were low weight. The matched data were obtained by randomly selecting, for each woman who gave birth to a low birthweight baby, a mother of the same age who did not give birth to a low birthweight baby. For three of the young mothers (age less than 17) it was not possible to identify a match since there were no mothers of normal weight babies of that age. The data consist of 56 age-matched case–control pairs. Variables selected for use in this example are a prior pre-term delivery (ptd, 1 = yes, 0 = no), smoking status (during pregnancy) of the mother (smoke, 1 = yes, 0 = no), history of hypertension (ht, 1 = yes, 0 = no), presence of uterine irritability (ui, 1 = yes, 0 = no), and the weight of the mother at the last menstrual period (lwt, pounds).

In ordinary logistic regression the coefficient for a model containing only one dichotomous variable is equal to the log of the cross-product ratio (odds ratio) from the **two-by-two table** of outcome by

the dichotomous variable. The same result is true when the conditional logistic model is used with a one-to-one matched study and the model contains a single dichotomous variable. The estimator of the odds ratio in a one-to-one matched study is the ratio of the frequencies of the discordant pairs. These are the frequencies in the off main diagonal cells of a 2×2 table cross-classifying the dichotomous variable for the case by the control. For example, consider the smoking status of the mother. The 2×2 table is shown in Table 1 and the results from fitting the conditional logistic regression model containing this variable are shown in Table 2. The odds ratio computed from Table 1 is $\hat{\psi} = 22/8 = 2.75$ and its log is $\ln \hat{\psi} = 1.012$. The results presented in Table 2 show that the coefficient for smoke is identically equal to the log of the odds ratio from Table 1. A confidence interval for the odds ratio may be obtained by exponentiating the end points of the confidence interval for the coefficient shown in Table 2. The resulting interval is (1.22, 6.18) indicating that, in these data, smoking during pregnancy is a risk factor for giving birth to a low birthweight baby. The significance of the coefficient may be tested using the Wald statistic (*see* **Likelihood**), labeled as z in Table 2, and whose two-tailed ***P* value** is 0.014. The appropriateness of both the confidence interval and test depend on an assumption that the sample size, 56 in this case, is large enough to employ the large-sample distributional properties (normality) of maximum likelihood estimators.

If one did not have available software specifically to perform conditional logistic regression, then the previously described method of creating difference variables could be used before beginning full-scale modeling of the data. This technique is not as important as it once was as most of the commonly available packages either have specific conditional logistic regression routines, or methods for adapting other routines are explained in their manuals. Again we wish to reinforce the point that the method of creating difference variables will only work for the one-to-one matched study. Any other design must be modeled through specific conditional logistic regression software.

We present in Table 3 the results of fitting a more complex model. The purpose of this model is to illustrate the use and interpretation of results from a multivariable conditional logistic regression model. See [3, Chapter 7] for a discussion of the issues involved in developing a model within the context of the current example and conditional logistic regression.

We obtain estimates of the odds ratios and their confidence intervals by exponentiating the estimated coefficients and end points of their confidence intervals in Table 3. These are shown in Table 4. The odds ratio and confidence interval presented for the weight of the mother at the last menstrual period is for a 10 pound increase in weight. The results for last menstrual period (lwt) are obtained from Table 3 by multiplying the coefficient and end points of the confidence interval by 10 before exponentiating. This is done since lwt is measured in pounds, and an odds ratio for a one pound weight difference is likely not to be clinically meaningful.

The odds ratios in Table 4 suggest an important increase in risk of delivering of a low birthweight baby for prior pre-term deliveries, smoking during pregnancy, presence of hypertension, and presence of uterine irritability. The odds ratio for the weight

Table 1 Cross-classification of the smoking status of the case by the control

Table 3 Results from fitting a conditional logistic regression model containing prior pre-term delivery, smoking status of the mother, presence of hypertension, presence of uterine irritability, and the weight of the mother at the last menstrual period to 56 matched pairs

Variable	Coeff.	Std. error	z	P	95% CIE
ptd	1.671	0.747	2.24	0.025	(0.207, 3.135)
smoke	1.480	0.562	2.63	0.009	(0.378, 2.582)
ht	2.330	1.003	2.32	0.020	(0.364, 4.296)
ui	1.345	0.694	1.94	0.052	(−0.015, 2.705)
lwt	−0.015	0.008	−1.88	0.060	(−0.031, 0.001)

Table 4 Estimated odds ratios and 95% confidence intervals for prior pre-term deliveries, smoking status of the mother, presence of hypertension, presence of uterine irritability, and the weight of the mother at the last menstrual period (10 lb increase)

Variable	Odds ratio	95% CIE
ptd	5.32	(1.23, 22.99)
smoke	4.39	(1.46, 13.22)
ht	10.28	(1.44, 73.41)
ui	3.84	(0.99, 14.95)
lwt	0.86	(0.73, 1.01)

of the mother at the last menstrual period suggests an approximate 14% decrease in risk per 10 pound increase in weight. This interpretation assumes that the logit is linear in lwt. One should always check the scale of all continuous variables in any regression model. We did this using a method based on design variables for the quartiles of lwt (see [3, p. 194]), which supported the linearity assumption for lwt.

The confidence interval estimates in Table 4 are quite wide for the dichotomous variables. This instability is due to the fact that the variance estimator is inversely related to the number of discordant pairs. The analysis presented in Tables 2 and 3 is based on 56 pairs and the numbers of discordant pairs are 19, 30, 10, and 16, respectively, for the dichotomous variables. The widths of the confidence intervals in Table 4 are a result of the relatively few discordant pairs. This points out an important consideration that must be kept in mind at the design stage of a study. The gain in precision obtained from matching and using conditional logistic regression may be offset by a loss owing to few discordant pairs for dichotomous covariates. In general, the variance estimator of the slope coefficient is a function of how different the subjects with $y = 1$ are from those with $y = 0$ within each stratum.

Likelihood ratio tests may be used for model testing and refinement in a manner similar to that discussed in the article on logistic regression. In the case of conditional logistic regression the likelihood for model zero, "the no data model", is obtained by setting the coefficient vector equal to zero in (7). This model is essentially a coin toss with stratum specific probability $\Pr(Y_{kj} = 1) = n_{k1}/n_k$.

Application of the conditional logistic regression model to other, more complicated, matched or highly stratified designs is, for all intents and purposes, identical to the one-to-one matched study discussed. The essential point to keep in mind is that one uses and interprets the estimated coefficients in a manner identical to ordinary logistic regression. Although not illustrated in the example, because of relatively few matched pairs, one may use matching or stratification variables to form interactions with variables in the model but one may not include them as main effect terms. Much of the content of this article is based on [3].

Logistic Regression

The goal of a logistic regression analysis is to find the best fitting and most parsimonious, yet biologically reasonable, model to describe the relationship between an outcome (dependent or response variable) and a set of independent (predictor or explanatory) variables. What distinguishes the logistic regression model from the **linear regression** model is that the outcome variable in logistic regression is categorical and most usually *binary* or *dichotomous* (*see* **Binary Data**).

In any regression problem the key quantity is the mean value of the outcome variable, given the value of the independent variable. This quantity is called the *conditional mean* and will be expressed as $\mathrm{E}(Y|x)$, where Y denotes the outcome variable and x denotes a value of the independent variable. In linear regression we assume that this mean may be expressed as an equation linear in x (or some transformation of x or Y), such as

$$\mathrm{E}(Y|x) = \beta_0 + \beta_1 x.$$

This expression implies that it is possible for $\mathrm{E}(Y|x)$ to take on any value as x ranges between $-\infty$ and $+\infty$.

Many distribution functions have been proposed for use in the analysis of a dichotomous outcome variable. Cox & Snell [2] discuss some of these. There are two primary reasons for choosing the logistic distribution. These are: (i) from a mathematical point of view it is an extremely flexible and easily used function, and (ii) it lends itself to a biologically meaningful interpretation.

To simplify notation, let $\pi(x) = \mathrm{E}(Y|x)$ represent the conditional mean of Y given x. The logistic regression model can be expressed as

$$\pi(x) = \frac{\exp(\beta_0 + \beta_1 x)}{1 + \exp(\beta_0 + \beta_1 x)}. \qquad (1)$$

The *logit transformation*, defined in terms of $\pi(x)$, is as follows:

$$g(x) = \ln\left[\frac{\pi(x)}{1 - \pi(x)}\right] = \beta_0 + \beta_1 x. \qquad (2)$$

The importance of this transformation is that $g(x)$ has many of the desirable properties of a linear regression model. The logit, $g(x)$, is linear in its parameters, may be continuous, and may range from $-\infty$ to $+\infty$ depending on the range of x.

The second important difference between the linear and logistic regression models concerns the conditional distribution of the outcome variable. In the linear regression model we assume that an observation of the outcome variable may be expressed as $y = \mathrm{E}(Y|x) + \varepsilon$. The quantity ε is called the *error* and expresses an observation's deviation from the conditional mean. The most common assumption is that ε follows a normal distribution with mean zero and some variance that is constant across levels of the independent variable. It follows that the conditional distribution of the outcome variable given x is normal with mean $\mathrm{E}(Y|x)$, and a variance that is constant. This is not the case with a dichotomous outcome variable. In this situation we may express the value of the outcome variable given x as $y = \pi(x) + \varepsilon$. Here the quantity ε may assume one of two possible values. If $y = 1$, then $\varepsilon = 1 - \pi(x)$ with probability $\pi(x)$, and if $y = 0$, then $\varepsilon = -\pi(x)$ with probability $1 - \pi(x)$. Thus, ε has a distribution with mean zero and variance equal to $\pi(x)[1 - \pi(x)]$. That is, the conditional distribution of the outcome variable follows a binomial distribution with probability given by the conditional mean, $\pi(x)$.

Fitting the Logistic Regression Model

Suppose we have a sample of n independent observations of the pair $(x_i, y_i), i = 1, 2, \ldots, n$, where y_i denotes the value of a dichotomous outcome variable and x_i is the value of the independent variable for the ith subject. Furthermore, assume that the outcome variable has been coded as 0 or 1 representing the absence or presence of the characteristic, respectively. To fit the logistic regression model (1) to a set of data requires that we estimate the values of β_0 and β_1, the unknown parameters.

In linear regression the method used most often to estimate unknown parameters is **least squares**. In that method we choose those values of β_0 and β_1 that minimize the sum of squared deviations of the observed values of Y from the predicted values based upon the model. Under the usual assumptions for linear regression the least squares method yields estimators with a number of desirable statistical

properties. Unfortunately, when the least squares method is applied to a model with a dichotomous outcome the estimators no longer have these same properties.

The general method of estimation that leads to the least squares function under the linear regression model (when the error terms are normally distributed) is **maximum likelihood**. This is the method used to estimate the logistic regression parameters. In a very general sense the maximum likelihood method yields values for the unknown parameters that maximize the probability of obtaining the observed set of data. To apply this method we must first construct a function called the *likelihood function* (*see* **Likelihood**). This function expresses the probability of the observed data as a function of the unknown parameters. The *maximum likelihood estimators* of these parameters are chosen to be those values that maximize this function. Thus, the resulting estimators are those that agree most closely with the observed data.

If Y is coded as 0 or 1, then the expression for $\pi(x)$ given in (1) provides (for an arbitrary value of $\boldsymbol{\beta}' = (\beta_0, \beta_1)$, the vector of parameters) the conditional probability that Y is equal to 1 given x. This will be denoted $\Pr(Y = 1|x)$. It follows that the quantity $1 - \pi(x)$ gives the conditional probability that Y is equal to zero given x, $\Pr(Y = 0|x)$. Thus, for those pairs (x_i, y_i), where $y_i = 1$, the contribution to the likelihood function is $\pi(x_i)$, and for those pairs where $y_i = 0$, the contribution to the likelihood function is $1 - \pi(x_i)$, where the quantity $\pi(x_i)$ denotes the value of $\pi(x)$ computed at x_i. A convenient way to express the contribution to the likelihood function for the pair (x_i, y_i) is through the term

$$\xi(x_i) = \pi(x_i)^{y_i}[1 - \pi(x_i)]^{1-y_i}. \tag{3}$$

Since the observations are assumed to be independent, the likelihood function is obtained as the product of the terms given in (3) as follows:

$$l(\beta) = \prod_{i=1}^{n} \xi(x_i). \tag{4}$$

The principle of maximum likelihood states that we use as our estimate of β the value that maximizes the expression in (4). However, it is easier mathematically to work with the log of (4). This expression, the *log likelihood*, is defined as

$$\begin{aligned} L(\beta) &= \ln[l(\beta)] \\ &= \sum \{y_i \ln[\pi(x_i)] + (1 - y_i) \ln[1 - \pi(x_i)]\}. \end{aligned} \tag{5}$$

To find the value of β that maximizes $L(\beta)$ we differentiate $L(\beta)$ with respect to β_0 and β_1 and set the resulting expressions equal to zero. These equations are as follows:

$$\sum_{i=1}^{n} [y_i - \pi(x_i)] = 0 \tag{6}$$

and

$$\sum_{i=1}^{n} x_i [y_i - \pi(x_i)] = 0, \tag{7}$$

and are called the *likelihood equations*.

In linear regression, the likelihood equations, obtained by differentiating the sum of squared deviations function with respect to β, are linear in the unknown parameters, and thus are easily solved. For logistic regression the expressions in (6) and (7) are nonlinear in β_0 and β_1, and thus require special methods for their solution. These methods are iterative in nature and have been programmed into available logistic regression software. McCullagh & Nelder [6] discuss the iterative methods used by most programs. In particular, they show that the solution to (6) and (7) may be obtained using a generalized weighted least squares procedure.

The value of β given by the solution to (6) and (7) is called the maximum likelihood estimate, denoted as $\hat{\boldsymbol{\beta}}$. Similarly, $\hat{\pi}(x_i)$ is the maximum likelihood estimate of $\pi(x_i)$. This quantity provides an estimate of the conditional probability that Y is equal to 1, given that x is equal to x_i. As such, it represents the fitted or predicted value for the logistic regression model. An interesting consequence of (6) is that

$$\sum_{i=1}^{n} y_i = \sum_{i=1}^{n} \hat{\pi}(x_i).$$

That is, the sum of the observed values of y is equal to the sum of the predicted (expected) values.

After estimating the coefficients, it is standard practice to assess the significance of the variables in the model. This usually involves testing a statistical hypothesis to determine whether the independent

variables in the model are "significantly" related to the outcome variable. One approach to testing for the significance of the coefficient of a variable in any model relates to the following question. *Does the model that includes the variable in question tell us more about the outcome (or response) variable than does a model that does not include that variable?* This question is answered by comparing the observed values of the response variable with those predicted by each of two models; the first with and the second without the variable in question. The mathematical function used to compare the observed and predicted values depends on the particular problem. If the predicted values with the variable in the model are better, or more accurate in some sense, than when the variable is not in the model, then we feel that the variable in question is "significant". It is important to note that we are not considering the question of whether the predicted values are an accurate representation of the observed values in an absolute sense (this would be called *goodness of fit*). Instead, our question is posed in a relative sense.

For the purposes of assessing the significance of an independent variable we compute the value of the following statistic:

$$G = -2\ln\left(\frac{\text{likelihood without the variable}}{\text{likelihood with the variable}}\right). \quad (8)$$

Under the hypothesis that β_1 is equal to zero, the statistic G will follow a chi-square distribution with one degree of freedom. The calculation of the log likelihood and this generalized **likelihood ratio test** are standard features of any good logistic regression package. This makes it possible to check for the significance of the addition of new terms to the model as a matter of routine. In the simple case of a single independent variable, we can first fit a model containing only the constant term. We can then fit a model containing the independent variable along with the constant. This gives rise to a new log likelihood. The likelihood ratio test is obtained by multiplying the difference between the log likelihoods of the two models by -2.

Another test that is often carried out is the Wald test, which is obtained by comparing the maximum likelihood estimate of the slope parameter, $\hat{\beta}_1$, with an estimate of its standard error (*see* **Likelihood**). The resulting ratio

$$W = \frac{\hat{\beta}_1}{\widehat{\text{se}}(\hat{\beta}_1)},$$

under the hypothesis that $\beta_1 = 0$, follows a standard normal distribution. Standard errors of the estimated parameters are routinely printed out by computer software. Hauck & Donner [3] examined the performance of the Wald test and found that it behaved in an aberrant manner, often failing to reject when the coefficient was significant. They recommended that the likelihood ratio test be used. Jennings [5] has also looked at the adequacy of inferences in logistic regression based on Wald statistics. His conclusions are similar to those of Hauck & Donner.

Both the likelihood ratio test, G, and the Wald test, W, require the computation of the maximum likelihood estimate for β_1. For a single variable this is not a difficult or costly computational task. However, for large data sets with many variables, the iterative computation needed to obtain the maximum likelihood estimates can be considerable.

The logistic regression model may be used with matched study designs. Fitting **conditional logistic regression** models requires modifications, which are not discussed here. The reader interested in the conditional logistic regression model may find details in [4, Chapter 7].

The Multiple Logistic Regression Model

Consider a collection of p independent variables which will be denoted by the vector $\mathbf{x}' = (x_1, x_2, \ldots, x_p)$. Assume for the moment that each of these variables is at least interval scaled. Let the conditional probability that the outcome is present be denoted by $\Pr(Y = 1|\mathbf{x}) = \pi(\mathbf{x})$. Then the logit of the multiple logistic regression model is given by

$$g(\mathbf{x}) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p, \quad (9)$$

in which case

$$\pi(x) = \frac{\exp[g(\mathbf{x})]}{1 + \exp[g(\mathbf{x})]}. \quad (10)$$

If some of the independent variables are discrete, nominal scaled variables (*see* **Nominal Data**) such as race, sex, treatment group, and so forth, then it is inappropriate to include them in the model as if they

were interval scaled. In this situation a collection of *design variables* (or **dummy variables**) should be used. Most logistic regression software will generate the design variables, and some programs have a choice of several different methods.

In general, if a nominal scaled variable has k possible values, then $k-1$ design variables will be needed. Suppose, for example, that the jth independent variable, x_j has k_j levels. The $k_j - 1$ design variables will be denoted as D_{ju} and the coefficients for these design variables will be denoted as $\beta_{ju}, u = 1, 2, \ldots, k_j - 1$. Thus, the logit for a model with p variables and the jth variable being discrete is

$$g(\mathbf{x}) = \beta_0 + \beta_1 x_1 + \cdots + \sum_{u=1}^{k_j-1} \beta_{ju} D_{ju} + \beta_p x_p.$$

Fitting the Multiple Logistic Regression Model

Assume that we have a sample of n independent observations of the pair $(\mathbf{x}_i, y_i), i = 1, 2, \ldots, n$. As in the univariate case, fitting the model requires that we obtain estimates of the vector $\boldsymbol{\beta}' = (\beta_0, \beta_1, \ldots, \beta_p)$. The method of estimation used in the multivariate case is the same as in the univariate situation, i.e. maximum likelihood. The likelihood function is nearly identical to that given in (4), with the only change being that $\pi(\mathbf{x})$ is now defined as in (10). There are $p + 1$ likelihood equations which are obtained by differentiating the log likelihood function with respect to the $p + 1$ coefficients. The likelihood equations that result may be expressed as follows:

$$\sum_{i=1}^{n} [y_i - \pi(\mathbf{x}_i)] = 0$$

and

$$\sum_{i=1}^{n} x_{ij} [y_i - \pi(\mathbf{x}_i)] = 0,$$

for $j = 1, 2, \ldots, p$.

As in the univariate model, the solution of the likelihood equations requires special purpose software which may be found in many packaged programs. Let $\hat{\beta}$ denote the solution to these equations. Thus, the fitted values for the multiple logistic regression model are $\hat{\pi}(\mathbf{x}_i)$, the value of the expression in (13) computed using $\hat{\beta}$ and $\mathbf{x}_i$.

Before proceeding further we present an example that illustrates the formulation of a multiple logistic regression model and the estimation of its coefficients.

Example

To provide an example of fitting a multiple logistic regression model, consider the data for the low birth weight study described in Appendix 1 of Hosmer & Lemeshow [4]. The code sheet for the data set is given in Table 1.

The goal of this study was to identify risk factors associated with giving birth to a low birth weight baby (weighing less than 2500 g). In this study data were collected on 189 women; $n_1 = 59$ of them

Table 1 Code sheet for the variables in the low birth weight data set

Variable	Abbreviation
Identification code	ID
Low birth weight (0 = birth weight ≥2500 g, 1 = birth weight <2500 g)	LOW
Age of the mother in years	AGE
Weight in pounds at the last menstrual period	LWT
Race (1 = white, 2 = black, 3 = other)	RACE
Smoking status during pregnancy (1 = yes, 0 = no)	SMOKE
History of premature labor (0 = none, 1 = one, etc.)	PTL
History of hypertension (1 = yes, 0 = no)	HT
Presence of uterine irritability (1 = yes, 0 = no)	UI
Number of physician visits during the first trimester (0 = none, 1 = one, 2 = two, etc.)	FTV
Birth weight (g)	BWT

delivered low birth weight babies and $n_0 = 130$ delivered normal birth weight babies. In this example the variable race has been recoded using the two design variables shown in Table 2. FTV was recoded to 0 = some, 1 = none, and PTL was recoded to 0 = none, 1 = one or more. The two newly coded variables are called FTV01 and PTL01.

The results of fitting the logistic regression model to these data are given in Table 3.

In Table 3 the estimated coefficients for the two design variables for race are indicated in the lines denoted by "RACE 1" and "RACE 2". The estimated logit is given by

$$\begin{aligned}\hat{g}(\mathbf{x}) = {} & 0.545 - 0.035 \times \text{AGE} - 0.015 \times \text{LWT} \\ & + 0.815 \times \text{SMOKE} + 1.824 \times \text{HT} + 0.702 \\ & \times \text{UI} + 1.202 \times \text{RACE 1} + 0.773 \times \text{RACE 2} \\ & + 0.121 \times \text{FTV01} + 1.237 \times \text{PTL01}.\end{aligned}$$

The fitted values are obtained using the estimated logit, $\hat{g}(\mathbf{x})$, as in (10).

Table 2 Coding of design variables for RACE

	Design variable	
RACE	RACE 1	RACE 2
White	0	0
Black	1	0
Other	0	1

Testing for the Significance of the Model

Once we have fit a particular multiple (multivariate) logistic regression model, we begin the process of assessment of the model. The first step in this process is usually to assess the significance of the variables in the model. The likelihood ratio test for overall significance of the p coefficients for the independent variables in the model is performed based on the statistic G given in (8). The only difference is that the fitted values, $\hat{\pi}$, under the model are based on the vector containing $p + 1$ parameters, $\hat{\boldsymbol{\beta}}$. Under the null hypothesis that the p "slope" coefficients for the covariates in the model are equal to zero, the distribution of G is **chi-square** with p **degrees of freedom**.

As an example, consider the fitted model whose estimated coefficients are given in Table 3. For that model the value of the log likelihood is $L = -98.36$. A second model, fit with the constant term only, yields $L = -117.336$. Hence $G = -2[(-117.34) - (-98.36)] = 37.94$ and the ***P* value** for the test is $\Pr[\chi^2(9) > 37.94] < 0.0001$ (see Table 3). Rejection of the **null hypothesis** (that all of the coefficients are simultaneously equal to zero) has an interpretation analogous to that in multiple linear regression; we may conclude that at least one, and perhaps all p coefficients are different from zero.

Before concluding that any or all of the coefficients are nonzero, we may wish to look at the univariate Wald test statistics, $W_j = \hat{\beta}_j / \widehat{\text{se}}(\hat{\beta}_j)$. These are given in the fourth column (labeled z) in Table 3.

Table 3 Estimated coefficients for a multiple logistic regression model using all variables from the low birth weight data set

Logit estimates — Number of obs. = 189
$\chi^2(9) = 37.94$
Prob > $\chi^2 = 0.0000$
Log likelihood = −98.36

Variable	Coeff.	Std. error	z	Pr > |z|	[95% conf.	interval]
AGE	−0.035	0.039	−0.920	0.357	−0.111	0.040
LWT	−0.015	0.007	−2.114	0.035	−0.029	−0.001
SMOKE	0.815	0.420	1.939	0.053	−0.009	1.639
HT	1.824	0.705	2.586	0.010	0.441	3.206
UI	0.702	0.465	1.511	0.131	−0.208	1.613
RACE 1	1.202	0.534	2.253	0.024	0.156	2.248
RACE 2	0.773	0.460	1.681	0.093	−0.128	1.674
FTV01	0.121	0.376	0.323	0.746	−0.615	0.858
PTL01	1.237	0.466	2.654	0.008	0.323	2.148
cons	0.545	1.266	0.430	0.667	−1.937	3.027

Under the hypothesis that an individual coefficient is zero, these statistics will follow the **standard normal** distribution. Thus, the value of these statistics may give us an indication of which of the variables in the model may or may not be significant. If we use a critical value of 2, which leads to an approximate level of significance (two-tailed) of 0.05, then we would conclude that the variables LWT, SMOKE, HT, PTL01 and possibly RACE are significant, while AGE, UI, and FTV01 are not significant.

Considering that the overall goal is to obtain the best fitting model while minimizing the number of parameters, the next logical step is to fit a reduced model, containing only those variables thought to be significant, and compare it with the full model containing all the variables. The results of fitting the reduced model are given in Table 4.

The difference between the two models is the exclusion of the variables AGE, UI, and FTV01 from the full model. The likelihood ratio test comparing these two models is obtained using the definition of G given in (8). It has a distribution that is chi-square with three degrees of freedom under the hypothesis that the coefficients for the variables excluded are equal to zero. The value of the test statistic comparing the models in Tables 3 and 4 is $G = -2[(-100.24) - (-98.36)] = 3.76$ which, with three degrees of freedom, has a P value of $P[\chi^2(3) > 3.76] = 0.2886$. Since the P value is large, exceeding 0.05, we conclude that the reduced model is as good as the full model. Thus there is no advantage to including AGE, UI, and FTV01 in the model. However, we must not base our models entirely on tests of statistical significance. Numerous other considerations should influence our decision to include or exclude variables from a model.

Interpretation of the Coefficients of the Logistic Regression Model

After fitting a model the emphasis shifts from the computation and assessment of significance of estimated coefficients to interpretation of their values. The interpretation of any fitted model requires that we can draw practical inferences from the estimated coefficients in the model. The question addressed is: *What do the estimated coefficients in the model tell us about the research questions that motivated the study?* For most models this involves the estimated coefficients for the independent variables in the model. The estimated coefficients for the independent variables represent the slope or rate of change of a function of the dependent variable per unit of change in the independent variable. Thus, interpretation involves two issues: (i) determining the functional relationship between the dependent variable and the independent variable, and (ii) appropriately defining the unit of change for the independent variable.

For a linear regression model we recall that the slope coefficient, β_1, is equal to the difference between the value of the dependent variable at $x + 1$ and the value of the dependent variable at x, for any value of x. In the logistic regression model $\beta_1 = g(x + 1) - g(x)$. That is, the slope coefficient represents the change in the logit for a change of one unit in the independent variable x. Proper interpretation of the coefficient in a logistic regression model depends on being able to place meaning

Table 4 Estimated coefficients for a multiple logistic regression model using the variables LWT, SMOKE, HT, PTL01 and RACE from the low birth weight data set

Logit estimates — Number of obs. = 189; $\chi^2(6)$ = 34.19; Prob > χ^2 = 0.0000

on the difference between two logits. Consider the interpretation of the coefficients for a univariate logistic regression model for each of the possible measurement scales of the independent variable.

Dichotomous Independent Variable

Assume that x is coded as either 0 or 1. Under this model there are two values of $\pi(x)$ and equivalently two values of $1 - \pi(x)$. These values may be conveniently displayed in a **2 x 2 table**, as shown in Table 5.

The **odds** of the outcome being present among individuals with $x = 1$ is defined as $\pi(1)/[1 - \pi(1)]$. Similarly, the odds of the outcome being present among individuals with $x = 0$ is defined as $\pi(0)/[1 - \pi(0)]$. The **odds ratio**, denoted by ψ, is defined as the ratio of the odds for $x = 1$ to the odds for $x = 0$, and is given by

$$\psi = \frac{\pi(1)/[1 - \pi(1)]}{\pi(0)/[1 - \pi(0)]}. \tag{11}$$

The log of the odds ratio, termed log odds ratio, or *log odds*, is

$$\ln(\psi) = \ln\left\{\frac{\pi(1)/[1 - \pi(1)]}{\pi(0)/[1 - \pi(0)]}\right\} = g(1) - g(0),$$

which is the *logit difference*, where the log of the odds is called the logit and, in this example, these are

$$g(1) = \ln\left\{\frac{\pi(1)}{1 - \pi(1)}\right\}$$

and

$$g(0) = \ln\left\{\frac{\pi(0)}{1 - \pi(0)}\right\}.$$

Using the expressions for the logistic regression model shown in Table 5 the odds ratio is

$$\psi = \frac{\left(\frac{\exp(\beta_0 + \beta_1)}{1 + \exp(\beta_0 + \beta_1)}\right)\left(\frac{1}{1 + \exp(\beta_0)}\right)}{\left(\frac{\exp(\beta_0)}{1 + \exp(\beta_0)}\right)\left(\frac{1}{1 + \exp(\beta_0 + \beta_1)}\right)}$$
$$= \frac{\exp(\beta_0 + \beta_1)}{\exp(\beta_0)} = \exp(\beta_1).$$

Hence, for logistic regression with a dichotomous independent variable

$$\psi = \exp(\beta_1), \tag{12}$$

and the logit difference, or log odds, is

$$\ln(\psi) = \ln[\exp(\beta_1)] = \beta_1.$$

This fact concerning the interpretability of the coefficients is the fundamental reason why logistic regression has proven such a powerful analytic tool for epidemiologic research. A confidence interval (CI) estimate for the odds ratio is obtained by first calculating the endpoints of a **confidence interval** for the coefficient β_1, and then exponentiating these values. In general, the endpoints are given by

$$\exp\left[\hat{\beta}_1 \pm z_{1-\alpha/2} \times \widehat{\text{se}}(\hat{\beta}_1)\right].$$

Because of the importance of the odds ratio as a measure of association, point and interval estimates are often found in additional columns in tables presenting the results of a logistic regression analysis.

In the previous discussion we noted that the estimate of the odds ratio was $\hat{\psi} = \exp(\hat{\beta}_1)$. This is correct when the independent variable has been

Table 5 Values of the logistic regression model when the independent variable is dichotomous

			Independent variable X	
			$x = 1$	$x = 0$
Outcome variable	Y	$y = 1$	$\pi(1) = \frac{\exp(\beta_0 + \beta_1)}{1 + \exp(\beta_0 + \beta_1)}$	$\pi(0) = \frac{\exp\beta_0}{1 + \exp\beta_0}$
		$y = 0$	$1 - \pi(1) = \frac{1}{1 + \exp(\beta_0 + \beta_1)}$	$1 - \pi(0) = \frac{1}{1 + \exp\beta_0}$
		Total	1.0	1.0

coded as 0 or 1. This type of coding is called "reference cell" coding. Other coding could be used. For example, the variable may be coded as -1 or $+1$. This type of coding is termed "deviation from means" coding. Evaluation of the logit difference shows that the odds ratio is calculated as $\hat{\psi} = \exp(2\hat{\beta}_1)$ and if an investigator were simply to exponentiate the coefficient from the computer output of a logistic regression analysis, the wrong estimate of the odds ratio would be obtained. Close attention should be paid to the method used to code design variables.

The method of coding also influences the calculation of the endpoints of the confidence interval. With deviation from means coding, the estimated standard error needed for confidence interval estimation is $\widehat{\text{se}}(2\hat{\beta}_1)$, which is $2 \times \widehat{\text{se}}(\hat{\beta}_1)$. Thus the endpoints of the confidence interval are

$$\exp\left[2\hat{\beta}_1 + z_{1-\alpha/2} \times 2 \times \widehat{\text{se}}(\hat{\beta}_1)\right].$$

In summary, for a dichotomous variable the parameter of interest is the odds ratio. An estimate of this parameter may be obtained from the estimated logistic regression coefficient, regardless of how the variable is coded or scaled. This relationship between the logistic regression coefficient and the odds ratio provides the foundation for our interpretation of all logistic regression results.

Polytomous Independent Variable

Suppose that instead of two categories the independent variable has $k > 2$ distinct values (*see* **Polytomous Data**). For example, we may have variables that denote the county of residence within a state, the clinic used for primary health care within a city, or race. Each of these variables has a fixed number of discrete outcomes and the scale of measurement is nominal.

Suppose that in a study of coronary heart disease (CHD) the variable RACE is coded at four levels, and that the cross-classification of RACE by CHD status yields the data presented in Table 6. These data are hypothetical and have been formulated for ease of computation. The extension to a situation where the variable has more than four levels is not conceptually different, so all the examples in this section use $k = 4$.

At the bottom of Table 6 the odds ratio is given for each race, using white as the reference group. For example, for hispanic the estimated odds ratio is $(15 \times 20)/(5 \times 10) = 6.0$. The log of the odds ratios are given in the last row of Table 6. This display is typical of what is found in the literature when there is a perceived referent group to which the other groups are to be compared. These same estimates of the odds ratio may be obtained from a logistic regression program with an appropriate choice of design variables. The method for specifying the design variables involves setting all of them equal to zero for the reference group, and then setting a single design variable equal to one for each of the other groups. This is illustrated in Table 7.

Table 7 Specification of the design variables for RACE using white as the reference group

	Design variables		
RACE (code)	D_1	D_2	D_3
White (1)	0	0	0
Black (2)	1	0	0
Hispanic (3)	0	1	0
Other (4)	0	0	1

Table 6 Cross-classification of hypothetical data on RACE and CHD status for 100 subjects

CHD status	White	Black	Hispanic	Other	Total
Present	5	20	15	10	50
Absent	20	10	10	10	50
Total	25	30	25	20	100
Odds ratio ($\hat{\psi}$)	1.0	8.0	6.0	4.0	
95% CI		(2.3, 27.6)	(1.7, 21.3)	(1.1, 14.9)	
$\ln(\hat{\psi})$	0.0	2.08	1.79	1.39	

Table 8 Results of fitting the logistic regression model to the data in Table 6 using the design variables in Table 7

Variable	Coeff.	Std. error	z	$P > \|z\|$	[95% conf. interval]	
RACE 1	2.079	0.632	3.288	0.001	0.840	3.319
RACE 2	1.792	0.645	2.776	0.006	0.527	3.057
RACE 3	1.386	0.671	2.067	0.039	0.072	2.701
cons	−1.386	0.500	−2.773	0.006	−2.367	−0.406

Variable	Odds ratio	[95% conf. interval]	
RACE 1	8	2.32	27.63
RACE 2	6	1.69	21.26
RACE 3	4	1.07	14.90

Use of any logistic regression program with design variables coded as shown in Table 7 yields the estimated logistic regression coefficients given in Table 8.

A comparison of the estimated coefficients in Table 8 with the log odds in Table 6 shows that $\ln[\hat{\psi}(\text{black, white})] = \hat{\beta}_{11} = 2.079$, $\ln[\hat{\psi}(\text{hispanic, white})] = \hat{\beta}_{12} = 1.792$, and $\ln[\hat{\psi}(\text{other, white})] = \hat{\beta}_{13} = 1.386$.

In the univariate case the estimates of the standard errors found in the logistic regression output are identical to the estimates obtained using the cell frequencies from the contingency table. For example, the estimated standard error of the estimated coefficient for design variable (1), $\hat{\beta}_{11}$, is $0.6325 = (1/5 + 1/20 + 1/20 + 1/10)^{1/2}$. A derivation of this result appears in Bishop et al. [1].

Confidence limits for odds ratios may be obtained as follows:

$$\hat{\beta}_{ij} \pm z_{1-\alpha/2} \times \widehat{\text{se}}(\hat{\beta}_{ij}).$$

The corresponding limits for the odds ratio are obtained by exponentiating these limits as follows:

$$\exp[\hat{\beta}_{ij} \pm z_{1-\alpha/2} \times \widehat{\text{se}}(\hat{\beta}_{ij})].$$

Continuous Independent Variable

When a logistic regression model contains a continuous independent variable, interpretation of the estimated coefficient depends on how it is entered into the model and the particular units of the variable. For purposes of developing the method to interpret the coefficient for a continuous variable, we assume that the logit is linear in the variable.

Under the assumption that the logit is linear in the continuous covariate, x, the equation for the logit is $g(x) = \beta_0 + \beta_1 x$. It follows that the slope coefficient, β_1, gives the change in the log odds for an increase of "1" unit in x, i.e. $\beta_1 = g(x+1) - g(x)$ for any value of x. Most often the value of "1" will not be biologically very interesting. For example, an increase of 1 year in age or of 1 mmHg in systolic blood pressure may be too small to be considered important. A change of 10 years or 10 mmHg might be considered more useful. However, if the range of x is from zero to one, as might be the case for some created index, then a change of 1 is too large and a change of 0.01 may be more realistic. Hence, to provide a useful interpretation for continuous scaled covariates we need to develop a method for point and interval estimation for an arbitrary change of c units in the covariate.

The log odds for a change of c units in x is obtained from the logit difference $g(x+c) - g(x) = c\beta_1$ and the associated odds ratio is obtained by exponentiating this logit difference, $\psi(c) = \psi(x + c, x) = \exp(c\beta_1)$. An estimate may be obtained by replacing β_1 with its maximum likelihood estimate, $\hat{\beta}_1$. An estimate of the standard error needed for confidence interval estimation is obtained by multiplying the estimated standard error of $\hat{\beta}_1$ by c. Hence the endpoints of the $100(1-\alpha)\%$ CI estimate of $\psi(c)$ are

$$\exp[c\hat{\beta}_1 \pm z_{1-\alpha/2} c\widehat{\text{se}}(\hat{\beta}_1)].$$

Since both the point estimate and endpoints of the confidence interval depend on the choice of c, the

particular value of c should be clearly specified in all tables and calculations.

Multivariate Case

Often logistic regression analysis is used to *adjust statistically* the estimated effects of each variable in the model for differences in the distributions of and associations among the other independent variables. Applying this concept to a multiple logistic regression model, we may surmise that each estimated coefficient provides an estimate of the log odds adjusting for all other variables included in the model. The term confounder is used by epidemiologists to describe a covariate that is associated with both the outcome variable of interest and a primary independent variable or risk factor. When both associations are present the relationship between the risk factor and the outcome variable is said to be *confounded* (*see* **Confounding**). The procedure for adjusting for confounding is appropriate when there is no interaction.

If the association between the covariate and an outcome variable is the same within each level of the risk factor, then there is no interaction between the covariate and the risk factor. When interaction is present, the association between the risk factor and the outcome variable differs, or depends in some way on the level of the covariate. That is, the covariate modifies the effect of the risk factor (*see* **Effect Modification**). Epidemiologists use the term effect modifier to describe a variable that interacts with a risk factor.

The simplest and most commonly used model for including interaction is one in which the logit is also linear in the confounder for the second group, but with a different slope. Alternative models can be formulated which would allow for other than a linear relationship between the logit and the variables in the model within each group. In any model, interaction is incorporated by the inclusion of appropriate higher order terms.

An important step in the process of modeling a set of data is to determine whether or not there is evidence of interaction in the data. Tables 9 and 10 present the results of fitting a series of logistic regression models to two different sets of hypothetical data. The variables in each of the data sets are the same: SEX, AGE, and CHD. In addition to the estimated coefficients, the log likelihood for each model and minus twice the change (deviance) is given. Recall that minus twice the change in the log likelihood may be used to test for the significance of coefficients for variables added to the model. An interaction is added to the model by creating a variable that is equal to the product of the value of the sex and the value of age.

Examining the results in Table 9 we see that the estimated coefficient for the variable SEX changed from 1.535 in model 1 to 0.979 when AGE was added in model 2. Hence, there is clear evidence of a confounding effect owing to age. When the interaction term "SEX $\times$ AGE" is added in model 3 we see that the change in the deviance is only 0.52 which, when compared with the chi-square distribution with one degree of freedom, yields a P value of 0.47, which clearly is not significant. Note that the coefficient for sex changed from 0.979 to 0.481. This is not surprising since the inclusion of an interaction term, especially when it involves a continuous variable, will usually produce fairly marked changes in the estimated coefficients of dichotomous variables involved in the interaction. Thus, when an interaction term is present in the model we cannot assess confounding via the change in a coefficient. For these data we would prefer to use model 2 which suggests that age is a confounder but not an effect modifier.

The results in Table 10 show evidence of both confounding and interaction due to age. Comparing model 1 with model 2 we see that the coefficient for sex changes from 2.505 to 1.734. When the age by sex interaction is added to the model we see that the deviance is 4.06, which yields a P value

Table 9 Estimated logistic regression coefficients, log likelihood, and the likelihood ratio test statistic (G) for an example showing evidence of confounding but no interaction

Model	Constant	SEX	AGE	SEX $\times$ AGE	Log likelihood	G
1	−1.046	1.535			−61.86	
2	−7.142	0.979	0.167		−49.59	24.54
3	−6.103	0.481	0.139	0.059	−49.33	0.52

Table 10 Estimated logistic regression coefficients, log likelihood, and the likelihood ratio test statistic (G) for an example showing evidence of confounding and interaction

Model	Constant	SEX	AGE	SEX × AGE	Log likelihood	G
1	−0.847	2.505			−52.52	
2	−6.194	1.734	0.147		−46.79	11.46
3	−3.105	0.047	0.629	0.206	−44.76	4.06

of 0.04. Since the deviance is significant, we prefer model 3 over model 2, and should regard age as both a confounder and an effect modifier. The net result is that any estimate of the odds ratio for sex should be made with respect to a specific age.

Hence, we see that determining if a covariate, X, is an effect modifier and/or a confounder involves several issues. Determining effect modification status involves the parametric structure of the logit, while determination of confounder status involves two things. First, the covariate must be associated with the outcome variable. This implies that the logit must have a nonzero slope in the covariate. Secondly, the covariate must be associated with the risk factor. In our example this might be characterized by having a difference in the mean age for males and females. However, the association may be more complex than a simple difference in means. The essence is that we have incomparability in our risk factor groups. This incomparability must be accounted for in the model if we are to obtain a correct, unconfounded estimate of effect for the risk factor.

In practice, the confounder status of a covariate is ascertained by comparing the estimated coefficient for the risk factor variable from models containing and not containing the covariate. Any "biologically important" change in the estimated coefficient for the risk factor would dictate that the covariate is a confounder and should be included in the model, regardless of the statistical significance of the estimated coefficient for the covariate. On the other hand, a covariate is an effect modifier only when the interaction term added to the model is both biologically meaningful and statistically significant. When a covariate is an effect modifier, its status as a confounder is of secondary importance since the estimate of the effect of the risk factor depends on the specific value of the covariate.

The concepts of adjustment, confounding, interaction, and effect modification may be extended to cover the situations involving any number of variables on any measurement scale(s). The principles for identification and inclusion of confounder and interaction variables into the model are the same regardless of the number of variables and their measurement scales.

Much of this article has been abstracted from [4]. Readers wanting more detail on any topic should consult this reference.

Loglinear Model

Multivariate analysis has occupied a prominent place in the classical development of statistical theory and methodology. The analysis of cross classified **categorical data**, or **contingency table** analysis as it is often called, represents the *discrete* multivariate analog of **analysis of variance** for continuous response variables, and now plays an important role in biostatistical practice. This article provides an introduction to some of the more widely used techniques for the analysis of contingency table data using loglinear models and to the statistical theory that underlies them, revising and extending an earlier review article [27] (for additional material on this topic, and related methods, *see* **Categorical Data Analysis**; **Contingency Table**).

The term *contingency*, used in connection with tables of cross classified categorical data, seems to have originated with **Karl Pearson** [61], who for an $s \times t$ table defined contingency to be any measure of the total deviation from "independent probability". The term is now used to refer to the table of counts itself. Prior to this formal use of the term, statisticians going back at least to Quetelet [64] worked with cross classifications of counts to summarize the association between variables. Pearson [59] had laid the groundwork for his approach to contingency tables when he developed his **chi-square test** for comparing observed and expected (theoretic) frequencies. Yet Pearson preferred to view contingency tables involving the cross classification of two or more polytomies as arising from a partition of a set of **multivariate, normal** data, with an underlying continuum for each polytomy. This view led Pearson [50] to develop his tetrachoric correlation coefficient for **2 × 2 tables**, and this work in turn spawned an extensive literature well chronicled by Lancaster [54] (*see* **Association, Measures of**).

The most serious problems with Pearson's approach were (i) the complicated infinite series linking the tetrachoric correlation coefficient with the frequencies in a 2×2 table, and (ii) his insistence that it always made sense to assume an underlying continuum, even when the dichotomy of interest was dead–alive or employed–unemployed, and that it was reasonable to assume that the probability distribution over such a continuum was normal. In contradistinction, Yule [72] chose to view the categories of a cross classification as fixed, and he set out to consider the structural relationship between or among the discrete variables represented by the cross classification, via various functions of the cross product ratio. Especially impressive in this, Yule's first paper on the topic, is his notational structure for n attributes or 2^n tables, and his attention to the concept of partial and joint association of dichotomous variables.

The debate between Pearson and Yule over whose approach was more appropriate for contingency table analysis raged for many years (see, for example, Pearson & Heron [63]), and the acrimony it engendered was exceeded only by that associated with Pearson's dispute with R.A. Fisher over the adjustment in the **degrees of freedom** (df) for the **chi-square test** of independence in the $s \times t$ table. [In this latter case Pearson was simply incorrect; as Fisher [34] first noted, $\mathrm{df} = (s-1)(t-1)$.]

Although much work on two-dimensional contingency tables followed the pioneering efforts by Pearson and Yule, it was not until 1935 that Bartlett, as a result of a suggestion by Fisher, utilized Yule's cross product ratio to define the notion of second-order **interaction** in a $2 \times 2 \times 2$ table, and to develop an appropriate test for the absence of such an interaction [6]. The multivariate generalizations of Bartlett's work, beginning with the work of Roy & Kastenbaum [67], form the basis of the loglinear model approach to contingency tables, which is described in detail below.

The past 40 years have seen a burgeoning literature on the analysis of contingency tables. Some of this literature emphasizes the use of the minimum modified chi-square approach (e.g. Grizzle et al. [47]) or the use of the minimum discrimination information approach (e.g. Gokhale & Kullback [K]), but the bulk of it follows Fisher in the use of **maximum likelihood**. For most contingency table problems, the minimum discrimination information approach yields maximum likelihood estimates. More recently, attention has turned to the development of hierarchical **Bayesian** approaches, which lead to the computation of *posterior distributions* (rather than point estimates) for quantities of interest (see, for example, Leonard [55], Albert & Gupta [3], Epstein & Fienberg [23], and Gelman et al. [37]).

Except for a few attempts at the use of additive (linear) models (see, for example, Bhapkar & Koch [7]), almost all of the papers written on the topic

emphasize the use of loglinear or logit models. Key papers by Birch [8], Darroch [14], Good [38], and Goodman [41, 42], plus the availability of high-speed computers, served to spur renewed interest in the problems of categorical data analysis, and culminated in a series of books first published in the 1970s and which focused in large part on the use of loglinear models for both two-dimensional and multidimensional tables (see, for example, [E, H, K, L, M, N, Q]). The past decade has seen an even greater flourishing of this expository literature, only some of which we reference here (see the review in [29]).

The subsequent sections of this presentation deal primarily with the analysis of contingency table data using loglinear models. The next section describes three examples that will serve to illustrate some of the methods of analysis, and the third section discusses briefly sampling models and estimation methods used in conjunction with categorical data analysis. The fourth section outlines the basic statistical theory associated with maximum likelihood estimation and loglinear models, including brief descriptions of the family of graphical loglinear models emanating from the work of Darroch et al. [19], and related work on the collapsing of contingency tables, as well as brief discussions of **capture–recapture** methods and latent trait (*see* **Latent Class Analysis**) and **Rasch models**, and their linkage to loglinear models. The fifth section contains examples of analysis to illustrate the basic theoretic results. The sixth section presents a brief introduction to Bayesian hierarchical approaches to loglinear models. We end with a guide to some computer programs for loglinear model analysis.

Three Examples

In this article we use three examples to illustrate the models and methods described. Two of these are classic examples, from Bartlett [6] and Waite [71], which have been analyzed repeatedly in the literature and have been used in many texts. The third, due to Edwards & Havranek [22], appears in the more recent texts by Edwards [I] and by Whitaker [S].

The data reported by Bartlett [6] in his pioneering article, and included here in Table 1, are from an *experiment* giving the response (alive or dead) of 240 plants for each combination of two explanatory variables, time of planting (early or late), and length of cutting (high or low).

Table 1 $2 \times 2 \times 2$ table

Time of planting:		Early		Late	
Length of cutting:		High	Low	High	Low
Response	Alive	156	107	84	31
	Dead	84	133	156	209
Total		240	240	240	240

Source: Bartlett [6].

Table 2 Fingerprints of the right hand classified by the number of whorls and small loops

	Small loops						
Whorls	0	1	2	3	4	5	Total
0	78	144	204	211	179	45	861
1	106	153	126	80	32		497
2	130	92	55	15			292
3	125	38	7				170
4	104	26					130
5	50						50
Total	593	453	392	306	211	45	2000

Source: Waite [71].

The questions to be answered are as follows: (i) What are the effects of time of planting and length of cutting on survival? (ii) Do they interact in their effect on survival?

The data in Table 2, from Waite [71], give the cross classification of right-hand fingerprints according to the number of whorls and small loops. The total number of whorls and small loops is at most five, and the resulting table is triangular. There the question of interest is more complicated because, as a result of the constraint forcing the data into the triangular structure, the number of whorls is "related to" the number of small loops. Such an array of counts is referred to as an *incomplete contingency table*, and the incomplete structure, in the case of the Waite data, was the cause of yet another controversy involving Pearson [62], this time with J.A. Harris (see Harris & Treloar [48]). The fit of a relatively simple model to these data is explored below. (See also [68], for a reexamination of Pearson's introduction of the methods used by Waite.)

The data in Table 3 come from a prospective epidemiologic study of 1841 workers in a Czechoslovakian car factory, intended to investigate the potential risk factors for coronary thrombosis (see

Table 3 Prognostic factors in coronary heart disease

F	E	D	C	B / A	No	Yes	No	Yes
Negative	<3	<140	No		44	40	112	67
			Yes		129	145	12	23
		≥140	No		35	12	80	33
			Yes		109	67	7	9

		≥140	No		4	0	13	11
			Yes		5	14	4	4

Source: Edwards & Havranek [22].

Edwards & Havranek [22]). There are six variables corresponding to prognostic factors in the table:

A (smoking: yes, no)
B (strenuous mental work: yes, no)
C (strenuous physical work: yes, no)
D (systolic blood pressure: <140, ≥140)
E (ratio of beta and alpha lipoproteins: <3, ≥3)
F (family anamnesis of coronary heart disease: yes, no).

Sampling Models and Estimation for Contingency Tables

Let $\mathbf{x}' = (x_1, x_2, \ldots, x_t)$ be a vector of observed counts for t cells, structured in the form of a cross classification such as in Tables 1 and 2, where $t = 2^3 = 8$ and $t = 21$, respectively. Now let $\mathbf{m}' = (m_1, m_2, \ldots, m_t)$ be the vector of expected values that are assumed to be functions of unknown parameters $\boldsymbol{\theta}' = (\theta_1, \theta_2, \ldots, \theta_s)$, where $s < t$. Thus one can write $\mathbf{m} = \mathbf{m}(\boldsymbol{\theta})$.

There are three standard sampling models for the observed counts in contingency tables.

1. *Poisson model*. The $\{x_i\}$ are observations from independent **Poisson** random variables with means $\{m_i\}$ and **likelihood** function

$$\prod_{i=1}^{t} \left[\frac{m_i^{x_i} \exp(-m_i)}{x_i!} \right]. \tag{1}$$

2. *Multinomial model*. The total count $N = \sum_{i=1}^{t} x_i$ is a random sample from an infinite population, where the underlying cell probabilities are $\{m_i/N\}$, and the likelihood is

$$N! \cdot N^{-N} \prod_{i=1}^{t} \left(\frac{m_i^{x_i}}{x_i!} \right) \tag{2}$$

(*see* **Multinomial Distribution**).
3. *Product-multinomial model*. The cells are partitioned into sets, and each set has an independent multinomial structure, as in the multinomial model.

For the Bartlett data in the preceding section, the sampling model is product-multinomial – there are actually four independent binomials, one for each of the four experimental conditions corresponding to the two factors, time of planting and length of cutting.

For each of these sampling models the estimation problem can typically be structured in terms of a "distance" function, $K(\mathbf{x}, \mathbf{m})$, where parameter estimates $\hat{\boldsymbol{\theta}}$ are chosen so that the distance between $\mathbf{x}$ and $\mathbf{m} = \mathbf{m}(\boldsymbol{\theta})$, as measured by $K(\mathbf{x}, \mathbf{m})$, is minimized. The *minimum chi-square method* uses the distance function

$$X^2(\mathbf{x}, \mathbf{m}) = \sum_{i=1} \frac{(x_i - m_i)^2}{m_i}, \tag{3}$$

and the *minimum discrimination information method* uses

$$G^2(\mathbf{x}, \mathbf{m}) = 2 \sum_{i=1}^{t} x_i \log \left(\frac{x_i}{m_i} \right). \tag{4}$$

For the three basic sampling models for contingency tables, choosing $\hat{\boldsymbol{\theta}}$ to minimize $G^2(\mathbf{x}, \mathbf{m})$ in (4) is equivalent to maximizing the likelihood function provided that

$$\sum_{i=1}^{t} m_i(\hat{\boldsymbol{\theta}}) = \sum_{i=1}^{t} x_i \tag{5}$$

(and that constraints similar to (5) hold for each of the sets of cells under product-multinomial sampling).

Moreover, the estimators that minimize each of (3) to (5) in such circumstances belong to the class of *best asymptotic normal* (**BAN**) *estimates* for **m** (see Bishop et al. [E] for further discussion of asymptotic equivalence). Because of various additional asymptotic properties, and because of the smoothness of maximum likelihood estimates in relatively sparse tables, many authors have preferred to work with maximum likelihood estimates (MLEs), which minimize (4). We restrict our attention to MLEs, except for the "related" material on Bayesian estimation in a later section.

Basic Theory for Loglinear Models

Set-up for Two- and Three-way Tables

For expected values $\{m_{ij}\}$ for a 2×2 table,

A \ B	1	2
1	m_{11}	m_{12}
2	m_{21}	m_{22}

a standard measure of association for the row and column variables, A and B, respectively, is the *cross product ratio* (also referred to as the **odds ratio**) proposed by Yule [72]:

$$\alpha = \frac{m_{11}m_{22}}{m_{12}m_{21}}. \tag{6}$$

Independence of A and B is equivalent to setting $\alpha = 1$, and can also be expressed in loglinear form:

$$\log m_{ij} = u + u_{1(i)} + u_{2(j)}, \tag{7}$$

where

$$\sum_{i=1}^{2} u_{1(i)} = \sum_{j=1}^{2} u_{2(j)} = 0. \tag{8}$$

Note that the choice of notation here parallels that for analysis of variance models.

Bartlett's [6] no-second-order interaction model for the expected values in a $2 \times 2 \times 2$ table,

m_{111}	m_{121}
m_{211}	m_{221}

m_{112}	m_{122}
m_{212}	m_{222}

is based on equating the values of α in each layer of the table; that is

$$\frac{m_{111}m_{221}}{m_{121}m_{211}} = \frac{m_{112}m_{222}}{m_{122}m_{212}}. \tag{9}$$

The expression given in (9) can be represented in loglinear form as

$$\log m_{ijk} = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{12(ij)} + u_{13(ik)} + u_{23(jk)}, \tag{10}$$

where, as in (8), each subscripted u-term sums to zero over any subscript; for example,

$$\sum_i u_{12(ij)} = \sum_j u_{12(ij)} = 0. \tag{11}$$

All of the parameters in (10) can be written as functions of cross product ratios (see Bishop et al. [E]). Our u-term notation follows that in Bishop et al. [E] and Fienberg [J], and differs somewhat from the λ notation adopted for example by Goodman [43, 44, 46] and by Agresti [B, C]. Furthermore, we have used symmetric linear constraints in (11), whereas other authors often choose to set selected u-terms equal to zero. The following results hold independent of the choice of parameterization and constraints.

For the sampling schemes described in the preceding section, the minimal **sufficient statistics** (msss) are the two-dimensional marginal totals, $\{x_{ij+}\}, \{x_{i+k}\}$, and $\{x_{+jk}\}$ (except for linearly redundant statistics included for purposes of symmetry), where a "+" indicates summation over the corresponding subscript. The MLEs of the $\{m_{ijk}\}$ under the model given in (10) must satisfy the likelihood equations,

$$\begin{aligned} \hat{m}_{ij+} &= x_{ij+}, \quad i, j = 1, 2, \\ \hat{m}_{i+k} &= x_{i+k}, \quad i, k = 1, 2, \\ \hat{m}_{+jk} &= x_{+jk}, \quad j, k = 1, 2, \end{aligned} \tag{12}$$

usually solved by some form of iterative procedure (*see* **Iterative Proportional Fitting**). For the Bartlett data, the third set of equations in (12) corresponds to the binomial sampling constraints.

General Results

The results described in the preceding section generalize directly to ones that are applicable to any form

of cross classification, and to a variety of models that are linear in the logarithmic scale for the expected cell values. It is helpful to have these results available in this general form so that we can adapt them to specific models for specific circumstances. Four results are described here: (i) the form of the data summaries or sufficient statistics for a model, which take the form of linear combinations of counts, often sums as in the preceding section; (ii) the form of the equations that produce maximum likelihoods, setting these data summaries equal to their expected values; (iii) the equivalence of MLEs under different sampling models; and (iv) the large-sample chi-square distribution for the usual **goodness-of-fit** statistics. The technical details follow, and some readers may wish to skip the remainder of the section until they have seen additional special cases.

Suppose that we have a collection of counts organized in the form of a vector, $\mathbf{x}$, with a corresponding vector of expected values, $\mathbf{m}$. We are interested in models for $\mathbf{m}$ such that we can represent the log expectations $\boldsymbol{\lambda}' = (\log m_1, \ldots, \log m_t)$ as linear combinations of the parameters $\boldsymbol{\theta}$. Then the following results hold under the Poisson and multinomial sampling schemes:

1. Corresponding to each parameter in $\boldsymbol{\theta}$ is an MSS that is expressible as a linear combination of the $\{x_i\}$. (More formally, if $\mathcal{M}$ is used to denote the loglinear model specified by $\mathbf{m} = \mathbf{m}(\boldsymbol{\theta})$, then the MSSs are given by the projection of $\mathbf{x}$ on to $\mathcal{M}$, $P_{\mathcal{M}}\mathbf{x}$. For a more detailed discussion, see Haberman [N].)
2. The MLE, $\hat{\mathbf{m}}$, of $\mathbf{m}$, if it exists, is unique and satisfies the likelihood equations

$$P_{\mathcal{M}}\hat{\mathbf{m}} = P_{\mathcal{M}}\mathbf{x}. \tag{13}$$

   (Note that the equations in (12) are a special case of those given by (13).)
   Necessary and sufficient conditions for the existence of a solution to the likelihood equations, (13), are relatively complex (see Haberman [L]). A sufficient condition is that all cell counts be positive – that is, $x > \mathbf{0}$ – but MLEs for loglinear models exist in many sparse situations in which a large fraction of the cells have zero counts.
   For product-multinomial sampling situations, the basic multinomial constraints (i.e. that the counts must add up to the multinomial sample sizes) must be taken into account. Typically, some of the parameters in $\boldsymbol{\theta}$ that specify the loglinear model $\mathcal{M}$, such as $\mathbf{m} = \mathbf{m}(\boldsymbol{\theta})$, are fixed by these constraints.
   More formally, let $\mathcal{M}$ be a loglinear model for $\mathbf{m}$ under product-multinomial sampling which corresponds to a loglinear model $\mathcal{M}$ under Poisson sampling such that the multinomial constraints "fix" a subset of the parameters, $\boldsymbol{\theta}$, used to specify $\mathcal{M}$. Then:
3. The MLE of $\mathbf{m}$ under product-multinomial sampling for the model $\mathcal{M}$ is the same as the MLE of $\mathbf{m}$ under Poisson sampling for the model $\mathcal{M}$.
   As a consequence of result 3, the expressions given in (12) are the likelihood equations for the $2 \times 2 \times 2$ table under the no-second-order interaction model for Poisson or multinomial sampling, as well as for product-multinomial sampling when any set of one-way or two-way marginal totals is fixed (i.e. these correspond to the multinomial constraints).
   A final result, which is used to assess the fit of loglinear models, can be stated in the following informal manner:
4. If $\hat{\mathbf{m}}$ is the MLE of $\mathbf{m}$ under a loglinear model, and if the model is correct, then the statistics

$$X^2 = \sum_{i=1}^{t} \frac{(x_i - \hat{m}_i)^2}{\hat{m}_i} \tag{14}$$

   and

$$G^2 = 2\sum_{i=1}^{t} x_i \log\left(\frac{x_i}{\hat{m}_i}\right) \tag{15}$$

   have asymptotic χ^2 distributions with $t - s$ degrees of freedom, where s is the total number of independent constraints implied by the loglinear model and the multinomial sampling constraints (if any). If the model is not correct, then X^2 and G^2, in (14) and (15), are stochastically larger than χ^2_{t-s}.

Expression 15) is the minimizing value of the distance function, (5), but (14) is not the minimizing chi-square value for the function given in (3). Both χ^2 and G^2 are special cases of the family of *power-divergence statistics*, the distance function of which takes the form

$$K(\mathbf{x}, \hat{\mathbf{m}}) = \frac{2}{\phi(\phi+1)} \sum_{i=1}^{t} x_i \left[\left(\frac{x_i}{\hat{m}_i}\right)^{\phi} - 1\right], \tag{16}$$

where ϕ is a real-valued parameter in the interval $-\infty < \phi < \infty$. The statistic χ^2 corresponds to $\phi = 1$, and the statistic G^2 corresponds to the limit as $\phi \to 0$. For further details on the properties of the general family of power divergence statistics, see Read & Cressie [66].

In the next section, these basic results are applied in the context of three data sets presented in the previous section.

Loglinear Models for High-dimensional Tables

The same ideas and ANOVA-like models in the logarithmic scale are useful for multiway tables. For such models, the minimal sufficient statistics are sets of marginal totals of the full table. Furthermore, all independence or conditional independence relationships are representable as loglinear models, and these models have estimated expected values that can be computed directly. There is a somewhat larger class of loglinear models with this direct or *decomposable* representation described below. For all loglinear models that are not decomposable, we require an iterative solution of likelihood equations.

Not all applications of loglinear models involve such simple structures as 2^3 tables or incomplete 6×6 arrays. Indeed, much of the methodology was developed in the mid-1960s to deal with very large, highly multidimensional tables. For example, in the National Halothane Study [10], investigators considered data on the use of (i) five anesthetic agents in operations involving (ii) four levels of risk, and patients of (iii) two sexes, (iv) ten age groups, with (v) seven differing physical statuses (levels of anesthetic risk) and (vi) previous operations (yes, no) for (vii) three different years, from (viii) 34 different institutions. Two sets of data were collected, the first consisting of all deaths within six weeks of surgery, and the second consisting of a sample (of comparable size) of all those exposed to surgery. Thus the data consisted of two very sparse $5 \times 4 \times 2 \times 10 \times 7 \times 2 \times 3 \times 34$ tables, each containing in excess of 57 000 cells. One of the more successful approaches used in the analysis of the data in these tables was based on loglinear models and the generalizations of the methods illustrated in this section.

One of the key reasons why loglinear models have become so popular in such analyses is that they lead to a simplified description of the data in terms of marginal totals – the minimal sufficient statistics of result 1 of the section "Basic theory for loglinear models". This is especially important when the table of data is large and sparse. For more details on the halothane study analyses, see Bishop et al. [E].

The doubly subscripted u-term notation introduced in the previous sections generalizes immediately to multiway tables. As in the previous section, we restrict attention to hierarchical models, in which if any u-term is set equal to zero, all of its higher order relatives must be set equal to zero; for example, setting $u_{12(ij)} = 0$ for all i, j implies setting $u_{123(ijk)} = 0$ for all i, j, k.

We need to think of parameters in loglinear models as deviations from lower-order parameters; they can also be represented and interpreted as a function of generalized odds ratios or cross product ratios; for example, see Fienberg [J] or Agresti [A, B].

In a multiway contingency table, the model that results from setting exactly one two-factor term (and all its higher-order relatives) equal to zero is called a *partial association* model. For example, in four dimensions, if we set $u_{12(ij)} = 0$ for all i, j, then the minimal sufficient statistics are $\{x_{i+kl}\}$ and $\{x_{+jkl}\}$, and the resulting partial association model corresponds to the conditional independence of variables 1 and 2 given 3 and 4. The corresponding maximum likelihood estimates for the expected cell frequencies are

$$\hat{m}_{ijkl} = \frac{x_{i+kl}x_{+jkl}}{x_{++kl}} \quad \text{for all } i, j, k, l. \tag{17}$$

For more details on partial association models and their uses, see Bishop et al. [E].

Loglinear Models and Graphical Representations

One of the major innovations of the past 15 years has been the development of methods associated with a subfamily of loglinear models known as *graphical loglinear models*. The formulation of graphical models is due originally to Darroch et al. [19], and has now found its way into several introductory textbooks on loglinear models (e.g. [F, I, R]), and serves as the basis for several monographs [O, S].

We begin with some special notation and then define the class of graphical models. We denote the situation in which F and G are conditionally independent given H by $F \perp G|H$. Thus, in a three-way table, if variables 1 and 2 are conditionally

independent given 3, we denote this by

$$1 \perp 2|3.$$

Similarly, in a four-way table, if variables 1 and 2 are conditionally independent given 3 and 4, we denote this by $1 \perp 2|\{3, 4\}$.

In formal mathematics, a *graph* $G = (K, E)$ is based on a set of vertices, K, and a set of edges, E, which consists of pairs of elements from K. We depict such a graph using a picture with vertices linked by edges. For example, the graph $G = (K, E)$ with $K = \{1, 2, 3, 4, 5, 6\}$ and $E = \{(1, 2), (1, 4), (2, 3), (3, 4), (3, 5), (4, 5), (4, 6)\}$ corresponds to Figure 1.

The following definition links partial association models to the absence of edges in a graph. Let $\mathbf{X} = (X_1, X_2, \ldots, X_k)$ be a vector of random variables, and $K = \{1, 2, \ldots, k\}$. Furthermore, let $K\backslash\{i, j\}$ be the set of vertices in K excluding i and j. An undirected graph is an independence graph if there is no edge between two vertices whenever the variables they represent are conditionally independent given all remaining variables, that is $i \perp j|K\backslash\{i, j\}$ for all $(i, j) \notin E$, which corresponds to the partial association model discussed in the preceding subsection. This simply means that we can represent all possible conditional independence relationships in terms of the absence of edges in an undirected graph.

In the above example with $K = \{1, 2, 3, 4, 5, 6\}$ and $E = \{(1, 2), (1, 4), (2, 3), (3, 4), (3, 5), (4, 5), (4, 6)\}$, there are $\binom{6}{2} = 15$ possible edges that could have connected the six vertices, nine of which are absent and each of which corresponds to a conditional independence statement of the form $1 \perp 3|\{2, 4, 5, 6\}$. Some of these conditional independence relationships can be combined and expressed in a more succinct form that is intuitive from the graph. For example, the single conditional relationship, $\{1, 2\} \perp \{5, 6\}|\{3, 4\}$, which can be seen from the "separation" of $\{1, 2\}$ from $\{5, 6\}$ by $\{3, 4\}$ in the graph, summarizes four different conditional independence relationships.

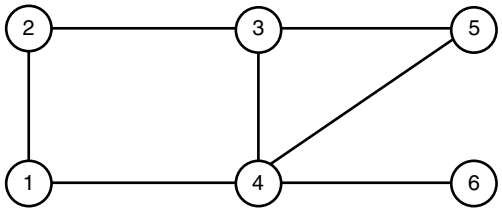

Figure 1 An illustrative graph with six vertices and seven edges, and a four-cycle

Independence graphs can be used in connection with all random variables with positive density (continuous or discrete), and many of the results for independence graphs discussed in Lauritzen [O] and Whittaker [S] are applicable to such random variables. For the purposes of this article, however, we can think in terms of categorical variables, and the models that have independence graph representations are said to be *graphical models*. For categorical variables, all graphical models are loglinear. (For further details, see Lauritzen [O] and Whittaker [S].)

For three-way tables, the models of complete independence (no edges), joint independence (two absent edges), and conditional independence (one absent edge) are graphical, but the no-second-order interaction model is not, because the graph with all three edges present corresponds to the saturated model. Thus, all graphical models for three-way tables are *decomposable*; that is, the expected values can be written *explicitly* as a product and/or ratio of the expected marginal totals corresponding to the sufficient statistics. In this sense, the expected values can be *directly decomposed* in terms of the corresponding margins. In such circumstances, the MLEs can be written out directly and have a simple interpretation; see [1, 18, 33]. There are also a number of especially interesting technical results that apply to decomposable loglinear models [O] and many of these results have proved useful for computing bounds on cell counts given the margins corresponding to a decomposable loglinear model (see [12]).

For four-way tables, the graph with four edges in a cycle; that is, corresponding to the joint occurrence of $2 \perp 3|\{1, 4\}$ and $1 \perp 4|\{2, 3\}$ and with $E = \{(1, 2), (2, 3), (3, 4), (1, 4)\}$, is graphical but also *nondecomposable*. This means that the model is not decomposable and thus the expected values under the model cannot be expressed as an explicit function of the marginal totals corresponding to the sufficient statistics $\{x_{ij++}\}$, $\{x_{+jk+}\}$, $\{x_{++kl}\}$, and $\{x_{i++l}\}$.

As we saw above, all graphical models for three-way tables are decomposable. For higher-way tables, a graphical model is nondecomposable whenever its independence graph includes a cycle involving four or more vertices. Thus in the above example involving six variables where $K = \{1, 2, 3, 4, 5, 6\}$ and $E = \{(1, 2), (1, 4), (2, 3), (3, 4), (3, 5), (4, 5), (4, 6)\}$,

there is a four-cycle involving the edges linking $\{1, 2, 3, 4\}$ and thus the corresponding graphical loglinear model is nondecomposable.

In general, we have the following relationship among classes of loglinear models:

hierarchical models

$\cup$

graphical models

$\cup$

decomposable models

$\cup$

conditional independence models.

Model Selection and Collapsing

Many authors have devised techniques for selecting among the class of loglinear models applicable for contingency table structures. These typically (although not always) resemble corresponding model selection procedures for analysis of variance and regression models (*see* **Variable Selection**). See, for example, the discussions in Agresti [B], Bishop et al. [E], and Fienberg [J]. Edwards [I] and Whitaker [S] have special sections on model selection that take special advantage of the form of graphical models and the link between edges and two-factor effects.

A special aspect of model selection relates to the issue of when is it possible to work with and report loglinear model effects from a reduced table, collapsing over one or more variables of initial interest. The problem of collapsing was first taken up in Bishop [9] and Bishop et al. [E], who defined the concept in terms of the parameters of the loglinear model itself, now referred to as *parametric collapsibility*. Their discussion led to an extensive literature, in which differing definitions of collapsibility were proposed, including *model collapsibility* in which MLEs for the probabilities associated with a subset of variables, say A, can be performed directly in the A-margin of the table (see Asmussen & Edwards [4] and Lauritzen [O] for further details and references).

When a contingency table is not collapsible with respect to a subset of variables, inferences about the relationships among the remaining variables drawn from the corresponding marginal table are inevitably misleading. The best known example of this problem is referred to as **Simpson's paradox** or Yule's paradox. It is usually described as a situation involving three binary variables A, B, and C, such that the cross product ratio between A and B is greater than 1 for each level of C (i.e. there is a positive conditional relationship) but the cross product ratio in the marginal table for A and B is less than 1 (i.e. there is a negative marginal relationship).

Capture Multiple Recapture Analyses

This type of analysis estimates the size of a nonchanging population (see, for example, Bishop et al. [E] and Fienberg [26]). If the members of nonchanging populations are sampled k successive times (possibly dependent), the resulting recapture history data can be displayed in the form of a 2^k table with one missing cell, corresponding to those never sampled. Such an array is amenable to loglinear analysis, the results of which can be used to project a value for the missing cell.

In recent years there have been a number of major applications of the capture–recapture methodology ($k = 2$), especially in the context of the US decennial **census**; for example, see Zaslavsky & Wolfgang [73] and Fienberg [28], and in a variety of epidemiologic settings. For a detailed description of the history of the methodology and its potential for use in the context of epidemiology and public health, see Hook & Regal [49], and the International Working Group for Disease Monitoring and Forecasting [50, 51].

A key assumption in the use of standard loglinear models for capture–recapture and multiple-recapture population estimation is that of constant capture probabilities, or homogeneity. A traditional approach to allow for heterogeneity has been stratification, with separate models used for individual homogeneous strata. The problem with stratification as a strategy is that it often leads to very sparse cross classifications, and a substantial increase in the variability associated with population estimates. Recent developments linked to a variation of the Rasch model have led to extensions of the standard models that allow for special multiplicative forms of heterogeneity; for example, see [1, 20].

(For further details on these and related models for population size estimation, *see* **Capture–Recapture**; **Rasch Models**.)

Latent Trait and Rasch Models

In psychologic tests or attitude studies, we are often interested in quantifying the value of an unobservable *latent trait*, such as mathematic ability or manual dexterity, on a sample of individuals. While latent traits are not directly measurable, we can either assume something about the way in which the latent trait relates to the observable or *manifest* variables or assume that we can assess indirectly a person's value for the latent trait from his/her responses to a set of well chosen items on a test (see, for example [5]).

In the 1970s, Goodman [44] and Haberman [N] developed a special representation for the analysis of contingency tables for manifest variables using loglinear models in the presence of latent variables, beginning with the traditional model in which the manifest variables are conditionally independent given the latent variables.

The second approach is prevalent in educational testing and has recently found its way into a wide variety of applications. The simplest model in this domain was introduced by Rasch [65], and is known as the Rasch model. Given responses from n individuals to k items in a test, the Rasch model permits the estimation of parameters associated with individuals and with items, as well as prediction of the person's behavior when confronted with a different set of items from the same domain. In the 1980s, an important relationship between the Rasch model and loglinear models was recognized by Tjur [70], Cressie & Holland [11], and Duncan [21]. The representation of these models in terms of symmetry and **quasi-symmetry** was presented in Fienberg & Meyer [32], Darroch [16] and Darroch & McCloud [17]. See also Anderson [D] and the article on **Rasch Models** for a presentation of this topic.

Association Models for Ordinal Variables

Loglinear models as described in this article ignore any structure linking the categories of variables, yet biostatistical problems often involve variables with ordered categories; for example, differing dosage levels for a drug or the severity of symptoms or side effects. Beginning in the late 1970s, methods for a special class of models, known as *association* models, moved to the forefront of methodological research. Goodman [45] provided a framework for association models that builds on extensions to standard loglinear models and utilizes multiplicative interaction terms. For a detailed description of these and other methods for ordinal variables, see Agresti [A] and Clogg & Shidadeh [G]. Etzioni et al. [25] provide a useful review of association models for ordinal variables in medical research using notation compatible with this article.

Loglinear Model Analyses

Bartlett's Data and No-second-order Interaction

For the 2^3 table of Bartlett, variables 2 (time of planting) and 3 (length of cutting) are fixed by design, so that $\hat{m}_{+jk} = 240$, and the estimated expected values under the no-second-order interaction model of the expressions given in (12) are shown in Table 4. These values were computed by Bishop et al. [E] using the method of *iterative proportional fitting* (IPF). Bartlett originally found the solution to (14) by noting that the constraints in his specification (11), reduced (14) to a single cubic equation for the discrepancy $\Delta = \hat{m}_{111} - x_{111}$. Note that the expected values satisfy (14), e.g., $\hat{m}_{12+} = 78.9 + 36.1 = 115 = 84 + 31 = x_{12+}$. The goodness-of-fit statistics for this model are $X^2 = 2.27$ and $G^2 = 2.29$. Using result 4 of the preceding section, one compares these values to tail values of the chi-square distribution with 1 df, for example $\chi_1^2(0.10) = 2.71$, and this suggests that the no-second-order interaction model provides an acceptable fit to the data.

Since the parameters u, $\{u_{2(j)}\}$, $\{u_{3(k)}\}$, and $\{u_{23(jk)}\}$ are fixed by the binomial sampling constraints for these data, the model given by (12)

Table 4 Observed and expected values for the Bartlett data, including the no-second-order interaction model

Cell	Observed x	Estimated expected $\hat{m}$
1,1,1	156	161.1
2,1,1	84	78.9
1,2,1	84	78.9
2,2,1	156	161.1
1,1,2	107	101.9
2,1,2	133	138.1
1,2,2	31	36.1
2,2,2	209	203.9

is often rewritten as

$$\log\left(\frac{m_{1jk}}{m_{2jk}}\right) = 2[u_{1(1)} + u_{12(1j)} + u_{13(2k)}]$$
$$= w + w_{2(j)} + w_{3(k)}, \qquad (18)$$

where

$$\sum_j w_{2(j)} = \sum_k w_{3(k)} = 0.$$

Expression (18) is referred to as a *logit* model for the log odds for alive versus dead (*see* **Logistic Regression**). The simple additive structure corresponds to Bartlett's notion of no-second-order interaction.

Waite's Fingerprint Data and Quasi-independence

For the Waite fingerprint data of Table 2, one model that has been considered is the simple additive loglinear model of (9), but only for those cells where positive counts are possible; that is, in the upper triangular section. For cells with $i > j, m_{ij} = 0$ a priori. This restricted version of the independence model is referred to as a **quasi-independence** model, and the results of the preceding section can be used in connection with it. The MSSs are still the row and column totals (result 1). The likelihood equations under multinomial sampling are (applying results 1 and 2):

$$\hat{m}_{i+} = x_{i+}, \quad i = 0, 1, 2, \ldots, 5,$$
$$\hat{m}_{+j} = x_{+j}, \quad j = 0, 1, 2, \ldots, 5, \qquad (19)$$

where $m_{ij} = 0$ for $i > j$. A solution of (19) satisfying the model can be found directly, or by using a standard iterative procedure. The estimated expected values for the fingerprint data under the model of quasi-independence are given in Table 5, and they satisfy the marginal constraints in (19).

The goodness-of-fit statistics for this model are $X^2 = 399.8$ and $G^2 = 450.4$, which correspond to values in the very extreme right-hand tail of the χ^2_{10} distribution. Thus the model of quasi-independence seems inappropriate. Darroch [15] describes the loglinear model of F-independence (with more parameters than the quasi-independence model), which takes into account the way in which the constraint – that the number of small loops plus the number of whorls cannot exceed 5 – makes the usual definition of independence inappropriate. This model in loglinear form is

$$\log m_{ij} = u + u_{1(i)} + u_{2(j)} + u_{3(5-i-j)}, \qquad (20)$$

where the u_3 parameters correspond to diagonals along which the sum of the numbers of whorls and small loops is constant. Darroch & Ratcliff [18] illustrate the fit of the F-independence model to a related set of fingerprint data involving large rather than small loops.

Table 5 Estimated expected values for fingerprint data under quasi-independence

	Small loops						
Whorls	0	1	2	3	4	5	Total
0	200.6	167.4	166.6	150.3	131.1	45.0	861
1	122.2	101.9	101.4	91.6	79.9		497
2	85.5	71.4	71.0	64.1			292
3	63.8	53.2	53.0				170
4	70.9	59.1					130
5	50.0						50

Application of Graphical Loglinear Models: Prognostic Factors for Coronary Disease

To illustrate some of the features of graphical models, we now analyze the data in Table 3 on prognostic factors for coronary heart disease among 1841 men in a Czech car factory. Our analysis follows closely that in Whittaker [S]. We begin by examining all partial association models and computing G^2 for each of the 15 partial association models found by setting one two-factor term equal to zero (see Table 6).

There are 16 df associated with each G^2 value. If we drop edges in a graph using the 0.05 P value for a χ^2 variable with 16 df, that is 26.30, then we end up with the graph shown in Figure 2.

Table 6 Goodness of fit of partial association models for coronary heart disease data

A	*					
B	22.65	*				
C	42.80	689.99	*			
D	28.72	12.23	14.81	*		
E	40.02	17.24	18.63	31.06	*	
F	21.31	22.79	22.15	18.35	18.32	*
	A	B	C	D	E	F

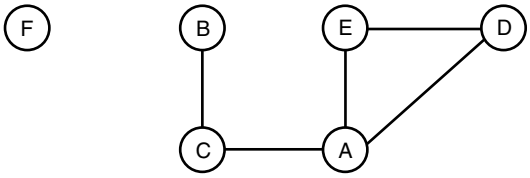

Figure 2 A preliminary graphical model for the prognostic factors example based on partial association models

The likelihood ratio statistic for the loglinear model corresponding to this graph is $G^2 = 83.75$ with 51 df. This corresponds to a P value of 0.0026, and suggests that we have deleted too many edges. A few additional steps of addition and deletion yield the model

$$[ABCE][ADE][BF],$$

for which the likelihood ratio statistic $G^2 = 44.59$ with 42 df suggests a well fitting model. The corresponding independence graph is shown in Figure 3.

The alternative graphical model shown in Figure 4, with two fewer edges, is somewhat simpler than the preferred model reported by Edwards [I] and fits the data well.

In Figure 4, F (family history) is conditionally independent of {D, E} (the physical symptoms), given {A,B,C} (the behavioral conditions). For further details on the analysis of this data set using graphical models, see Edwards [I] and Whitaker [S].

Bayesian Approaches

Background

In recent years, much attention has been directed to the development of Bayesian approaches for contingency tables and loglinear models. Early references include Good [39, 40] and Fienberg & Holland [31]. Initial attempts at formulating a Bayesian approach to estimation in contingency tables concentrated on the problem of incorporating *prior knowledge* about unobservable cell proportions or about expected cell counts. Those early efforts resulted in the derivation of the Dirichlet family of distributions as the *conjugate* family of **prior distributions** for cell proportions and expected counts. More recently, emphasis has been placed on formulation of more complex prior distributions that permit incorporating information about the underlying structure in a contingency table (e.g. Albert & Gupta [2, 3], Knuiman & Speed [52], and Epstein & Fienberg [23, 24]), and on computational issues (e.g. Gelman & Rubin [36], Epstein & Fienberg [23], and Gelman et al. [37]).

The general approach adopted by most of these authors has been as follows: using either the multinomial or the Poisson sampling models, incorporate uncertainty about the expected cell proportions (or expected cell counts) via the Dirichlet conjugate family of prior distributions, with variations to account for more or less structure in the expected cell means. **Markov chain Monte Carlo** methods (see, for example, Gelfand & Smith [35]) can then be used to approximate the marginal posterior distributions of the expected cell values or of any continuous functions of m.

A different, but parallel line of development is described in the work of, for example, Leonard [55], Laird [53], and Nazaret [58]. These authors address the problem of estimation in contingency tables from a loglinear model approach, and attempt to use Bayesian results similar to those developed by Lindley & Smith [56] for the linear model. Except where convenient for computations, we will describe the Bayesian methods that address contingency tables directly, without resorting to results from the linear models literature.

To introduce the Bayesian approach to estimation, we consider the counts $\{x_i\}, i = 1, \ldots, t$ (t equals the number of cells), to be observations from independent Poisson random variables, with means or expected

values $\{m_i\}$. In the Bayesian framework, the $\{m_i\}$ are random variables having some prior distribution, and the statistician's task is to update the prior to a *posterior distribution* by incorporating the information about the $\{m_i\}$ provided by the observed counts $\{x_i\}$. For the multinomial sampling model, we are interested in the marginal posterior distributions of parameters of a loglinear model, $\{\theta_i\}$, or the posterior distribution of the expected cell values, $\{m_j\}$. For the Poisson and the multinomial sampling models, likelihood functions are given in (1) and (2).

Estimation and Computation

Here we refer to the Poisson sampling model. Results, however, also apply to the multinomial model after appropriate normalization (see, for example, Gelman et al. [37]).

The simplest way to incorporate prior information about the value of the expected cell counts $\{m_i\}$ is via the Dirichlet conjugate family of prior distributions. If $\{m_i\}$ are jointly distributed a priori as independent Dirichlet random variables with parameters k and $\{\eta_i\}$, then the joint prior distribution has density function

$$p(\mathbf{m}|k, \boldsymbol{\eta}) \propto \prod_{i=1}^{t} m_i^{k\eta_i - 1}, \tag{21}$$

where $k > 0$ and $\eta_i > 0$. For $\boldsymbol{\eta} = \{\eta_i\}$, parameters η_i can be thought of as our prior "guess" about the value of $\{m_i\}$, while the *flattening constant* k [30, 39] represents our prior certainty about those guesses.

For the likelihood corresponding to the Poisson sampling model in (1), and for $p(\mathbf{m}|k, \boldsymbol{\eta})$ as in (21), the posterior distribution of the expected cell counts $\mathbf{m}$ is proportional to the product of the likelihood function and the prior distribution

$$\begin{aligned} p(\mathbf{m}|\mathbf{x},k, \boldsymbol{\eta}) &\propto \prod_i p(x_i|m_i) \times p(m_i|k, \eta_i) \\ &\propto \prod_i \exp\{-m_i\} m_i^{x_i + k\eta_i - 1}. \end{aligned} \tag{22}$$

Gelman & Rubin [36] and Gelman et al. [37] have developed a Bayesian version of IPF (BIPF) starting from (22) and using the multiplicative version of the loglinear model. Their algorithm produces estimates of marginal posterior distributions of the $\{m_i\}$ (or of continuous functions of the $\{m_i\}$) rather than point estimates (as does the standard IPF). In this sense, BIPF is a misnomer, since it incorrectly suggests that the Bayes estimates obtained are, as in the frequentist case, just point estimates of the $\{m_i\}$. For some details on the derivation of BIPF, the reader is referred to Gelman & Rubin [36].

Examples

In the previous section, we applied the BIPF to the Bartlett 2^3 table and to Edwards & Havranek's [22] six-way table on prognostic factors for heart disease. In both examples we used a multinomial sampling model with the constraints imposed by the sampling scheme.

The loglinear models that we fit to each data set were those described earlier. Thus, for the $2 \times 2 \times 2$ table of Bartlett, we used a loglinear model with main effects and all two-way interactions, while for the six-way table we used a model corresponding to

$$[ABC][ACE][ADE][BF].$$

We incorporated prior information via the Dirichlet conjugate family (see (21)), with $k\eta_i = 0.5$ for all i, that results is noninformative prior densities for the expected cell counts $\{m_i\}$. For a somewhat different Bayesian analysis of these data along with an excellent discussion of Bayesian model search focusing on graphical models, see [57]. Dobra, Karr, Sanil, and Fienberg [13] use similar tools in the context of disclosure limitation problems and apply them to these data as well.

Our Bayesian results for the Bartlett data are given in Table 7. To highlight the differences between results obtained from the frequentist and the Bayesian approaches (see Table 4 for the former), we provide not only a point estimate for the expected counts $\{m_i\}$ (we chose the means of the marginal posterior distributions as our point estimates) but also the posterior 5th, 25th, 50th, 75th, and 95th percentiles of the distributions of each $\{m_i\}$.

Note that, as required by the sampling scheme, $\hat{m}_{12+} = 78.75 + 36.01 = 114.8 = 84 + 31 = x_{12+}$ (within numerical error), and that the same holds true for $\hat{m}_{11+}$, $\hat{m}_{21+}$, and $\hat{m}_{22+}$.

We give results obtained for the prognostic factors for heart disease data in Table 8, which shows the means of the marginal posterior distributions of the expected cell counts $\{m_i\}$. Note that, as required, the

Table 7 Observed values, posterior means of expected values, and percentiles of posterior distribution of expected values for the Bartlett data, including the no-second-order interaction model

Cell	Observed x	Posterior mean	Posterior percentiles				
			5th	25th	50th	75th	90th

sum of the estimated expected counts equals N, the total number of individuals in the study.

Brief Guide to Computer Programs for Loglinear Model Analysis

As with other forms of multivariate analysis, the analysis of multidimensional contingency tables relies heavily on computer programs. A large number of these have been written to compute estimated parameter values for loglinear models and associated test statistics, and most computer installations at major universities have one or more programs available for users (*see* **Software, Biostatistical**).

The most widely used numerical procedure for the calculation of maximum likelihood estimates for loglinear models a decade ago was IPF, which iteratively adjusts the entries of a contingency table to have marginal totals equal to those used in specifying the likelihood equations. The IPF approach has been implemented in the BMDP 4F Program and in SPSS. The major advantage of the IPF method is that it requires limited computer memory capabilities since it does not require matrix inversion or equivalent computations, and thus can be used in connection with the analysis of very high-dimensional tables. Its major disadvantage is that it does not provide, in an easily accessible form, estimates of the basic loglinear model parameters (and an estimate of their asymptotic covariance matrix); it provides only estimated expected values.

MIM is an excellent Windows program for graphical modeling that is useful for fitting graphical (and other loglinear) models designed in part to accompany Edwards [I]. A student version is available free from `www.hypergraph.dk`.

The other numerical approaches suggested for the computation of maximum likelihood estimates are typically based on classical procedures for solving nonlinear equations, such as modifications of Newton's method or the Newton–Raphson method (*see* **Optimization and Nonlinear Equations**). Since such approaches can be implemented as part of the methods for the broader class of **generalized linear models** of which loglinear and logit models are special cases (see, for example, McCullagh & Nelder [P]), a common approach in several computer packages is to embed loglinear and logit models approaches as part of GLM routines, see; for example **S-PLUS** GLIM, SAS (PROC GENMOD),

STATA, and SYSTAT. The virtue of these programs is that they produce both estimated expected values and estimated parameter values, and an estimate of the asymptotic covariance matrix. The user of a GLM package should be sure to check the specific parameterization used, as the constraints on the loglinear models typically vary from package to package. No matter what the choice of parameterization for the loglinear model parameters, the estimates of the expected values and the goodness of fit statistic values should agree with those computed using the IPF algorithm. Some packages such as BMDP and SPSS also have separate subroutines for logit and logistic regression models. SAS's JMP has only a logistic regression routine.

Agresti [C] includes an especially nice appendix with a guide to SAS and SPSS programming, and Agresti [B] includes examples from GLIM and BMDP. Stokes et al. [69] provide a detailed guide with examples for the SAS PROC CATMOD, which can be used for loglinear models as well as a number of other approaches to the analysis of categorical data.

Before running any of the loglinear model or generalized linear model routines referred to above on sparse multiway tables with one or more zero entries, users should read the package documentation with care, since some packages may treat zeros in an unexpected fashion.

STEPHEN E. FIENBERG

Lognormal Distribution

The lognormal distribution is one of the most commonly used distributions for modeling the data arising in biostatistical studies.

The **random variable** X has a two-parameter lognormal distribution with parameters μ and σ^2 if $Y = \ln X$ has a **normal distribution** with mean μ and variance σ^2. The probability density function of the lognormal distribution is

$$f(x) = \frac{1}{x\sigma(2\pi)^{1/2}} \exp\left[-\frac{(\ln x - \mu)^2}{2\sigma^2}\right],$$
$$x > 0, -\infty < \mu < \infty, \quad \sigma > 0,$$

where σ is called the shape parameter.

The three-parameter lognormal distribution, a generalization of the two-parameter lognormal distribution, is obtained when X in the above definition is replaced by $(X - c)$ with $x > c$, where c is any real number (see [10] for further details). c is called the location parameter.

Properties

The properties of the two-parameter lognormal distribution are:

1. Mean $= \exp(\mu + \sigma^2/2)$.
2. Variance $= \exp(2\mu + \sigma^2)[\exp(\sigma^2) - 1]$.
3. Median $= \exp(\mu)$.
4. Mode $= \exp(\mu - \sigma^2)$.
5. The 100 pth percentile **(quantile)** $= \exp(\mu + z_p\sigma^2)$, where z_p is the pth percentile of the standard normal distribution.
6. The standardized lognormal distribution tends to the standard normal distribution as σ tends to zero.
7. The **moment generating function** of the lognormal distribution does not exist.

For more properties of the two- and three-parameter lognormal distributions, see [6] and [10].

Estimation of Parameters

The estimation of parameters μ and σ^2 of the two-parameter lognormal distribution, in general, follows from the above logarithmic transformation (of the data) and related estimation methods for the normal distribution. We refer the reader to [19] and [13] for an extensive discussion of statistical inference for the two-parameter lognormal distribution. The methods of estimation for the three-parameter lognormal and the truncated lognormal distributions are more complicated [4, 5]. The estimation in the presence of **censored data** is discussed in [4].

Applications

Aitchison & Brown [1] provide an extensive discussion of early history, the geneses and applications of lognormal distributions. Koch [11, 12] has discussed the geneses of lognormal distributions arising from biological and pharmacological mechanisms; for example, he considered the lognormal distribution for modeling the metabolic turnover. Many applications of the lognormal distributions in biochemistry are discussed in [15] and its references.

The lognormal distributions are useful for modeling data arising in many medical studies. The *hazard* function of the lognormal distribution first increases and then decreases. In many cancer studies the lognormal distribution is used as a survival distribution [2, 8, 9, 20] (*see* **Parametric Models in Survival Analysis**).

Lawrence [14] and the references cited in his paper provide an extensive review of the applications of the lognormal distribution in medical studies such as the incubation period of disease, the time to recovery, and duration of survival.

The delta–lognormal distribution, a variant of a lognormal distribution, appears in the analysis of ichthyoplankton data [17]. The **Poisson** mixture using the lognormal distribution arises in many ecologic studies such as the analyses of species frequency data [3, 8] (*see* **Contagious Distributions**). For more applications of the lognormal distribution arising in ecologic studies, see [7].

Mosimann & Campbell [16] discuss the lognormal distribution as a model for tissue growth. In the same paper, they also discuss the uses of the multivariate lognormal distribution for size and shape analyses arising in **allometry** studies.

M. RATNAPARKHI

Logrank Test

The *logrank test* (so named by Peto & Peto [1]) is a rank test for comparing two samples of right-censored survival data. A careful description of its several origins, history, and connection to other tests for one-, two- and k-sample problems in censored survival data is given in the article **Linear Rank Tests in Survival Analysis**. Here we merely define the test in the simplest situation.

Let $\tilde{X}_{hi}$, for $i = 1, \ldots, n_h, h = 1, 2$, be independent nonnegative **random variables** with absolutely continuous distribution function F_h and **hazard rate** α_h. We do not observe the $\tilde{X}_{hi}$ but rather the right-censored samples (X_{hi}, D_{hi}), $X_{hi} = \tilde{X}_{hi} \wedge U_{hi}$, and $D_{hi} = I\{X_{hi} = \tilde{X}_{hi}\}$ for some censoring times $U_{hi}, i = 1, \ldots, n_h, h = 1, 2$. It is assumed that there is *independent censoring* (*see* **Censored Data**), which would be true if the U_{hi} were independent random variables, independent of the $\tilde{X}_{hi}$. In accordance with the assumption of absolutely continuous distributions, we assume that all $\tilde{X}_{hi}$ are distinct (no ties). *See* **Tied Survival Times** for further generalization.

The (two-sample) logrank test tests the hypothesis $\mathrm{H}_0 : F_1 = F_2$ (or equivalently $\alpha_1 = \alpha_2$) by comparing the observed number of events in group 1,

$$O_1 = \sum_{i=1}^{n_1} D_{hi},$$

with the so-called expected number of events in group 1 under H_0 (*see* **Expected Number of Deaths**). The latter is estimated as

$$E_1 = \sum_{h=1}^{2} \sum_{i=1}^{n_h} D_{hi} \frac{Y_1(X_{hi})}{Y_1(X_{hi}) + Y_2(X_{hi})},$$

where $Y_h(t) = \sum_{k=1}^{n_h} I\{X_{hk} \geq t\}$ is the *number at risk* in group h at time t (*see* **Risk Set**). Indeed, it may be shown (still assuming no ties) that in large samples, $(O_1 - E_1)/\sqrt{V}_1$ is asymptotically **standard normal**, with

$$V_1 = \sum_{h=1}^{2} \sum_{i=1}^{n_h} D_{hi} \frac{Y_1(X_{hi}) Y_2(X_{hi})}{(Y_1(X_{hi}) + Y_2(X_{hi}))^2}.$$

NIELS KEIDING

Lomb Periodogram

The Lomb periodogram is a generalization of the periodogram (*see* **Spectral Analysis**) for unequally spaced series. Many biomedical time series are sampled irregularly because of missing data due to instrumental failures or because the nature of the measured variable makes the sampling interval intrinsically uneven. Since traditional spectral estimators need even sampling rates, unevenly spaced series should be interpolated and resampled before spectral analysis. By contrast, the method proposed by Lomb does not require interpolation and resampling [4]. Given N data $[y_i]$ sampled at times t_i, the normalized Lomb periodogram $P(\omega)$ (with ω the angular frequency $2\pi f$) is:

$$P(\omega) = \frac{1}{2\sigma^2}\left\{\frac{\left[\sum_{i=1}^{N}(y_i - \overline{y}) \times \cos\omega(t_n - \tau(\omega))\right]^2}{\sum_{i=1}^{N}\cos^2\omega(t_n - \tau(\omega))} + \frac{\left[\sum_{i=1}^{N}(y_i - \overline{y}) \times \sin\omega(t_n - \tau(\omega))\right]^2}{\sum_{i=1}^{N}\sin^2\omega(t_n - \tau(\omega))}\right\}, \quad (1)$$

where $\overline{y} = (1/N)\sum_1^N y_i$ and $\sigma^2 = (1/(N-1))\sum_1^N (y_i - \overline{y})^2$ are the mean and the variance of the data and

$$\tau(\omega) = \frac{1}{2\omega}\arctan\left\{\frac{\sum_{i=1}^{N}\sin 2\omega t_i}{\sum_{i=1}^{N}\cos 2\omega t_i}\right\}$$

is an offset that makes $P(\omega)$ invariant to time translation. An implementation in code by a fast algorithm can be found in [5]. Equation (1) defines a *normalized* periodogram because of the term σ^2 in the denominator. Scargle showed that with this normalization, $P(\omega)$ of a white Gaussian noise approximately follows an **exponential** probability distribution with unit mean [6]. A statistical test for detecting a periodicity in the data derives from this property. Given M independent spectral lines, if the highest periodogram ordinate exceeds the critical value $P_\alpha = -\ln(1-(1-\alpha)^{1/M})$, then it is significant at the false-alarm probability α, that is, the null hypothesis that the time series is a white Gaussian noise is rejected. A procedure for searching multiple periodicities is reported in [8].

The performances of the Lomb periodogram were extensively analyzed in studies assessing the heart-rate variability [3], the respiratory arrhythmia in neonates [2], and the **circadian** rhythms in oral temperature and urinary cortisol secretion [8]. This method shows some limitations when the data contain fractions of non-Gaussian noise or periodic signals with nonsinusoidal shapes [7] or when the sampling rate is not random, but depends on the value of the signal [1].

PAOLO CASTIGLIONI

Longitudinal Data Analysis, Overview

Longitudinal data arise when each member of one or more *cohorts* or *panels* of subjects provides a measurement on a number of occasions [21]. The cohort may be defined, for example, in terms of the date of birth of its members, the time of onset of a disease or, in the case of a clinical trial, the beginning of treatment or time of randomization. The *repeated (serial) measures* might be quantitative or qualitative, and may also be multivariate. For simplicity, however, the present discussion will be limited to univariate measures. Together, the results of these measurements will form a *response profile* (particular examples being *growth curves* (*see* **Nonlinear Growth Curve**) and time *trends* arising from **pharmacokinetic experiments**). Typically, longitudinal or repeated measures data are collected prospectively, but it is also possible to collect them retrospectively through the use of medical records, for example.

Time series data are similar to those described in this section but, on the whole, they can be distinguished from the latter because they usually arise from a single or, at most, a few extended sequences of observations as opposed to a larger number of shorter sequences. **Survival data**, *event history data* (*see* **Repeated Events**) *multistate* (e.g. states of well-being, morbidity, and death) *transition data* (*see*, **Fix–Neyman Process**) and **competing risks data** are also similar to repeated measures data in that they all involve observation over time. However, instead of enquiring about the state of a patient at each of a series of discrete times, investigators interested in survival times, for example, usually aim to record the exact date of death of each of the patients (i.e. the time of death is, in theory, a continuous rather than a discrete variable). The methods of analysis required for such data are distinctive, often involving time as an explicit response variable, and are covered for example, in **Survival Analysis, Overview**. In practice, many event recording systems do not record continuously but only to within discrete intervals of time, and continuously recorded data can be well approximated by grouping over short intervals of time. Such discrete event history or survival data can then be considered as a series of repeated qualitative measurements on each subject and analyzed using the methods of this article in which time is a covariate or design factor [44].

Studies may involve more than one timescale. For example, treatment studies often consider both time under treatment and subject's age, and multistate transition processes may involve effects due to time since entry to the current state and the cumulative time spent in that and other states. Care may be required to insure that effects on each scale are all **identifiable**. The difficulties posed by **age–period–cohort** effects are a well known example.

Longitudinal studies may be observational (e.g. **cohort studies** epidemiologic surveys) or experimental (e.g. controlled **clinical trials**). In a clinical trial, the treatment might remain constant for any particular cohort or group of patients (with random allocation of patients to the competing treatments) or vary from one occasion to another (with random allocation to groups defined by the order in which the treatments are received). In the case of the latter, the trial is an example of the use of a **crossover design**.

The simplest kind of longitudinal study involves taking measurements on all subjects at the same times: that is, each patient provides exactly the same set of measures. It is possible, however, for both the number and spacing of the repeated measures to vary from one subject to another. The latter may arise from the design of the study, but in addition may be due to unintentionally missing observations. Patients might, for example, fail to keep an appointment on a given date, might be too ill to be interviewed, or might permanently drop out of or be lost from the study through a variety of causes (e.g. death, emigration, or refusal to continue treatment). The various approaches to the statistical analysis of longitudinal data differ in their ability to cope with missing data and in the assumptions made concerning the mechanism by which the missing data might arise. Missing data are a challenge to valid inference from longitudinal studies (*see* **Diggle–Kenward Model for Dropouts**; **Nonignorable Dropout in Longitudinal Studies**). (For details of modeling missing data mechanisms, see, for example, Little [45] or Diggle & Kenward [14].) Investigators should minimize the occurrence of missing values, avoiding them altogether wherever possible. If missing values are inevitable, then investigators should collect as much information as possible about the reasons for the missing data and to try to incorporate this information in their analysis.

Examples of Longitudinal Studies

First, let us consider experimental studies. Frison & Pocock [26] describe a clinical trial in which 152 patients with heart disease were randomly allocated to treatment using an active drug or a placebo during a 12-month follow-up period. The concentration of the liver enzyme creatine phosphokinase (CPK) in the patients' serum was measured as an indicator of liver damage arising as a side effect of the treatment. Each patient had three pretreatment measurements which were taken at 2 months before, 1 month before, and at the time of randomization. They also had eight posttreatment measurements taken every 1.5 months after randomization. An example of a simple crossover trial is provided by Hills & Armitage [32]. The experiment was a comparison of the effects of an active drug and a placebo in the treatment of enuresis. One group of patients received 14 consecutive days of treatment with the active treatment, followed by a similar period of treatment using the placebo. A second group received the treatment combinations in the reverse order: placebo followed by active drug. The response variable was the number of dry nights out of 14: that is, each patient provided two measures – one corresponding to each of the two periods of treatment.

Longitudinal surveys are also common in medical research. Here we describe three longitudinal studies of lung function. Laird & Ware [39], for example, describe a survey in which pulmonary function in about 200 school children was examined under normal conditions, then during an air pollution alert and on three successive weeks following the alert. The main aim of the study was to determine whether the volume of air exhaled in the first second of a forced exhalation (FEV_1) was depressed during the alert. The analysis of repeated **categorical** measures has been illustrated by Ware et al. [55]. Children were assessed annually at ages 9–12 to evaluate the potential effects of air pollution on persistent wheeze. Parents were asked about wheezing by their children during the previous year and responses were grouped into three mutually exclusive categories or states: no wheeze, wheeze with colds, or wheeze apart from colds. Our final example concerns a survey with many missing observations. Lavange & Helms [41] analyzed data from a study of 72 children aged from 3 to 12 years. These data are also discussed by Little [45]. A measure of maximum expiratory flow rate was obtained annually, and differences in the resulting growth curve were related to the sex and race of the children. The number of actual measurements recorded on each child ranged from 1 to 8 (with an average of 4.2). Some values were missing because the child was either older than 3 at the beginning of the study, or younger than 12 at the end of it.

In the analysis of longitudinal data, the critical feature to recognize is that, since sets of measures are obtained from the same subjects, these measures are likely to be **correlated**, and can rarely be considered as independent even after conditioning upon known predictors or **explanatory variables**. How that dependence is dealt with is a principal distinguishing feature of different methods of analysis. However, before outlining these, we now consider more preliminary examination of the data.

Graphical Displays and Data Exploration

Diggle et al. [15] give the following simple guidelines for the exploration of longitudinal data using **graphical displays**:

1. show as much of the relevant data as possible rather than data summaries;
2. highlight aggregate patterns of potential scientific interest;
3. identify both **cross-sectional** and longitudinal patterns in the data;
4. make easy the identification of unusual individuals or unusual observations.

Here we produce a few simple plots for data on salsolinol levels (Table 1). These data were collected during an investigation into the role that the alkaloid salsolinol plays in bodily dependence on alcohol [30]. Fourteen individuals attending an alcohol treatment unit were observed over a period of four days immediately after being admitted to the unit, measurement of salsolinol being made from urine samples taken daily throughout the study period. The individuals were categorized as being in one of two groups: those considered to be severely dependent and those judged to be only moderately dependent. The response variables for the study are the four repeated measurements of urine concentrations of salsolinol. First, box plots (*see* **Graphical Displays**) of the distributions of the measurements at any one time point (see

Table 1 Salsolinol concentrations on four successive days

Obs.	Group	Day 1	Day 2	Day 3	Day 4
1	2	0.64	0.70	1.00	1.40
2	1	0.33	0.70	2.33	3.20
3	2	0.73	1.85	3.60	2.60
4	2	0.70	4.20	7.30	5.40
5	2	0.40	1.60	1.40	7.10
6	2	2.60	1.30	0.70	0.70
7	2	7.80	1.20	2.60	1.80
8	1	5.30	0.90	1.80	0.70
9	1	2.50	2.10	1.12	1.01
10	2	1.90	1.30	4.40	2.80

Figure 1) indicates **skewness**. A logarithmic **transformation** (base ten) of the salsolinol concentrations was therefore carried out prior to any further analysis. We next plot the time course for each individual subject, distinguishing the subjects from each of the two alcohol dependency groups (Figure 2).

In Figure 3 is shown a plot of the mean values of the logged salsolinol levels for the two groups, together with their **standard errors**. An alternative would have been to plot a series of box plots, perhaps revealing more information about between-subject differences at each of the time points. Figure 3 highlights the difference between the two groups in rates of change over time, although the main message appears to be that the groups are, in fact, very

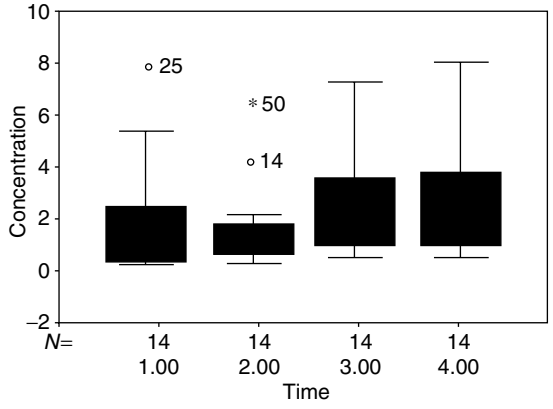

Figure 1 Salsolinol concentrations over time

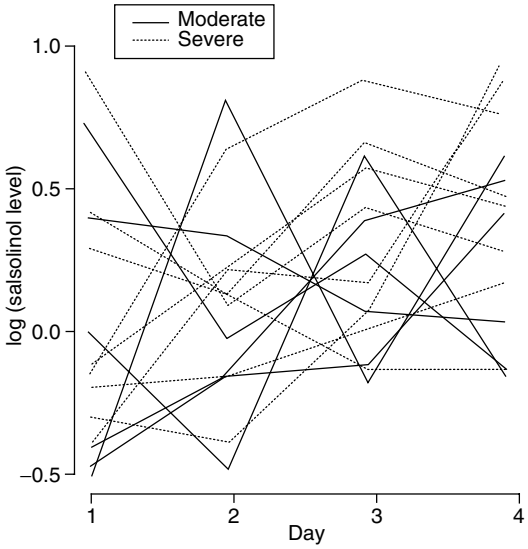

Figure 2 Salsolinol data – individual profiles after log transformation

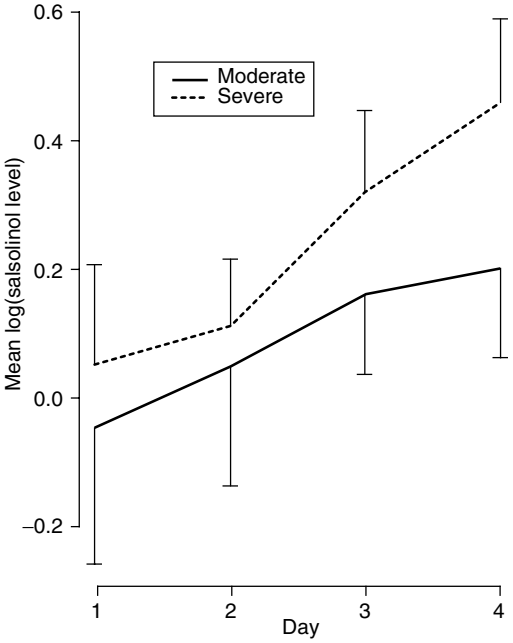

Figure 3 Mean profiles of salsolinol levels after log transformation for severe and moderate alcohol dependent groups

similar. Although graphs of means such as that found in Figure 3 (and, less often, box plots) are much more commonly seen than those for the response

profiles for individual subjects, great care must be taken in their interpretation. Figure 3 hides the pattern of *within-subject* changes. A graph of the latter type might also be very misleading if there were increasing numbers of dropouts over time, with the plotted means being calculated from the survivors at each time. If the dropping out is any way dependent on the present or previous state of the subject then the later means will be **biased**. One way of avoiding this bias is to plot means derived from cases with complete data, but the latter approach might be very inefficient if there are lots of dropouts.

Plots such as those provided in Figures 2 and 3 might indicate how one might extract suitable summary measures for each subject for a subsequent simple analyses of these response features. Visualizing the patterns in the data, and the subsequent extraction of the required response features, might be aided by smoothing each of the individual time courses. A search for the time of maximum response in a pharmacokinetic experiment, for example, might be quite difficult in the presence of considerable within-subject "noise". An example of smoothing in a pharmacokinetic experiment using a **moving average** prior to response feature extraction (the time of maximal response) is provided in Durcan et al. [18]. Other applications of smoothing methods, together with examples of their use, are described in Diggle et al. [15].

Another possibility is a simple multiple scatter plot (ignoring group differences) for the logged salsolinol concentrations. This sort of plot is ideal for the exploration of the correlation structure of repeated measures, although in a more complex data set with greater group differences, it would be preferable to remove the effects of explanatory variables and produce plots using the **residuals**. The results are not presented here, because there seems to be very little evidence of **serial correlation**. Finally, a plot that can be helpful in revealing the relative magnitudes of the sources of variance that give rise to correlations in continuous measures over time is the **variogram**.

Methods of Analysis for Continuous Responses

This section will be concerned with a few of the more commonly used strategies for the analysis of longitudinal data, with particular reference to continuous (usually **normally distributed**) outcome measures. We assume that the primary interest lies in changes in the average response over time at different levels of various explanatory factors, taking into account possible dependencies during **hypothesis testing** and **estimation**. The technical aspects of the methods will not be discussed in any detail but will be covered elsewhere. Methods for the analysis of categorical responses, transitions, and responses in the form of counts will be covered briefly in the next section.

Multivariate Generalizations of Paired t Tests

The **paired *t* test** is one of the basic methods for analyzing a simple two period, pretest/posttest study, comparing an estimate of the simple time 1 − time 2 difference contrast with the variance of this estimate. For greater numbers of measurement occasions, the multivariate generalization of this test is **multivariate analysis of variance** (MANOVA), that extends this approach to various linear contrasts relating to different aspects of change. As the paired *t* test can be generalized to an analysis of change scores, in which differences are regressed against factors and covariates, so too can this be done within MANOVA, in the form of *multivariate analysis of covariance (MANCOVA)*. These procedures enable one to test the differences between vectors of means with an entirely arbitrary pattern of correlations between the repeated measures. This method is therefore not dependent on any unrealistic assumptions concerning the patterns of serial dependencies, but is also likely to be less powerful than more refined methods that explicitly acknowledge the serial nature of the observations and correctly model the dependencies between them. These methods fail altogether when there are more design cells than subjects, a common occurrence where there are numerous measurement occasions.

Autoregression and Ante-Dependence

Another standard method for dealing with the correlation in the responses from a simple two-period study is **analysis of covariance** – analyzing the time-2 response conditional upon the time-1 response and predictors of change. This approach too can be generalized to larger numbers of measurement occasions. The **autocorrelation** or *autocovariance* between responses can either be considered as a nuisance to be allowed for in an analysis or, in

some applications, it can be regarded as the property of particular interest. Consider a possible model for serial dependencies between repeated quantitative measurements. Let $e_1, e_2, \ldots, e_T$ be uncorrelated random variables, where e_t has a mean of zero and variance σ_t^2 for $t = 1, 2, \ldots, T$. Now define a series of measurements $Y_1, Y_2, \ldots, Y_T$ by

$$Y_1 = e_1,$$
$$Y_t = \gamma_t Y_{t-1} + e_t, \quad t = 2, 3, \ldots, T.$$

If the γs are all equal ($\gamma_t = \gamma$ for all t) and so are the variance terms ($\sigma_t^2 = \sigma^2$ for all t), then these equations describe a stationary first-order *autoregressive process* (*see* **ARMA and ARIMA Models**). If, however, these parameters are permitted to vary with time then the equations describe first-order **ante-dependence**. A measurement at time t (that is Y_t) is dependent on the value of Y_{t-1} but, conditional on the value of Y_{t-1}, it is independent of all previous measurements. In general, a set of ordered measurements $Y_1, Y_2, \ldots, Y_T$ is said to have an independence structure of order r if the measurement at time t (with t greater than r), given the preceding r measurements, is independent of all further preceding measurements. Kenward [35] describes a method of assessing the order of a sequence of observations.

A simple unrestricted autoregressive model will involve $T(T+1)/2$ variance and covariance parameters, as would the equivalent MANOVA. An advantage of the ante-dependence approach is that it provides a simple but flexible path for specifying more restrictive dependencies, increasing efficiency for the testing of contrasts of interest and giving the capability of analyzing studies with few subjects and numerous measurement occasions.

In the analysis of a longitudinal data set, one can approach the problem of serial dependencies from several points of view. If we ignore their possible existence the analysis will be simpler, but the resulting inferences are likely to be invalid. If we can replace the response profile for each subject by one or possibly more summary statistics (*derived variables*) which extract the distinct features of interest then the problem is side-stepped. Any resulting analysis of these extracted *response features* will be unaffected by the serial dependencies in the original observations. Again, we might also choose to modify our original approach to analyze the data as if there were no serial dependencies (as in the traditional **analysis of variance** for a *nested* or **split-plot** experiment – the repeated measures being nested within subjects) but then to make adjustments to the resulting test statistics (or their degrees of freedom) to allow for them. This is the rationale for the well-known *Greenhouse–Geisser adjustment* (see [29]) (*see* **Analysis of Variance for Longitudinal Data**).

The more refined methods will be more difficult to carry out and interpret and, more importantly, will not necessarily be robust to an incorrect specification of these serial dependencies. Great care must be exercised in their use.

A related problem concerning the analysis of data from crossover studies is the possible presence of *carryover effects*. In the simplest design – the two-period, two-treatment crossover experiment – this is completely confounded with the treatment by period interaction or order effect. A carryover effect arises when an effect of an early treatment persists in later periods of the trial. This might be due to an inadequate washout period between two periods of chemotherapy, for example, or because the first treatment has induced some permanent change in the patient. Many authors have suggested that this design should only be used when it can be assumed a priori that such carryover effects are absent. Crossover designs should only be used when the short-term relief of chronic symptoms, rather than a cure, is the goal of the trial (examples being the use of lithium in the control of manic symptoms, or the use of insulin to control blood sugar levels).

Time-by-time Analysis

Following the common practice of plotting of group means for each separate time point, it comes as no surprise to find that investigators very frequently carry out separate statistical analyses at each of the time points. If there are n time points being considered, then there will be n separate analyses. On the whole, this is not a method of analysis that should be encouraged – it lacks power and the repeated tests are not statistically independent – although Finney [24] has advocated this **time-by-time analysis** when the number of times is small and the intervals between them large. Quite often, the researcher is interested in the question "At what time do the groups become significantly different?" and this is frequently the motivation for time-by-time analyses. If the latter is the case, then a modification of the approach by Kenward

[35] might be preferred. This is essentially a series of analyses of covariance looking at group differences at any given time point, typically using the previous one or two values as covariates. The method is based on assumptions concerning the ante-dependence structure of the data and the reader is referred to Kenward [35] for technical details. Examples of the use of Kenward's method under the assumption of second-order ante-dependence can be found in Crowder & Hand [13], and for the analysis of the salsolinol data under the assumption of first order ante-dependence in Everitt & Dunn [22].

Derived Variables

Inspection of the individual time courses in Figure 3 leads naturally to two related ideas. The first is to ask what summary statistic or derived variable might be extracted for each case which best describes the main feature of interest in the serial measurements. There may, however, be more than one feature of interest in a series of repeated measures. For our salsolinol data, for example, the two which immediately come to mind are the average of the four measurements for each individual and an overall rate of change (linear trend) for that individual. The second idea is based on fitting a separate **regression** model (growth curve) to each case. One might, for instance, use ordinary **least squares** to fit a straight line to each individual's data. The resulting estimates for the intercept term and slope parameter would, of course, convey the same information as the derived variables from the first approach, but they do suggest that one might extend the idea to the fitting of some sort of **multilevel** or **random effects** model to the data. This will be developed in the following subsection. Here we deal with the analysis of derived variables.

Having obtained the derived variables, we then enter them into a second stage of analysis to estimate their mean for two or more groups and to test for possible differences between these groups. Returning to the salsolinol data, it is in fact possible to derive a mean for the concentrations at the four times and three orthogonal polynomial trends (that is, linear, quadratic, and cubic trends) (*see* **Orthogonality**; **Polynomial Regression**). Differences in the means and trends across groups can be tested using simple t tests (or, in general, using ANOVA models) – each of the four derived variables being analyzed separately. Alternatively, we might wish to test for differences in all three trends simultaneously using **Hotelling's T^2 statistic** or, more generally, through the use of multivariate analysis of variance (MANOVA) procedures. One could, of course, include the average over time in this multivariate test, but this is usually analyzed separately so that one carries out separate analyses for the overall level and for the pattern of temporal change.

Random Effects Models

Returning once more to the salsolinol measurements, let Y_{ijk} represent the logarithm of the salsolinol concentration for the jth subject in the ith group on the kth day. Note that subjects are nested within groups. A possible regression model to describe the whole data set is

$$Y_{ijk} = \beta_0 + \alpha_i + \omega_{ij} + (\beta_i + \beta_{ij})t_k + \varepsilon_{ijk},$$

where t_k is the time to the kth measurement, and the parameters β_0, α_i, and β_i (the so-called fixed effects) correspond to the intercept term, the effect of being in the ith group on the intercept ($i = 1, 2$) and the linear effect of time in the ith group, respectively. The random effects are ω_{ij}, the effect on the intercept of subject j within group i, β_{ij}, the variation of the linear effect of time which is characteristic of subject j within the ith group, and the residual "error" term ε_{ijk}. In terms of the derived variables described above, the linear trend for the ijth individual is equivalent to the estimate of $\beta_i + \beta_{ij}$, but note that we are not now interested in estimating it explicitly – only its variance and possibly covariance with other effects. The random effects are all assumed to have zero expectation and the effects of real interest to the investigator are the β_is and possibly the α_is. Assuming that the responses are conditionally **multivariate normal**, we can then use **maximum likelihood** to estimate the fixed effects and the variances and covariances of the random effects, together with their respective standard errors [39].

Structural Equation and Latent Variable Models

Consider the observed variable, Y, which is now acknowledged to be measured with error. Typically,

$$Y = F + E,$$

where F is a latent variable or factor and E is the corresponding measurement error. If we now consider a series of repeated measures, $Y_t, t = 1, 2, \ldots, T$, with $Y_t = F_t + E_t$, it might be realistic to assume that the Fs are serially correlated, but that the Es are statistically independent. We also usually assume that the Fs and Es are independent. A latent first-order autoregressive model, for example, would have the form

$$Y_1 = F_1 + E_1$$
$$Y_t = \gamma F_{t-1} + E_t, \quad t = 2, 3, \ldots, T.$$

This simple latent variable model might well provide a **parsimonious** description of a series of measures when a similar first-order autoregressive model for the observed measurements would be hopeless. By acknowledging measurement error in this way, we can often considerably simplify the interpretation of the relationships within a set of serial measures. The above model (and any other) implies a particular structure for the covariance matrix of the repeated measures, and the model can therefore be fitted and its **goodness of fit** tested using covariance structure or **structural equation modeling** software (see [17], for example).

Another possibility is a random walk or Wiener model (*see* **Brownian Motion and Diffusion Processes**). Here

$$Y_1 = F_1 + E_1,$$
$$Y_t = F_1 + F_2 + \cdots + F_t + E_t, \quad t = 2, 3, \ldots, T.$$

Here the F_ts are random increments (or decrements) in the response variable Y_t which are "frozen in", accumulating over time. A third possibility is a latent growth curve model of the following form:

$$Y_1 = F_1 + E_1,$$
$$Y_2 = F_1 + F_2 + E_2,$$
$$Y_t = F_1 + \gamma_t F_2 + E_t, \quad t = 3, 4, \ldots, T.$$

In this case the two factors, F_1 and F_2, represent a baseline and a rate of growth (or decline), respectively, and it is quite usual to see that they are correlated; a relatively large child at the start of a longitudinal study, for example, also growing at a rate greater than most of the other children. The reader will note the similarity of this and the random effects model of a previous section.

Quite often, it is of interest to compare growth curves of two or more cohorts of subjects. The covariance structure software can easily deal with this by simultaneously fitting growth curve models to two or more observed **covariance** (or moments) **matrices**. One can then test for the equality of parameters of interest across the groups.

Robust Parameter Covariance Estimates

It will have become apparent that for analyzing longitudinal data, although the main interest may lie in estimating the effects of risk factors and exposures on the expected value of the response, it often seems necessary to expend more effort to ensure that the model for the variances and covariances among the response is correct. Huber [34], and subsequently White [57] and Royall [51], proposed a heteroscedastic consistent "sandwich" estimator for the parameter covariance matrix (*see* **Generalized Estimating Equations**). Variants of this covariance estimator are available among many of the software implementations of procedures described above (e.g. EQS). At the cost of reduced efficiency – often trivial but sometimes large – the use of this method provides some relief from an excessive concern that the random part need be correctly specified in every detail (*see* **Robustness**).

Methods for Responses in the Form of Counts and Categorical Responses

Multivariate distributions for categorical and count data lack the flexibility of the multivariate normal distribution that underlies many of the methods for analyzing repeated continuous responses. In general, choices of distribution that have simple expressions for marginal distributions yield unpleasant expressions for joint or conditional distributions. The statistical literature is awash with models based on various distributions and parameterizations that may cleverly fit the particular needs of the problem illustrated by the authors, but that lack generality. We consider here only methods that we believe have wide scope for application. The principal styles of analysis of repeated count and categorical data tend to focus upon one of two rather different aspects of the overall process. The methods of *survival analysis* tend to focus on issues of timing and on problems, where

the observation scheme is – at least nominally – continuous in time (*see* **Survival Analysis, Overview**). The remaining methods tend to focus rather more on *state occupancy* and *transition*, and often assume a discrete (and often equally spaced) observation scheme shared by all subjects and an analysis in which the treatment of the timescale is often implicit or simply another within subjects factor. These latter are the methods discussed here. This separation in styles of analysis is not always desirable, hampering our ability to generalize conclusions across observation and sample design schemes [4]. Methods that combine these two styles, such as *competing risk models*, are available but are typically cumbersome in use.

Contingency Tables and Loglinear Models

There is an extensive literature examining cross tabulated data from longitudinal studies of discrete outcomes, in particular making use of **loglinear models**. While in general useful as a preliminary tool, for scientific analysis of repeated measures data the interpretation of the parameters presents problems [6]. Kenward & Jones [36], for example, argue that the approach is more suited to "correlation rather than regression analysis". Discrete time Markov transition models (*see* **Markov Chains**) have received considerable attention, even though exactly how results relate to the process measured on a continuous timescale often remains open. Transition tables relating to social and economic mobility have been much studied [5]. Typically, all such tables show strong temporal associations among categories, often largely due to a tendency for simple persistence within the current class (*spurious contagion* [23]; *cumulative inertia* [47]). This has generated more specific forms of **contingency table** test for **quasi-independence** and **quasi-symmetry** (see Everitt [20]).

Latent Class Models

These inertia effects led to the exploration of *mover–stayer* models, a simple form of **latent class model** [42], in which attempts are made to explain a complex temporal association among categories by the admixture of populations each following a more simple temporal process. In this instance, the "stayer" population simply persists in the same category, while the movers might all share a uniform transition rate. Of course, latent class methods have also been applied to longitudinal data to tackle problems of misclassification. The estimation of so-called **hidden Markov chains** is a more recent interest, whether for transitions between states of psychopathology and estimated by maximum likelihood [60], or for repeated screenings for cervical cancer and estimated by Gibbs sampling [52, 58] (*see* **Markov Chain Monte Carlo**). An approach using continuous latent variables for categorical data is discussed below under GEE estimation.

Conditional or Fixed Effects Models

Although the inclusion of subject specific fixed effects as dummy variables into **logistic regression** models for repeated binary measures does not lead directly to a satisfactory form of analysis (due to the *incidental parameter* problem [50]; *see* **Estimating Functions**), an analysis conditioning on the **sufficient statistic** for such a subject-specific effect does. In the simple two-period case without covariates, this corresponds to the **McNemar test** [48]. More generally, it corresponds to a form of **conditional logistic regression** [2, 9, 10], a method familiar to those analyzing matched **case–control studies**. This approach yields estimates only of risk factors or exposures that are time-varying, and can be inefficient where there is substantial use between subject information on effects of interest.

Random Effects or Integrated Likelihood Models

At the cost of assuming subject effects to be uncorrelated with included explanatory variables, a random effects approach provides estimation of time-constant effects and more efficient estimates of time-varying effects. Assuming some distribution for subject-specific effects provides a likelihood for a sequence of discrete outcomes of the form

$$L_i = \int \prod_{j=1}^{T} h^{-1}(Y_{ij}|X_{ij}; \boldsymbol{\beta}, \tau_i)\, \mathrm{d}G(\tau).$$

In general, however, most choices of link function $h(\cdot)$ and parametric distribution $G(\cdot)$ for the subject-specific effects do not lead to an analytically tractable expression, even when the problem is simplified to one of time-constant subjects effects (the so-called

"one factor" model). Choice of the complementary log–log link together with a distribution of subject effects from the Hougaard family [33], for example the **gamma distribution**, offers some possibilities and can be combined with discrete latent classes [53]. Recourse to computational brute force – for example, using quadrature [27] or Monte Carlo methods [52] – allows the use of the potentially more flexible multivariate normal distribution for subject effects. Somewhat curiously, the computational burden becomes little greater if parametric restrictions are eased and instead the **nonparametric maximum likelihood estimator** of the random effects distribution is used [38]. In this case the distribution is represented by mass points with both weights and locations as free parameters, reducing the integration of the above equation to a summation (and almost always over fewer points than that required for "parametric quadrature"). The relationship between the nonparametric and conditional estimators is discussed in Lindsay et al. [43].

Penalized or Predictive Quasi-likelihood and Generalized Linear Mixed Models

An alternative approach to the computation of L_i is through some linearizing approximation, described as *penalized quasi-likelihood* (PQL) by Breslow & Clayton [7]. Essentially, this involves the iteratively reweighted least squares equations of standard GLM estimation [46] being extended to include current estimates of the random effects as well as those for fixed effects. For binary response data and few measurement occasions, this approach does not perform well [8, 16], particularly with respect to estimation of the random effects parameters. However, in many other circumstances it performs much better and offers a flexible and simple approach that yields satisfactory estimates for covariate effects of interest. A similar approach can be used to estimate the parameters of **marginal models** [28] that are considered in more detail in the next two sections.

Empirical Generalized Least Squares

All the preceding approaches have involved specifying some model for the covariance among observations due to the impact of subject-specific effects and past history, and estimating effects of interest conditional upon these effects. An alternative approach is to specify functional forms for the relationships of primary interest – say, the marginal relationship between outcomes and features of the study design – with the rest of the model that deals with covariances being saturated. In the *empirical generalized least squares* approach of Koch et al. [37], implemented in the SAS procedure CATMOD (*see* **Categorical Data Analysis**), the marginal expected proportions are replaced directly by their observed values to provide empirical logits, limiting this method to design matrices involving only discrete variables. These are then linearly related to explanatory variables. Since these proportions are neither independent nor equally variable, ordinary least squares estimation is not appropriate. However, the covariance matrix for these empirical logits will typically be block diagonal with one block for each unique combination of between subjects factors. The ith block is then estimated by $\mathbf{D}_i\mathbf{V}_i\mathbf{D}_i^{\mathrm{T}}$, where $\mathbf{D}_i$ is the matrix of partial derivatives of the logits with respect to the marginal proportions and $\mathbf{V}_i$ is their covariance matrix. With the need to avoid undefined empirical logits and singularities in the estimated covariance matrix, this approach has trouble with sparse data. Kenward & Jones [36] suggest 25–30 responses for each response function for reliable results, typically limiting this method to very few repeated measures. The general approach has been extended to tackle incomplete data and other response functions [40].

Estimation Using a "Working Covariance Matrix" and Generalized Estimating Equations

This powerful and flexible approach is described in the article on **Generalized Estimating Equations**. The approach represents a multivariate generalization of **quasi-likelihood** estimation, allowing a Fisher-scoring method of estimation for models for which a full likelihood may not be known. Although more commonly used to estimate marginal or population-average models, the generalized estimating equations (GEE) approach can also be used to estimate models including subject specific random effects [59].

Muthén [49] presented a related general approach that fits mixed effects and latent variable models to categorical data using a two-stage estimation method. This was based on first estimating fixed effects (thresholds and coefficients), their covariance matrix, a conditional covariance matrix of errors and their covariance matrix, all based on pairwise bivariate

probit. The second stage then fits models to these first-stage estimates. For large samples without complex patterns of missing data and with response measures of mixed type, this is a flexible and powerful method.

Marginal Maximum Likelihood Models

In fact, there are a number of parameterizations that include the marginal means as parameters and that allow closed form likelihood representations for binary sequences. Bahadur [3] described how the joint distribution of a binary sequence could be parameterized in terms of the marginal means and the marginal correlations. Estimation is, however, nonstandard in that the marginal correlations are subject to a reasonably complex set of linear inequality constraints. Fitzmaurice & Laird [25] provided a "mixed" parameterization, one involving the marginal means but parameterizing the association in terms of conditional odds ratios. These latter are unconstrained, and this parameterization also provides orthogonality between the regression and association parameters. It has the disadvantage of conditional parameterizations in that the association measures are specific to a fixed sequence length, and thus this model is not suitable in circumstances involving missing data (or variable length sequences) without further adaptation. Eckholm et al. [19] have provided a third parameterization, this time using the marginal means and the dependence ratio, the first-order dependence ratios being of the form $\mathrm{E}[Y_{ij} = 1, Y_{ik} = 1]/(\mathrm{E}[Y_{ij} = 1]\mathrm{E}[Y_{ik} = 1])$. Within this parameterization, the dependence ratios are subject to relatively simple constraints, the mean and association parameters are not orthogonal, and the model is asymmetric; different results will be obtained depending upon which response is coded 1 or 0.

Time-by-time Analysis

A structured approach to time-by-time analysis, one that provides a rather straightforward method for dealing with missing data, has been provided by Wei & Stram [56]. They provided an estimator for the covariance matrix of the sets of parameters estimated at each time and a method for tackling the problem of multiple testing.

Derived Variable Analysis

The summary measures method can be applied as for continuous data but with the obvious modification of changes in the form and estimation of the derived variables.

Ordinal Data

Extensions from binary to ordinal responses (*see* **Ordered Categorical Data**) are possible for most, though not all, of the methods described [1]. Among random effects approaches, the log-gamma mixed complementary-log–log link models extend directly to ordinal data [12]. The **proportional odds** generalization of the logistic model [11] with random effects can be estimated directly by ML [28] or, if the ordinal response is transformed into a set of binary responses each indicating a response above or below each threshold, then PQL or GEE estimation become easily implemented [7]. In principle, the empirical generalized least squares approach may be applied, but the problems associated with sparse data become still more pressing than with binary data. The multivariate probit-based latent variable approach of Muthén [49] generalizes naturally to the ordinal case.

Count Data

Where the response measure represents an accumulation of discrete events over an interval of time, the **Poisson** likelihood offers a natural starting point. Variable interval lengths are straightforwardly dealt with by means of an *offset*. Extra-variation between subjects beyond that due to the included explanatory variables of the model may be accounted for either by a random effect or by *quasi-likelihood* or robust parameter covariance estimation. Assuming a gamma distribution for the subject-specific variation in rate leads to the well known **negative binomial** model.

Where there have been repeated observation intervals with explanatory variables that vary between intervals, then the approaches available are essentially parallel to those described for repeated binary outcomes. Conditional and parametric random effects estimation are both feasible [31]. Thall & Vail [54] describe a GEE approach. Little progress has been made with latent variable models for count data.

Loss Function

The consequences of any decision will depend on the true state of nature, which determines whether the action corresponding to that decision is beneficial or harmful. The statistical formalization of this concept (*see* **Decision Theory**) has the following components:

Θ	is the set of all possible states of nature θ.
D	is the set of all possible decisions (actions) d.
$L(\theta, d)$	is the loss function that expresses the consequences of decision d when the state of nature θ holds.

By convention, the loss function is usually taken to be nonnegative, and is to be minimized. Since losses are to be compared or minimized, only the relative values of the losses of different decisions are important. Some synonyms for loss are "regret" and "cost". Alternatively, consequences are sometimes described in terms of "gain" or **"utility"**, and then maximization is the objective.

The loss function is useful in both statistical theory and in practical applications. A decision theoretic formulation of an existing procedure can clarify its interpretation by identifying its implicit loss function, and suggest generalizations. Practical applications include setting criteria to determine decisions related to disease for **screening**, setting treatment policy, **quality of life** issues, and study design.

Theoretical Uses of Loss Functions

A statistical decision procedure $\delta(X)$ yields a decision $d \in D$ based on the data X. Members of a set Δ of statistical procedures $\delta(X)$ are compared based on the loss function $L[\theta, \delta(X)]$ which, being a function of X, is a **random variable**. The risk of a decision procedure $\delta(X)$ is the **expectation** of the loss function, $R(\theta, \delta) = \mathrm{E}\{L[\theta, \delta(X)]|\theta\}$. Frequentist approaches (*see* **Inference**) compare procedures $\delta_1(X)$ and $\delta_2(X)$ by comparing the **risk** functions $R(\theta, \delta_1)$ and $R(\theta, \delta_2)$. In general, no procedure will minimize $R(\theta, \cdot)$ for all θ, so additional conditions are usually imposed. In ideal cases, the set Δ can be restricted according to a criterion such as **unbiasedness** (*see* **Minimum Variance Unbiased (MVU) Estimator**; **Most Powerful Test**), symmetry, or invariance [4], so that the risk function of some $\delta \in \Delta$ is dominated by all others, making the choice clear. Another approach, **minimax**, chooses the procedure which minimizes the maximum possible expected loss for any θ. **Bayesian** solutions minimize the expectation of $R(\theta, \delta)$ taken with respect to the **prior distribution** of θ.

Hypothesis testing can be viewed in terms of loss functions. Consider a hypothesis test of a **null hypothesis** H_0: $\theta = \theta_0$ vs. an **alternative hypothesis** H_1: $\theta = \theta_1$. Defining our loss to be 0 for a correct conclusion and 1 for an incorrect one gives the loss function shown in Table 1. The test is a decision function defined so that $\delta(x) = 1$ leads to rejection of the null hypothesis and $\delta(x) = 0$ leads to acceptance. The corresponding expected loss is shown in Table 2.

Thus $0-1$ loss leads to expected losses which are type I and type II errors in hypothesis testing. The traditional approach to hypothesis testing restricts Δ so that all tests considered have a fixed type II error. Minimizing the risk then amounts to maximizing the **power** of the test. Structuring the problem in this way aids in formulating more complex problems. For example, Emerson & Tritchler [3] elaborate the decision problem to incorporate a third type of error (Type III error) for a two-sided testing strategy (*see*

Table 1 Loss function for a hypothesis test

True parameter value	Decision: Decide $\theta = \theta_0$	Decision: Decide $\theta = \theta_1$
	Losses	
H_0: θ_0	0	1
H_1: θ_1	1	0

Table 2 Expected losses for a hypothesis test

True parameter value	Risk
θ_0	$0 + 1 \times \Pr(\text{decide } \theta = \theta_1 \mid \theta_0)$
θ_1	$1 \times \Pr(\text{decide } \theta = \theta_0 \mid \theta_1) + 0$

Alternative Hypothesis), concluding that a treatment is beneficial when the null hypothesis is false, but the treatment is actually harmful.

Parameter **estimation** can also be expressed in terms of an underlying loss function. Consider the decision procedure to be the parameter estimate $\hat{\theta}(X)$, which asserts the decision that the true parameter has value $\hat{\theta}(x)$. If $L[\theta, \hat{\theta}(X)] = [\hat{\theta}(X) - \theta]^2$, then $R(\theta, \hat{\theta})$ is **mean square error**.

Practical Applications of Loss Functions

Besides illuminating and guiding statistical theory, loss functions are of use in specific applications. Often the initial step of posing a problem in a decision theoretic framework will help to clarify aspects of a problem, even if the full decision theoretic solution is not required. Formulating loss functions will enable us to incorporate practical considerations into methodology, which are ignored in standard techniques. Some examples follow.

Suppose that the cost of the estimation error can be quantified in monetary units by the loss function $L(\mu, \overline{X}) = \lambda(\overline{X} - \mu)^2$. Then $R(\mu, \overline{x}) = \lambda\sigma_x^2/n$ is a function of only the sample size n, where the risk falls as n grows. We can add a term $C(n)$ to the loss function which states the cost of obtaining a sample of that size, and determine the n which minimizes the resulting loss given assumptions about σ_x^2 [1] (*see* **Sample Size Determination**).

Colton [2] proposed a loss function to guide the design of **clinical trials**. A treatment to be studied will affect two populations of patients: the $2n$ subjects on the two arms of the trial, and the "patient horizon", which consists of the N future patients who will be treated based on the results of that trial until future research provides an even newer treatment. Colton assigns a loss of λ to receiving the inferior treatment and 0 for the better treatment. Then, if the trial results are erroneous and lead to the adoption of the inferior treatment, the loss is $\lambda[n + (N - 2n)]$, since one arm of the trial and the patient horizon will receive the inferior treatment. If the correct treatment is chosen, a loss of λn is incurred by the arm on the inferior treatment. The relevant state of nature is the true treatment difference; a value for this is assumed and λ is taken to be proportional to it. Thus, the risk is $\lambda[n + (N - 2n)\,\Pr(\text{choose inferior})]$ for an assumed value of λ. This risk is a function of the sample size n; the first term of the above sum increases as n, but both factors of the second term decrease. This expresses the tradeoff between the welfare of the trial subjects and the patient horizon. Colton's loss formulation provides an interesting perspective on the impact of clinical trials.

Table 3 Loss function for eligibility screening

	Decision	
	Evaluate	Discard
True state	Losses	
Eligible	1	ϕ
Ineligible	1	0

Shannon et al. [6] consider the screening of patients for clinical trial eligibility. An initial screening of potential trial participants is done to select patients for further evaluation to determine eligibility. Table 3 shows the losses incurred by screening. The cost of evaluation is taken to be 1, and the loss due to discarding an eligible subject is ϕ times that, where $\phi > 1$ is specified subjectively.

In the examples, numerical losses were assigned to outcomes such as losing a trial participant or administering an inferior treatment. Losses of such a nature can be very difficult to quantify. Also, even if only monetary costs are involved, their direct interpretation as loss may be inadequate, especially after expectations are taken. These assessment and representation problems are addressed by utility theory, which derives techniques for quantifying perceptions of losses associated with complex outcomes having many incommensurate attributes [5]. If certain axioms hold, such loss functions accurately reflect preference when expectations are taken.

D. TRITCHLER

Louis, Pierre–Charles–Alexandre

Born: 1787, in Aï, France.
Died: June 9, 1872, in France.

P.-C.-A. Louis initially studied to be a lawyer; however, he abandoned law for medicine at the age of 20. After completing his initial medical training in Paris in 1813, he traveled throughout Russia for a period of seven years, eventually settling in Odessa. When Louis's medical training proved inadequate to combat an epidemic of diphtheria that occurred in Odessa in 1820, he resolved to return to Paris for additional study; however, he did not find much of use in the lectures of contemporary Parisian physicians.

With his appointment to the hospital, La Charité, in the early 1820s, Louis hoped to forge a more scientific foundation for medicine by collecting extensive records about the patients in the hospital, e.g. their ages, length of residence in Paris, the number who died and recovered from each disease, and the number of days duration of the disease. Louis used these records to determine the **mean** (or average) value for each analytical category and published his findings. In his study of typhoid fever, for example, Louis determined that it was primarily a disease of the young since the mean age of the 50 fatal cases was 23 and the mean age of the 88 who recovered was 21. In his 1835 treatise, *Recherches sur les effets de la saignée*, Louis provided the most famous example of his so-called "numerical method"; he demonstrated that the then common therapeutic practice of bloodletting was not as efficacious as its advocates believed, since 18 patients died out of 47 who had been bled (i.e. 38%) whereas only nine died out of the 36 patients who were not bled (i.e. 25%).

Louis's impact on the Parisian medical scene was most pronounced during the second quarter of the nineteenth century. In 1832, his followers founded the Société Médicale d'Observation to publish findings based on the numerical method. Although the society published three memoirs in 1837, 1844, and 1856, it did not survive after the retirement of Louis from public life in the mid 1850s following the premature death of his only son. Nevertheless, Louis had a long-term impact through the many students that he trained, including such prominent contributors to nineteenth century medicine and public health as the English physician and vital statistician **William Farr** and the American physician, Oliver Wendell Holmes.

J. ROSSER MATTHEWS

Machine Learning

Machine learning is the ability of a machine to recognize **patterns** that have occurred repeatedly and improve its performance based on past experience. According to Mitchell [4], a computer program is said to *learn* from experience E with respect to some class of tasks T and performance measure P, if its performance at tasks in T, as measured by P, improves with experience E. The underlying idea is to learn theory automatically from data. Machine learning **algorithms** are being applied to practical problems in a wide variety of contexts. Examples include **data mining**, such as searching for irregularities in patient **databases**, **image** recognition problems, and analyses of genomic data (*see* **Human Genome Project**). Machine learning is inherently a multidisciplinary field, drawing on results from **artificial intelligence**, probability and statistics, computational complexity theory, control theory, information theory, philosophy, psychology, neurobiology, and other fields [3]. Developments are occurring in many areas that are familiar to biostatisticians, such as **Bayesian** modeling, graphical models (*see* **Path Analysis**), **Markov Chain Monte-Carlo** methods, **neural networks** and **hidden Markov models**, as well as areas that could be better known such as vector support machines (SVMs). Machine learning tools include methods for **cluster analysis** (unsupervised learning), **discrimination** (supervised learning), **factor analysis**, **regression** and **time series** problems, to name a few. It is generally believed that machine-learning approaches are best suited for areas where there is a large quantity of data but little theory, and so in computational biology such approaches are being widely used; see [2]. Moreover in turn, the explosion of genomic data, and resultant questions and problems, has motivated many advances in machine learning.

The strength of the approach offered by machine learning is the ability to automate the process of fitting very flexible models (which are characterized by large numbers of parameters) to extremely large databases. Currently a weakness is the lack of appropriate techniques for model criticism and validation (*see* **Model Checking**; **Model, Choice of**). The training and validation set approach is often used (*see* **Cross-validation**), but care needs to be taken in its application; see, for example, [1].

Hastie et al. [3] present machine learning from a statistical viewpoint. So, for example, E, T, and P above translate in statistical terms to E: training examples, T: parameterized models, and P: loss/risk measures. Many of the novel ideas in machine learning such as neural networks, boosting, and SVMs have been strengthened by incorporation of statistical rigor and interpretation.

SUSAN R. WILSON

Magic Square Designs

A *magic square* of size n is a set of integers in an $n \times n$ square such that each of the n rows, n columns, and the two main diagonals have the same sum m. A magic square is called *pandiagonal* if all the $2\ (n-1)$ wrap-around diagonals (the combined diagonals that are $+g$ and $-(n-g)$ from a main diagonal, for $g = 1, \ldots, n-1$) also sum to m, and *symmetrical* if all pairs of cells that are symmetrically opposite the center of the square sum to $2m/n$. In the usual case of a *magic square of order n*, the integers used are 1 to n^2, and $m = n(n^2+1)/2$. A pandiagonal and a symmetric magic square of order 4 ($m = 34$, $2m/n = 17$) are, respectively,

15	10	3	6
4	5	16	9
14	11	2	7
1	8	13	12

16	2	3	13
5	11	10	8
9	7	6	12
4	14	15	1

For further discussion and methods of construction, see Dénes & Keedwell [6] and Freeman [8], and the references therein.

Phillips [10] showed how the entries of a magic square of size n with distinct integers can be used to give the times at which the n^2 runs for a **factorial experiment** are made so that the main effects are *linear-trend-free*; that is, **orthogonal** to a straight line trend over time. If n has k factors, $n = n_1 n_2 \ldots n_k$, $n_i > 1$, then a design for (up to) $2k$ factors with levels $n_1, n_2, \ldots, n_k$ (each twice) can be obtained for which the main effects and at least some of the two-factor **interactions** are linear-trend-free (more if the magic square is symmetrical). For example, consider the $n = 4$ pandiagonal magic square above. Letting rows 1 to 4 represent a_0b_0, a_0b_1, a_1b_0, and a_1b_1, respectively, and columns 1 to 4 represent c_0d_0, c_0d_1, c_1d_0, and c_1d_1, respectively, gives, in the usual notation, the following run order for a 2^4 design for which all two-factor interactions are linear-trend-free:

$$(a, abcd, cd, b, bd, c, abc, ad, bc,$$
$$d, abd, ac, acd, ab, 1, bcd).$$

Fewer factors can be used with levels that are products of the n_i, and some n_i can be omitted. For example, a magic square of size 6 can be used for a complete replicate $2^2 \times 3^2$, $2 \times 3 \times 6$ or 6^2 design, or for two replicates of a 2×3^2 or a 3×6 design, or three replicates of a $2^2 \times 3$ or a 2×6 design, etc. If there is more than 1 replicate, then it may be possible to measure order effects within each replicate. A pandiagonal magic square of order n can be used to obtain an n^{3-1} **Latin square** (three factors each at n levels) or, for n odd, an n^{4-2} **Graeco-Latin square** (four factors each at n levels) for which main effects are linear-trend-free. There has been considerable further progress made on trend-free and trend-**robust** designs; see, for example, Bailey et al. [1], Bradley & Yeh [5], and Lin & Dean [9].

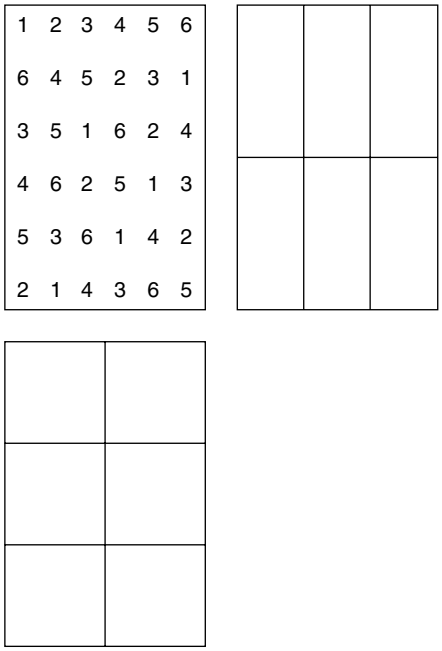
There are many connections between magic squares and *Latin squares*; see, for example, Dénes & Keedwell [6]. Amongst these are that if the integers $\{1, \ldots, n\}$ are used n times, then the magic square is a *diagonal Latin square*, and a pandiagonal magic square is a *Knut Vik design*. The Knut Vik design, which generalizes the well-known 5×5 knight's move Latin square, has five orthogonal constraints (block or treatment structures) of size n: rows, columns, the two sets of wrap-around diagonals, and the labels.

Another Latin square design, intended for n treatments in a spatial row–column layout, with one further block structure is the *Magic Latin square* (attributed to **G. M. Cox** – see Federer [7]). This requires a composite $n = n_1 \times n_2$, and forms spatially compact blocks using congruent $n_1 \times n_2$ rectangular blocks formed by the intersection of n_1 adjoining rows and n_2 adjoining columns. The extra set of blocks is not orthogonal to rows and columns, and care is needed in the analysis – see Bailey et al. [2, 3]. An example with $n = 4 = 2 \times 2$, showing the extra block boundaries, is

1	2	3	4
3	4	1	2
2	1	4	3
4	3	2	1

When $n_1 \neq n_2$, a *super magic Latin square* uses both $n_1 \times n_2$ blocks, and $n_2 \times n_1$ blocks to form

two extra sets of blocks. An example with $n = 6 = 2 \times 3 = 3 \times 2$ (with the two blocking structures to the right) is



The nonaliased contrasts in the two extra sets of blocks are not orthogonal – see Bailey et al. [2].

The *gerechte designs* introduced by Behrens [4] can be regarded as a generalization of magic Latin squares which use any convenient spatially compact blocks of size n. The block shapes do not need to be congruent, so that gerechte Latin square designs can be obtained for any n. Gerechte designs also exist for rectangular arrays. Careful analysis is required – see Bailey et al. [2, 3].

RICHARD J. MARTIN

Mahalanobis Distance

In 1936, **P.C. Mahalanobis** [22] proposed a measure, known as the generalized distance, or Mahalanobis distance, to assess the divergence between two populations based on observations on p characters or variates; the square of this distance is given by

$$\Delta^2 = \frac{1}{p}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2),$$

where $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ are the mean vectors of the p variates in the two populations, and $\boldsymbol{\Sigma}$ is the common **covariance matrix**.

Historical Background

In the 1920s, **Karl Pearson** and his associates considered the problem of "asserting significant resemblance or divergence" between racial groups based on anthropological observations (*see* **Anthropometry**). Following Pearson's suggestion, Tildesley [45] considered a measure, known as the "Coefficient of Racial Likeness" (CRL), given by

$$\frac{1}{p}\sum_{i=1}^{p}\frac{(m_{i1} - m_{i2})^2}{\sigma_{i1}^2/n_{i1} + \sigma_{i2}^2/n_{i2}} - 1,$$

where m_{i1}, σ_{i1}^2, and n_{i1} denote the mean, the variance, and the sample size, respectively, corresponding to the ith variate in the first population, and m_{i2}, σ_{i2}^2, and n_{i2} similarly correspond to the second population. In 1926, Pearson [29] considered only the first term of the above expression. Romanovsky [39] also considered some similar criteria.

Mahalanobis, during his study on caste-groups in India, observed that the coefficient of racial likeness was influenced by sample sizes and it failed to measure the divergence [14]. He [21] suggested a general class of measures, and, in particular, considered the following when homoscedasticity holds:

$$D_0^2 = \frac{1}{p}\sum_{i=1}^{p}\frac{(m_{i1} - m_{i2})^2}{\overline{\sigma}_i^2} - \frac{1}{p}\sum_{i=1}^{p}\left(\frac{1}{n_{i1}} + \frac{1}{n_{i2}}\right),$$

where $\overline{\sigma}_i^2$ is a "reliable" value for the common variance of the ith variate. Mahalanobis cited a number of comparisons in which the coefficient of racial likeness and his D_0^2 measure gave widely different results, but he claimed that the values of D_0^2 gave better representation of known anthropological facts. Furthermore, Mahalanobis also proposes measures to assess divergence in variance, **skewness**, and **kurtosis**.

Later, Mahalanobis [22] introduced the correlations among the variates in defining such a measure, and proposed the measure Δ^2 given above. The sample version of Δ^2 for known Σ is given by

$$D_1^2 = \frac{1}{p}(\overline{\mathbf{x}_1} - \overline{\mathbf{x}_2})'\boldsymbol{\Sigma}^{-1}(\overline{\mathbf{x}_1} - \overline{\mathbf{x}_2}),$$

as well as by

$$D_2^2 = \frac{1}{p}(\overline{\mathbf{x}_1} - \overline{\mathbf{x}_2})'\boldsymbol{\Sigma}^{-1}(\overline{\mathbf{x}_1} - \overline{\mathbf{x}_2}) - \left(\frac{1}{n_1} + \frac{1}{n_2}\right),$$

where $\overline{\mathbf{x}_1}$ and $\overline{\mathbf{x}_2}$ are the sample mean vectors based on samples of sizes n_1 and n_2, respectively. It may be noted that D_2^2 is **unbiased** for estimating Δ^2. For unknown Σ, the sample version of Δ^2 is given by

$$D^2 = \frac{1}{p}(\overline{\mathbf{x}_1} - \overline{\mathbf{x}_2})'\mathbf{S}^{-1}(\overline{\mathbf{x}_1} - \overline{\mathbf{x}_2}),$$

where $\mathbf{S}$ is the pooled within-group sample covariance matrix with degrees of freedom (df) $n_1 + n_2 - 2$.

Under the assumption that the p variates are distributed as a normal distribution in each of the two populations, the distribution of $pD_1^2 n_1 n_2/(n_1 + n_2)$ is noncentral **chi-square** with p df and noncentrality parameter $p\Delta^2 n_1 n_2/(n_1 + n_2)$. R.C. Bose [3, 4] obtained this result along with the **moments** of D_1^2. S.N. Bose [6, 7] also obtained the moments of D_1^2, but without using its distribution explicitly.

For the problem of testing equality of mean vectors of two p-variate normal distributions with common but unknown covariance matrix $\boldsymbol{\Sigma}$, Hotelling [19] suggested the **Hotelling's** T^2 statistic, given by

$$T^2 = n_1 n_2 (n_1 + n_2)^{-1} pD^2,$$

as the test statistic and also as a modified form of the Coefficient of Racial Likeness. It was shown by Hotelling [19] that the null distribution of

$$\frac{T^2}{n_1 + n_2 - 2}\,\frac{n_1 + n_2 - p - 1}{p}$$

is the ***F* distribution** with p and $n_1 + n_2 - p - 1$ df. This result was also obtained by Fisher [17, 18] in his pioneering papers on **discriminant analysis**; however, Fisher's derivation is not rigorous. Mahalanobis [22] obtained the first four moments of D^2, assuming Σ to be a diagonal matrix. The nonnull distribution of the above statistic is F with df p and $n_1 + n_2 - p - 1$, and noncentrality parameter $n_1 n_2 (n_1 + n_2)^{-1} p\Delta^2$; this was first obtained by Bose & Roy [5]. For a review of the evolution of the D^2-statistic, see DasGupta [14].

Mahalanobis Δ as a Distance

The frame of reference for the work of Mahalanobis was the p-variate normal distribution for the variates under study. It is now known that many standard distance measures, such as Kolmogorov's variational distance, the Hellinger distance, Rao's distance, and so on, are increasing functions of Δ when the two distributions are p-variate normal distributions with mean vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, and common covariance matrix $\boldsymbol{\Sigma}$ [27]. This result also holds for a variety of distance measures for elliptic distributions with different locations but common shape parameters [28]. For other related developments on distance functions, see Rao [31, 33, 37], Matusita [26], and Burbea & Rao [8].

Role of Mahalanobis Distance in Discriminatory Analysis

In order to discriminate between two populations based on observations on p characters $\mathbf{X}$, Fisher [17, 18] considered a linear discriminant function $\mathbf{l}'\mathbf{X}$ to maximize $[\mathbf{l}'(\overline{\mathbf{X}_1} - \overline{\mathbf{X}_2})]^2/(\mathbf{l}'\mathbf{S}\mathbf{l})$. The optimal $\mathbf{l}$ turns out to be proportional to $\mathbf{S}^{-1}(\overline{\mathbf{X}_1} - \overline{\mathbf{X}_2})$ and correspondingly, the above ratio becomes pD^2. Fisher then suggested to consider pD^2 as the test statistic to test "significance of the discriminant function", which means testing the equality of the population mean vectors. In this development, Fisher's frame of reference was of course two p-variate normal distributions with common covariance matrix. For the problem of discrimination between two p-variate normal distributions with different covariance matrices, see Anderson [2] and McLachlan [27].

For detailed developments on discriminatory analysis, see Cacoullos [9]. For discrimination of Gaussian processes, see Rao & Varadarajan [38].

Test on Distance

As discussed earlier, Hotelling [19] first proposed a test for $\Delta^2 = 0$ when the underlying distributions are normal with common but unknown covariance matrix. Rao [30, 32] proposed a test for "additional distance", which may be posed as $p\Delta_p^2 = q\Delta_q^2 (q < p)$, where Δ_p^2 denotes the value of Δ^2 based on p variates. DasGupta & Perlman [16] have shown that the power of Hotelling's T^2-test based on p variates may be smaller than the power of the test based on a subset of q variates unless the increase $p\Delta_p^2 - q\Delta_q^2$ is sufficiently large; they have suggested a test based on a preliminary sample so that the effectiveness of inclusion of additional variates could be ascertained.

Rao [35] considered tests for assigned (linear) discriminant functions, as well as for specifications of the ratios of discriminant function coefficients. All of these, in principle, fall into the realm of testing additional distance.

The null distribution of D^2 can be used to obtain simultaneous confidence intervals for $\mathbf{l}'(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)$; see Anderson [2].

Role of Mahalanobis Distance in Classificatory Analysis

The problem of classifying an observation vector $\mathbf{X}$ into one of two p-variate distributions with mean vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, and common covariance matrix $\boldsymbol{\Sigma}$, was first posed by Fisher [17] and developed later by Wald [47], Rao [34, 36], and Anderson [1], among many others; see McLachlan [27] for an extensive collection of results on this topic. For reviews of earlier work, see DasGupta [11, 13], Cacoullos [9], and Krishnaiah & Kanal [20].

When the parameters are known, the class of Bayes rules is given by the following: classify $\mathbf{X}$ into the first population if

$$(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)' \boldsymbol{\Sigma}^{-1} \left\{ \frac{\mathbf{X} - (\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2)}{2} \right\} \geq C;$$

otherwise classify into the second population. The probabilities of misclassification of any such rule are functions of Δ; in particular, if $C = 0$, the probabilities of misclassification are equal and the common value decreases as Δ increases. This result also holds when the parameters $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_2$, and $\boldsymbol{\Sigma}$ are unknown and they are respectively replaced by $\overline{\mathbf{X}_1}$,

$\overline{\mathbf{X}_2}$, and $\mathbf{S}$ in the above rule, and $n_1 = n_2$; for more detailed results, see DasGupta [12].

DasGupta & Kinderman [15] posed the concept of classifiability which sought condition on the structure of the populations in order to control probabilities of misclassification arbitrarily; for a related development, see Schaafsma & Steerneman [41]. For bounds, approximations, and asymptotic expansions relating to probabilities of misclassification, see McLachlan [27] and DasGupta [12]. For the problem of classification into one of two p-variate normal distributions with different covariance matrices, and the related role of Mahalanobis distance, see McLachlan [27]. Statistical methods for selecting variables in relation to the problem of classification and discriminatory analysis have been discussed in McLachlan [27] and Seber [44] (*see* **Variable Selection**).

Asymptotic Distribution of Δ

For the case of normal distributions, it follows from DasGupta [10] that

$$\mathrm{E}(pD^2) = f(f-p-1)^{-1}p\Delta^2 + (n_1^{-1}+n_2^{-1})f(f-p-1)^{-1}p,$$

where $f = n_1 + n_2 - 2$. Hence

$$\hat{\Delta}^2 = (f-p-1)f^{-1}D^2 - (n_1^{-1}+n_2^{-1})$$

is unbiased for estimating Δ^2. Moreover, the variance of $\hat{\Delta}^2$ is given by

$$(f-p-3)^{-1}\left\{2(p\Delta^2)^2 + 4n_1^{-1}n_2^{-1}(n_1+n_2)(f-1)p\Delta^2 + 2p(f-1)(n_1+n_2)^2n_1^{-2}n_2^{-2}\right\}$$

(see Schaafsma [40]).

It has been shown by Schaafsma & Van Verk [42, 43] that

$$\mathrm{E}(\sqrt{p}D) = \sqrt{p}\Delta + (4f)^{-1}(2p+1)(\sqrt{p}\Delta) + (2f)^{-1}(p-1)\kappa(\sqrt{p}\Delta)^{-1} + O(f^{-2}),$$

and

$$\mathcal{L}\left[f^{1/2}(\sqrt{p}D - \sqrt{p}\Delta)\right] \to \mathrm{N}\left(0, \kappa + \tfrac{1}{2}p\Delta^2\right],$$

as $n_1, n_2 \to \infty$, where $f(n_1+n_2)n_1^{-1}n_2^{-1} \to \kappa \in (0, \infty)$.

Other Applications

The domain of applications of Mahalanobis distance is quite extensive. In particular, the role of Mahalanobis distance in profile analysis (*see* **Summary Measures Analysis of Longitudinal Data**) and cluster analysis is significant (*see* **Cluster Analysis of Subjects, Nonhierarchical Methods**). See Mardia et al. [25], Van Ryzin [46], and Rao [36], in particular. The first application of Mahalanobis distance in cluster analysis is given in Mahalanobis et al. [23]. It may be noted that Mardia [24] has introduced a concept called "Mahalanobis angle", and illustrated its usefulness.

SOMESH DASGUPTA

Mahalanobis, Prasanta Chandra

Born: June 29, 1893, in Calcutta, India.
Died: 1972, in India.

Prasanta Chandra Mahalanobis was educated at Presidency College, Calcutta, and King's College, Cambridge, where he completed the Tripos in Mathematics and Natural Science (Physics). In Part II of the Tripos, he was the only candidate to receive a first class in physics. Cambridge University awarded him a research scholarship. Before starting his research, he traveled to Calcutta for a short vacation, but never returned to England. The war intervened. Also, he had found a teaching job and plenty of other interesting things to do in Calcutta.

Just before Mahalanobis left England for this vacation, his tutor, W.H. Macaulay, drew his attention to the journal ***Biometrika***. Mahalanobis found the articles interesting and purchased an entire set of available volumes and brought these back to Calcutta. A window was opened to a new area of science, permanently changing the direction of his life.

Early on, one of his mentors, Acharya Brojendranath Seal, a philosopher and an encyclopedist who was also interested in statistics, said to him "Prasanta, ... you have to do work in India similar to that of Karl Pearson in England. In today's world, whether it is science or social service, without statistical methods there is no way. This is your job." (Translated from a note in Bengali by P.C. Mahalanobis dated April 17, 1945.) Mahalanobis, who had already begun to read **Karl Pearson's** papers in *Biometrika*, took this challenge seriously. He thus developed an interest in statistical analysis of biological data, which was to last throughout his life and to which he was to make profound contributions.

In 1920, Mahalanobis met the Director of the Zoological and Anthropological Survey of India, Nelson Annandale, who requested Mahalanobis to analyze some **anthropometric** data on a group of Anglo-Indians of Calcutta. Mahalanobis analyzed the data and published his first paper on statistics [1]. He continued to analyze the other anthropometric data in this sample, and presented a synthesis of results in his Presidential Address to the anthropology section of the Indian Science Congress in 1925. In the address, "Analysis of race-mixture in Bengal", Mahalanobis sought to provide answers to several anthropological questions by using statistical methods. (An expanded version of this address was later published by him in 1927 [3].) For example, do Anglo-Indians show a greater affinity with the higher castes of Bengal or with the lower castes? Or, is there any appreciable admixture with aboriginal tribes? To answer such questions, a measure of distance between population groups based on anthropometric measurements was necessary. The only available statistic for comparing resemblance between populations was Pearson's coefficient of racial likeness (CRL) [11, 13]. Mahalanobis realized that the CRL provided a test of divergence between samples drawn from two populations rather than a measure of the actual magnitude of the divergence, because the magnitude of the CRL was dependent on sample sizes. In the study on Anglo-Indians, Mahalanobis proposed and used a measure of the actual magnitude of divergence that he called the "first (provisional) measure of caste distance", D. The resulting inferences derived by Mahalanobis have been found to be largely valid from his own work conducted later in the United Provinces [10] and in Bengal, as well as in later studies of others using more extensive data and more sophist-icated statistical techniques.

During the period 1926–1927, Mahalanobis spent about six months in Karl Pearson's laboratory in the University College, London. During this period, he undertook an extensive analysis of anthropometric data of various European population groups, and closely examined the utility of the CRL for measuring population relationships. In the process, the statistical shortcomings of the CRL became clearer. Upon returning to India, Mahalanobis's ideas on the problem of incorporating the observed **correlations** among anthropometric measurements used in measuring distance took a more concrete form. He published a seminal paper, "On tests and measures of Group Divergence" in 1930, in which the famous D^2-statistic was proposed (*see* **Mahalanobis Distance**) [4]. Based primarily on work done by him in Pearson's laboratory, Mahalanobis published a paper in *Biometrika* in the same year [5]. This paper was the "first application of CRL to the discrimination of racial differences to be ascertained from measurements on the living" (p. 94). It dealt with the populations of Sweden, and Mahalanobis presented an innovative graphical display of anthropometric interrelationships among the populations, taking two

additional extrinsic variables into account, geographical location of habitat and occupation. Thus, the concept of forming clusters of populations began to take shape (*see* **Cluster Analysis, Variables**).

Mahalanobis subsequently proposed the "natural" generalized distance D^2 for correlated variates, as well as its Studentized form using sample values of parameters [8]. In retrospect, it is clear that both measures play a fundamental, important role in statistics and data analysis. The practical impact of the D^2 statistic has been enormous, and continues to be used in many branches of science.

Mahalanobis was apparently not satisfied with simply providing a valuable tool (D^2) for cluster analysis. He began to raise fundamental issues about the application of the D^2 statistic, and argued that inferences on affinities among populations may depend on the number of measurements chosen for assessing distances between populations; in which case, conclusions would not have the desired practical significance. Affinity configurations may change if one set of measurements is replaced by another. Mahalanobis thus laid down an important axiom for the validity of cluster analysis, "dimensional convergence of D^2" [9]. Suppose D_p^2 and D_∞^2 denote, respectively, the distance between a pair of populations based on a set of p measurements and the distance based on all of the measurements. Since it is not possible practically to study all possible measurements, biometrical studies must rely on a finite number, p, of measurements. For affinity relationships to be stable, the distance based on p characters should be a good approximation of that based on the set of all possible characters. For Mahalanobis's distance measure, it can be shown that $D_p^2 \leq D_\infty^2$ and $D_p^2 \to D_\infty^2$ as $p \to \infty$. Mahalanobis's axiom of dimensional convergence states that a suitable choice of p can be made if and only if D^2 is finite. Unfortunately, this important axiom is not mentioned in most textbooks on numerical taxonomy or cluster analysis.

The formulation of the D^2 statistic, derivation of its properties, and its applications are undoubtedly the most profound contributions of Mahalanobis to biostatistics. However, Mahalanobis made many other interesting contributions. Some of the early statistical studies he undertook were on **experimental designs** in agriculture. In 1924, he made some important discoveries pertaining to the probable error of results of agricultural experiments, which put him in touch with **R.A. Fisher**. Later, in 1926, he met Fisher at the Rothamsted Experimental Station and a close personal relationship was immediately established that lasted until Fisher's death. He possessed an uncanny sense of numbers and could quickly point out recording mistakes in data. In two papers entitled, "Revision of Risley's anthropometric data", Mahalanobis [6, 7] reconstructed the large series of anthropometric data, which were earlier condemned as faulty and unsuitable for statistical analysis. This work was highly praised by Sir Ronald Fisher [12]. He also conducted studies on dextrality of snail shells, correlates of disease prevalence in humans and plants, **demography**, and so on. In most of these studies, Mahalanobis developed novel statistical methods or made innovative applications of known methods. For example, in one of his early statistical studies on the **prevalence** of dysentery and its correlates, Mahalanobis [2] developed some useful smoothing techniques for **time-series** data using Fourier series (*see* **Fast Fourier Transform (FFT)**). Such techniques are now commonly used.

Mahalanobis's contributions to large-scale sample surveys, which are among his most significant and lasting gifts to statistics, began with problems of the estimation of area and yield of the jute crop in Bengal in 1937. He was able to demonstrate that estimates based on sample surveys were often more accurate than those based on complete enumeration, and that sample surveys could yield estimates with small margins of error within a short time and at a smaller cost than complete enumeration. He made many methodological contributions to survey sampling that included optimal choice of sampling design (*see* **Optimal Design**) using **variance** and cost functions, and the technique of an **interpenetrating** network of subsamples for assessment and control of errors, especially **nonsampling errors**, in surveys. The concept of pilot surveys was a forerunner of **sequential analysis** developed by **Abraham Wald**, as acknowledged by Wald. In addition to introducing these concepts, Mahalanobis raised important and difficult philosophical questions on the **randomness** and representativeness of a sample, which remain relevant and challenging even today. He was elected Chairman of the United Nations Sub-Commission on Statistical Sampling in 1947, and held this post till 1951. His tireless advocacy of the usefulness of sample surveys resulted in the final recommendation of this Sub-Commission that sampling methods should be extended to all parts of the world. Mahalanobis

received the Weldon Medal from Oxford University in 1944 and was elected a Fellow of The Royal Society, London, in 1945, for his fundamental contributions to statistics, particularly in the area of large-scale sample surveys.

As a scientist, Mahalanobis was, above all, a great applied statistician. Statistics were to be used for a better understanding of scientific data, and for decision-making for the welfare of society. Innovation, systematization and concrete applications are the hallmarks of the applied statistics practiced by Mahalanobis.

J.K. GHOSH & PARTHA P. MAJUMDER

Mainland, Donald

Born: April 5, 1902.
Died: July 1985 in Kent, Connecticut.

Donald Mainland graduated in medicine at Edinburgh. He later taught anatomy in Edinburgh and received a Doctor of Science degree there for his research in embryology and histology. He moved to Manitoba, Canada, in 1927 and in 1930 became Professor and Chairman of the Department of Anatomy at Dalhousie University.

His early publications showed a concern about measurement issues, and foreshadowed an increasing interest in statistics. In 1936 he wrote on problems of chance in clinical work [2] and the following year he published his first book on statistics in medicine [3]. In 1950 he became Professor of Medical Statistics at New York University and shortly afterwards published his best known book, *Elementary Medical Statistics* [4]. Thereafter, Mainland was a prolific and influential writer on statistical topics.

In addition to his books, Mainland's notable contributions included several series of short essays on statistical topics, most of which were not published in journals but circulated to those "who were lucky enough to learn about 'the Notes', and to satisfy Mainland's hardy standards for the mailing list" [1]. From August 1959 to September 1966 he produced 145 items in the series, *Notes from a Laboratory of Medical Statistics* [5], a further 104 items in the series, *Notes on Biometry in Medical Research* [7], and 16 longer articles as "statistical ward rounds" from 1967 to 1969 in *Clinical Pharmacology and Therapeutics* [6].

After his retirement, Mainland continued to publish occasionally on statistical issues, with two typical outspoken and readable papers published in the *British Medical Journal* when he was in his eighties [8, 9].

The common sense consistently displayed in his writings was undoubtedly greatly aided by his extensive research and teaching in biology – he had also published a textbook on anatomy – and active participation in clinical research.

In 1970, when Mainland ceased writing his series in *Clinical Pharmacology and Therapeutics*, his successor in that role, Alvan Feinstein, described Mainland's contributions to improving the understanding and practice of statistics in medicine [1]. Among his generous comments Feinstein observed, "With his textbook . . . and his many other writings, he has probably contributed as much as any single person to the statistical sensibility of clinical investigators in North America" [1].

DOUGLAS G. ALTMAN

Mallows' C_p Statistic

This criterion can be helpful in selecting a biased linear model with fewer parameters and lower **mean square error** (MSE) than one with more parameters and their associated estimation errors. If a p-parameter linear model is fitted by unweighted **least squares** to n observations $y_1, \ldots, y_n$ (supposed uncorrelated and homoscedastic with variance σ^2) giving a residual sum of squares RSS_p (*see* **Analysis of Variance**), then C_p is defined by

$$C_p = \left(\frac{\mathrm{RSS}_p}{s^2}\right) - (n - 2p),$$

where s^2 is a trustworthy estimate of σ^2.

This criterion was introduced by Jones [2] in the equivalent form

$$JC_p(\text{say}) = \frac{\left[\mathrm{RSS}_p - (n - 2p)s^2\right]}{n}.$$

Under the conditions stated and if $\mathrm{E}(s^2) = \sigma^2$, JC_p is an **unbiased** estimate of the MSE, $\mathrm{E}\{\sum \hat{y}_i - \mathrm{E}(y_i)]^2/n\}$, of the model's fitted values as estimates of the true expectations of the observations. (A model with low MSE, as thus defined, may have good performance only for values of the independent variables in the region already observed.)

In order to guide the delicate practical choice of linear model from a number of alternatives, Mallows [3] developed his independent discovery of C_p into a graphical plot of C_p against p on which the line $C_p = p$ is drawn. In this plot the value of p is (roughly) the contribution to C_p from the variance of the estimated parameters, while the remainder $C_p - p$ is (roughly) the contribution from the **bias** of the model. This feature makes the plot a useful device for a broad assessment of the C_p values of a range of models. Its use does not (or at least should not) in itself inhibit choice of the model with the minimum value of C_p. Moreover, if that choice is made, the plot gives no obvious quantitative indication of the extent to which that minimum value, converted to JC_p, underestimates, as a consequence of selection bias, the actually operative MSE. (In [4], Mallows uses asymptotics in which, realistically, p goes to infinity with n – to provide such a quantitative indication, for a range of applications of the plot.)

The numerical comparisons in Burman [1] suggest that the use of just a "one-deep", leave-one-out cross-validatory criterion (*see* **Cross-validation**) may be more **robust** than C_p with respect to that selection bias. However, suggestions like this should be treated cautiously: the whole area abounds in competing and only partially substantiated claims.

For the relationship between C_p and Akaike's AIC, *see* **Akaike's Criteria**.

M. STONE

Malthus, Thomas Robert

Born: February 17, 1766, in Guildford, UK.
Died: December 23, 1834, in Bath, UK.

After an early education by private tutors, Malthus went to Jesus College, Cambridge, where he studied history, poetry, modern languages, classics, and mathematics. He was elected to a Fellowship at Jesus in 1793, and became a curate in a small town, Albury, in 1798. In that year he published the first version of his celebrated *Essay on the Principle of Population as it affects the Future Improvement of Society*, to be followed in his lifetime by five further editions. Malthus argued that a population would tend to increase geometrically, whereas the means of subsistence would increase only linearly. The consequent pressure caused by increasingly inadequate means of support would be a major determinant of political events and structures. The task of government was to counteract this dire prognosis by measures of population control, such as the encouragement of later marriage, rather than relying on increased poverty and mortality. Malthus's gloomy views ran counter to those of many progressive thinkers, but influenced Darwin's thought.

Malthus was a strong advocate of statistical investigation, and was a founder member of the Statistical Society of London (later the **Royal Statistical Society**) in 1834. His death, only nine months later, led the Society's Council to lament the loss of one "so celebrated in every part of the world where the science of Statistics is cultivated", describing him as "an ardent lover of truth, ... a sedulous investigator of facts, and a generous encourager of all who have followed in the same laborious path" [2] (see also [1, 3]).

The "Malthusian parameter" denotes the rate of increase that would ultimately be achieved by a population with observed age-specific birth and death-rates (*see* **Demography**).

PETER ARMITAGE

Mantel, Nathan

Born: February 16, 1919 in New York City, New York.
Died: May 26, 2002 in Potomac, Maryland.

Nathan Mantel, pioneering biostatistician, and author of more than 380 published articles, was born in New York City to Polish and Hungarian immigrants, Rose Steinberg and Hyman (Nehemiah) Mantel. Nathan was the middle child between two sisters, Ray (Rifka, born 1917) and Anne (Channa, born 1920). Like many Jewish immigrants at the time, Nathan (Naftoolyah) grew up on the lower east side of New York City in tenement housing. He was raised poor, speaking Yiddish at home and at Hebrew School, but speaking and writing in English at his public school [11]. During the great depression, his Judaic studies took a turn away from the Orthodox Judaism of his parents when he and his sisters began residence in the Hebrew Orphan Asylum at 137th Street, Amsterdam Avenue. This unassuming orphanage provided safe harbor for many other future notables. Also in residence were Art Buchwald (syndicated columnist), Aaron L. Jacoby (politician), Dr. Herman Schwartz (biologist), Harold Tovish (sculptor), and many others [2]. During his adolescence, Nathan's maternal grandparents and 11 aunts, who had all remained in Eastern Europe instead of immigrating to the United States, were killed in the holocaust. Many of his paternal relatives immigrated to America successfully.

Nathan's academic training began at New York City's Stuyvesant High School. This premier school for science and mathematics helped to cultivate Nathan's interest and ability in mathematics, though his mature interest did not manifest itself until much later in his life. By most accounts, he was only a mediocre student [11]. However, even in high school, he participated in mathematics competitions. In his senior year, he derived a novel way to solve the Diophantine equation ($ax - by = c$), which was later published in the *American Mathematical Monthly* [7]. This would be the first of his numerous publications. In 1939, he graduated from City College of New York with a major in statistics. At City College, he took courses with other future statisticians, including Marvin **Schneiderman** and Bernard **Greenberg**. He later went on to earn a Master's degree in statistics from American University in 1956, already having published twenty-one articles in the field.

His career as a professional statistician began in 1940, after a series of low-level federal jobs. At this time, Nathan was recruited into what later became the War Production Board, where his skills helped increase the output of the nation's factories. Later, a portion of his World War II military service in the Army Air Force involved statistical analysis of medical research. But, with the war's end, the agency closed down and Nathan, who at that time was living with his family in temporary government housing in what is today the National Park Service's Kenilworth Aquatic Gardens, was jobless.

In 1947, Mantel went for a job interview at the National Cancer Institute (NCI) in the **National Institutes of Health** (NIH). He was quickly hired by Harold **Dorn** as a member of a new biometry group and set to work with such biostatisticians as Jerome **Cornfield**, Samuel **Greenhouse**, Jacob Lieberman, and Marvin Schneiderman (an old college pal of Nathan's). The rest, as they say, is history. Of this time period, Sam Greenhouse wrote, "... among statisticians the world over, we had probably the greatest artist of all – Nathan Mantel. No one could match him in quickly identifying the information in the data related to the questions and the swiftness with which he was able to choose an optimum method of analysis. The statistical procedures which bear his

name are really nothing compared to his ability to analyze data. The former would have eventually been derived by others, but it is doubtful whether anyone else has had his intuition" [5].

In the field of biostatistics, Nathan Mantel has published papers on leukemia, lung cancer, Down's syndrome, chemotherapy, breast cancer, passive smoking, vehicle emissions, and much more. Most notably, he developed the **Mantel–Haenszel** procedure and its extensions. William **Haenszel**, who had been working on interpreting the **case–control studies** of the connection between **smoking** and lung cancer, requested Mantel's assistance on how to analyze the retrospective data. Mantel then collaborated with Haenszel on a paper that aimed to reach the same conclusions "in a retrospective study as would have been obtained from a forward study, if one had been done" [10]. Their highly cited paper, "Statistical Aspects of the Analysis of Data from Retrospective Studies of Disease", [10] presents the Mantel–Haenszel procedure, which provides a summary estimate of the exposure effect stratified by multiple sources (i.e. different studies) or **confounding** factors (such as age and sex), which is a weighted average of the **odds ratios** across various strata.

The applications and extensions of this procedure are many. Since this test allows for combining data from different sources, it can be used in a variety of contexts: retrospective studies, prospective studies, and laboratory experiments, including those with litter-matched samples. Mantel used the procedure to develop the first version of the **logrank test**, a test that compares **censored** time-to-response distributions [8], and later extended the test to the evaluation of response time data involving transient states [9]. These important applications contributed greatly to the development of **survival analysis** [4]. Mantel notes about his 1959 paper: "It turned out that the procedures in the paper could be extended so that they met perhaps 90 to 95 per cent of the kinds of problems that people were encountering" [6].

In addition, Mantel offered abundant insights to both **epidemiology** and laboratory research: He demonstrated that a prospective logistic risk model can be used to analyze case–control data [6]. He also explored the distribution of cancers among related diseased pairs to test whether the cause of the cancer was due to environmental exposure in addition to hereditary factors [4]. Further, Mantel developed methods to investigate temporal and spatial **clustering** of diseases such as polio, hepatitis, and childhood leukemia [4]. In 1961, Nathan devised the Mantel–Bryan approach to test for safety of carcinogenic agents (*see* **Tumor Incidence Experiments**). His definition of a "virtual safe" dose as a risk of one per 100 million or less was used by the **Food and Drug Administration** for several years before the standard was adapted to a less conservative definition of "safety" at one per million or less [6]. He later commented in an EPA Watch newsletter about the arbitrary nature of the original standard: "We just pulled it out of a hat" [1]. Upon hearing that a bureaucrat had dropped two zeros from his standard of one per 100 million, Nathan is reported to have remarked, "Well, that's government science for you!" Describing his overall approach to problem solving, Mantel wrote, "I generally don't generate ideas of my own. Someone has to come to me with a problem. And, apparently, I'm pretty good at coming up with solutions or ideas for solutions. Identifying problems is what is important – solutions just follow." [3].

A recipient of many professional honors, after retiring from the NCI, Mantel served as a research professor at George Washington University and later at American University. He was a visiting scientist at the New York University School of Medicine, a visiting professor at the University of Tel Aviv, and a visiting professor in neuroepidemiology at Temple University School of Medicine. He was also a lecturer at the China National Center for Preventive Medicine in Beijing. At its 2002 Annual Meeting, the **American Statistical Association** announced the establishment of the Nathan Mantel Lifetime Achievement Award for statisticians who have made significant contributions to the field of biostatistics over their careers. Nathan did not live to see the presentation of this award, as he died in his sleep on May 26, 2002. The epitaph on his gravestone reads, "One in a million", which serves as a concrete reminder of his lasting contributions to statistics and public policy. For additional biographical information and summaries of Nathan's work, refer to [2–6, 11].

LAUREN HALE & BENJAMIN HALE

Mapping Disease Patterns

For as long as disease patterns have been mapped there has been skepticism over the value of the pictures which are drawn. For instance, a map of the geography of the 1832 influenza epidemic in Glasgow (Scotland) was produced by the inmates of a lunatic asylum, mainly to occupy their time [1]. Later, in the nineteenth century, the value of mapping disease patterns was recognized as specific epidemiologic breakthroughs were attributed to the insight gained from mapping. Often cited is a map of the distribution of deaths from the 1848 cholera epidemic in London (England) which, so the tale goes, inspired the removal of the handle of the water pump at the center of a cluster of dots on the map, resulting in the curtailing of the epidemic [12].

Maps of diseases are like news pictures of crowd trouble. Viewers should always ask themselves what is not being shown in the map while looking at what is there. In particular, look around the edge of the map. Ask why it ends where it does. For instance, maps of diseases are often centered on the point the author thinks is most important. Figure 1 shows the central section of John Snow's map of deaths from cholera in Soho. Note how the eye is drawn to the pump in the center, particularly by the very high number of deaths at the intersection of Cambridge and Broad Streets. Had Snow drawn his map of all of London he would have discovered a greater density of deaths just south of the river Thames, as shown in Figure 2. This concentration would have changed location again had Snow had recourse to an isodemographic base map, as shown in Figure 3. As our picture of a disease pans out, as we include more cases and as we change the way we view the picture, the patterns on our maps show change too.

Disease mapping has been most strongly influenced by the history of diseases. Figure 4 shows the prevalence of 12 major causes of death in England and Wales since the publication of Snow's map of cholera. Infectious diseases now account for a tiny fraction of deaths in developed countries (which can afford most disease mapping and research). It is causes of death which are not declining, such as suicide, and those which are rising in importance, such as cancers, which increasingly interest researchers. For these causes of illness and death the analysis of point patterns around particular sites is still a major issue, but the patterns are usually far less clearly spatially defined than were outbreaks of cholera.

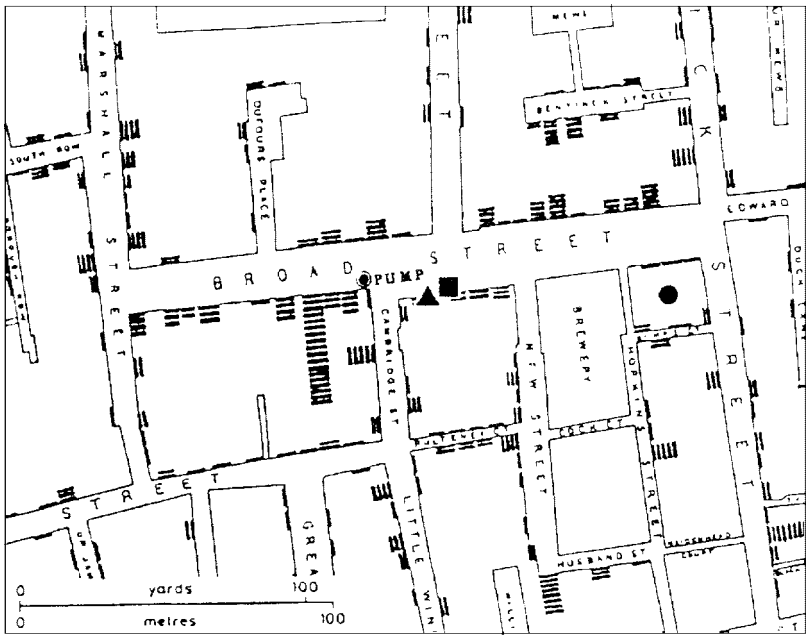

Figure 1 John Snow's map of cholera deaths in Soho, London, 1854 – taken from Cliff & Haggett [1, Figure 1.15D]

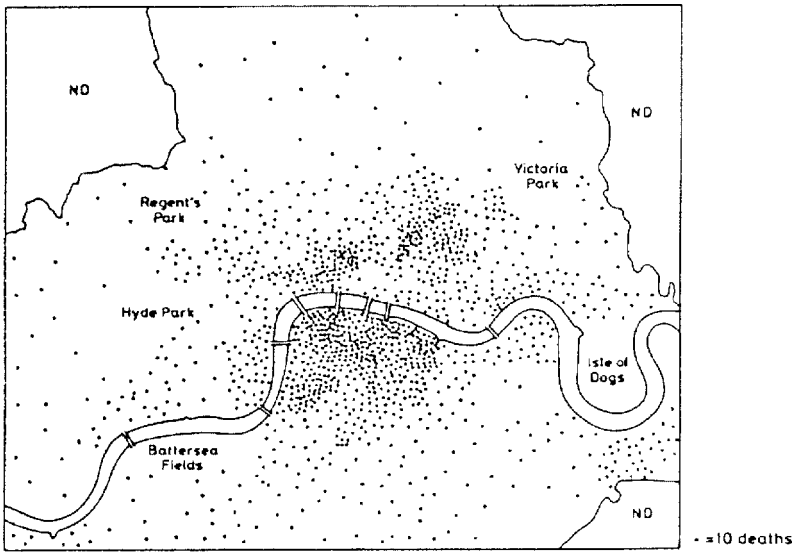

Figure 2 Cholera deaths in London in 1849 – taken from Cliff & Haggett [1, Figure 1.3B]

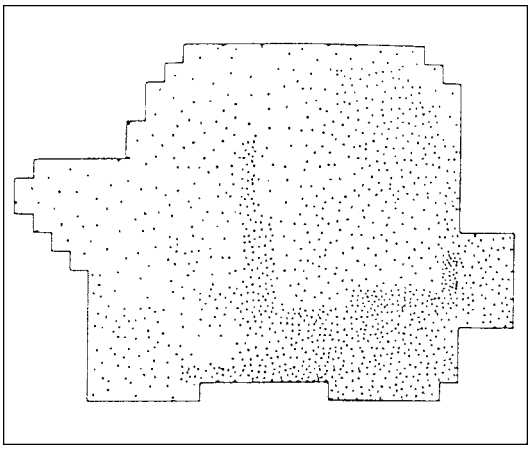

Figure 3 Figure 2 on a population cartogram – taken from Cliff & Haggett [1, Figure 1.18D]

More importantly, it is increasingly being accepted that more abstract factors, such as social inequality, can lie behind particular patterns of disease, and these require more abstract mappings for their study.

There are many different ways of mapping disease but here there is only space to explore one alternative. The alternatives include traditional choropleth mapping, where areas on a map are shaded according to statistics about the population. Most common in epidemiology is the mapping of areas colored by their standardized mortality ratios (*see* **Standardization Methods**). Another common form of mapping is to map points or the incidences of disease, and often color is also used here to highlight different types of disease. Various different point symbols can be used in mapping, particularly common is the use of proportional circles which are colored or segmented to highlight different features of a disease. The size of the circles is often made proportional to the population at risk of contracting a disease, at which point this type of cartography begins to merge into isodemographic mapping [4, 5].

Diseases occur across a population as much as across land. That is not to say that geographic distributions are not important, but that we should take account of the distribution of the population at risk to a particular disease, or cause, before mapping its pattern. One way in which this can be done is to use a map projection which draws every area in proportion to the number of people at risk living in that area – hence the term isodemographic ("equal people"). Isodemographic maps, more commonly called cartograms, are used for many purposes, mostly obviously in mapping the geography of elections. However, their most established use has been in disease mapping. Figure 5 shows one of the earliest examples of a cartogram designed for epidemiologic purposes [15, p. 1023]. Figure 5(a) is the conventional map of the counties of Iowa State, and Figure 5(b) is an equal

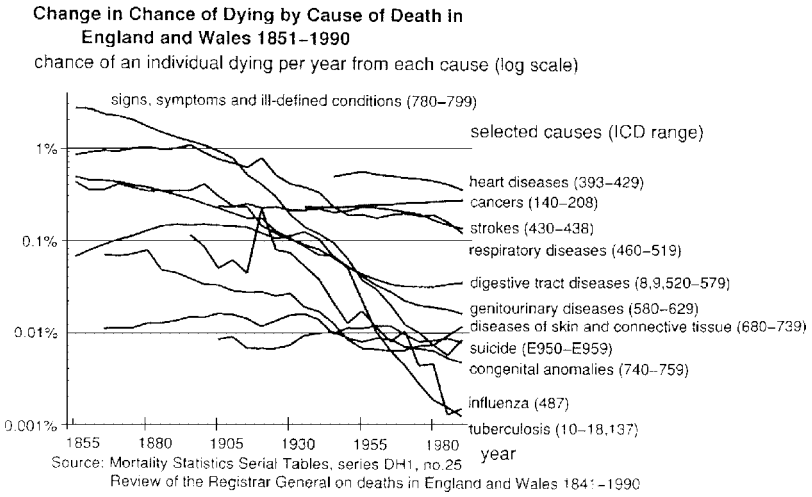

Figure 4 Cause of death 1855–1990 – taken from Dorling [3, Figure 5.21]

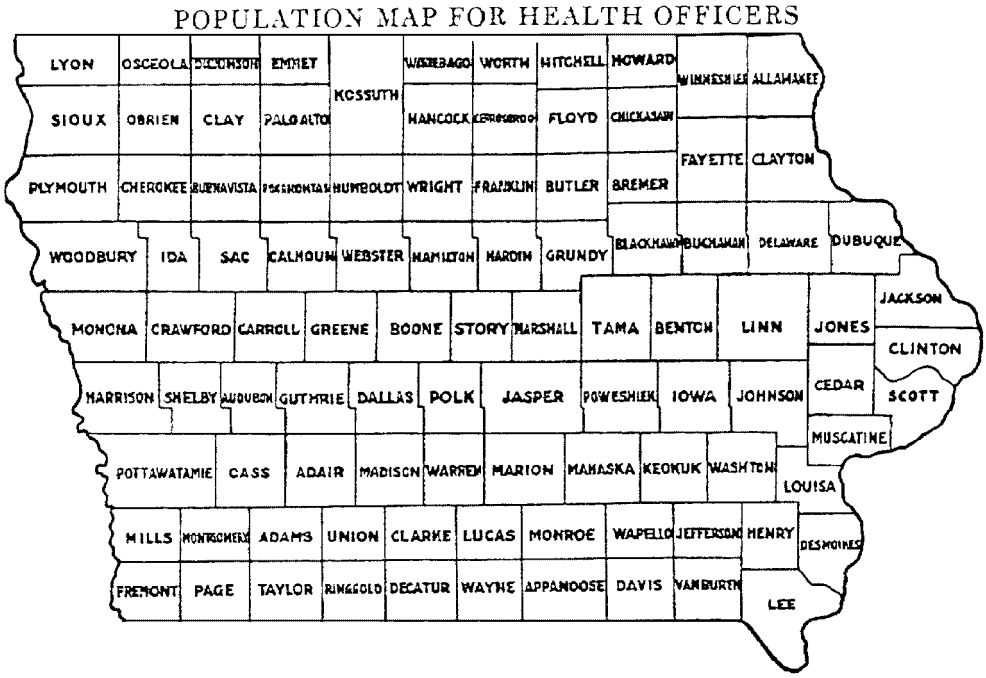
population cartogram upon which colored pins were placed to show the locations of reportable diseases. The square in the middle of the cartogram is Des Moines city in Polk County.

The designer of the Iowa cartogram was a doctor working in the state department of health. Many researchers have been struck by the idea that they could learn more about disease through mapping it in unconventional ways. The first cartogram of London was an "epidemiologic map" produced by a doctor working for the then London County Council Department of Public Health [14]. The cartogram (Figure 6) contained crosses drawn in the borough rectangles to show the incidence of polio during the 1947 epidemic. Because the rectangles were each drawn with the same height, their widths are proportional to population as well as their areas. The borough with the highest rate of polio and hence the tallest column of crosses in the Figure was Shoreditch. Almost exactly 100 years separates the two London epidemics, which were first drawn on a map and cartogram, respectively. Cartograms showing distributions within countries came later.

A claim was made to have produced the first cartograms showing national disease distributions only a decade after the crude cartogram of London was first drawn [6]. The nation was Scotland, and a separate cartogram was constructed by hand for each of eight age–sex groups. Figure 7 shows the cartogram being used to study the 1959–1963 mortality of women in Scotland aged 45–54. The author of this cartogram concluded that a national series of cartograms should be produced for each age–sex group for use in epidemiologic studies in Britain. This was never done, and it is debatable whether such an exact mapping base is needed in most studies. A single isodemographic base map of the whole population will usually suffice to uncover all but the most subtle of patterns.

A National Atlas of Disease Mortality in the UK was published in 1963 under the auspices of the Royal Geographical Society; the atlas contained no cartograms. However, a revised edition was published a few years later which made copious use of a "demographic base map" [7]. It is interesting to note that, when the revised edition was being prepared, the president of the Society was Dudley Stamp, who believed that "The fundamental tool for the geographical analysis is undoubtedly the map or, perhaps more correctly, the cartogram" [13, p. 135]. In the cartogram which was used in the revised national atlas (Figure 8), squares were used to represent urban areas, while diamonds were used to show statistics for rural districts. No attempt was made to maintain contiguity, but a stylized coastline was placed around the symbols, which were all drawn with their areas in proportion to the populations at risk from the disease being shown on each particular cartogram.

In the *National Atlas of Disease Mortality in the United Kingdom*, Howe used a national cartogram to display the distribution of standardized mortality between 1959 and 1963 from separate as well as



(a)

all causes of death for both men and women. High rates were seen in northern districts and some Inner London boroughs (including Shoreditch, which is also highlighted on one of the earliest cartograms of London; see above). Extremely high rates in central Scotland were particularly noticeable, as were the low rates in districts which surround London. At the extremes the average man living in Salford was 50% more likely to die each year than his counterpart in Bournemouth [7]. Both these areas are shrunk on a "normal" map. The pattern for women was very similar to that for men although, in general, it was less pronounced. However, women did have the highest mortality rate of any area on the map in rural Dunbartonshire, where they were more than twice as likely to die each year than were women nationally (allowing for local age structure). The cartogram highlights this area, but also puts it in the perspective of the populations at risk from the high mortality rates for women in and around the Glasgow area. Questions for investigation are immediately generated by comparing the maps in Howe's atlases with those produced by Forster for a decade earlier (see Figure 7).

Isodemographic mapping is also used to study the prevalence of disease – individual cases of a disease or death which together might possibly be connected. Figure 9 shows the distribution of cases of Wilm's tumor, a childhood cancer, identified in New York State between 1958 and 1962, drawn upon an equal

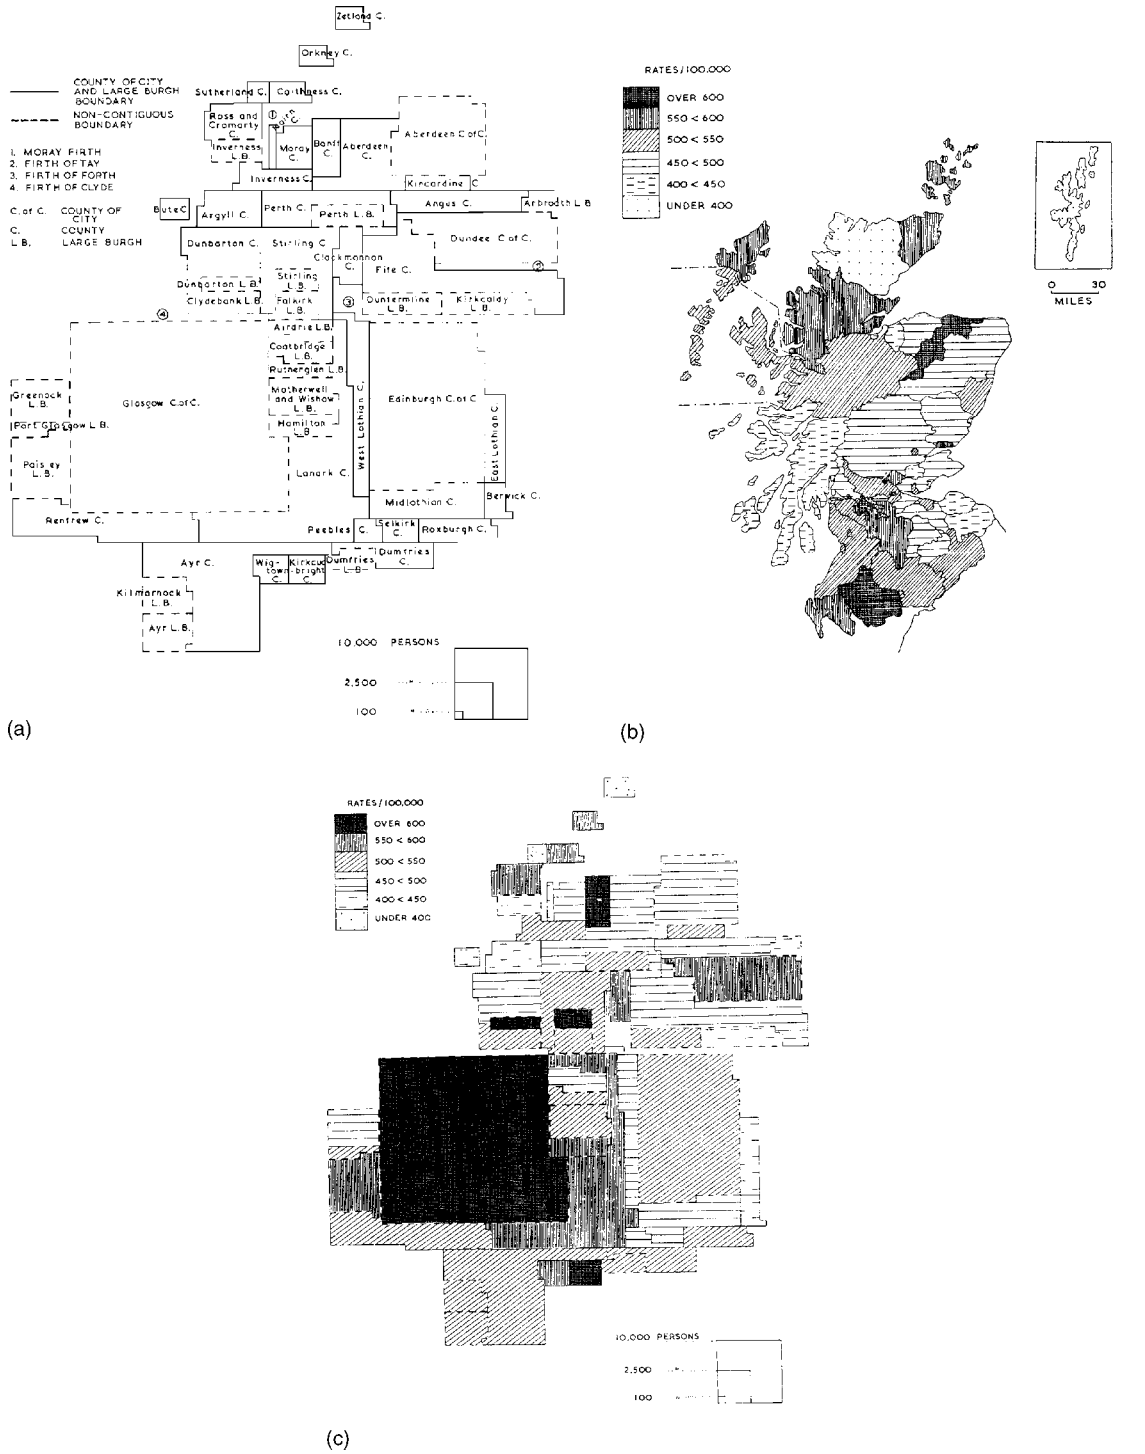

Figure 7 Cartogram and map of Scottish health districts – taken from Forster [6]. (a) Cartogram of females aged 45–54 in 1961 by Scottish health districts; (b) map of 1959–63 mortality rates of females aged 45–54 by district; (c) 1959–63 mortality rates of females aged 45–54 shown in (a)

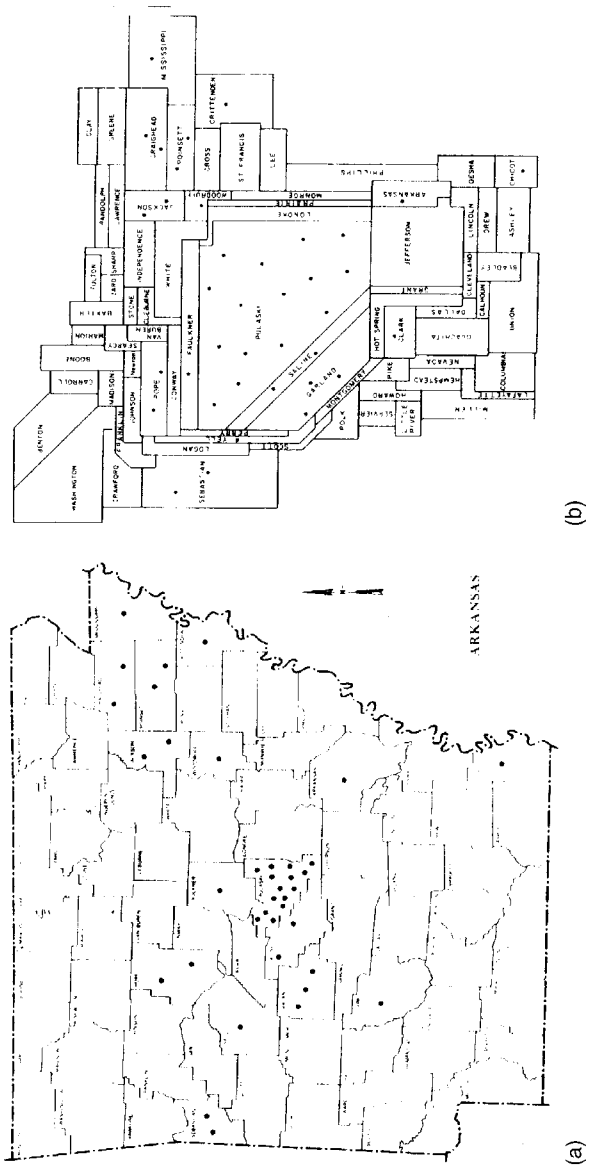

Figure 10 Salmonella Newport cases on (a) map and (b) cartogram in Arkansas State – taken from Dean [2]

land area map. Apparent clusters of cases have been marked on the map [8]. In the second diagram in Figure 9, the same cases are drawn upon an equal population cartogram and the apparent clusters can be seen to have been quite evenly dispersed across the population. The same process has been used in Figure 10 to illustrate how cases of Salmonella food poisoning occurring in Arkansas in 1974 were not unduly clustered in Pulaski county [2].

In recent years researchers have turned their attention to trying to develop cartograms upon which actual, rather than illusory, clusters of disease can be identified (*see* **Clustering**). The major problem with using population cartograms to identify clusters of disease is that the choice of which areas are closest to which on a cartogram can be quite arbitrary. For instance, if the same set of incidences of one particular disease were plotted on three different cartograms, then different parts of the country may appear to have dense clusters of cases depending on which cartogram was chosen. This would be true regardless of whether the clusters were to be identified by eye or by statistical procedures; the different base maps would result in different patterns emerging. The proposition that there is no single "true answer" as to whether a disease is clustered does not go down too well in some circles. Because of this problem a group of researchers at Berkeley developed a computer algorithm for identifying incidences of disease [9]. The algorithm was used to produce the cartogram in Figure 11 of San Francisco county, upon which apparent clusters of disease were shown to be false [11]. However, application of the method to another California county did provide evidence of some clustering of high cancer rates near oil refineries [10].

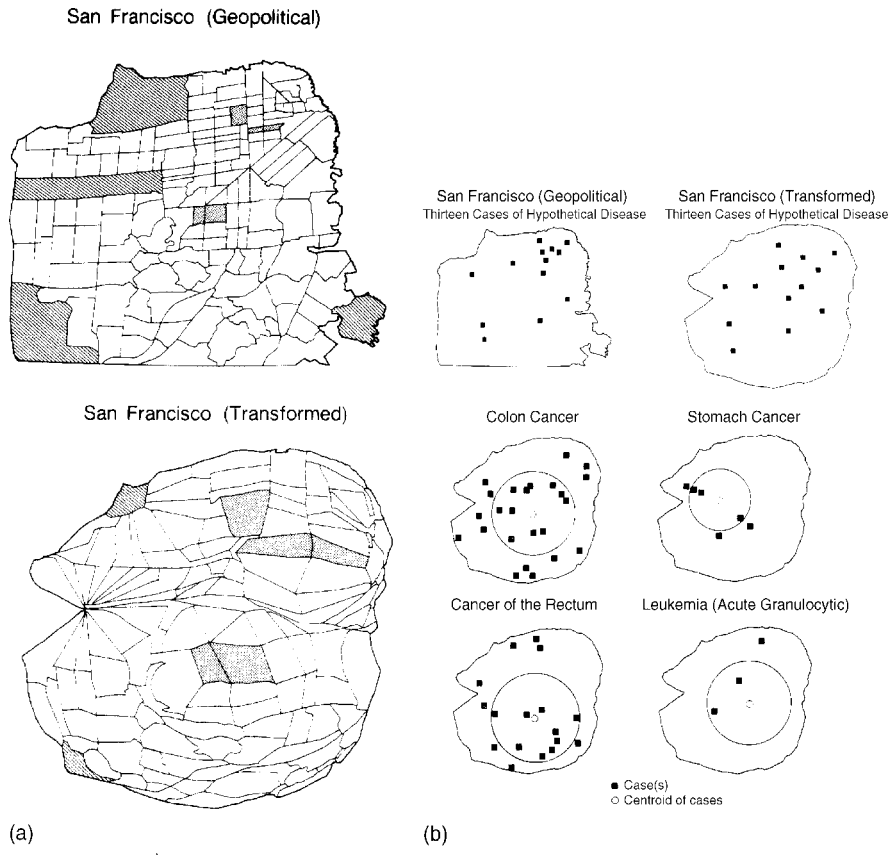

Figure 11 San Francisco map (a) for 1980 census, and cartogram (b) of hypothetical and actual diseases – taken from Selvin et al. [11]

Mapping of disease patterns is becoming increasingly common due to the proliferation of computer mapping. However, many of these programs were designed to produce general maps of any subject and are often most appropriate to show land use or the distribution of points in physical space. Over most of the course of the last century, doctors, public health officials, and researchers have discovered and rediscovered that traditional maps often do not provide the most appropriate projection to look for patterns of disease. Here, a few alternatives have been shown of just one different form of disease mapping to try to explain why it involves more than just sticking pins in paper.

Marginal Likelihood

Suppose that $\mathbf{X} = (X_1, \ldots, X_n)'$ is a vector of random variables whose distribution depends on parameter vectors $\boldsymbol{\beta}$ and $\boldsymbol{\lambda}$. We suppose that $\boldsymbol{\beta}$ is of primary interest, whereas $\boldsymbol{\lambda}$ is a **nuisance parameter** and typically is of very high dimension. Our aim is to define a derived **likelihood** that would be suitable for inference about $\boldsymbol{\beta}$ when $\boldsymbol{\lambda}$ is unknown.

Let $f(\mathbf{x}; \boldsymbol{\beta}, \boldsymbol{\lambda})$ be the probability density function (pdf) of $\mathbf{X}$; on data $\mathbf{X} = \mathbf{x}$, it defines the joint likelihood function

$$L(\boldsymbol{\beta}, \boldsymbol{\lambda}; \mathbf{x}) \propto f(\mathbf{x}; \boldsymbol{\beta}, \boldsymbol{\lambda}),$$

which can be used for inference. However, when $\boldsymbol{\lambda}$ is of high dimension, it becomes difficult to interpret the information about $\boldsymbol{\beta}$. In fact, the **maximum likelihood** estimator (MLE) of $\boldsymbol{\beta}$ can have very poor properties, even asymptotically, if the dimension of $\boldsymbol{\lambda}$ increases with that of $\mathbf{X}$. To make inferences about $\boldsymbol{\beta}$ itself without regard to $\boldsymbol{\lambda}$, it is useful to define a derived likelihood which, by some method, eliminates $\boldsymbol{\lambda}$. Marginal likelihood provides one way of doing this.

Suppose that there exists a one-to-one transformation of $\mathbf{X}$ into ($\mathbf{A}$, $\mathbf{T}$) and that the joint pdf of ($\mathbf{A}$, $\mathbf{T}$) factors as

$$f(\mathbf{a}, \mathbf{t}; \boldsymbol{\beta}, \boldsymbol{\lambda}) = f(\mathbf{a}; \boldsymbol{\beta}) f(\mathbf{t}|\mathbf{a}; \boldsymbol{\beta}, \boldsymbol{\lambda}), \qquad (1)$$

where the marginal density of $\mathbf{A}$ does not depend on $\boldsymbol{\lambda}$.

The *marginal likelihood* of $\boldsymbol{\beta}$ based on $\mathbf{A}$ is

$$L_{\mathrm{m}}(\boldsymbol{\beta}; \mathbf{a}) \propto f(\mathbf{a}; \boldsymbol{\beta}), \qquad (2)$$

and this could be used for inference about $\boldsymbol{\beta}$. In general, there is a loss of information in restricting attention to (2) for inference; sometimes, however, invariance or other arguments suggest that A contains the whole of the available information about $\boldsymbol{\beta}$. Even when such arguments do not apply, however, there may still be advantage to using (2) as the basis of inference since it conveniently eliminates $\boldsymbol{\lambda}$.

Two examples serve to illustrate the ideas.

Example 1

Suppose that variability in the measurement of blood glucose is of interest and that pairs of measurements are taken on n independent individuals. Thus, we might assume that X_{1i}, X_{2i} are independent $\mathrm{N}(\lambda_i, \beta^2)$ variates, where λ_i represents the true glucose level for the ith individual and β^2, the variance of the measurement error, is of interest. The maximum likelihood estimate of β^2 is

$$\hat{\beta}^2 = \frac{\sum (x_{1i} - x_{2i})^2}{(4n)},$$

which converges to $\beta^2/2$ in probability as $n \to \infty$. This is an instance in which the mle is inconsistent.

A marginal likelihood, in this problem, is naturally based on the statistics, $A_i = X_{1i} - X_{2i}$, $i = 1, \ldots, n$, which are independent $\mathrm{N}(0, 2\beta^2)$ variates. This gives rise to the marginal likelihood

$$L_{\mathrm{m}}(\beta^2; a) = \beta^{-n} \exp\left[\frac{-\sum a_i^2}{(4\beta^2)}\right].$$

The corresponding marginal mle, $\hat{\beta}^2_{\mathrm{m}} = \sum a_i^2/(2n)$ converges in probability to the correct value β^2 as $n \to \infty$. The choice of the A_is as the basis for inference about β^2 is a natural one; the difference in the measurements for each individual provides the information about β^2 intuitively.

Example 2

A second example arises in Cox's **proportional hazards** model [3] (*see* **Cox Regression Model**). The hazard function for the time to failure T is

$$\lambda(t; z) = \lambda_0(t) \exp(\mathbf{z}'\boldsymbol{\beta}), \qquad (3)$$

where $\mathbf{z} = (z_1, \ldots, z_p)'$ is a vector of fixed covariates. In this model, the baseline hazard rate $\lambda_0(t)$ is left arbitrary and the covariates z are assumed to act multiplicatively on the baseline rate with $\boldsymbol{\beta} = (\beta_1, \ldots \beta_p)'$, the vector of regression parameters being of primary interest.

Suppose that $T_1, \ldots, T_n$ is a sample with covariates $\mathbf{z}_1, \ldots, \mathbf{z}_n$. Let $T_{(1)}, \ldots, T_{(n)}$ be the **order statistic** from $T_1, \ldots, T_n$ with corresponding covariates $\mathbf{z}_{(1)}, \ldots, \mathbf{z}_{(n)}$ and let $\mathbf{R} = (R_1, \ldots, R_n)$ be the rank vector. Thus, R_i is the **rank** of the variate T_i among $(T_1, \ldots, T_n)$. The distribution of $\mathbf{R}$ can be shown to be

$$f(\mathbf{r}; \boldsymbol{\beta}) = \Pr(\mathbf{R} = \mathbf{r})$$

$$= \prod_{i=1}^{n} \left[\frac{\exp(\mathbf{z}'_{(i)}\boldsymbol{\beta})}{\sum_{j=1}^{n} \exp(\mathbf{z}'_{(j)}\boldsymbol{\beta})} \right], \qquad (4)$$

and this defines a marginal likelihood for $\boldsymbol{\beta}$. This likelihood (4) is identical to Cox's **partial likelihood** [3]. These arguments can be extended to allow right **censoring** in the data [6].

We conclude with a number of remarks.

1. Marginal likelihood was first introduced by Fraser [4, 5] in the context of the structural model. In his work and in the related work of Kalbfleisch & Sprott [8], the A_is are allowed to depend on the parameter $\boldsymbol{\beta}$.
2. Group invariance arguments can be used in both of the examples given here to justify the use of **A** or **R** as the basis of inference for $\boldsymbol{\beta}$. Barnard [1] describes these arguments in general, and Kalbfleisch & Prentice [6, 7] apply them to the proportional hazards model (3). Other approaches to assessing the "**sufficiency**" of **A** for inference have been discussed by Sprott [9] and Barndorff-Nielsen [2], among others.
3. Marginal likelihood is one of several methods for obtaining derived likelihoods about a parameter of interest. Conditional likelihood (*see* **Conditional Probability**), partial likelihood and **profile likelihood** are other approaches which can apply, depending upon the structure of the statistical problem.

JOHN D. KALBFLEISCH

Marginal Models for Multivariate Survival Data

Multivariate survival or failure-time data arise when each study subject may experience several events or when there exists some natural or artificial grouping of subjects which induces dependence among failure times of the same group. Biomedical examples include the sequence of tumor recurrences or infection episodes, the development of physical symptoms or diseases in several organ systems, the occurrence of blindness in the left and right eyes, the onset of a disease among family members, the initiation of cigarette smoking by classmates, and the appearance of tumor in litter-mates exposed to a carcinogen.

Suppose that there are n independent units each of which can potentially experience K types of failures. Let T_{ik} be the time when the kth type of failure occurs on the ith unit, and let C_{ik} be the corresponding **censoring** time. Define $X_{ik} = \min(T_{ik}, C_{ik})$ and $\Delta_{ik} = I(T_{ik} \le C_{ik})$, where $I(\cdot)$ is the indicator function (*see* **Dummy Variables**). Also, let $\mathbf{Z}_{ik}(\cdot) = [Z_{1ik}(\cdot), \ldots, Z_{pik}(\cdot)]'$ denote a p-vector of possibly **time-dependent covariates** for the ith unit with respect to the kth type of failure. The failure time vector $\mathbf{T}_i = (T_{i1}, \ldots, T_{iK})$ and the censoring time vector $\mathbf{C}_i = (C_{i1}, \ldots, C_{iK})$ are assumed to be independent, conditional on the covariate vector $\mathbf{Z}_i = (\mathbf{Z}'_{i1}, \ldots, \mathbf{Z}'_{iK})$, $i = 1, \ldots, n$. The units are allowed to have unequal numbers of failures, which is achieved by setting C_{ik} to zero whenever T_{ik} is missing.

It is natural and convenient to formulate the marginal distribution for each type of failure with a **proportional hazards model**. Depending on whether the baseline hazard functions are different or identical among the K types of failures, the marginal hazard function for the kth type of failure on the ith unit is

$$\boldsymbol{\lambda}_k(t; \mathbf{Z}_{ik}) = \boldsymbol{\lambda}_{0k}(t) \exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(t)], \tag{1}$$

or

$$\boldsymbol{\lambda}_k(t; \mathbf{Z}_{ik}) = \boldsymbol{\lambda}_0(t) \exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(t)], \tag{2}$$

where $\boldsymbol{\lambda}_{0k}(t)$, $k = 1, \ldots, K$, and $\boldsymbol{\lambda}_0(t)$ are unspecified baseline hazard functions, and $\boldsymbol{\beta}$ is a p-vector of unknown regression parameters. In some applications it is necessary to allow $\boldsymbol{\lambda}_{0k}(t)$, $k = 1, \ldots, K$, to be different, whereas in others it suffices to assume a common baseline hazard function. In both models (1) and (2), we set $\boldsymbol{\beta}$ to be the same among the K submodels, which entails no loss of generality since this structure can always be achieved by introducing appropriate type-specific covariates.

Inference Procedures

If all the failure times were independent, then the **partial likelihood** functions for $\boldsymbol{\beta}$ would be

$$L(\boldsymbol{\beta}) = \prod_{i=1}^{n} \prod_{k=1}^{K} \left\{ \frac{\exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(X_{ik})]}{\sum_{j=1}^{n} Y_{jk}(X_{ik}) \exp[\boldsymbol{\beta}' \mathbf{Z}_{jk}(X_{ik})]} \right\}^{\Delta_{ik}}$$

under model (1) and

$$L(\boldsymbol{\beta}) = \prod_{i=1}^{n} \prod_{k=1}^{K} \left\{ \frac{\exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(X_{ik})]}{\sum_{j=1}^{n} \sum_{l=1}^{K} Y_{jl}(X_{ik}) \exp[\boldsymbol{\beta}' \mathbf{Z}_{jl}(X_{ik})]} \right\}^{\Delta_{ik}}$$

under model (2), where $Y_{ik}(t) = I(X_{ik} \ge t)$. The corresponding score functions would be

$$\mathbf{U}(\boldsymbol{\beta}) = \sum_{i=1}^{n} \sum_{k=1}^{K} \Delta_{ik} \left[\mathbf{Z}_{ik}(X_{ik}) - \frac{\mathbf{S}_k^{(1)}(\boldsymbol{\beta}, X_{ik})}{S_k^{(0)}(\boldsymbol{\beta}, X_{ik})} \right] \tag{3}$$

and

$$\mathbf{U}(\boldsymbol{\beta}) = \sum_{i=1}^{n} \sum_{k=1}^{K} \Delta_{ik} \left[\mathbf{Z}_{ik}(X_{ik}) - \frac{\overline{\mathbf{S}}^{(1)}(\boldsymbol{\beta}, X_{ik})}{\overline{S}^{(0)}(\boldsymbol{\beta}, X_{ik})} \right], \tag{4}$$

where

$$\mathbf{S}_k^{(0)}(\boldsymbol{\beta}, t) = \sum_{j=1}^{n} Y_{jk}(t) \exp\left[\boldsymbol{\beta}' \mathbf{Z}_{jk}(t)\right],$$

$$\mathbf{S}_k^{(1)}(\boldsymbol{\beta}, t) = \sum_{j=1}^{n} Y_{jk}(t) \exp\left[\boldsymbol{\beta}' \mathbf{Z}_{jk}(t)\right] \mathbf{Z}_{jk}(t),$$

$$k = 1, \ldots, K,$$

and

$$\overline{\mathbf{S}}^{(r)}(\boldsymbol{\beta}, t) = \sum_{k=1}^{K} \mathbf{S}_k^{(r)}(\boldsymbol{\beta}, t), \; r = 0, 1.$$

In both cases, the solution to $[\mathbf{U}(\boldsymbol{\beta}) = \mathbf{0}]$ is denoted by $\hat{\boldsymbol{\beta}}$.

Although the failure times within the same unit tend to be **correlated**, the estimator $\hat{\boldsymbol{\beta}}$ can be shown to be consistent for $\boldsymbol{\beta}$ and asymptotically p-variate normal provided that the marginal models are correctly specified. However, the conventional **covariance matrix** estimator $\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$, where $\mathcal{I}(\boldsymbol{\beta}) = -\partial^2 \log L(\boldsymbol{\beta})/\partial \boldsymbol{\beta}^2$, is no longer valid, the reason being that $\mathcal{I}(\boldsymbol{\beta})$ is not the covariance matrix of $\mathbf{U}(\boldsymbol{\beta})$ in the presence of intraclass dependence. By approximating $\mathbf{U}(\boldsymbol{\beta})$ with a sum of independent and identically distributed zero-mean random vectors, one can show that, for large n and relatively small K, the random vector $\mathbf{U}(\boldsymbol{\beta})$ is approximately zero-mean normal with covariance matrix estimator

$$\mathbf{V}(\boldsymbol{\beta}) = \sum_{i=1}^{n} \sum_{k=1}^{K} \sum_{l=1}^{K} \mathbf{W}_{ik}(\hat{\boldsymbol{\beta}}) \mathbf{W}_{il}(\hat{\boldsymbol{\beta}})',$$

where

$$\begin{aligned} \mathbf{W}_{ik}(\boldsymbol{\beta}) = {} & \Delta_{ik} \left[\mathbf{Z}_{ik}(X_{ik}) - \frac{\mathbf{S}_k^{(1)}(\boldsymbol{\beta}, X_{ik})}{S_k^{(0)}(\boldsymbol{\beta}, X_{ik})} \right] \\ & - \sum_{j=1}^{n} \frac{\Delta_{jk} Y_{ik}(X_{jk}) \exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(X_{jk})]}{S_k^{(0)}(\boldsymbol{\beta}, X_{jk})} \\ & \times \left[\mathbf{Z}_{ik}(X_{jk}) - \frac{\mathbf{S}_k^{(1)}(\boldsymbol{\beta}, X_{jk})}{S_k^{(0)}(\boldsymbol{\beta}, X_{jk})} \right] \end{aligned}$$

and

$$\begin{aligned} \mathbf{W}_{ik}(\boldsymbol{\beta}) = {} & \Delta_{ik} \left[\mathbf{Z}_{ik}(X_{ik}) - \frac{\overline{\mathbf{S}}^{(1)}(\boldsymbol{\beta}, X_{ik})}{\overline{S}^{(0)}(\boldsymbol{\beta}, X_{ik})} \right] \\ & - \sum_{j=1}^{n} \sum_{l=1}^{K} \frac{\Delta_{jl} Y_{ik}(X_{jl}) \exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(X_{jl})]}{\overline{S}^{(0)}(\boldsymbol{\beta}, X_{jl})} \\ & \times \left[\mathbf{Z}_{ik}(X_{jl}) - \frac{\overline{\mathbf{S}}^{(1)}(\boldsymbol{\beta}, X_{jl})}{\overline{S}^{(0)}(\boldsymbol{\beta}, X_{jl})} \right] \end{aligned}$$

under models (1) and (2), respectively. Consequently, $\hat{\boldsymbol{\beta}}$ is approximately normal with covariance matrix estimator $\mathbf{D}(\hat{\boldsymbol{\beta}}) = \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \mathbf{V}(\hat{\boldsymbol{\beta}}) \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$. We call $\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$ and $\mathbf{D}(\hat{\boldsymbol{\beta}})$ the naive and robust estimators, respectively. In the case of $K = 1$, the matrix $\mathbf{D}(\hat{\boldsymbol{\beta}})$ reduces to the Lin–Wei [14] robust covariance matrix estimator for the maximum partial likelihood estimator under **misspecified** proportional hazards models. To test the global hypothesis that $\boldsymbol{\beta} = \boldsymbol{\beta}_0$, one may use the chi-square statistic $\mathbf{U}'(\boldsymbol{\beta}_0) \mathbf{V}^{-1}(\boldsymbol{\beta}_0) \mathbf{U}(\boldsymbol{\beta}_0)$ or $(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0)' \mathbf{D}^{-1}(\hat{\boldsymbol{\beta}})(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}_0)$; to test the general linear hypothesis H_0: $\mathbf{L}\boldsymbol{\beta} = \mathbf{d}$, where $\mathbf{L}$ is an $r \times p$ matrix of constants and $\mathbf{d}$ is an $r \times 1$ vector of constants, one refers $(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{d})' \{\mathbf{L}\mathbf{D}(\hat{\boldsymbol{\beta}})\mathbf{L}'\}^{-1} (\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{d})$ to the **chi-square distribution** with r **degrees of freedom**.

The above results are analogous to those of the **generalized estimation equations** (GEE) for the analysis of **marginal models** for **longitudinal data** with an independence working assumption. A similar idea can be used to estimate the cumulative baseline hazard functions $\Lambda_{0k}(t) = \int_0^t \lambda_{0k}(u) \mathrm{d}u$, $k = 1, \ldots, K$, and $\Lambda_0(t) = \int_0^t \lambda_0(u) \mathrm{d}u$ for models (1) and (2). Specifically, under the independence working assumption, the Aalen–Breslow type estimators for $\Lambda_{0k}(t)$ and $\Lambda_0(t)$ are

$$\hat{\Lambda}_{0k}(t) = \sum_{i=1}^{n} \frac{I(X_{ik} \le t) \Delta_{ik}}{S_k^{(0)}(\hat{\boldsymbol{\beta}}, X_{ik})}, \quad k = 1, \ldots, K, \quad (5)$$

and

$$\hat{\Lambda}_0(t) = \sum_{i=1}^{n} \sum_{k=1}^{K} \frac{I(X_{ik} \le t) \Delta_{ik}}{\overline{S}^{(0)}(\hat{\boldsymbol{\beta}}, X_{ik})}. \quad (6)$$

These estimators are consistent and asymptotically normal. In fact, the p-vector of random processes,

$$n^{1/2} [\hat{\Lambda}_{01}(t) - \Lambda_{01}(t), \ldots, \hat{\Lambda}_{0K}(t) - \Lambda_{0K}(t)]',$$

converges weakly to a p-dimensional zero-mean Gaussian random field, and the covariance between $\hat{\Lambda}_{0k}(t)$ and $\hat{\Lambda}_{0l}(s)$ can be estimated by $\sum_{i=1}^{n} \xi_{ik}(t; \hat{\boldsymbol{\beta}}) \xi_{il}(s; \hat{\boldsymbol{\beta}})$, where

$$\begin{aligned} & \xi_{ik}(t; \boldsymbol{\beta}) \\ & = \frac{I(X_{ik} \le t) \Delta_{ik}}{S_k^{(0)}(\boldsymbol{\beta}, X_{ik})} \\ & \quad - \sum_{j=1}^{n} \frac{I(X_{jk} \le t) \Delta_{jk} Y_{ik}(X_{jk}) \exp[\boldsymbol{\beta}' \mathbf{Z}_{ik}(X_{jk})]}{S_k^{(0)}(\boldsymbol{\beta}, X_{jk})^2} \\ & \quad - \left[\sum_{j=1}^{n} \frac{I(X_{jk} \le t) \Delta_{jk} S_k^{(1)}(\boldsymbol{\beta}, X_{jk})}{S_k^{(0)}(\boldsymbol{\beta}, X_{jk})^2} \right]' \\ & \quad \times \mathcal{I}^{-1}(\boldsymbol{\beta}) \sum_{l=1}^{K} \mathbf{W}_{il}(\boldsymbol{\beta}). \end{aligned}$$

In addition, $n^{1/2}[\hat{\Lambda}_0(t) - \Lambda_0(t)]$ converges weakly to a zero-mean Gaussian process, and the covariance between $\hat{\Lambda}_0(t)$ and $\hat{\Lambda}_0(s)$ can be estimated by

$\sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{l=1}^{K}\xi_{ik}(t;\hat{\boldsymbol{\beta}})\xi_{il}(s;\hat{\boldsymbol{\beta}})$, where

$$\begin{aligned}\xi_{ik}(t;\boldsymbol{\beta}) &= \frac{I(X_{ik}\le t)\Delta_{ik}}{\overline{S}^{(0)}(\boldsymbol{\beta},X_{ik})} \\ &\quad - \sum_{j=1}^{n}\sum_{l=1}^{K}\frac{I(X_{jl}\le t)\Delta_{jl}Y_{ik}(X_{jl})\exp[\boldsymbol{\beta}'\mathbf{Z}_{ik}(X_{jl})]}{\overline{S}^{(0)}(\boldsymbol{\beta},X_{jl})^2} \\ &\quad - \left[\sum_{j=1}^{n}\sum_{l=1}^{K}\frac{I(X_{jl}\le t)\Delta_{jl}\overline{\mathbf{S}}^{(1)}(\boldsymbol{\beta},X_{jl})}{\overline{S}^{(0)}(\boldsymbol{\beta},X_{jl})^2}\right]' \\ &\quad \times \mathcal{I}^{-1}(\boldsymbol{\beta})\mathbf{W}_{ik}(\boldsymbol{\beta}).\end{aligned}$$

The large-sample properties for the corresponding baseline survival function estimators $\exp[-\hat{\Lambda}_{0k}(t)]$, $k=1,\ldots,K$, and $\exp[-\hat{\Lambda}_0(t)]$ follow from the **delta method**. Furthermore, simple modifications can be made to estimate the survival functions associated with specific covariate values.

Software Availability

The estimators $\hat{\boldsymbol{\beta}}$, $\hat{\Lambda}_{0k}, k=1,\ldots,K$, and $\hat{\Lambda}_0$ are constructed under the independence working assumption, and therefore can be obtained from any existing software for the **Cox regression**. The robust covariance matrix estimator for $\hat{\boldsymbol{\beta}}$ is available in **S-PLUS**, SAS, and STATA packages, as well as in a special FORTRAN program [12]. The robust variance–covariance estimators for $\hat{\Lambda}_{0k}, k=1,\ldots,K$, and $\hat{\Lambda}_0$ have not been implemented in commercially available software packages.

An Example

We now provide an illustration with the well-known Diabetic Retinopathy Study [4], which was conducted by the National Eye Institute to evaluate the effectiveness of laser photocoagulation in delaying the onset of blindness in patients with diabetic retinopathy. The study enrolled 1742 patients. One eye of each patient was randomly selected for photocoagulation and the other eye was observed without treatment. The patients were followed over several years for the occurrence of blindness in their left and right eyes.

We confine our attention to a subset of the data with 197 high-risk patients previously analyzed by Huster et al. [7] and Lin [13]. By the end of the study, 54 treated eyes and 101 control eyes in this subsample had developed blindness. In this example, each patient could potentially experience blindness in both eyes; therefore, there are two failure types with $k=1$ and 2, denoting the left and right eyes, respectively. Since there are no biological differences between the left and right eyes, it is natural to assume a common baseline hazard function for the two failure types.

As mentioned above, the primary objective of this study was to assess whether laser photocoagulation delays the occurrence of blindness. Because juvenile and adult diabetes have very different courses, it is desirable to examine how the age at onset of diabetes may affect the time to blindness. Thus, we consider model (2) with $\mathbf{Z}_{ik}=(Z_{1ik},Z_{2ik},Z_{3ik})', i=1,\ldots,197; k=1,2$, where

$$Z_{1ik}=\begin{cases}1, & \text{if the } k\text{th eye of the } i\text{th patient was on treatment,}\\ 0, & \text{otherwise;}\end{cases}$$

$$Z_{2ik}=\begin{cases}1, & \text{if the } i\text{th patient had adult onset diabetes,}\\ 0, & \text{if the } i\text{th patient had juvenile onset diabetes;}\end{cases}$$

and $Z_{3ik}=Z_{1ik}\times Z_{2ik}$. The results for the estimation of the regression parameters are shown in Table 1. The robust standard error estimates are appreciably smaller than the naive estimates, the latter ignoring the dependence between the left and right eyes. The treatment appears to be effective, and this effect is much stronger for adult-onset diabetes than for juvenile-onset diabetes.

Figure 1 displays the estimates and pointwise 95% confidence intervals for the survival functions, namely, the probabilities of retained visual acuity, for adult-onset diabetes, separated by treatment groups. As expected, these probabilities are much higher for the treated eyes than for the untreated ones.

Table 1

Variable	Parameter estimate	Stand. error estimate	
		Naive	Robust
Treatment (Z_1)	−0.425	0.218	0.185
Diabetic type (Z_2)	0.341	0.199	0.196
Interaction ($Z_1\times Z_2$)	−0.846	0.351	0.304

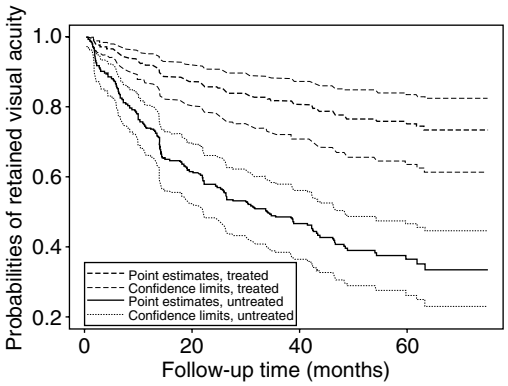

Figure 1 Estimates and pointwise 95% confidence intervals for survival functions

Further Results

The estimation of $\boldsymbol{\beta}$ under models (1) and (2) was first studied by Wei et al. [23] and Lee et al. [9], respectively, and further developed by Lin [13], while the estimation of $\Lambda_{0k}, k = 1, \ldots, K$, and Λ_0 was investigated by Spiekerman & Lin [22]. The latter authors established a rigorous asymptotic theory for the estimation of both the regression parameters and baseline hazard functions under a general marginal model which allows $M, 1 \leq M \leq K$, different baseline hazard functions among the K types of failures. In a separate paper, they [21] developed a class of graphical and numerical techniques for checking the adequacy of models (1) and (2). The readers are referred to the aforementioned papers for further theoretical details as well as additional numerical examples. Incidentally, Huster et al. [7] studied model (2) with a parametric baseline hazard function, while Guo & Lin [6] deal with discrete-time versions of models (1) and (2).

Liang et al. [11] proposed a different procedure for analyzing model (2). Their estimating function is similar to (4), but they replaced $\overline{\mathbf{S}}^{(1)}/\overline{S}^{(0)}$ by an analog which exploits pairwise comparisons of independent observations. The actual form of their **estimating function** is

$$\sum_{i=1}^{n}\sum_{k=1}^{K} I[n_i(X_{ik}) > 0]\Delta_{ik} \times \left[\mathbf{Z}_{ik}(X_{ik}) - n_i^{-1}(X_{ik})\sum_{j\neq i}\sum_{l}\mathbf{e}_{ik,jl}(\boldsymbol{\beta}, X_{ik})\right],$$

where $n_i(t) = \sum_{j\neq i}\sum_l Y_{jl}(t)$ and

$$\mathbf{e}_{ik,jl}(\boldsymbol{\beta}, t) = \frac{Y_{ik}(t)\mathbf{Z}_{ik}(t)\exp[\boldsymbol{\beta}'\mathbf{Z}_{ik}(t)] + Y_{jl}(t)\mathbf{Z}_{jl}(t)\exp[\boldsymbol{\beta}'\mathbf{Z}_{jl}(t)]}{Y_{ik}(t)\exp[\boldsymbol{\beta}'\mathbf{Z}_{ik}(t)] + Y_{jl}(t)\exp[\boldsymbol{\beta}'\mathbf{Z}_{jl}(t)]}.$$

The resultant estimator is **consistent** and asymptotically normal. The relative efficiency of $\hat{\boldsymbol{\beta}}$ vs. the Liang et al. estimator has not been investigated.

Estimating functions (3) and (4) were derived under the independence working assumption. As in the case of **longitudinal data**, it may be more efficient to use estimating functions that take into account the nature of dependence explicitly. This amounts to incorporating certain weight functions into estimating functions (3) and (4). The resultant estimators remain consistent and asymptotically normal with a sandwich-type variance estimator under mild regularity conditions on the weight function. Due to censoring and the nonlinear nature of the proportional hazards model, it is difficult to construct optimal weight functions. Cai & Prentice [2] investigated a weight function that is the inverse of the covariance matrix of the marginal martingales associated with the T_{ik}s. Their theoretical calculations and simulation studies indicated that the efficiency gains in using such weighted estimating functions over estimating functions (3) and (4) are small unless the correlations of failure times are unusually high.

There has been considerable research on semiparametric multivariate failure time distributions which characterize the strength of association among failure time components by a limited number of parameters while leaving the forms of the marginal distributions unspecified (e.g. [3, 18, 1]). One may extend these multivariate distributions by formulating their marginal distributions with model (1) or (2). One may then estimate the marginal regression parameters and baseline hazard functions by (3) and (5) or (4) and (6) and proceed to estimate the association parameters by the pseudo-**maximum likelihood** method [5]. This approach was mentioned by Bandeen-Roche & Liang [1], but its inferential properties have yet to be investigated.

Prentice & Hsu [19] studied simultaneous regression on the marginal hazard ratios and pairwise dependencies, which is analogous to the regression on the means and covariances of noncensored multivariate responses [20]. They used the estimating

function of Cai & Prentice [2] for the marginal hazard ratio parameters and developed a similar *ad hoc* estimating function for the dependence parameters. They showed that the solutions to this pair of estimating functions are consistent and asymptotically normal, with a sandwich-type covariance matrix estimator.

The **accelerated failure-time** and **additive hazards models** are two important alternatives to the proportional hazards model. The former relates the logarithm of the failure time linearly to the covariates [8], while the latter relates the conditional hazard function linearly to the covariates [16]. One may formulate the marginal distributions of multivariate failure time data with accelerated failure time models or additive hazards models rather than proportional hazards models. The corresponding inference procedures were studied, respectively, by Lin & Wei [15] and Lee et al. [10], and by Lin & Ying [17].

Marginal Models

When several response variables are simultaneously of interest on each subject in a study, we may expect these responses to be interdependent simply because the same subject is involved for all observations. Because of this dependence among the observations, a **multivariate distribution** will be required to model them adequately. In most cases, repeated measurements will be involved; for simplicity, we shall restrict our examples to such studies. In other words, the *same* response variable will be measured several times on subjects, either because they are found in clusters or because they are observed longitudinally over time [11], (*see* **Longitudinal Data Analysis, Overview**).

The full multivariate distribution will describe the dependence among the responses on each subject. Such distributions can always be factored into a product of univariate marginal and conditional distributions in a number of ways (*see* **Marginal Probability**; **Conditional Probability**). As well, as many univariate marginal distributions exist as the number of dimensions of the response variable. Models based on multivariate distributions can be parameterized in a number of different ways, using various combinations of the conditional and/or marginal distributions, although care must be taken in such constructions [2]. Thus, if a proper probability model is constructed for such data, it necessarily contains both marginal and conditional aspects. A "marginal model" refers to a multivariate model where emphasis is placed on the margins; usually, parameters in the margins are related in simple ways to the **covariates**. As we shall see, this generally induces complex relationships for the conditional distributions.

In certain situations, such as in the experimentation of a **clinical trial**, the dependence relations among responses will be of direct interest. Thus, for example, in a longitudinal setting, we may be concerned with how a response depends on the previous history of a subject, including dependence on previous responses. Then, study of conditional distributions will be appropriate [12]. However, in other situations, such as epidemiological population studies of **prevalence**, we may be interested in the marginal distribution of responses within the population at each point in time or for each member of a cluster or matched group (*see* **Clustering**). The term *marginal* means that the distribution of each response separately is concerned, conditional on covariates but not on any of the other responses. In such a marginal approach, the observations are analyzed as if they were a series of **cross-sectional studies** instead of repeated measurements on the same individuals.

A special kind of conditional distribution involves **random effects**. By conditioning on one or more latent variables accounting for heterogeneity among subjects, a multivariate distribution is induced. In the simplest case, it has uniform dependence among all responses within a cluster. In what follows, the term, conditional distribution, will refer to conditioning directly on the other responses of a subject, and not to random effects.

Clustered and longitudinal studies pose fairly distinct problems. The observations on a cluster are generally not ordered, so that they are interchangeable. The same marginal model will often be appropriate for any member of the cluster, although, in some cases, responses will depend on cluster size. However, in a longitudinal study, observations are ordered in time, so that early observations cannot be made to depend on more recent ones. A model at any time point should be constructed in ignorance of future observations. In most situations, the marginal distribution may be expected to change over time.

To see the relationships between multivariate, conditional, and marginal distributions, consider the simplest example of a repeated categorical response. If we have two observations of the response, the joint or multivariate (here bivariate) distribution can be represented by the probabilities, π_{ij}, where the two indices indicate the combination of categories observed. The marginal distributions are given by the probabilities, $\pi_{i\bullet} = \sum_j \pi_{ij}$ and $\pi_{\bullet j} = \sum_i \pi_{ij}$, and the conditional distributions by $\pi^1_{i|j} = \pi_{ij}/\pi_{\bullet j}$ and $\pi^2_{j|i} = \pi_{ij}/\pi_{i\bullet}$.

To take a concrete example, consider first a clustered, rather than a longitudinal, response. Suppose that we have a sample of subjects for whom we classify each eye as having either good or poor vision. Observations can be represented as a simple **2 × 2 table** with entries being the frequencies, n_{ij}, where the indices refer to the responses on the two eyes. Information on the bivariate distribution, π_{ij}, is contained in the body of the table. A conditional distribution corresponds to fixing the value of one of the two responses, so that information is obtained from the corresponding row or column. We can reconstruct the complete multivariate distribution from a pair of

conditional distributions. Finally, information on the marginal distributions is contained in the marginal totals. This pair of marginal distributions, by itself, does not allow us to reconstruct the complete multivariate distribution. Attempts to do so involve what is called the **ecologic fallacy** [12].

Marginal distributions inform us about the average state of a population. They tell us nothing about the relationships among the responses for individual members of the population. Two responses may have identical marginal distributions without there being a similar dependence between the responses for many, or indeed any, individual subjects. Consider two rather extreme fictitious examples of the joint distributions that might correspond to results under two treatments:

	Left eye			Left eye	
Right eye	Good	Poor	Right eye	Good	Poor
Good	0.01	0.47	Good	0.46	0.02
Poor	0.47	0.05	Poor	0.02	0.50

In the left table, there is a large probability that only one eye of any given individual will be good; the treatment helps only one eye, but for almost all individuals. In the right table, the probability is high that both eyes will be similar; this treatment helps both eyes of half of the individuals. Thus, in the first case, the conditional probability is 0.02 ($= 0.01/0.48$) that one eye will be good, given that the other is, while, in the second case, it is 0.96 ($= 0.46/0.48$). However, marginally, under both treatments, both eyes have exactly the same distribution, known as marginal homogeneity, with the same probability of 0.48 for a good left and a good right eye. Thus, the fact that the marginal probabilities of both left and right eyes being good are the same tells us nothing about whether both eyes of a given subject will be good. Conversely, if the relationship between marginal distributions were different under two treatments, this would not exclude the individual response relationships between eyes being the same for both treatments [1], (*see* **Matched Pairs With Categorical Data**).

For the cluster of two eyes, a reasonable bivariate distribution that allows for interchangeability would set $\pi_{12} = \pi_{21}$, or equivalently, the conditional probabilities, $\pi^1_{1|1} = \pi^2_{1|1}$, to yield a trinomial distribution. From this bivariate distribution, the marginal probabilities are easily obtained as $\pi_{1\bullet} = \pi_{\bullet 1} = \pi_{11} + (\pi_{12} + \pi_{21})/2$.

Consider now a slightly more complex example with a binary response, this time in a longitudinal context [15]. Subjects are followed over time, all beginning in one state, but at some point switching to a second state. This may be represented by a horizontal line, running through time on a graph, starting at level one but jumping vertically down to level zero at the switch point, then continuing horizontally at that level. Each subject may change state at a different time, so that the vertical lines do not coincide. The average or typical individual will have the vertical line situated at the mean of all jump times. However, the marginal model, calculated from the mean number in state one at each time point, will be a sigmoid curve dropping slowly from one and flattening off at zero. Individuals cannot follow such a curve because they must be in one state or the other, not part way in between. The marginal curve gives the average number of subjects in each state at each point in time, but tells us nothing about the trajectory of a typical individual.

From these examples, we can see that marginal probabilities refer to averages, not individuals. Thus, models for such probabilities are sometimes called *population-averaged*, whereas conditional models are called *subject-specific* [16]. The choice between the two types will depend on the question being asked. For example, if the response is the presence or the absence of repeated infections under two treatments, the population-averaged model describes the global difference in infection rates between the treatments, while the subject-specific one looks at the probability of infection of a typical individual, given treatment. Effects in population-averaged models depend on the degree of heterogeneity in the population; the same process in two populations with different heterogeneity will yield different population-averaged effects. The dependence of marginal response on an **explanatory variable** will be smaller than the corresponding individual average dependence in a random effects model, this difference increasing with heterogeneity.

Care must be taken that a marginal model does correspond to a population of interest. For example, in the setting of a clinical trial, the "population" is rather artificial for a number of reasons including the facts that the subjects are volunteers and that all are started on treatments at arbitrary points in time. In

such a context, marginal statements would appear to have limited value.

A marginal model can be constructed in two opposing ways. We may start with some known multivariate distribution (or set of conditional distributions) and construct the marginal distributions by summing or integration. Or we may specify directly the marginal distributions. We have already seen that, in the latter case, the multivariate distribution will not be uniquely defined, so that additional relationships will have to be specified. One common way is by using **copulas** [8]. Each approach has certain advantages and disadvantages.

First, we should note that the **multivariate normal distribution** is quite exceptional and should not be taken as a general example for model construction. Both the conditional and the marginal distributions are easy to derive, and both are also **normal**. The Bernoulli distribution (*see* **Binary Data**) has similar properties, but the **binomial** does not. Both the normal and Bernoulli distributions are very special.

Generally, if the conditional distributions are of a simple known form, the marginal distributions will be complex, usually analytically intractable, and vice versa. This means that if we start with some reasonable conditional distributions that might be appropriate to describe the dependencies of the phenomenon under study at the individual level, the marginal distributions will be complex and difficult to handle. But if we start with some simple and well-known marginal distributions that we find easy to understand at the population level, we are implicitly imposing one of a number of possible conditional distributions implying a complex relationship at the individual level.

Consider an example involving the number of infections in one month in each eye. If we took the conditional distribution, say for the left eye given the condition of the right eye, to be **Poisson**, we would only be assuming that individuals under the same condition of the right eye had the same distribution of responses for the left eye. The marginal distribution would be a weighted average of the two Poisson distributions. On the other hand, if we took the marginal to be Poisson, again for the left eye, we would be assuming that *all* members of the population had on average this same probability distribution.

Scientifically, it should be clear that the first approach is more reasonable. Marginal or population descriptions do not generally have a meaning on their own, but only as built upon acceptable underlying individual dependence relationships. Nevertheless, certain statisticians have argued that the second is justifiable to answer some population questions.

A conditional model generally depends on the number of other responses to which a given response is related (think of a cluster of teeth instead of eyes), while a marginal model does not. The latter is said to be reproducible [10]. Thus, a marginal model can have the same interpretation for clusters of all sizes, while a conditional model may not. Random effects models also have this characteristic. Hence, direct conditioning may not be appropriate for clustered data. On the other hand, reproducibility is generally not a desirable property for longitudinal data. Unequal sized longitudinal "clusters" have histories of different lengths.

For simple categorical data, such as two-way tables, both conditional and marginal models can be constructed fairly easily. Suppose that we want to study the influence of some explanatory variable, x_k, on the two binary responses, $i = 1, 2$ and $j = 1, 2$. The state of two eyes, used above, would be one example, but the study could also be longitudinal. We can construct a model based on a series of **multinomial distributions** such that $\sum_i \sum_j \pi_{ijk} = 1$ for all k. Then, the **loglinear** regression functions for a conditional model, based on a bivariate Bernoulli distribution, are

$$\begin{aligned}
\log\left(\frac{\pi_{11k}\pi_{12k}}{\pi_{21k}\pi_{22k}}\right) &= \log\left(\frac{\pi^1_{1|1,k}\pi^1_{1|2,k}}{\pi^1_{2|1,k}\pi^1_{2|2,k}}\right) \\
&= 2\log\left(\frac{\dot{\pi}_{1\bullet k}}{\dot{\pi}_{2\bullet k}}\right) \\
&= \beta_{10} + \beta_{11}x_k \\
\log\left(\frac{\pi_{11k}\pi_{21k}}{\pi_{12k}\pi_{22k}}\right) &= \log\left(\frac{\pi^2_{1|1,k}\pi^2_{1|2,k}}{\pi^2_{2|1,k}\pi^2_{2|2,k}}\right) \\
&= 2\log\left(\frac{\dot{\pi}_{\bullet 1k}}{\dot{\pi}_{\bullet 2k}}\right) \\
&= \beta_{20} + \beta_{21}x_k \\
\log\left(\frac{\pi_{11k}\pi_{22k}}{\pi_{12k}\pi_{21k}}\right) &= \beta_{30} + \beta_{31}x_k, \qquad (1)
\end{aligned}$$

where $\dot{\pi}_{\bullet jk}$ and $\dot{\pi}_{i\bullet k}$ are the geometric means. Although the conditional probabilities must be adjusted to follow the linear regression across tables, indexed by k, this allows the marginal frequencies, upon

which they are conditioned, to be held constant at their observed values. Inferences are then independent of these observed marginal totals, and of wide applicability. Although the conditional probability distributions are Bernoulli, the same for all subjects with a given value of x_k, the corresponding marginal distributions are weighted averages over all values of x_k.

Consider now the corresponding regression functions for a marginal model,

$$\begin{aligned}
\log\left(\frac{\pi_{11k}+\pi_{12k}}{\pi_{21k}+\pi_{22k}}\right) &= \log\left(\frac{\pi_{1\bullet k}}{\pi_{2\bullet k}}\right)\\
&= \beta_{10}+\beta_{11}x_k\\
\log\left(\frac{\pi_{11k}+\pi_{21k}}{\pi_{12k}+\pi_{22k}}\right) &= \log\left(\frac{\pi_{\bullet 1k}}{\pi_{\bullet 2k}}\right)\\
&= \beta_{20}+\beta_{21}x_k\\
\log\left(\frac{\pi_{11k}\pi_{22k}}{\pi_{12k}\pi_{21k}}\right) &= \beta_{30}+\beta_{31}x_k. \qquad (2)
\end{aligned}$$

Here, we have chosen the log **odds ratio** to describe the dependence between the two binary responses (a less elegant solution being to use the **correlation**). The observed marginal frequencies are not held fixed, unless a saturated model is fitted because those in individual tables indexed by k, must be estimated so as to follow the linear regression function. Because inference is not made conditional on the observed marginal frequencies, this limits the applicability of any empirical conclusions concerning dependence, drawn from this model, to tables with the same marginal frequencies.

The conditional distributions obtained from a marginally-specified model or vice versa are complex because the marginal probabilities are sums of multivariate probabilities and probabilities are nonlinearly (here logit) related to the covariates. For example, in the second model, the marginal probabilities are Bernoulli, the same for all subjects with a given value of x_k, whereas the joint and conditional ones vary in some complex way among subjects with the same x_k. In contrast, in the first model, the conditional probabilities are Bernoulli, the same for all subjects with a given value of x_k.

These models have several interesting contrasting characteristics. The first of them, loglinear regression, is a **generalized linear model**, whereas the second is not. This means that the parameter estimates are considerably more difficult to obtain in the latter case. This is further complicated if correlations are used (for more than two responses), because inequality constraints must be applied. At the same time, the conditional model, but not the marginal one, fixes the marginal totals at their observed values, something that has often been considered to be a prerequisite for analyzing a contingency table. Finally, from general properties of the **exponential family**, the dependence parameters, (β_{31}, β_{31}), in the above marginal model are information orthogonal to the marginal regression parameters, $(\beta_{10}, \beta_{11}, \beta_{20}, \beta_{21})$. In other words, the elements of the **information matrix** relating these parameters together are zero so that their estimates are asymptotically uncorrelated. This is not true in the conditional model. Fitzmaurice and Laird [4] and several other authors have developed more complex probability models based on marginal parameters.

To avoid the complexities of the specification of dependence relationships when marginal distributions are the primary point of interest, one widely promoted approach has been to set up regression equations only describing how the marginal responses are believed to depend on the explanatory variables (similar to the first two of the three equations for the marginal model above). As members of the generalized linear model family, the score equations for estimating the parameters are well understood. But because responses are not independent, some matrix of "working" correlations is introduced into these equations, yielding **generalized estimating equations** (GEE) [10, 16].

Such equations have the property that, if the regression is correctly specified, the point estimates of the regression coefficients will be asymptotically consistent no matter what "working" matrix is chosen (although there is no simple empirical way of checking correctness). However, this is accompanied by at least two major inconveniences. Except in special cases, the GEE corresponds to no probability model in the accepted sense of the term, that is, no model that allows one to calculate the probability of the observed or any future data. Thus, no **likelihood** function is available, singularly complicating the tasks of obtaining useful measures of precision of the point estimates and of comparing "models". Generally, only quasi-standard errors and a quasi-score function are available for making inferences and there has been considerable debate about the choice of the former. Standard errors are well-known to be unreliable in small samples of categorical data [5] so that care must be taken, in the same way as asymptotic

chi-squared tests need to be replaced by **Fisher's exact test** in sparse **contingency tables** (*see* **Exact Inference for Categorical Data**).

Although, the examples given here have involved simple binary responses, extensions to more complex **polytomous**, including ordinal, responses are available (*see* **Ordered Categorical Data**). However, a search of the literature shows that publishing on marginal models has reached a low level over the past five years after considerable activity in the preceding decade. Recent publications on more complex models include [3, 6, 7, 9, 13]. The reader may also wish to consult the review paper by Pendergast et al. [14].

Marginal Probability

In many situations, interest focuses on probability distributions for multiple random variables. For example, one may be studying height, weight, blood pressure, and cholesterol levels in a population, variables likely to be **correlated** with one another. Knowledge of the joint distribution of these variables allows one to calculate the probabilities associated with any particular outcome of interest. Marginal probabilities relate to the univariate distribution, or marginal distribution, associated with any of the variables under consideration.

To fix notation, first consider a **bivariate** model for two random variables X and Y. Let $f_{X,Y}(x, y)$ denote the joint probability mass function if X and Y are discrete or the joint probability density function if X and Y are continuous. If X and Y are discrete, the marginal probability mass functions of X and Y are given by

$$f_X(x) = \sum_y f_{X,Y}(x, y)$$

and

$$f_Y(y) = \sum_x f_{X,Y}(x, y),$$

where the summations are taken over all of the values of Y or X. In this case, the joint probability mass function can be written in tabular form, with the columns corresponding to the possible values of X and the rows to the values of Y. Then the marginal distribution of X corresponds to the column sums of the table, and the marginal distribution of Y corresponds to the row sums of the table.

When X and Y are continuous, the marginal probability density functions of X and Y are given by

$$f_X(x) = \int_{-\infty}^{\infty} f_{X,Y}(x, y)\, \mathrm{d}y$$

and

$$f_Y(y) = \int_{-\infty}^{\infty} f_{X,Y}(x, y)\, \mathrm{d}x.$$

As a special case, when (X, Y) follows a **bivariate normal distribution** with means (μ_X, μ_Y) and **covariance matrix**

$$\begin{pmatrix} \sigma_X^2 & \sigma_{XY} \\ \sigma_{XY} & \sigma_Y^2 \end{pmatrix},$$

then the marginal probability density function of X follows a univariate **normal distribution** with mean μ_X and variance σ_X^2, and similarly for Y.

These marginal distributions can be used to compute probabilities or expectations that involve only X or Y. However, the marginal distributions do not completely describe the joint distribution of X and Y. In fact, many different joint distributions can yield the same marginal distributions. The variables X and Y are independent if and only if the joint distribution of (X, Y) is given by the product of the marginal distributions of X and Y. **Conditional probability** distributions refer to the distribution of one variable for a given value of the other variable.

For multivariate distributions with more than two variables, the corresponding summations or integrals are carried out over the complete range of the other variables under consideration. Extensions to mixtures of discrete and continuous variables are straightforward. For further information, see Casella & Berger [1, Chapter 4]. Regression modeling of multivariate responses sometimes focuses on modeling the marginal mean responses of the observations as a function of covariates, with the correlations between responses possibly being viewed as **nuisance parameters**. Diggle et al.[2, Chapter 8] review marginal modeling of multivariate discrete and continuous responses.

Marker Processes

In many survival studies, individuals give rise to **stochastic processes**, called *marker processes*, that in some way measure the state of "health" of the individuals. Thus, the observed path of the marker process provides information on the propensity of the individual to fail. Such covariates have the potential to be useful in various ways and, in this brief introductory article, we attempt to identify some of these and to give entry points to the developing literature in this area.

Many examples of marker processes arise in survival studies (*see* **Survival Analysis, Overview**). In **clinical trials**, for example, it is common at each follow-up visit to take repeated measures of general health status or of the stage or severity of the disease. In equipment reliability studies, there are often repeated measures of the wear or degradation of the item under study. In the study of the time to breakdown of automobiles, for example, a simple and highly informative marker process is total kilometers traveled. In the study of infection with the Human Immunodeficiency Virus (HIV), much attention has been focused on the estimation of the distribution of "incubation time"; that is, the time from infection with HIV until the diagnosis of AIDS (*see* **AIDS and HIV**). Various marker processes, such as CD4-lymphocyte counts, have been studied and used to provide information both on the time since infection began and on the probability of developing AIDS.

Jewell & Kalbfleisch [5] outline some potential uses of marker processes and their classification forms the basis of the following summary:

1. *Improving estimation of a survival distribution*. In many instances the observed path of the marker provides information on the residual life of the individual under study. The basic idea is that the marker can be utilized to provide an estimate of the residual life for an individual who is **censored**. This can provide more and better information for the estimation of the survivor function (*see* **Survival Distributions and Their Characteristics**). In some instances this allows for adjustment for dependent or informative censoring mechanisms. Taylor et al. [14] and Robins & Rotnitzky [12] give good discussion and examples.
2. *Serving as a surrogate for survival in a comparative trial*. If the time to failure is typically long, then a full survival study may be prohibitively expensive or else require too long for completion. In such instances there may be substantial advantage to using marker processes as **surrogates** for the failure time in investigating the existence and size of treatment effects. In this approach it is required that the survival time be directly related to the marker so that a treatment effect on the marker will have a consequent effect on survival. This potential use of markers was the motivation of Cox [3] in his original paper in this area. Prentice [10] gives a detailed and comprehensive discussion of surrogate endpoints, potential uses, and caveats.
3. *Estimating the time of onset of a disease*. Sometimes the time of onset of a disease is not or cannot be observed. In such instances a marker measured on an affected individual may provide information on the elapsed time since onset. For example, in HIV the time of infection is typically unknown and markers may assist in estimating the time of onset. In a comparative trial, **confounding** of the time of onset with treatment or other comparison has the potential to introduce **bias** into the estimation of effects. The marker's information on time of onset can be used to adjust comparisons in this context and so help to compensate for the onset of confounding. Applications involving unknown onset have been considered by several authors. In the estimation of the incubation period in AIDS, Berman [1] and Munõz et al. [8] provide examples. Rai & Matthews [11] consider the use of tumor size at death in animal carcinogenicity trials (*see* **Tumor Incidence Experiments**) to estimate the unobserved time since tumor onset. Brookmeyer & Gail [2] and Munõz et al. [7] consider some theoretical issues associated with the onset of confounding.

In modeling the relationship between the marker process and the survival probabilities, it is convenient to utilize the hazard function. Let $\{X(t) : t > 0\}$ represent the marker process and let $T > 0$ be the time to failure. Conditionally upon the current and past

values of the marker, the **hazard** function or failure rate is naturally specified as

$$\lambda(t|X(s), 0 \le s \le t) = \lim_{\Delta t \to 0} \frac{\Pr\{T \in [t, t+\Delta t) | T \ge t, X(s),\ 0 \le s \le t\}}{\Delta t}. \quad (1)$$

Various more specific parametric and nonparametric models based on (1) could be specified and considered. In applications, other covariates, either fixed or **time-dependent**, may also be present and one may wish to extend (1) to incorporate them into the model. In a comparative trial, for example, (1) could be extended to include treatment effects.

To utilize the marker to estimate residual life or time since onset, as discussed above, the stochastic laws governing $X(t)$ as well as the relationship between $X(t)$ and the failure rate must both be considered. Jewell & Kalbfleisch [4, 5] have provided one example. They consider an additive model for (1),

$$\lambda(t|X(s) : 0 \le s \le t) = h_0(t) + \beta X(t),$$

where $h_0(t)$ is a baseline hazard and β is a regression parameter relating the nonnegative valued marker $X(t)$ to the failure rate. To complete the model, they make various assumptions about $h_0(t)$ and specify simple Markov models for $X(t)$ (*see* **Markov Processes**). From these specifications the dependence of the distribution of residual and past life on current marker values is investigated. Other approaches to jointly modeling the marker process and the failure mechanism are given in Pawitan & Self [9], Shi et al. [13], Jewell & Nielson [6], and Tsiatis et al. [15].

JOHN D. KALBFLEISCH

Markov Chain Monte Carlo, Recent Developments

Introduction

The preceding article on **Markov chain Monte Carlo** covers developments up to about 1997. There has recently been an explosion of interest in Markov Chain Monte Carlo for biostatistical modeling and analysis, particularly, but not exclusively in a **Bayesian** framework.

Recall that the aim is to estimate **expectations** (expected values) of θ (or functions of θ) from a probability density function $f(\theta)$. If f is nonstandard or high dimensional, MCMC algorithms allow **simulation** of (dependent) values of θ from a **Markov chain** whose stationary distribution is $f(\theta)$. In a Bayesian context, $f(\theta|x)$ is a posterior distribution with parameters θ, given data x.

The preceding entry describes the properties of principal MCMC algorithms, including Metropolis–Hastings, Gibbs, adaptive rejection sampling, and reversible-jump MCMC. It also discusses issues of burn-in, convergence, proposal distributions, and improved mixing through reparametrization. Applications considered there comprise **hierarchical models**, **missing data**, **censored data**, **measurement error**, and temporally or spatially correlated data (*see* **Geographic Epidemiology**; **Time Series**).

The aim of this update is to describe some of the new developments in MCMC methodology and their application in biostatistics.

MCMC Methods

Metropolis–Hastings and Gibbs

Metropolis–Hastings and Gibbs **algorithms** remain popular choices in biostatistical applications. Their appeal lies in the generality of their application, the ability to reduce hierarchical and high-dimensional problems to forms that are amenable to these algorithms, their theoretical properties, and their inclusion as standard tools in the more popular MCMC software (see below).

Many variations on the original Metropolis–Hastings and Gibbs samplers have been developed. The more well known of these include adaptive rejection sampling and adaptive rejection Metropolis sampling (see Gilks' original Entry on MCMC and Gilks et al. [38]) and slice sampling (see below). Other potential *black box* algorithms have been proposed; see, for example, [20].

Hybrid methods, which employ combinations of MCMC algorithms in a single analysis, are also described in **Markov Chain Monte Carlo**. These have continued to grow in popularity because of their flexibility, improved exploratory ability, theoretical validity, and appealing properties of estimation and convergence [99]. Hybrid methods embrace a diversity of constructions, including different Metropolis–Hastings and Gibbs algorithms for different components of θ [7], the insertion of a Metropolis–Hastings step with larger dispersion or probability of acceptance at every nth iteration, mode-jumping proposals [102], the insertion of a Metropolis–Hastings step after each Gibbs cycle [74], and Metropolis-within-Gibbs algorithms [20, 61, 69, 70]; see [83, pp. 319–326] for a formal definition of a hybrid method, comprehensive discussion, and examples. Importantly, building on their results and those of Tierney [99], hybrid methods can be almost automatically constructed to ensure *uniform convergence* to the target distribution.

Other *adaptive algorithms* include mode-jumping proposals [102], methods based on *tempering* (see Celeux et al. [18] and references therein), and approaches based on *regeneration* [38, 46]. See also the algorithms based on sequential Monte Carlo, described below.

Parameterization of the model has an impact on the choice and effectiveness of MCMC methods. The positive impact of reparameterization of hierarchical models is also achieved for other model formulations such as mixtures, $f(\theta) = \Sigma_{j=1}^{k} p_j f(\theta_j)$, where $\Sigma_{j=1}^{k} p_j = 1$, $0 \le p_j \le 1$. Like hierarchical models, mixtures have enjoyed increasing popularity as flexible modeling tools due to the enhanced computational ability afforded by MCMC. However, the application of standard MCMC algorithms to the usual formulation of a mixture density can lead to **identifiability** problems and the possibility of "trapping states" caused by allocation of a small number of observations to a particular component.

Robert and Titterington [90] have proposed effective reparameterizations to overcome these drawbacks. Two such alternatives are discussed by Robert and Casella [83] in the context of a mixture of **normal** densities, $\Sigma_{j=1}^{k} p_j \mathcal{N}(\mu_j, \tau_j^2)$; here, τ^2 is the inverse of the variance. The first, $\Sigma_{j=1}^{k} p_j \mathcal{N}(\mu + \tau\theta_j, \tau^2\sigma_j^2)$, with $\theta_1 = 0, \sigma_1 = 1$, is a simple expression of each component as a perturbation from a global location μ and a global scale τ. An alternative, more stable reparameterization proposed by Robert and Mengersen [84] expresses each component as a perturbation of the previous component. Thus, a two-component normal mixture is expressed as $p\mathcal{N}(\mu, \tau^2) + (1-p)\mathcal{N}(\mu + \tau\sigma, \tau^2\sigma^2)$ and the three-component analog is $p\mathcal{N}(\mu, \tau^2) + (1-p)q\mathcal{N}(\mu + \tau\sigma, \tau^2\sigma^2) + (1-p)(1-q)\mathcal{N}(\mu + \tau\sigma + \tau\sigma\varepsilon, \tau^2\sigma^2\omega^2)$. With an identifiability constraint $\sigma_1 \leq 1, \ldots, \sigma_{k-1} \leq 1$, an improper **prior** for (μ, τ) and a **uniform distribution** on the σ_i's can be adopted and standard MCMC algorithms can be employed.

The desired *acceptance rate* of a Metropolis–Hastings algorithm has also been a matter of recent research. Optimal rates for random walk algorithms have been carefully investigated by Roberts et al. [86] and corresponding guidelines have been suggested. As described and illustrated by Robert and Casella [83, pp. 252–254], high acceptance rates are desirable if the proposal density g approximates the target f such that f/g is bounded for uniform ergodicity. However, low acceptance rates are preferable if a random walk proposal is adopted. These authors also propose the use of the rejected values in a Metropolis–Hastings algorithm through **Rao–Blackwellization** and give references to other acceleration methods.

Active research continues on the *theoretical properties* of Gibbs and Metropolis–Hastings algorithms. In a general state-space context, Tierney [100] identifies necessary and sufficient conditions on the Metropolis–Hastings proposal kernel and the acceptance probability function for the resulting transition kernel and invariant distribution to satisfy the detailed balance conditions. References to recent results on MCMC convergence are given below.

Model Choice

Model choice via MCMC is now a standard practice, as indicated by the recent reviews of the variety of available methods (*see* **Bayesian Methods for Model Comparison**). See, for example, the papers by Han and Carlin [45], Brooks [10] and Dellaportas et al. [28] and the summaries by Carlin and Louis [15, Chapter 5] and Congdon [22, Chapter 10].

As discussed by these authors, methods based on **Bayes factors** include variations on marginal density estimation (see also [21]) and sampling over the model space. Weakliem [104] gives a broad discussion and critique of the Bayes information criterion (BIC) $= \log P(y|\hat{\theta}, M) - p/2 \log n$ for a given model M and sample size n. Bayesian ***P* values**, penalized likelihood methods, and predictive model selection approaches are also available.

Green's [39] *reversible jump Markov Chain Monte Carlo* (RJMCMC) algorithm has recently become a key tool for model choice. Sampling can now be extended to different parameter spaces, such as the dimensions of a model, components of a mixture, or subsets of variables in a regression. This approach has inspired other methodological developments in model selection and a diversity of applications. As conceded by Robert and Casella ([83], pp. 259–264), however, RJMCMC can be difficult to implement because of the requirement for reversible moves and a (differentiable) dimension-matching transform. Moreover, inefficient moves between dimensions can require complicated tuning steps. An alternative to RJMCMC is described by Stephens [97]. Under this method, the parameters of interest are considered as a marked point process.

Instead of choosing a single model based on the above methods, an increasingly common practice is *model averaging*. This is the practice of combining expected values obtained from different models (perhaps describing different dimensions or different combinations of variables) weighted by their corresponding posterior probabilities. Of course, adoption of this approach depends on the aim of the analysis and achieving a balance between improved estimation and easy interpretation.

Slice Sampling

A technique that enables the Gibbs sampler to be used for almost any distribution is the slice sampler. Introduced by Wakefield et al. [103] as a "ratio-of-uniforms" method for generating random variables, developed by Neal [73] as a method for "slicing" distributions, and described by Tierney and Mira

[101] in the context of adaptive MCMC models, the slice sampler enjoys increasing popularity and is part of most modern MCMC texts; see, for example, [14, 83]. The latter authors describe the slice sampler as follows.

If $f(\theta)$ can be written as a product $\Pi_{i=1}^{k} f_i(\theta)$, where the f_i's are positive functions (not necessarily densities), then f can be expressed as $\Pi_{i=1}^{k} \mathcal{I}_{0 \le \omega_i \le f_i(\theta)}$, where $\mathcal{I}$ is the indicator function.

Thus at the tth iteration, $\theta^{(t)}$ is simulated by generating k uniform random variables $\omega_1^{(t)} \sim \mathcal{U}[0, f_1(\theta^{(t-1)})], \ldots, \omega_k^{(t)} \sim \mathcal{U}[0, f_k(\theta^{(t-1)})]$ and taking $\theta^{(t)} \sim U(A^{(t)})$, with $A^{(t)} = \{y; f_i(y) \ge \omega_i^{(t)}, i = 1, \ldots, k\}$.

It can be shown that this chain converges geometrically when f is bounded and converges uniformly when $k = 1$. An upper bound for the rate of convergence has also been established. Moreover, given an independent Metropolis–Hastings algorithm, it is always possible to construct a slice sampler that has a smaller asymptotic variance and smaller second-largest **eigenvalue**, thus ensuring faster convergence to the target distribution. See [68, 88, 101] for a discussion of these and other theoretical properties.

Perfect Simulation

Another development in MCMC that has created its own domain of research is perfect simulation, also known as *exact sampling*. As described in the original paper by Propp and Wilson [79] and subsequently by Kendall [50], the aim of perfect simulation is to sample directly from the stationary distribution $f(\theta)$.

Although this appears to be exactly what MCMC is aiming to avoid, there are several reasons for pursuing the idea. First, independent samples drawn directly from $f(\theta)$ may be preferable to samples obtained from MCMC algorithms, depending on the degree of dependence in the latter and the comparative computational time and complexity. Second, a single sample drawn directly from $f(\theta)$ can be used as a starting point for standard MCMC algorithms. This avoids the well-known problem of *burn-in*, in which the initial value of the chain may induce long-term bias.

For a finite state-space $\mathcal{X}$ of size k, Propp and Wilson [79] proposed an exact sampling algorithm called *coupling from the past* (CFTP). Here, k chains corresponding to all possible starting points in $\mathcal{X}$ are started at time t and run in parallel *back* in time, often in a *coupled manner*, until all the chains *coalesce* (take the same value) at time 0 or earlier. The realizations of the chains at time 0 then form a single $\theta^{(0)}$ from the required distribution.

If the chains have not coalesced by time 0, the chains are run again from time $2t$ and this is continued until the desired result is achieved. It can be shown that coalescence under CFTP will indeed occur in a finite number of backward iterations. In practice, however, the computation time can be unacceptably long. Alternative algorithms have been developed to improve this and other aspects of the original CFTP idea. For example, Fill [35] proposed an *interruptible* algorithm for perfect simulation, in which the chains can be stopped before reaching time 0 but maintain the properties of the CFTP algorithm. As a second example, if a *monotonicity* constraint can be constructed, so that there is stochastically a maximum state x_1 and a minimum state x_0 in $\mathcal{X}$, then CFTP reduces to running only two chains from x_0 and x_1 until they coalesce at time 0, since all the intermediary paths will be between these two extreme cases. As a second example, Kendall and Møller [51] describe extensions to the original CFTP approach, focusing, in particular, on perfect simulation methods based on dominating processes on ordered spaces.

As noted by Robert and Casella [83], the extension of perfect simulation ideas from finite state spaces to the statistical context is an area of current active research. Potential improvements in the speed and control of convergence under this method are mitigated by the concern that the time that is typically required to simulate one realization of $\theta^{(0)}$ under CFTP is much greater (by orders of magnitude) than the computation time of a $\theta^{(t)}$ from a standard MCMC algorithm. Moreover, algorithms for continuous spaces are more difficult to construct. Murdoch and Green [71] originally explored standard statistical examples in a continuous setting. Casella et al. [16] proposed a perfect simulation method for mixture modeling using slice sampling. Perfect slice samplers are also discussed by Mira et al. [66, 67].

Delayed Rejection

Consider a standard Metropolis–Hastings algorithm with target density f, such that if a proposed value y is rejected, the chain remains in the current state x. This preserves the stationary distribution but induces **autocorrelation** in the realized chain. Tierney and

Mira [101] proposed an alternative based on *delayed rejection* or *splitting rejection*. When a proposed value is rejected, a second proposal is made using a different distribution possibly dependent on the previously rejected values and is accepted with probability modified to account for the previous rejection. This is continued until a stopping rule is met, such as a maximum number of attempts or until acceptance is achieved. Thus, a first proposal x is generated from $q_1(x, y)$ and accepted with probability $\min\{1, [f(y)q_1(y, x)]/[f(x)q_1(x, y)]\}$. If y is rejected, a new value z is proposed from $q_2(x, y, z)$ and accepted with probability $\min\{1, [f(z)q_1(z, y) q_2(z, y, x)(1 - \alpha_1(z, y))]/[f(x)q_1(x, y)q_2(x, y, z) (1 - \alpha_1(x, y))]\}$.

Green and Mira [40] proposed a generalization of this idea, extended the method to reversible jump algorithms, and presented a comparison of the performance of their proposed delayed rejection algorithm with other samplers. Performance was defined in terms of the efficiency of estimating the desired expectation on the state space and computed as the product of the running time needed to obtain a fixed number of sweeps and the integrated autocorrelation time.

Sequential Monte Carlo

The term *sequential Monte Carlo* embraces a variety of algorithms, including Langevin or diffusion algorithms, population Monte Carlo or iterated **importance sampling**, and particle filters.

Langevin algorithms, also known as *diffusion algorithms*, were proposed by Grenander and Miller [42] and Phillips and Smith [78] and arise from the discretized solution of a stochastic differential equation, also known as a diffusion equation. Thus, $x^{(t+1)} = x^{(t)} + 0.5\sigma^2 \Delta \log f(x^{(t)}) + \sigma\varepsilon_t$ where $\varepsilon_t \sim \mathcal{N}_p(0, I_p)$ and σ^2 corresponds to the discretization size. Following Besag [6], $x^{(t+1)}$ is then accepted according to a regular Metropolis step.

The theoretical properties of this approach have been investigated by Roberts and Tweedie [91] and Stramer and Tweedie [98], among others. Robert and Casella [83, pp. 264–266] describe and illustrate various diffusion algorithms. Extensions include switching diffusion models and their variations [59] and variations on proposal distributions [95].

Population Monte Carlo, or *iterated importance sampling*, involves simultaneous generation of a vector of random variables $(\theta_1^{(t)}, \ldots, \theta_M^{(t)})$ at each iteration of a Monte Carlo algorithm. Such systems of particles were shown by Mengersen and Robert [64] to be capable of producing i.i.d. samples for a given target distribution, a feature that is only achieved with difficulty via perfect sampling in regular MCMC algorithms.

The increased interest in population Monte Carlo methods is evidenced by the different algorithms proposed by Haario, Sacksman, and Tamminen [44], Mengersen and Robert [64] and others. The latter authors, for example, proposed a "pinball" Metropolis–Hastings algorithm that features "bouncing" via delayed rejection and "repulsion" via an updating mechanism based on a self-avoiding random walk, that is, a standard random walk with corrections to avoid the immediate vicinity of other particles. Paradoxically, the corresponding importance resampling particle system based on the same proposal enjoys poor properties like high degeneracy and low mixing.

Recent interest has also focused on MCMC methods for *particle filters*, which are usually implemented in sequential settings or for processing and analysis of large datasets. A particle filter describes a dynamic state-space model of a process with an underlying state of interest that evolves over time. The posterior distribution of the state is approximated by a set of weighted particles, with the weight of a particle inversely proportional to its probability mass. Numerous algorithms for updating the particles and their weights over time have been proposed. Most of these enjoy rigorous convergence properties [27], and under certain conditions can claim a **Central Limit Theorem** [29].

Most particle filter methods include a resampling step in which particles are replicated in order to convert an unequally weighted set of particles into an equally weighted set with the same distribution. However, this does not prevent the widely acknowledged problem of a continued loss of accuracy in approximation over time, which is reflected in increasing clustering of the particles in a single region of the state-space. This may be resolved by the inclusion of MCMC methods into the particle filter algorithm, as described by Gilks and Berzuini [37] and the references therein. Because the initial set of weighted particles is approximately from the target density, there is no need for a burn-in period

in the MCMC algorithm. Fearnhead [33] proposed the use of MCMC based on **sufficient statistics** as summaries of the trajectory of each particle, thus eliminating the need to store the whole particle history and consequently reducing memory requirements and computational complexity.

Detailed reviews and applications of these methods are given by Liu and Chen [62], Fearnhead [33], and Doucet et al. [32].

MCMC Convergence

Assessment of the convergence of MCMC algorithms remains a major theoretical and practical issue. In fact, it is becoming increasingly important with the development of more complicated models, the construction of new hybrid and dimension-changing algorithms, and the wider uptake of MCMC as a standard statistical tool.

There is now a substantial body of theoretical knowledge about the existence and form of convergence for certain types of target distributions and different MCMC algorithms. These are currently used to build practical bounds on convergence in particular cases, construct Metropolis–Hastings and hybrid algorithms so that geometric or subgeometric (e.g. polynomial, logarithmic, subexponential) rates of convergence are assured, make statements about new algorithms such as Langevin diffusions, and so on; see, for example, [11, 36, 49, 65, 87, 89, 92, 93, 98].

Despite these advances, convergence assessment in most practical setups is based on a (subjective) selection of a subset of the wide array of available empirical diagnostic methods. These methods guide the determination of the length of burn-in, the number of iterations after burn-in, the use of parallel chains and, if necessary, the batch size (also known as the thinning interval or subsampling). Although the latter is inefficient with respect to estimation of expected values, it may be beneficial for other reasons; see [63]. Similarly, debate surrounds the benefits and drawbacks of parallel chains, that is, simulation of independent chains from different initial values, and is discussed by Robert and Casella [83, pp. 365, 366] and references therein.

It is convenient to guide the choice of diagnostic by identifying specific convergence goals. Following Mengersen and Robert [63], these might include convergence of the chain $\theta^{(t)}$ to the stationary distribution f; convergence of the empirical average, $\Sigma_{t=1}^{T} g(\theta^{(t)})/T$ to $E_f(g(\theta))$ for an arbitrary function g; application of the Central Limit Theorem; and generation of an i.i.d. sample $(\theta_1^{(t)}, \ldots, \theta_1^{(t)})$. This identification also assists in the resolution of the often conflicting results from different diagnostics.

In a similar manner, convergence diagnostics can be broadly categorized as methods based on graphical assessment, estimated distance between the empirical and target densities, renewal and regeneration results, variance approximations and comparisons, and discretization of the Markov chain.

Not all of these methods are applicable to convergence assessment of dimension-changing algorithms such as RJMCMC. This special case is discussed by Brooks and Giudici [12].

Detailed reviews of these various approaches have been compiled by Best et al. [8], Cowles and Carlin [26], Mengersen and Robert [63], Brooks and Roberts [13], and Robert and Casella [83, pp. 365–413]. More recently, "movies" for the visualization of MCMC output have been proposed by Lazar and Kadane [57].

Applications of MCMC in Biostatistics

The discussion below highlights a small selection of biostatistics-related areas in which MCMC has become a familiar computational tool.

Classification and regression trees (CART), originally proposed by Breiman et al. [9], are nonparametric description or predictions of a response in the form of binary splits of selected **explanatory variables** (*see* **Tree-structured Statistical Methods**). A Bayesian alternative was independently proposed by Denison et al. [31] based on RJMCMC estimation of the probability distribution over the space of possible trees. Other approaches have also been proposed.

Latent variable models were introduced in **Markov Chain Monte Carlo** as mechanisms for describing complex physical and conceptual systems. Conditional on the latent, or unobserved, variables, hierarchical models can be constructed and corresponding posterior (conditional) distributions can be more simply described. These models can also be considered as *missing data models*.

As an illustration of a popular latent variable approach, Robert [81] and coauthors have described the analysis of mixture models $\Sigma_{j=1}^{k} p_j f(x|\theta_j)$, discussed above. Here, the analysis is considerably

simplified by the introduction of latent variables $z_i, i = 1, \ldots, n$ that indicate the component $j, j \in \{1, \ldots, k\}$, to which each observation x_i belongs. The MCMC algorithm involves estimating z_i given the component parameters, then estimating the component parameters and weights based on the allocation of the z's. The number of components, k, can also be a random variable by extending the MCMC algorithm to have a dimension-jumping step. The exposition of RJMCMC in this context by Richardson and Green [80] has generated a large number of applications. Fernández and Green [34] describe the analysis of spatially correlated **Poisson** data by a Poisson mixture model in which the weights of the mixture vary across locations and the number of components is unknown. RJMCMC is also employed in the context of **nonparametric regression** by Denison et al. [31], Perron and Mengersen [77], and Lindstrom [60].

More generally, the enhanced computational ability afforded by MCMC has led to increased interest in **hidden Markov models** (HMMs); see [85] for extended discussion of these methods.

Time series models continue to attract attention with respect to the development of corresponding MCMC algorithms, the construction of models to represent complex systems, and their application to diverse problems. A comprehensive discussion of developments in this area is given by West and Harrison [105] in the context of *dynamic linear modeling*. See also the recent developments in particle filters, dynamic Bayesian networks, and perfect sampling. MCMC methods for temporal modeling of epidemics and **infectious diseases** have also been widely considered; see, for example, [76].

The analysis of **factorial experiments** using MCMC methods has been investigated by Nobile and Green [75] using mixture models.

MCMC methods for analyzing *spatially correlated* data remain an area of active interest. Knorr–Held and Besag [53], Knorr–Held and Raser [55], Lawson [56], Knorr–Held and Best [54], and Green and Richardson [41] describe Markov random fields [5], RJMCMC and hidden Markov models in the context of disease **mapping**. Various methods for analyzing spatially correlated Poisson data have been proposed by Castelloe [17], Wolpert et al. [106], and Fernandez and Green [34]. As discussed by Anselin and Griffith [2], spatial effects can also describe measurement errors, heteroscedasticity, and unobserved covariates.

Meta-analysis models and corresponding MCMC analysis is now a standard biostatistical tool. Multivariate approaches have been described by Nam et al. [72] and references therein. Wolpert and Mengersen [107] describe adjustments to the **likelihood** in a meta-analysis context that can take account of **misclassification**, **bias**, and other features of individual studies.

Approaches to the design and analysis of **clinical trials** using MCMC are described by Carlin and Louis [15]. Attention is also paid to the analysis of **survival** *models* by these authors and subsequently by Albert and Chib [1].

Bioinformatics is an emerging field that was once considered to be the part of computational biology that explicitly dealt with the development of the increasing number of large **databases**, including methods for data retrieval and analyses, and algorithms for sequence similarity searches, structural predictions, functional predictions and comparisons, and so forth. Very recently, the field has been rapidly evolving, not only because of the impact of the various genome projects, but also because of the development of experimental technologies, particularly microarrays (*see* **Genetic Markers**). Currently bioinformatics is being increasingly widely viewed as a more fundamental discipline that also encompasses mathematics, statistics, physics, and chemistry. A detailed discussion of the current state of bioinformatics is provided by Kenehisa and Bork [52]. MCMC and RJMCMC provide a convenient method of analysis of the complex models and datasets encountered in this field. Very recent applications include evolutionary analysis [24], the analysis of microarray experiments [58] and genome analysis [94]. Baldi and Brunak [3] include a chapter on using MCMC as a "machine learning algorithm" for bioinformatics.

As with any numerical method, sensitivity to the model description and the adopted MCMC algorithm should be an integral part of the analysis. Huelsenbeck et al. [47] discuss this in the context of estimating probabilities of phylogenetic trees.

Software

Gibbs and Metropolis–Hastings algorithms are now standard tools in some statistical packages (*see* **Software, Biostatistical**). See, for example, the SAS procedure for estimating missing data and algorithms available in **S-Plus** and **R**.

BUGS and WinBUGS [96] remain popular specialist software for MCMC analysis. The freely available suite of algorithms has improved and expanded over a number of versions. Congdon [22] almost exclusively uses BUGS to illustrate many applications of Bayesian modeling and provides detailed discussion of its implementation and interpretation.

Other established software packages include a Bayes Linear Programming Package (B/D), Bayesian Knowledge Discover (BKD), a general data analysis tool B-Course, and JavaBayes for Bayesian networks.

CODA [8] remains the most accessible source of generic convergence diagnostics.

Application-specific software is also widely available. For example, S-Plus code for Bayesian model selection is available from Adrian Raftery's website and for particular biostatistics applications from the MD Anderson Cancer Centre. Individual papers also often advertise software.

Books

The popularity of MCMC and its place as a standard statistical tool is evidenced by the recent publication of books devoted to or strongly focused on these methods.

Robert and Casella [83] provide excellent discussion and illustrations of a variety of established and new MCMC approaches and their connections with other **Monte Carlo methods**. They cover theoretical and practical aspects of the methods and give detailed algorithms.

The text by Carlin and Louis [15] introduces Bayes and **empirical Bayes** methods and their applications in a wide variety of settings. Their descriptions are complemented by worked examples using BUGS. Recent developments in MCMC, including RJMCMC, slice sampling, structured MCMC, the computation of MCMC standard errors, and MCMC convergence are also discussed. Case studies include the analysis of longitudinal **AIDS** data, analysis of clinical trials and spatio-temporal modeling of lung cancer rates.

The text by Congdon [22] has become popular among both researchers and practitioners. It gives a very readable account of the general Bayesian method, MCMC algorithms, standard distributions, and a variety of specialist models. The text also details the implementation of the approaches in the software package BUGS. Congdon [23] extends this discussion into more applied Bayesian modeling.

More focused books that describe MCMC algorithms include West and Harrison [105], Robert [82] and Cowell et al. [25], and Chen et al. [19], Ibrahim et al. [48], Banerjee et al. [4], Denison et al. [30], and Gustafson [43].

Published conference proceedings also contain many expositions of recent MCMC advances. See, for example, the "Bayesian Statistics" series arising from the four-yearly Valencia meetings, published by Oxford University Press.

Markov Chain Monte Carlo

Markov chain Monte Carlo (MCMC) is a powerful technique for performing integration by **simulation**. In recent years, MCMC has revolutionized the application of **Bayesian** statistics. Many high-dimensional, complex models which were formerly intractable can now be handled routinely. MCMC has also been used in specialized non-Bayesian problems. Introductory material on MCMC methods and biostatistical applications can be found in Gilks et al. [20] and Gelman & Rubin [13].

Suppose that we wish to evaluate the expected value (**expectation**) of some function $g(\boldsymbol{\theta})$ over a probability density function $f(\boldsymbol{\theta}) : \mathrm{E}_f[g(\boldsymbol{\theta})] = \int g(\boldsymbol{\theta}) f(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}$. If we could draw samples $\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \ldots, \boldsymbol{\theta}^{(n)}$ independently from $f(\boldsymbol{\theta})$, then we could estimate

$$\hat{\mathrm{E}}_f[g(\boldsymbol{\theta})] = \frac{1}{n} \sum_{i=1}^{n} g(\boldsymbol{\theta}^{(i)}). \tag{1}$$

This technique is called **Monte Carlo** *integration*. We have $\mathrm{var}\{\hat{\mathrm{E}}_f[g(\boldsymbol{\theta})]\} = \mathrm{var}_f[g(\boldsymbol{\theta})]/n$, so the estimate $\hat{\mathrm{E}}_f[g(\boldsymbol{\theta})]$ can be made as accurate as desired by increasing the sample size n. In Bayesian applications, our density $f(\boldsymbol{\theta})$ is a posterior distribution $f(\boldsymbol{\theta}|\mathbf{x})$, where $\boldsymbol{\theta}$ is a collection of model unknowns (parameters and missing data), and $\mathbf{x}$ denotes observed data. The function $g(\boldsymbol{\theta})$ might be the kth element of the vector $\boldsymbol{\theta}$, for example, in which case $\mathrm{E}_f[g(\boldsymbol{\theta})]$ would be the posterior expectation of θ_k. Other forms for $g(\cdot)$ could be used to evaluate posterior **variances**, **correlations**, **quantiles**, etc. Note that the accuracy of $\hat{\mathrm{E}}_f[g(\boldsymbol{\theta})]$ is not limited by the amount of data in $\mathbf{x}$.

Typically in Bayesian applications, $\boldsymbol{\theta}$ is high-dimensional and $f(\boldsymbol{\theta}|\mathbf{x})$ has a complicated, nonstandard form. Sampling independently from $f(\boldsymbol{\theta}|\mathbf{x})$ is generally not possible. Therefore we could try to devise sampling schemes which generate *dependent* samples $\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \ldots, \boldsymbol{\theta}^{(n)}$, but for which (1) is still a **consistent** estimator of $\mathrm{E}_f[g(\boldsymbol{\theta})]$. One possibility is to use a **Markov chain**: this is then *Markov chain* Monte Carlo. A Markov chain generates each iterate $\boldsymbol{\theta}^{(i)}$, taking into account only the previous value $\boldsymbol{\theta}^{(i-1)}$. Subject to some regularity conditions, a Markov chain will generate samples $\boldsymbol{\theta}^{(i)}$ from its *stationary* distribution, for large i.

In general, it is surprisingly easy to construct a Markov chain the stationary distribution of which is our target distribution $f(\boldsymbol{\theta}|\mathbf{x})$, and for which (1) is a consistent estimator of $\mathrm{E}_f[g(\boldsymbol{\theta})]$. The method was first proposed in 1953 by Metropolis et al. [24], and was generalized in 1970 by Hastings [23]. For many years, the **algorithm** was used mainly in the field of statistical mechanics. In 1984 the *Gibbs sampling* algorithm (later recognized as a special case of the Metropolis–Hastings algorithm) was proposed by Geman & Geman [15] as a tool for image reconstruction (*see* **Image Analysis and Tomography**). In 1990, the considerable potential of the Gibbs sampler was brought to the attention of the wider statistical community by Gelfand & Smith [8]. A generalization of the Metropolis–Hastings algorithm was proposed by Green [22] in 1995.

The Metropolis–Hastings Algorithm

We now describe the Metropolis–Hastings algorithm. For notational convenience we suppress dependence on data $\mathbf{x}$, and for the moment we continue to assume that $\boldsymbol{\theta}$ is a continuous random vector. We begin the chain with an arbitrary starting value, $\boldsymbol{\theta}^{(0)}$, and then produce the chain $\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \ldots$ by iterating around the following two steps. At each iteration $i + 1$:

Step 1: generate a *candidate* value $\boldsymbol{\theta}'$ from a *proposal distribution* $q(\cdot|\boldsymbol{\theta}^{(i)})$;

Step 2: with probability

$$\alpha(\boldsymbol{\theta}^{(i)}, \boldsymbol{\theta}') = \min\left[1, \frac{f(\boldsymbol{\theta}')q(\boldsymbol{\theta}^{(i)}|\boldsymbol{\theta}')}{f(\boldsymbol{\theta}^{(i)})q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(i)})}\right] \tag{2}$$

accept the candidate (i.e. set $\boldsymbol{\theta}^{(i+1)}$ equal to $\boldsymbol{\theta}'$); otherwise reject the candidate (i.e. set $\boldsymbol{\theta}^{(i+1)}$ equal to $\boldsymbol{\theta}^{(i)}$).

Heuristically, we aim to generate dependent samples from $f(\cdot)$ by sampling from a more convenient distribution at Step 1, and then correcting for this in a rather unintuitive but appropriate way at Step 2. To implement Step 2, generate a **pseudo-random number** u from a **uniform (0, 1) distribution**. If $u \leq \alpha(\boldsymbol{\theta}^{(i)}, \boldsymbol{\theta}')$ accept $\boldsymbol{\theta}'$; otherwise reject it. The choice of the proposal density $q(\cdot|\cdot)$ is largely up to the user, the prime considerations being computational convenience and rapid mixing (see below). Note that the target density $f(\cdot)$ need not be normalized to integrate to one, since the normalization constant cancels

in (2). This is particularly convenient for Bayesian analyses, where the posterior distribution $f(\boldsymbol{\theta}|\mathbf{x})$ is proportional to the **likelihood** $p(\mathbf{x}|\boldsymbol{\theta})$ times the **prior** $p(\boldsymbol{\theta})$. Thus $p(\mathbf{x}|\boldsymbol{\theta})p(\boldsymbol{\theta})$ can be used in place of $f(\cdot)$ in (2), and there is no need to evaluate the normalization constant $\int p(\mathbf{x}|\boldsymbol{\theta})p(\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{\theta}$.

For the Metropolis–Hastings chain to be useful, it must be *irreducible*. Informally, irreducibility means that the chain is able to reach anywhere within the domain of $f(\cdot)$ within a finite number of iterations (see [37] for a more careful definition). If the chain is irreducible, it will eventually settle down to produce samples $\boldsymbol{\theta}^{(i)}$ from its *stationary* distribution, which can be shown to be $f(\cdot)$. Thus the choice of starting value $\boldsymbol{\theta}^{(0)}$ is not important, although it is generally advisable to avoid starting values well into the tails of $f(\boldsymbol{\theta})$, which could delay convergence to $f(\cdot)$. There is no particular advantage in starting the chain at the mode of $f(\cdot)$, since the chain must still be run long enough for it to "forget" its starting value. If the chain is reducible, it will never forget its starting value, since the starting value will determine which parts of the space can be reached. Irreducibility is generally easily verified by inspecting the form of $q(\cdot|\cdot)$, although in some genetics applications involving complex pedigrees, establishing irreducibility can be difficult (see [30]).

When applied to output from an irreducible Metropolis–Hastings chain, (1) is a consistent estimator of $\mathrm{E}_f[g(\boldsymbol{\theta})]$. In calculating (1) it is usual to discard the first m iterates of the chain (the *burn-in*), during which the chain exhibits dependence on the starting value $\boldsymbol{\theta}^{(0)}$. Several methods have been developed for diagnosing *convergence* (i.e. determining m) and for determining the run length n. Most are approximate in some way, and the most popular [12, 25] monitor the sample path of only univariate quantities, such as a single element of $\boldsymbol{\theta}$. Some methods rely on output from a single chain, and others require multiple chains to be run. For a recent review of convergence diagnostics, see Cowles & Carlin [5]. There is some debate in the literature regarding the number of chains to run: Gelman & Rubin [11, 12] advocate several long chains, while Geyer [16] recommends one very long chain. There is no justification for running a large number of short chains.

There is no justification for attempting to create pseudo-independent samples for input into (1) by *thinning* the output (i.e. using only every jth iterate from the chain) or, even worse, by running a large number of short chains and using only the last iterate from each. The theory of ergodic Markov chains guarantees the consistency of (1), despite the obvious lack of independence within the chain. The only justification for thinning is to reduce computer storage requirements.

Besides being irreducible, it is also important that the chain is *geometrically ergodic*; in other words, that convergence towards the stationary distribution $f(\cdot)$ proceeds at a geometric rate (see [37]). Unless the chain is geometrically ergodic, it is not possible to say anything useful about the variance of (1), and the chain may be very badly behaved, producing long meanders and erratic behavior. Nongeometrically ergodic chains are therefore effectively useless. Unfortunately, establishing geometric ergodicity in any particular context is not trivial, and theory tends to lag somewhat behind practice, although useful results have been obtained (see [28] and references therein). If the chain is geometrically ergodic, the variance of (1) can be estimated. A popular method is the method of *batch means*: the output is divided into n_1 consecutive batches of size n_2, and the sample mean $\overline{g}_j$ of $g(\cdot)$ within each batch j is calculated. If n_2 is large enough, the batch means will be approximately independent, and the variance of (1) can be estimated as n_1^{-1} times the usual sample variance of $\overline{g}_1, \overline{g}_2, \ldots, \overline{g}_{n_1}$. Often, n_1 is set to about 20. Other methods of variance estimation are given by Geyer [16]. An estimate of the variance of (1) can be used to calculate how much longer to run the chain.

The Metropolis–Hastings algorithm is not limited to situations in which $\boldsymbol{\theta}$ is a continuous random vector, although this is the usual situation in biostatistical applications. Discrete variables occur in genetics applications, where some elements of $\boldsymbol{\theta}$ are unobserved **genotypes**, and in applications where discrete-valued covariates are missing. The same form of acceptance probability (2) applies regardless of whether $f(\cdot)$ is a probability, a probability density, a product of probabilities and densities, or a density with respect to an arbitrary measure.

Proposal Distributions

Considerable freedom can be exercised in the choice of proposal distribution $q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(i)})$, provided that the resulting chain is both irreducible and geometrically ergodic. In a Bayesian context, $q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(i)})$ may also depend on the data $\mathbf{x}$. A *symmetric* proposal,

for which $q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(i)}) = q(\boldsymbol{\theta}^{(i)}|\boldsymbol{\theta}')$ for all $\boldsymbol{\theta}'$ and $\boldsymbol{\theta}^{(i)}$, results in an acceptance probability (2) which does not depend on $q(\cdot|\cdot)$. This is the form described in the original algorithm of Metropolis et al. [24]. An *independence* proposal is one which does not depend on $\boldsymbol{\theta}^{(i)}$, so $q(\boldsymbol{\theta}'|\boldsymbol{\theta}^{(i)}) = q(\boldsymbol{\theta}')$. Independence proposals can be either very good (trivially, setting $q(\boldsymbol{\theta}') = f(\boldsymbol{\theta}')$ results in an acceptance probability of 1.0 and independent sampling from $f(\cdot)$), or very bad (if the tails of $q(\cdot)$ are lighter than those of $f(\cdot)$, then the chain will not even be geometrically ergodic [28]).

Many other forms of proposal are possible; see Tierney [36]. Different choices will result in different rates of *mixing*. A rapidly mixing chain will move about the domain of $f(\cdot)$ fluidly, and will quickly converge to $f(\cdot)$. A slow-mixing chain will exhibit significant long-lag **autocorrelations**, and will require a very long run to obtain adequate precision in (1). It is difficult in general to predict the behavior of any particular choice of proposal. A proposal distribution which nearly always results in rejection at Step 2 will be slow-mixing, since the chain will only occasionally move. However, a proposal distribution which nearly always results in acceptance may also be slow mixing, if the high acceptance rate is achieved by proposing only very small steps. Gelman et al. [14] show, for a large class of problems using a symmetric proposal, that one should aim for acceptance rates in the range 0.15–0.5.

Hybrid chains [36] employ a set of proposal distributions $q_1(\cdot|\cdot), q_2(\cdot|\cdot), \ldots$, at each iteration choosing one proposal either randomly, or deterministically by cycling through the set. For example q_1 could be a symmetric proposal, and q_2 an independence proposal. A hybrid chain is often better than the sum of its parts; for example, it may be irreducible and geometrically ergodic even if none of the constituent single-proposal chains are.

Single-component Metropolis–Hastings is a special case of a hybrid chain. Vector $\boldsymbol{\theta}$ is partitioned into k components $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \ldots, \boldsymbol{\theta}_k)$; for example, each component could be just one element of $\boldsymbol{\theta}$. For each component j, a proposal $q_j(\boldsymbol{\theta}'_j|\boldsymbol{\theta}^{(i)})$ is defined which updates only component j, generating a candidate point $\boldsymbol{\theta}' = (\boldsymbol{\theta}_1^{(i)}, \ldots, \boldsymbol{\theta}_{j-1}^{(i)}, \boldsymbol{\theta}'_j, \boldsymbol{\theta}_{j+1}^{(i)}, \ldots, \boldsymbol{\theta}_k^{(i)})$. The acceptance probability (2) then becomes

$$\alpha(\boldsymbol{\theta}^{(i)}, \boldsymbol{\theta}') = \min\left[1, \frac{f(\boldsymbol{\theta}')q_j(\boldsymbol{\theta}_j^{(i)}|\boldsymbol{\theta}')}{f(\boldsymbol{\theta}^{(i)})q_j(\boldsymbol{\theta}'_j|\boldsymbol{\theta}^{(i)})}\right], \qquad (3)$$

assuming that the choice of proposal q_j does not depend on the current $\boldsymbol{\theta}$. Most applications of Metropolis–Hastings use single-component updating, since it is much easier to construct proposals in low dimensions. However, when $f(\cdot)$ specifies high correlations between elements of $\boldsymbol{\theta}$, single-component updating can produce very slow mixing, unless highly correlated elements are blocked into the same component.

The *Gibbs sampler* is a special case of single-component Metropolis–Hastings, in which

$$q_j(\boldsymbol{\theta}'_j|\boldsymbol{\theta}^{(i)}) = f(\boldsymbol{\theta}'_j|\boldsymbol{\theta}_1^{(i)}, \ldots, \boldsymbol{\theta}_{j-1}^{(i)}, \boldsymbol{\theta}_{j+1}^{(i)}, \ldots, \boldsymbol{\theta}_k^{(i)}), \qquad (4)$$

where the conditional distribution $f(\boldsymbol{\theta}_j|\cdot)$ is derived from the target joint distribution $f(\boldsymbol{\theta})$, and is called the *full conditional distribution* of $\boldsymbol{\theta}_j$. When $f(\boldsymbol{\theta})$ is a product of terms, as in the applications described below, the full conditional distribution for $\boldsymbol{\theta}_j$ is proportional to the product of those terms containing $\boldsymbol{\theta}_j$. With proposal distributions of the form of (4), the acceptance probability (3) is equal to 1.0, so the chain never rejects. As for generic single-component Metropolis–Hastings, an iteration of the Gibbs sampler involves updating only one $\boldsymbol{\theta}_j$; subsequent iterations may choose j at random, or deterministically by cycling through $j = 1, \ldots, k$. Thus the Gibbs sampler consists entirely in sampling from full conditional distributions, at each iteration updating one parameter, conditioning on the current values of all the other parameters (and data). Note that, in other articles, a Gibbs iteration is sometimes defined as one complete cycle of updating. Below we use $f(\boldsymbol{\theta}'_j|\cdot)$ to denote (4).

Sampling from full conditional distributions can be difficult, but if they are univariate and log-concave (which they often are), *adaptive rejection sampling (ARS)* can be used [19]. See Gilks [17] for further details on constructing and sampling from full conditional distributions. Gibbs sampling and ARS are implemented in the BUGS **software** [33], for general-purpose Bayesian modeling.

Slow mixing in the Gibbs sampler, or any other single-component updating method, can sometimes be resolved by reparameterization. An important example occurs in Bayesian linear models. The linear predictor $\alpha_0 + \alpha_1 x_{1\ell} + \cdots + \alpha_p x_{p\ell}$, where $x_{1\ell}, \ldots x_{p\ell}$ denote **covariates** for individual ℓ, should be reparameterized as $\beta_0 + \alpha_1(x_{1\ell} - \overline{x}_1) + \cdots + \alpha_p(x_{p\ell} - \overline{x}_p)$, where $\overline{x}_j$ denotes the sample mean of $\{x_{j\ell}, \ell = 1, 2, \ldots\}$. Centering the covariates in

this way will reduce posterior correlations between the intercept α_0 and the regression coefficients α_j. Another important example of reparameterization occurs in **hierarchical models**. Consider the Bayesian **random effects model**

$$y_{j\ell} \sim \mathrm{N}(\mu + \alpha_j, \sigma_1^2), \quad \alpha_j \sim \mathrm{N}(0, \sigma_2^2),$$
$$\mu \sim \mathrm{N}(0, \sigma_3^2), \tag{5}$$

where $j = 1, \ldots, m, \ell = 1, \ldots, n$, and the $y_{j\ell}$ are observed data. Gelfand et al. [9] show that the Gibbs sampler mixes poorly for this problem if n is large in relation to m. Thus the mixing rate deteriorates as information on the random effects increases, contradicting a common supposition that mixing is worst when information is scarce. Gelfand et al. [9] suggest a simple reparameterization, which they call *hierarchical centering*:

$$y_{j\ell} \sim \mathrm{N}(\beta_j, \sigma_1^2), \quad \beta_j \sim \mathrm{N}(\mu, \sigma_2^2).$$

With this parameterization, the mixing rate increases with both m and n. The idea extends to more complex hierarchical models with nested random effects. See Roberts & Sahu [29] for a rigorous theoretical evaluation of reparameterization strategies in hierarchical models.

Various other strategies have been devised for improving mixing: see Gilks & Roberts [18] for a review.

Reversible-Jump MCMC

The preceding discussion implicitly assumes that the length of vector $\boldsymbol{\theta}$ is fixed and known. However, Green [22] has recently demonstrated that important classes of models contain a variable number of parameters, and that the Metropolis–Hastings algorithm extends naturally to these situations. Examples of such models include mixture models [27] where the number of mixture components is unknown, and **change-point problems** with an unknown number of changepoints. Such models allow an essentially nonparametric approach to curve-fitting. Another important example concerns **model choice** or model averaging, where several models must be entertained, possibly varying in number of parameters. From a Bayesian perspective, the individual models can be thought of as components of an encompassing model (*see* **Bayesian Methods for Model Comparison**).

The general problem is best conveyed with a toy example. Assume that survival times $\mathbf{x}$ in a clinical trial are **exponentially** distributed, and let θ_1 and θ_2 denote log-mortality rates for each arm of the trial. We consider two models: Model 1 asserts that $\theta_1 = \theta_2$; and Model 2 that $\theta_1 \neq \theta_2$. Let $k = 1, 2$ index the models. We place **priors** on k; on θ_1 given $k = 1$; and on θ_1 and θ_2 given $k = 2$. These ingredients define the posterior distribution $f(k, \theta|\mathbf{x})$, where the length of θ is equal to k. We can consider various types of proposal distribution. For example, proposal type A could change $\boldsymbol{\theta}$ without changing k, and since this does not affect the dimensionality, the usual acceptance formula (2) applies. Proposal type B could change k. For example, if $k^{(i)} = 1$, type B1 could set $k' = 2, \theta_1' = \theta_1^{(i)}$ and sample $\theta_2' \sim \mathrm{N}(\theta_1^{(i)}, \sigma^2)$, where σ^2 is fixed. If $k^{(i)} = 2$, type B2 could set $k' = 1, \theta_2' = \theta_1' = \theta_1^{(i)}$. Note that, in this example, proposal B2 involves no sampling. Assume that, at any iteration, a type B proposal is chosen with probability 0.5. Then the acceptance probability of a B1 move is, from (2),

$$\min\left[1, \frac{f(2, \theta_1', \theta_2'|\mathbf{x})\,\mathrm{d}\theta_1'\,\mathrm{d}\theta_2' \times I(\theta_1' = \theta_1^{(i)})}{\left\{\begin{array}{l} f(1, \theta_1^{(i)}|\mathbf{x})\,\mathrm{d}\theta_1^{(i)} \times (2\pi)^{-1/2}\sigma^{-1} \\ \times \exp\{-[1/(2\sigma^2)](\theta_2' - \theta_1^{(i)})^2\}\,\mathrm{d}\theta_2' \end{array}\right\}}\right]. \tag{6}$$

where $I(\cdot)$ denotes the indicator function (*see* **Dummy Variables**). Notice that each density in (6) is converted into a probability through postmultiplication by dimensional terms $\mathrm{d}\theta_1^{(i)}$, etc. However, these dimensional terms cancel in the numerator and denominator, and so they can be ignored. This is a consequence of *dimension matching* in the proposal distributions. Dimension matching is not automatic. For example, suppose that the B1 proposal samples both $\theta_1' \sim \mathrm{N}(\theta_1^{(i)}, \sigma^2)$ and $\theta_2' \sim \mathrm{N}(\theta_1^{(i)}, \sigma^2)$, but the B2 proposal is as before; then the denominator in (6) would become

$$f(1, \theta_1^{(i)}|\mathbf{x})\,\mathrm{d}\theta_1^{(i)} \times (2\pi)^{-1/2}\sigma^{-1} \exp\left\{-\left[\frac{1}{(2\sigma^2)}\right] \times [(\theta_1' - \theta_1^{(i)})^2 + (\theta_2' - \theta_1^{(i)})^2]\right\} \mathrm{d}\theta_1'\,\mathrm{d}\theta_2'.$$

Now the dimensional terms no longer cancel, so the algorithm is not well-defined.

This example illustrates that the usual Metropolis–Hastings algorithm can be used when the dimensionality of $\boldsymbol{\theta}$ is unknown. Proposal distributions may propose changes to the dimension, but for each such proposal it must be checked that the reverse proposal satisfies the dimension-matching requirement. Of course, all the usual problems of mixing still apply to this more general framework.

Applications

By now, Markov chain Monte Carlo techniques have been applied in most areas of statistics, in particular biostatistics. For example, the book edited by Gilks et al. [20] contains applications in vaccine efficacy (*see* **Vaccine Studies**), clinical monitoring (*see* **Data and Safety Monitoring**), **pharmacokinetics**, disease **mapping**, medical imaging (*see* **Image Analysis and Tomography**), genetics (*see* **Human Genetics, Overview**), and epidemiologic **measurement error**. Also, the book edited by Berry & Stangl [2] includes applications in medical **decision analysis**, **clinical trial** design, **crossover trials**, **meta-analysis** and changepoint analysis of randomized trials, pharmacokinetics, tumor hemodynamics (*see* **Tumor Growth**) and perinatal mortality (*see* **Infant and Perinatal Mortality**). Rather than attempting to review biostatistical applications of MCMC *per se*, we focus on applications of MCMC in modeling situations familiar to biostatisticians; specifically hierarchical models, **missing data**, **censored data**, measurement error, and temporally or spatially correlated data (*see* **Geographic Epidemiology**; **Time Series**).

Hierarchical Models

By far the most common area of application of MCMC has been to hierarchical models, such as (5) (see, for example, [7, 8], and [10]). Most applications employ the Gibbs sampler, since full conditional distributions for the random effect parameters involve only a small subset of the data, and are generally log concave. For example, in the simple hierarchical model (5), assuming for convenience that variance parameters are known, the full conditional distributions are:

$$p(\alpha_j|\cdot) = \mathrm{N}\left(\frac{\overline{y}_{j\cdot} - \mu}{1 + n^{-1}\sigma_1^2\sigma_2^{-2}}, \frac{1}{n\sigma_1^{-2} + \sigma_2^{-2}}\right), \quad (7)$$

$$p(\mu|\cdot) = \mathrm{N}\left(\frac{\overline{y}_{\cdot\cdot} - \overline{\alpha}}{1 + m^{-1}n^{-1}\sigma_1^2\sigma_3^{-2}}, \frac{1}{mn\sigma_1^{-2} + \sigma_3^{-2}}\right), \quad (8)$$

where $\overline{y}_{j\cdot} = \sum_{\ell=1}^{n} y_{j\ell}/n$, $\overline{y}_{\cdot\cdot} = \sum_{j=1}^{m}\sum_{\ell=1}^{n} y_{i\ell}/(mn)$, and $\overline{\alpha}_{\cdot} = \sum_{j=1}^{m}\alpha_j/m$. Running the Gibbs sampler corresponds to sampling from (7) for each j, and from (8), where all variables being conditioned upon take on their most recently sampled values.

Much more elaborate hierarchical models, with covariates, multivariate responses, and more levels in the hierarchy, can also be handled straight forwardly using Gibbs sampling; see for example, Gilks et al. [21]. In most applications, the Gibbs sampler mixes well, and when it does not, reparameterization strategies can be tried (see above). The current popularity of MCMC owes much to its successful application to hierarchical models, which are ubiquitous in biostatistics. In particular, Smith et al. [31] have applied such models to meta-analysis problems.

Imperfect Data

Most, if not all, biostatistical data sets contain imperfections due to missing, censored, or inaccurately measured data. In the pre-Gibbs era, such imperfections were often difficult to handle, and required problem-specific solutions. Here we show that a wide class of data-imperfection problems can be handled in a generic framework, using the Gibbs sampler.

Suppose that a dependent variable, y_ℓ, and a **covariate**, x_ℓ, have been recorded for each individual $\ell = 1, \ldots, n$. Assuming that the y_ℓ are conditionally independent, with probability density specified by $p(y_\ell|x_\ell, \boldsymbol{\theta})$, the posterior distribution of the model parameters $\boldsymbol{\theta}$ is proportional to

$$\prod_{\ell}^{n} p(y_\ell|x_\ell, \boldsymbol{\theta}) \cdot p(\boldsymbol{\theta}), \quad (9)$$

where $p(\boldsymbol{\theta})$ denotes the prior density for $\boldsymbol{\theta}$.

Now suppose that the data are imperfect in some way. Let z_ℓ denote the observations on individual ℓ, and let $p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi})$ be a model describing the relationship between the observed, imperfect, data and the ideal data. Assuming that covariates are conditionally independent in the population, with probability specified by $p(x_\ell|\boldsymbol{\psi})$, the joint posterior

distribution of $\boldsymbol{\theta}, \boldsymbol{\phi}, \boldsymbol{\psi}$ and $\{x_\ell, y_\ell\}$ is proportional to

$$\prod_\ell^n p(x_\ell|\boldsymbol{\psi}) \times p(y_\ell|x_\ell, \boldsymbol{\theta}) \times p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi}) \times p(\boldsymbol{\psi})p(\boldsymbol{\theta})p(\boldsymbol{\phi}), \quad (10)$$

assuming independent priors.

For example, if the covariates x_ℓ are measured with error, then z_ℓ represents the measured value of x_ℓ and $\boldsymbol{\phi}$ will include parameters specifying the bias and precision of the measurement process (*see* **Errors in Variables**). In many applications, the dependence of z_ℓ on y_ℓ in the measurement model will be dropped. Similarly, if the dependent variable is measured with error, then z_ℓ represents the measured value of y_ℓ, and the measurement model may drop the dependence on x_ℓ. If the covariates are error-free, the first term in (10) may be omitted, as it will not affect inference for the other variables. See Spiegelhalter et al. [32] for an application in which both dependent and independent variables are measured with error. In studies containing substantial measurement error, external validation studies may be performed, which will introduce further multiplicative terms in (10): see Richardson & Gilks [26] for details.

The above set-up also includes missing data as a special case. Suppose that x_ℓ is not recorded for some individuals. Then z_ℓ records whether x_ℓ has been recorded (for example, $z_\ell = 1$ if x_ℓ is missing; $z_\ell = 0$ otherwise), and $p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi})$ describes the probability that x_ℓ is missing. The set-up allows for the possibility that the missingness of x_ℓ may depend on x_ℓ itself, or on y_ℓ, or both. If z_ℓ does not depend on x_ℓ, the term $p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi})$ in (10) may be omitted. However, it is important that this term is retained if it does depend on x_ℓ, as this will affect the posterior distribution of x_ℓ, and hence of $\boldsymbol{\theta}$ (i.e. the missingness is informative; *see* **Nonignorable Dropout in Longitudinal Studies**). Similar considerations apply if y_ℓ is missing for some individuals: here z_ℓ indicates the missingness of y_ℓ, which is informative if it depends on y_ℓ. The above set-up also accommodates situations in which both x_ℓ and y_ℓ can be missing. An important class of missing data problems occurs in the field of genetics, where the missing covariate data x_ℓ are unobserved genotypes in a pedigree, and the observed data y_ℓ are phenotypes or marker genotypes. In such problems, the x_ℓ are not conditionally independent given $\boldsymbol{\psi}$, so the analysis framework described here would need to be adapted; see, for example, Thompson & Guo [35] or Thomas & Gauderman [34].

Censored data can also be accommodated in the above framework. If the dependent variable is right-censored at y_ℓ^*, then $z_\ell = (y_\ell^{**}, c_\ell)$, where $y_\ell^{**} = \min(y_\ell, y_\ell^*)$ and $c_\ell = 1$ if $y_\ell > y_\ell^*$, $c_\ell = 0$ otherwise. The model allows for informative censoring; noninformative censoring obtains when y_ℓ^* does not depend on y_ℓ, given x_ℓ. Similarly, censored covariates can also be accommodated; see Gilks et al. [21] for an example.

The Gibbs sampler, applied to the posterior (10), involves the following full conditional distributions:

$$p(\boldsymbol{\theta}|\cdot) \propto \prod_\ell^n p(y_\ell|x_\ell, \boldsymbol{\theta})p(\boldsymbol{\theta}), \quad (11)$$

$$p(\boldsymbol{\psi}|\cdot) \propto \prod_\ell^n p(x_\ell|\boldsymbol{\psi})p(\boldsymbol{\psi}), \quad (12)$$

$$p(\boldsymbol{\phi}|\cdot) \propto \prod_\ell^n p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi})p(\boldsymbol{\phi}), \quad (13)$$

$$p(x_\ell|\cdot) \propto p(x_\ell|\boldsymbol{\psi}) \times p(y_\ell|x_\ell, \boldsymbol{\theta}) \times p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi}), \quad (14)$$

$$p(y_\ell|\cdot) \propto p(y_\ell|x_\ell, \boldsymbol{\theta}) \times p(z_\ell|x_\ell, y_\ell, \boldsymbol{\phi}). \quad (15)$$

Running the Gibbs sampler corresponds to sampling from (11)–(13) and, for each ℓ, from (14) and (15), where all variables being conditioned upon take on their most recently sampled values. If any of these full conditional distributions is awkward to sample from directly, it can be replaced by a set of lower-dimensional full conditional distributions, or by a single Metropolis–Hastings step. The point to note about (11) is that it has the same form as the posterior distribution of $\boldsymbol{\theta}$ given full, accurately measured data, as in (9), so the sampling involved in this part of the Markov chain presents no new difficulties. The full conditionals (14) and (15) should be easy to sample from, since they involve only a small subset of the data and would typically be low-dimensional.

A special problem arises when n itself is unknown, due to an unknown number of individuals being selectively lost from the study (for whom, of course, x_ℓ and y_ℓ are unknown). Thus the posterior distribution is variably dimensioned, since it involves an unknown number of missing x_ℓ and y_ℓ variables. For this problem, a reversible-jump Metropolis–Hastings

step would need to be included in the sampling, in which missing individuals are added or removed. De Angelis et al. [6] consider such a problem in AIDS epidemiology, where the missing individuals are those who have not yet been diagnosed with AIDS, but who are infected with the HIV virus (*see* **AIDS and HIV**).

Temporally or Spatially Correlated Data

In many biostatistical applications, it is useful to be able to specify relatedness between data items without attempting to model the causal connections between them. For example, in disease maps (*see* **Mapping Disease Patterns**), disease incidence in one county might be expected to be similar to disease incidence in neighboring counties, but direct causal links between them might not be realistic. Similarly, disease incidence in one calendar year might be expected to be similar to disease incidence in adjacent years, or changes in disease incidence might be similar to changes in adjacent years. Markov random field (MRF) models allow such dependence to be expressed purely descriptively, without causal implications. Four example, suppose that μ_ℓ is the disease incidence rate at time ℓ: then a MRF model might specify

$$p(\mu_\ell|\mu_{-\ell}, \boldsymbol{\theta}) = p(\mu_\ell|\mu_{\ell-1}, \mu_{\ell+1}, \boldsymbol{\theta}), \qquad (16)$$

for $\ell = 2, \ldots, n-1$, with some related form for $\ell = 1, n$, where $\mu_{-\ell}$ denotes $\{\mu_1, \ldots, \mu_{\ell-1}, \mu_{\ell+1}, \ldots, \mu_n\}$, and $\boldsymbol{\theta}$ is a set of parameters specifying the similarity of disease rates in adjacent years. Equation (16) says that μ_ℓ is conditionally independent of $\mu_1, \ldots, \mu_{\ell-2}, \mu_{\ell+2}, \ldots, \mu_n$, given $\mu_{\ell-1}$, $\mu_{\ell+1}$, and $\boldsymbol{\theta}$. This structure could be used to induce some smoothness in the **time series**. Note that a MRF model is nondirected, since, for example, the distribution of μ_ℓ is specified in terms of $\mu_{\ell-1}$, and vice versa. A second-order MRF model might specify

$$p(\delta_\ell|\delta_{-\ell}, \boldsymbol{\theta}) = p(\delta_\ell|\delta_{\ell-1}, \delta_{\ell+1}, \boldsymbol{\theta}), \qquad (17)$$

where $\delta_\ell = \mu_\ell - \mu_{\ell-1}$. This structure could be used to induce smoothness in the gradient of the time series.

Eq. (16) or (17) defines a MRF prior distribution on the unobserved, underlying, rates of disease incidence. For a noncontagious disease, observed disease incidence y_ℓ for each ℓ might be assumed to be independently **Poisson** (μ_ℓ). Bayesian inference for this problem, for known $\boldsymbol{\theta}$, is straightforward using Gibbs sampling, despite the nondirected structure of the MRF prior. Under (16), the full conditional distribution for μ_ℓ is simply

$$p(\mu_\ell|\cdot) \propto p(\mu_\ell|\mu_{-\ell}, \boldsymbol{\theta}) \times p(y_\ell|\mu_\ell), \qquad (18)$$

where $p(y_\ell|\mu_\ell)$ is Poisson (μ_ℓ). The Gibbs sampler simply involves sampling from (18) for each ℓ, always conditioning upon the most recently sampled values in $\mu_{-\ell}$. If $\boldsymbol{\theta}$ is unknown, it should be sampled from its full conditional distribution, but this is generally difficult to derive from (18). Besag et al. [4] discuss MRF prior models which are specified through joint "pairwise-difference" distributions, from which derivations of all full conditional distributions is straightforward. Besag et al. [3] and Bernardinelli & Montomoli [1] discuss Gibbs sampling for disease maps using MRF priors.

Markov Chains

Markov chains refer to a collection of **random variables** with a special dependency structure. We begin by discussing discrete time Markov chains which are sequences of random variables, denoted by $\{X_n, 0 \leq n < \infty\}$. These stochastic processes are a generalization of a sequence of independent discrete random variables. The random variables, X_n, assume a common discrete set of possible values, $\mathcal{S}$, called the *state space*. Since $\mathcal{S}$ is countable, we can, by relabeling the states, assume that they are labeled by the positive integers. For a finite state space, $\mathcal{S} = \{0, 1, \ldots, K\}$ for some K, while for a countably infinite state space $\mathcal{S} = \{0, 1, \ldots\}$. The dependency structure is defined by the *Markov property*, which is defined by:

$$\Pr(X_{n+1} = j | X_1 = i_1, \ldots, X_{n-1} = i_{n-1}, X_n = i) = \Pr(X_{n+1} = j | X_n = i).$$

If we allow the index n to represent the present time and $\{1, \ldots, n-1\}$ to represent the past, then the Markov property can be interpreted to imply that future events are conditionally independent of the past given the present. The Markov property implies that the chain, upon entering state i, will stay in that state for a random period governed by a **geometric** probability distribution.

The probability $\Pr(X_{n+1} = j | X_n = i)$ is called a *one-step transition probability*, a transition from state i to state j in one time unit. This probability depends upon three quantities: i, j, and n. If the transition probability is independent of n, then we say the transitions are *time homogeneous* or *stationary*. If, in addition, the transition probabilities are independent of i, then the Markov chain is a sequence of independent, identically distributed (iid) random variables. For the rest of this article, we assume time homogeneous transitions, the most commonly considered case.

It is convenient to represent the transition probabilities $p_{ij} = \Pr(X_1 = j | X_0 = i)$ in matrix form, $\mathbf{P} = (p_{ij})$, a square matrix the dimension of which equals that of $\mathcal{S}$. Each row of $\mathbf{P}$ is a discrete probability distribution, so the rows must satisfy two conditions; (i) $p_{ij} \geq 0$ and (ii) $\sum_{j \in \mathcal{S}} p_{ij} = 1$. A matrix $\mathbf{P}$ satisfying (i) and (ii) is called a one-step transition probability matrix. Such matrices include the case of identical rows where the underlying random variables are independent.

To give a complete description of a time homogeneous Markov chain, one needs to specify three components: (i) the state space $\mathcal{S}$; (ii) the transition probability matrix $\mathbf{P}$; and (iii) the initial probability distribution, $\Pr(X_0 = i), i \in \mathcal{S}$. Given those three quantities, the entire evolution of the Markov chain can be characterized. Often that evolution is described in two ways, the n-step transition probabilities; that is, $\Pr(X_{n+m} = j | X_m = i) = p_{ij}^{(n)}$, and the marginal probability distribution at time n, $\Pr(X_n = j)$. Both can be derived from the *Chapman–Kolmogorov equations*. For n-step transitions write $\Pr(X_{n+m} = j | X_0 = i) = \sum_{k \in \mathcal{S}} \Pr(\{X_m = k\} \cap \{X_{n+m} = j\} | X_0 = i) = \Pr(X_m = k | X_0 = i) \cdot \Pr(X_{m+n} = j | X_m = k) = \sum_{k \in \mathcal{S}} p_{ik}^{(m)} p_{kj}^{(n)}$. These equations can be most conveniently expressed in matrix form: $\mathbf{P}^{(m+n)} = \mathbf{P}^{(m)} \mathbf{P}^{(n)}$, where $\mathbf{P}^{(n)} = (p_{ij}^{(n)})$, the n-step transition probability matrix. By iterating this expression, it is easy to show that $\mathbf{P}^{(n)} = \mathbf{P}^n$; that is, the n-step transition probability matrix is the nth power of the one-step transition matrix.

If the Markov chain is initiated at time 0 with a probability distribution, $\pi^{(0)}$, then it follows that the marginal probability distribution at time n, $\pi^{(n)} = \pi^{(0)} P^{(n)} = \pi^{(0)} P^n$, the product of the initial probability distribution vector with the n-step transition matrix.

An important consideration is the limiting behavior of the Markov chain. Does it **converge** to a single state or does it continue to move through all the states in the state space? To answer this question, a classification of each state and a partitioning of the state space is introduced. This is done by first defining a relation between two states:

Definition. State $i \in \mathcal{S}$ communicates with state $j \in \mathcal{S}$ if and only if there exists an $n \geq 0$ such that $p_{ij}^{(n)} > 0$.

So state i communicates with state j if there is a positive probability that a chain starting in i will reach j in finite time.

Definition. States $i, j \in \mathcal{S}$ intercommunicate if i communicates with j and j communicates with i.

The relation defined by state intercommunication is an equivalence relation and it partitions the state space $\mathcal{S}$ into equivalence classes of intercommunicating states. When a Markov chain has a single

equivalence class of states, that chain is said to be *irreducible*.

The long-run behavior of the Markov chain can be deduced from a very simple idea, whether a Markov chain which starts in a state i is certain to eventually return to that state. If $\Pr(X_n = i \text{ for some } n > 0 | X_0 = i) = 1$, then eventual return is certain. However, because of the Markov property, if we are guaranteed of returning a single time, then once we return, we are guaranteed of a second return, and so on. Consequently, if one return is certain, then an infinite number of returns is also certain, and we say that state i is *recurrent*. However, if the probability of eventual return to i is less than 1, then with each return to i, there is a positive probability of this being the final visit to i. Eventually, no further returns will occur. In this case, the state i is called *transient*, and the number of visits to state i will be a random variable with a geometric distribution. One important result is that for any single equivalence class of states, all of those states are recurrent or all are transient.

If we are interested in the long-run fraction of time that the Markov chain spends in state i, we can restrict attention to recurrent states, because this relative frequency must converge to 0 for the transient states. For an irreducible Markov chain, the vector $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \ldots)$, where α_i represents the long-run fraction of time spent in state i, satisfies the system of linear equations

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}\mathbf{P}, \qquad \sum_{i \in \mathcal{S}} \alpha_i = 1.$$

The vector $\boldsymbol{\alpha}$ represents a probability distribution. According to the theory of Markov chains, for an irreducible Markov chain these equations will have a unique solution giving a probability distribution or no solution at all. In the former case, the states of the Markov chain are *positive recurrent*, and the mean value of the time to return to state i is $1/\alpha_i$. In the latter case, either all the states are transient, or all the states are recurrent, but the mean value of the time to return to a state is infinite, in which case, the states are said to be *null recurrent*.

In the positive recurrent case, this distribution $\boldsymbol{\alpha}$ is referred to by a variety of names: the "equilibrium", "stationary", or "invariant" distribution; even the "steady state" distribution. The latter is often subject to misinterpretation, since the Markov chain continues to sojourn throughout the state space. The vector $\boldsymbol{\alpha}$ gives the long-run fraction of time spent in any state. It is also the invariant distribution in that if the chain is initiated according to the distribution $\boldsymbol{\alpha}$, then the marginal distribution of the chain at all future times is also $\boldsymbol{\alpha}$.

One can also look at the limiting behavior of the n-step transition probabilities, $\lim_{n\to\infty} p_{ij}^{(n)}$. Of course, this limit will be 0 if i does not communicate with j or if j is transient. However, even if $\alpha_j > 0$, this still does not guarantee that the limit exists. The phenomenon that must be considered is called *periodicity*.

Definition. A state $i \in \mathcal{S}$ is periodic with period k if $p_{ii}^{(n)} > 0$ only for $n = jk$, $j = 1, 2, \ldots$.

In words, a state i is periodic with period k implies that if the Markov chain is initially in state i, it can return to that state only in even multiples of k units of time. A chain with period 1 is *aperiodic*. Periodicity is also a class property; that is, all states in an equivalence class of states have the same period.

Theorem. For an aperiodic, irreducible, positive recurrent Markov chain, $\lim_{n\to\infty} p_{ij}^{(n)} = \alpha_j$.

Thus, for an aperiodic, irreducible, positive recurrent (also called an *ergodic*) Markov chain, the probability vector solution to the system of equilibrium equations $\boldsymbol{\alpha} = \boldsymbol{\alpha}\mathbf{P}$ gives the long-run average fraction of time that the chain spends in each state and is the limiting probability that the chain will be found in each state of $\mathcal{S}$ at a time far in the future. Notice that in the ergodic case, $\lim_{n\to\infty} p_{ij}^{(n)} = \alpha_j$, independent of i, the initial state. In this case, the long-run behavior of the chain is independent of its starting location.

A final concept that is useful in biostatistical applications is that of an *absorbing state*, a state i satisfying $p_{ii} = 1$. Once the chain enters i, it can never leave that state. Such states arise, for example, in cell metastasis models (*see* **Cell Cycle Models**). Starting with a normal cell, the cell may transition through a series of reversible states; however, if it reaches a cancerous state, then it continues to be cancerous for ever after. One can also use the concept as a method to determine the expected amount of time required for the chain, starting in state i, to first reach j. If we let e_{ij} represent the expected value of the first time the chain reaches j, then these quantities satisfy the system of equations: $e_{ij} = 1 + \sum_{k \in \mathcal{S}} p_{ik} e_{kj}$ for $j \neq i$, while $e_{ii} = 0$.

It is straightforward to estimate the elements of the transition matrix, **P**, by **maximum likelihood**. Assume that we are given a single path of a Markov chain that is observed over the time interval $[0, N]$. Each time the chain enters state i, the next transition is independent of the entire transition history, and that step is given by a discrete probability distribution on $\mathcal{S}$ given by $\{p_{ij}, j \in \mathcal{S}\}$. If we observe transitions over N steps, and N_{ij} gives the number of transitions from state i to j, then the maximum likelihood estimator of p_{ij} is given by N_{ij}/N_i, where $N_i = \sum_{j\in\mathcal{S}} N_{ij}$. In some models, the transition probabilities are constrained to have a special form which is a parametric function of some variable θ; that is, $p_{ij} = p_{ij}(\theta)$. Here, one must write the **likelihood** function of θ, an expression which will have the following **multinomial** form: $L(\theta|N_{ij}, i, j \in \mathcal{S}) = p_{X_0}(\theta) \prod_{i\in\mathcal{S}} \prod_{j\in\mathcal{S}} (p_{ij}(\theta))^{N_{ij}}$, where $p_{X_0}(\theta)$ represents the likelihood of the initial state of the Markov chain. This multinomial-like expression must be maximized over θ. The resulting estimators are asymptotically normally distributed, and the methodology is similar to what would be done with data from a **contingency table**. The seminal work on estimation of Markov chains was done by Anderson & Goodman [1]. The reader should also consult Billingsley [2].

Continuous Time Markov Chains

Many Markov chain models are formulated in continuous time, rather than discrete time. In this situation, the Markov chain is represented by $\{X_t, t \geq 0\}$. The state space, $\mathcal{S}$ is also discrete and is again taken to be $\{1, 2, \ldots, N\}$ for a finite Markov chain or $\{1, 2, \ldots, \}$ for the countable state space case.

The Markov property for the continuous time case is expressed by the relation

$$\Pr(X_{t+s} = j | X_s = i, X_u = i_u, 0 \leq u < s) = \Pr(X_{t+s} = j | X_s = i).$$

We consider only the time homogeneous case; that is, $\Pr(X_{t+s} = j|X_s = i) = p_{ij}(t)$, a transition from i to j over t time units which does not depend upon s. Again, the future evolution of the chain is conditionally independent of the past given the present state. Suppose at some time t, the chain is in state i, and we are interested in how much longer it will stay in state i before it jumps to a different state. The Markov property indicates that the remaining sojourn time in i must be independent of the past; hence it must be independent of the amount of time it has already sojourned in state i. This "memoryless" property implies that the sojourn time in each state is governed by an **exponential** distribution.

The basic ideas developed earlier for discrete time Markov chains carry over directly to continuous time Markov chains. For example, the state space can be decomposed into equivalence classes of intercommunicating states, and those classes contain states which are all recurrent or all transient. There is, however, a major difference between the discrete time and continuous time Markov chains. In the discrete time case, there is a smallest increment of time, one time unit. In the continuous time case, there is no smallest unit of time, so one can consider state transitions over arbitrarily small periods of time. Consequently, the concept of a one-step transition probability matrix, **P**, does not apply to the continuous time case. In its place, a *transition rate* matrix, $\mathbf{Q} = (q_{ij})$, is introduced. The individual transition rates are defined by $q_{ij} = p'_{ij}(0)$. Since $\sum_{j\in\mathcal{S}} p_{ij}(t) = 1$ for all t, it follows that $\sum_{j\in\mathcal{S}} q_{ij} = 0$. Consequently, each row of **Q** must sum to 0. The diagonal elements of **Q** are nonpositive, while the off-diagonal elements are nonnegative, since

$$q_{ij} = \begin{cases} \lim_{h\to 0} \dfrac{p_{ii}(h) - 1}{h} \leq 0, & \text{if } i = j, \\ \lim_{h\to 0} \dfrac{p_{ij}(h)}{h} \geq 0, & \text{if } i \neq j. \end{cases}$$

The elements of the **Q** matrix have direct interpretations concerning the behavior of the Markov chain. Recall that the holding time in each state is governed by an exponential distribution. The parameter of that distribution for state i is given by $-q_{ii} = \sum_{j\neq i} q_{ij}$. Once the chain leaves state i, it must jump to another state $j \neq i$. The probability that it jumps to j is given by $q_{ij}/\sum_{k\neq i} q_{ik}$. One could also associate each $\{q_{ij}, j \neq i\}$ with an independent exponential (q_{ij}) random variable, T_{ij}. Suppose that $T_i = \min_{j\neq i} T_{ij}$ and $T_{ij} < T_{ik}, k \neq i, j$. Then, upon entering state i, the chain will stay in state i for T_i time units, then jump to j.

The Chapman–Kolmogorov equations for the continuous time case are $\mathbf{P}(s + t) = \mathbf{P}(s)\mathbf{P}(t)$. These can be rewritten, $\mathbf{P}(t + h) = \mathbf{P}(t)\mathbf{P}(h)$. By subtracting

$\mathbf{P}(h)$ from both sides and taking the limit as $h \to 0$, we obtain the Kolmogorov forward equations,

$$\mathbf{P}'(t) = \mathbf{P}(t)\mathbf{Q}, \qquad \mathbf{P}(0) = \mathbf{I},$$

a system of first-order differential equations with constant coefficients. These equations have a solution,

$$\mathbf{P}(t) = \exp(\mathbf{Q}t) = \mathbf{I} + t\mathbf{Q} + \frac{t^2}{2!}\mathbf{Q}^2 + \cdots.$$

Suppose that one introduces the **eigenvalue** decomposition of $\mathbf{Q}$, $\mathbf{Q} = \mathbf{USV}$, where $\mathbf{U}$ and $\mathbf{V}$ are orthogonal matrices of **eigenvectors**, and $\mathbf{S}$ is a diagonal matrix of eigenvalues of $\mathbf{Q}$. Using this representation of $\mathbf{Q}$, one can write $\mathbf{P}(t) = \mathbf{UD}(t)\mathbf{V}$, where $\mathbf{D}(t)$ is the diagonal matrix $\exp(t\mathbf{S})$. In the case of a positive recurrent, irreducible Markov chain, the transition probabilities converge to a limiting probability distribution, $\boldsymbol{\alpha}$, and this distribution is characterized by the equations

$$\mathbf{O} = \boldsymbol{\alpha}\mathbf{Q}, \sum_{i \in \mathcal{S}} \alpha_i = 1.$$

This equilibrium or stationary vector is the eigenvector corresponding to the eigenvalue 0 of $\mathbf{Q}$. For continuous time Markov chains, the concept of periodicity does not appear; hence, in the positive recurrent case, $\boldsymbol{\alpha}$ represents the long-run fraction of time the Markov chain spends in each of the states in the state space. In addition, $\alpha_j = \lim_{t \to \infty} p_{ij}(t)$.

The most common continuous time Markov chain is the birth–death process (*see* **Stochastic Processes**), a process in which transitions take place only to adjacent states in $\mathcal{S}; q_{ij} = 0$ if $j \neq i-1, i$ or $i+1$. Often, one uses the notation $\lambda_i = q_{ii+1}$ and $\mu_i = q_{ii-1}$, which denote the birth and death rates in state i. In the positive recurrent case, the stationary distribution of the chain is given by

$$\alpha_i = k \prod_{j=1}^{i} \frac{\lambda_{j-1}}{\mu_j},$$

where k is a normalization constant to insure that this gives a probability distribution.

The estimation of the parameters of a continuous time Markov chain is similar to estimation in discrete time. We consider the case in which $\mathcal{S} = \{1, \ldots, K\}$. Assume that we are given a single sample path that is observed over the time interval $[0,T]$, and that the initial state is chosen at random. From this sample path, we can reduce to the **sufficient statistics** $\{N_{ij}, 1 \leq i, j, \leq K, i \neq j\}$, the total number of transitions from state i to state j and $\{\tau_i, 1 \leq i \leq K\}$, where τ_i represents the total amount of time spent in state i. The likelihood function is given by

$$L = \left[\prod_{i=1}^{K} \prod_{j=1, j \neq i}^{K} \left(\frac{q_{ij}}{-q_{ii}}\right)^{N_{ij}}\right] \left[\prod_{i=1}^{K} \exp(q_{ii}\tau_i)\right].$$

By taking logarithms, recalling that $q_{ii} = -\sum_{j \neq i} q_{ij}$ and maximizing this expression over q_{ij}, we find the maximum likelihood estimates of q_{ij} to be given by $\hat{q}_{ij} = N_{ij}/\tau_i$, provided that the denominator is positive. If $I_i = 0$, then state i was never entered, and we have no data from which to estimate the transition rates departing from state i. One can also use **Bayesian methods** in this problem. It is possible that a particular model might impose a parametric structure on the transition rates, a situation requiring a different estimation procedure.

Examples of Markov Chains in Biostatistics

We now illustrate the basic concepts discussed above using two classical examples in biostatistics.

Example 1. Radiation Damage

Reid & Landau [4] introduced a Markov chain to model the increase in or recovery from **radiation** damage to an organism. There are $K+1$ states, $\{0, \ldots, K\}$, where 0 denotes no radiation damage, K denotes an absorbing state with perceptible damage, and $\{1, \ldots, K-1\}$ denote intermediate states with increasingly severe states of damage. In discrete time, the one step transition probability matrix is given by the following $(K+1) \times (K+1)$ matrix in which $q_i + p_i = 1, 1 \leq i < K$,

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 & 0 & \ldots & 0 \\ q_1 & 0 & p_1 & 0 & \ldots & 0 \\ 0 & q_2 & 0 & p_2 & \ldots & 0 \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & \ldots & 0 & q_{K-1} & 0 & p_{K-1} \\ 0 & 0 & \ldots & 0 & 0 & 1 \end{pmatrix}.$$

In this model, the states 0 and K are absorbing states. If the chain is any intermediate state, $1 \le i < K$, then it will move to an adjacent state. Once the chain hits an absorbing state, it stays there forever, hence the equivalence classes are $\{0\}, \{K\}, \{1, \ldots, K-1\}$. The single state classes are recurrent, while the intermediate class is transient. One might ask for the probability, given the chain is initiated in state i, $1 \le i \le K-1$, that it will reach the healthy state 0 before it reaches the permanently damaged state K. Reid & Landau studied this model under the assumption that $p_i = i/K$ and $q_i = 1 - i/K$. For this particular set of transitions, they showed that if the chain is in state i, then the probability of the chain hitting state K before it returns to the normal state 0 is given by

$$\frac{1}{2^{K-1}} \sum_{j=0}^{i-1} \binom{K-1}{j}, \quad \text{for } 1 \le i \le K.$$

Example 2. Compartment Models

Compartment models are a very large class of models used in **pharmacokinetics** and pharmacodynamics, tracking the flow of substances in the body. The compartments refer to containers such as organs or the blood stream itself. Jacquez [3] gives a comprehensive treatment of these models. While the number of particles of drug or pollutant will be very large, these models often assume independence of movement within the compartments. Thus, these models give the transition structure for one particle, and the behavior of the aggregate can be predicted using the **central limit theorem** and the **law of large numbers**.

A typical compartment model is formulated in continuous time. Consider, for example, a three-state model given by the $\mathbf{Q}$ matrix

$$\mathbf{Q} = \begin{pmatrix} q_{11} & q_{12} & q_{13} \\ q_{21} & q_{22} & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Recall that $q_{11} = -(q_{12} + q_{13})$ and $q_{22} = -q_{21}$. State 1 refers to the bloodstream, 2 refers to the liver, while 3 refers to the bladder, from which the pollutant will be expelled. The drug will reside in the bloodstream for an exponential period, then move either to the bladder or to the liver. The drug will stay in the liver for an exponential period, then move back to the bloodstream. Finally, any drug that reaches the bladder will be removed from the system, so this represents an absorbing state. Again, the bloodstream state and the liver state are transient, while state 3 is absorbing. Consequently, it is of interest to calculate the total amount of time that the pollutant will spend in the liver where damage can occur, and the time it spends in the system before it is removed.

Consider the following numerical example. Suppose that

$$\mathbf{Q} = \begin{pmatrix} -2 & 1 & 1 \\ 1 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

The eigenvalues of $\mathbf{Q}$ are $(0, -0.382, -2.618)$. If we assume that there is a bolus injection of pollutant at time 0 into the bloodstream, then the transition probabilities for a single particle can be found from the Kolmogorov forward equations. Specifically, we find that

$$\begin{aligned} p_{11}(t) &= 0.276\exp(-0.382t) + 0.724\exp(-2.618t), \\ p_{12}(t) &= 0.448\exp(-0.382t) - 0.448\exp(-2.618t), \\ p_{13}(t) &= -0.724\exp(-0.382t) \\ &\quad -0.276\exp(-2.618t) + 1. \end{aligned}$$

Thus, the pollutant concentration decreases in the bloodstream according to a mixture of exponentials. It increases, then decreases in the liver, and eventually it all resides in the bladder.

Markov Processes

A Markov process is often described as a "process without memory": our estimate of the probability of a future event concerning its behavior *given (complete)* information about its present state will not change if we are given in addition any information about its past behavior. See the first section for an illustration of this.

The concept of a "Markov process" is so general as to embrace most models of random systems evolving in time (*see* **Stochastic Processes**): from "classical" *random walks*, **Markov chains**, **branching processes**, *birth-and-death processes, diffusions* and their associated *stochastic differential equations*, to the "postclassical" *branching diffusions, measure-valued diffusions, interacting systems* (which include *contact processes* etc.), which are destined to play an ever more important part in **mathematical biology**. Each of the italicized topics has a huge literature and its own special methods; and it is often better to search the literature for *these* "keywords" rather than the all-embracing "Markov processes". However, Markov-process theory has, of course, unifying themes and methods (*martingale theory, large-deviation theory*, etc.) which pervade all of its branches.

We take a brief tour through the subject, designed to allow glimpses of several topics italicized above.

Simple Random Walk

Suppose that we toss a fair coin just before times 1, 2, 3, ..., and regard the state of our system at time n (which can be 0, 1, 2, ...) as the number of heads minus the number of tails obtained by that time. (We have $X_0 = 0$.) For illustration, regard time 100 as the "present". Suppose that we know that $X_{100} = 6$. *Given* this information and any additional information about the "past" results of the first 99 tosses, X_{101} is either 5 or 7 with probability 1/2 each. The Markov property is obvious here.

We can prove, for example, that the distribution of X_n at time n is approximated by the **normal distribution** of mean 0 and variance n (hence standard deviation $n^{1/2}$), and that, "almost surely" (that is, with probability exactly 1), X_n will fluctuate infinitely, taking every integer (whole-number) value infinitely often.

Markov Chain in Discrete Time

For a Markov chain in discrete time with stationary probabilities, $X_n, n = 0, 1, 2, \ldots$, is a random integer describing the state of the system at time n. The probabilistic law of the system is described by the ("initial") distribution of X_0 and by a "matrix" (or array) of transition probabilities p_{ij}: for each n, the (conditional) probability of the "future" event that $X_{n+1} = j$, given the "present" information that $X_n = i$ and any extra information about the "past" $X_0, X_1, \ldots, X_{n-1}$, is p_{ij}. [Our random walk has $p_{ij} = 1/2$ if $j = i + 1$ or $j = i - 1$, and $p_{ij} = 0$ otherwise.] The sort of questions in which we are interested are the following. Is the system "ergodic" in that, over the long term, it will almost surely share out its time amongst the various states in a predetermined way? At the other extreme, if there is an absorbing state a for which $p_{aa} = 1$, will the system almost surely eventually end up in state a? (For example, is some population almost surely destined to die out?)

Markov Chain in Continuous Time

We modify things so that our system can jump at *any* time, not just at integer-valued times, and this requires us to define *jump-rates* q_{ij} rather than "jump probabilities" p_{ij}. We denote the integer-valued state of our system at time t, where $t \geq 0$, by X_t. Suppose that $j \neq i$. Given the "present" information that $X_t = i$ and any information about the past values X_s for $s < t$, the probability that the system will jump from i to j between times t and $t + h$, where h is a small number, will be $q_{ij}h + o(h)$, where $o(h)$ is a term negligibly small *compared with* h when h tends to 0.

Generalized Birth-and-Death (GBD) Process

This has the property that $q_{ij} = a_i$ for some a_i if $j = i + 1$, $q_{ij} = b_i$ for some b_i if $j = i - 1$, and $q_{ij} = 0$ for other pairs (i, j), where $j \neq i$. Thus X can only jump to a neighboring state. We can answer the analogues of the questions raised in the section "Markov chain in discrete time".

Continuous-Time Random Walk (CTRW)

This is a GBD process with $a_i = b_i = 1/2$ for every i. It will behave rather like the random walk in the first section.

(Standard) Birth-and-Death (BD) Process

This (the simplest type of continuous-time *branching process*) is a GBD process in which only nonnegative integer states 0, 1, 2, ... are allowed, and we have $a_i = \lambda i, b_i = \mu i$ for some constants λ (the "birth rate" per individual) and μ (the "death rate" per individual). Here, we think of X_t as the size of a population at time t. If $X_t = i$, then there are i animals alive at time t, each of which can give birth (to one child) "at rate λ", resulting in a jump rate of $a_i = \lambda i$ for X from i to $i + 1$; if $i > 0$, then each of the i animals can die "at rate μ", resulting in a jump rate of $b_i = \mu i$ for X from i to $i - 1$. State 0 is absorbing. Here are some unsurprising results. In the subcritical case when $\mu > \lambda$, so the death rate exceeds the birth rate, and then the population will almost surely die out. In the supercritical case when $\lambda > \mu$, then, almost surely, the population will either die out or will grow "exponentially" in a sense which can be made precise. In the critical case when $\lambda = \mu$, the population will almost surely die out.

(Mathematical) Brownian Motion (BM) *B*

We now take the first of several steps in building more complex processes from the processes already introduced. If we renormalize CTRW suitably, then we obtain as a limit the most important of all stochastic processes: **Brownian motion**. We take a large number N, and let X be a GBD process with $a_i = N/2$ and $b_i = N/2$. This process is jumping very fast. Consider $Y_t = X_t/N^{1/2}$. Then Y is jumping just as fast as X, but is making only small jumps of size $1/N^{1/2}$. We choose $N^{1/2}$ because of the fact that a standard deviation of $n^{1/2}$ appeared in our discussion in the first section. What happens is that the law of the rescaled process Y converges as N tends to infinity to the law of Brownian motion B. The process B takes real values, not integer values. The Markov property of B is conveyed by the fact that conditional on the "present" information that $B_t = x$ and any information about the past $(B_s : s < t)$, the "future" random variable B_{t+s} has exactly the normal distribution of mean x and variance s. (The fact that the mean value of B_{t+s} given the values $(B_s : s \le t)$ is the value of B_t signifies that B is a *martingale*.)

It is no accident that, if $p(t, x)$ is the density function at x of the law of B_t if $B_0 = 0$, i.e. of the normal distribution with mean 0 and variance t, then

$$p(t, x) = \frac{1}{(2\pi t)^{1/2}} \exp\left(-\frac{x^2}{2t}\right)$$

solves the heat equation

$$\frac{\partial p}{\partial t} = \frac{1}{2}\frac{\partial^2 p}{\partial x^2}.$$

This explains the frequent occurrence of second-derivative "diffusion terms" in books on mathematical biology. The function $p(s; x, y) = p(s, y - x)$ is now the transition probability density for B from x to y in an interval of duration s: it plays a role analogous to that of the one-step transition probability p_{ij} for a Markov chain in discrete time.

Brownian motion B is quite remarkable. It approximates many processes. It is amazingly rich and we can "find within B" many other processes including all those we have so far studied. This gives a very illuminating way of proving (rigorously) the celebrated **Central Limit Theorem** on the ubiquitous nature of the normal distribution. We can even "find within B" seemingly much more complicated processes such as the Dawson–Watanabe process described later. We can use B to describe "white-noise perturbations" of ordinary differential equations, turning them into the stochastic differential equations which describe diffusions, and so on.

Diffusions

Brownian motion is the most important diffusion process. We can think of a more general diffusion process on the real line in two ways: either as the limit of a GBD process produced in a way analogous to that in which we obtained BM from CTRW; or as the solution of a *stochastic differential equation (SDE)* of the form

$$\frac{\mathrm{d}X}{\mathrm{d}t} = b(X_t) + \sigma(X_t)\frac{\mathrm{d}B}{\mathrm{d}t},$$

where σ and b are functions. This SDE can be thought of as a random perturbation of the ordinary

differential equation (ODE) $dX/dt = b(X_t)$. (The b here has a quite different connotation from that of the b_i in GBDs.) The Brownian path is nowhere differentiable, so dB/dt is completely meaningless in Newtonian terms. Even so, the great Japanese mathematician, K. Itô, constructed the *stochastic calculus* (nowadays based on *martingale theory*), which allows rigorous formulation and analysis of SDEs. Solutions of SDEs inherit the Markov property from the (particularly strong version of the) Markov property possessed by Brownian motion. Conversely, any (real-valued) Markov process X which fluctuates continuously in time (and which satisfies very mild regularity conditions) is the solution of an SDE as above.

The transition density function $p(s; x, y)$ of the solution X of our *first*-order SDE solves the *second*-order partial differential equation (PDE)

$$\frac{\partial p}{\partial s} = \frac{1}{2}\sigma(x)^2 \frac{\partial^2 p}{\partial x^2} + b(x)\frac{\partial p}{\partial x},$$

which amazing fact allows us to prove even the deepest known theorems on these and certain other PDEs of importance in mathematical biology by probabilistic methods (see below).

Diffusion theory has seen truly spectacular development over the last 40 years. One important way in which diffusions are used is again in approximating other processes: choosing a diffusion with the same "infinitesimal characteristics" as a more complex process can often give a good guide to how that process behaves.

Branching Brownian Motion and the FKPP Equation

The FKPP equation for $u(t, x)$ studied by Fisher and independently by Kolmogorov, Petrovskii, and Piskunov,

$$\frac{\partial u}{\partial t} = \frac{1}{2}\frac{\partial^2 u}{\partial x^2} + u(1-u),$$
$$u(0, x) = \begin{cases} 1, & \text{if } x < 0, \\ 0, & \text{if } x > 0, \end{cases} \qquad (1)$$

is perhaps the most famous in mathematical biology: it is the simplest *reaction–diffusion equation*. Here, $u(t, x)$ is thought of as describing the density at time t and position x of a population of animals, where there is a logistic constraint on population growth and where the animals diffuse around. (This statement does not in itself specify any random model!) Strange to say: by far the deepest analytic results on the equation have been obtained by H.P. McKean, M. Bramson, J. Neveu, and B. Chauvin & A. Rouault, using probabilistic methods on a stochastic model, branching Brownian motion (BBM), with "free" (rather than logistic) growth. The birthing is exactly as for the pure-birth process, which is a BD process with $\lambda = 1$ and $\mu = 0$. Each child is born at its parent's current position. Once born, animals perform independent Brownian motions. The whole system is Markov, the state of the system at time t summarizing both how many animals are then alive and exactly where they all are. McKean showed that the unique solution $u(t, x)$ of (1) is given by the probability that if we start with one animal born at position x at time 0, then at least one animal is to the left of 0 at time t. If $l(t)$ denotes the leftmost particle position at time t and we start with one animal born at time 0 at position 0, then we have, almost surely, as $t \to \infty$,

$$\frac{l(t)}{t} \to -2^{1/2},$$

and this explains the celebrated "approximate traveling-wave" nature of the solution to (1). If we simulate the situation when at time 0 there is just one animal at position 0, we see that the tracks of the animals almost exactly fill a triangle. All the exact traveling-wave solutions of the FKPP equation have explicit probabilistic representations, even though BBM is the wrong model in biological terms (see the section "MVDs with interaction; improving on FKPP" below).

Measure-Valued Diffusions (MVDs)

The simulation mentioned above is enough to convince one of the good sense of thinking of the random flows of measures ("mass distributions"). Let me explain the most fundamental MVD: the *Dawson–Watanabe (D–W) process*. We take a large number N. We think of each animal as having mass $1/N$, and start with N animals at position 0. Births and deaths are according to a BD process with $\lambda = N/2$ and $\mu = N/2$. Note that this is a critical situation, in which the process will eventually die out. Each particle performs BM, independently of all others. As

N tends to infinity, the law of evolution converges to that of the Dawson–Watanabe process. In one dimension, but only in one dimension, we can think of the value of the (D–W) process at time $t > 0$ as being a positive density function u of a mass distribution. This evolves as the solution of a *stochastic partial differential equation (SPDE)*, a perturbed heat equation

$$\frac{\partial u}{\partial t} = \frac{1}{2}\frac{\partial^2 u}{\partial x^2} + [u(t,x)]^{1/2} W,$$

where W now denotes a space–time white-noise process derived from a "Brownian motion" (the "Brownian sheet") with two-dimensional "time". Leading experts in this field include D.A. Dawson, E.B. Dynkin, S.N. Evans, J.F. le Gall, E. Perkins, and J.B. Walsh. Important biological applications, especially to genetics, have been given by D.A. Dawson, P. Donnelly, S.N. Ethier, and T.G. Kurtz.

Interacting Systems

Complicated as they are, the above-mentioned models are not complicated enough. Their particles perform their Brownian motions independently of one another: no account is taken of overcrowding or of the interaction between different particles. By contrast, the theory of interacting systems allows more or less anything. One has to be aware of the scope of this theory, even if only a handful of people can currently claim deep understanding. Leading experts include R. Durrett, G. Grimmett, H. Kesten, R. Holley, and T.M. Liggett.

One of the simplest interacting systems is the three-dimensional *contact-process* model for the spread of disease through cells which are considered to be cubes stacked together, and occupying the whole of space. A healthy cell becomes infected at "jump-rate" (a constant) I times the number of infected neighbors while an infected cell recovers at constant "jump-rate" R. (This system is too complicated to be a Markov chain – its state-space is "uncountable" – but it is a Markov process.) We suppose that at time 0 only a finite number of cells are infected. The system exhibits phase transition: if I/R is less than some critical number c (the precise value of which is currently unknown), then the disease will almost surely die out; while if I/R is greater than c, then the disease can (with positive probability) persist for ever, infecting ever more cells. The *time-dependent Ising model* from magnetism, now much used by statisticians in *image processing*, (*see* **Image Analysis and Tomography**), is closely related.

MVDs with Interaction; Improving on FKPP

Some extremely interesting work has been done by C. Mueller, R.B. Sowers and R. Tribe on an interacting system with "logistic" inhibition of **population growth**: an MVD with density satisfying the FKPP equation with an extra term $[u(1-u)]^{1/2} W$ on the right-hand side, with W as before. The system possesses a "coherence" not present in the deterministic model, and can be regarded as superior to it in many respects. Mueller, Sowers, and Tribe study "traveling-wave" aspects.

Self-Organization; Adapting to the Environment

A striking feature of (naturally occurring and man-made) interacting systems is their ability to behave in a pseudo-intelligent way. Brilliant use of this was made in the *Dynamic Alternative Routing* strategy for telephone networks developed by F.P. Kelly and R. Gibbens along with British Telecom. Similar use is made in **neural nets**. Biological "networks" in fungi, ant colonies, anastomosis of blood vessels near tumors (bad!), or in wound healing (good!), are complex interacting systems; at present, models of such systems can only be studied by **simulation**, which can certainly identify bad models even if it cannot conclusively validate good ones.

A Plea

There is a great need to make the more modern material described in this article a lot more accessible to applied workers – and to mathematicians too!

A Few References

The literature is truly vast. Most of it can be discovered via the key names given, in the various databases now available, and in the following. For the first five

sections, see, for example, Feller [6, 7], Grimmett & Stirzacker [8], and Karlin & Taylor [9, 10]. For the next two sections, see, for example, Breiman [1], Ethier & Kurtz [5], and Øksendal [12]. For the following two sections – and things are getting much harder now – see, for example, Dawson [2], Donnelly & Kurtz [3], Durrett & Levin [4], and Mueller & Sowers [11].

DAVID WILLIAMS

Martini, Paul

Born: January 25, 1889, in Frankenthal, Germany.
Died: September 8, 1964, near Bonn, Germany.

Paul Martini was born in Frankenthal (Palatinate) in the southwestern region of Germany. He studied medicine at the universities of Munich and Kiel. He worked on his thesis in the Institute of Physiology in Munich and obtained his doctorate in medicine in 1917.

He was an assistant in the II. Medizinische Universitätsklinik in Munich which was at that time headed by one of the famous German internists, Friedrich von Mueller. In 1926 he become "extraordinary" professor of medicine. He left the university when he was appointed head physician in the St Hedwigskrankenhaus in Berlin, a large community hospital. In 1932 Martini returned to university life. From that time until he retired he held the chair of internal medicine at the University of Bonn and was director of the Universitätsklinik für Innere Medizin und Nervenkrankheiten.

Among his scientific work, his 1932 Monograph *Methodenlehre der therapeutischen Forschung* [1] is of particular importance. This book contains all the elements of the controlled **clinical trial** and is the first in modern times addressing the problem of a scientific methodology as regards therapeutic research. It is evident that the use of placebo (*see* **Blinding or Masking**) is meant even when this word is not used. Martini wrote: "the medicines have to be given to the patient in a form or in a galenic preparation that their special character or their purpose can not be recognized, they have to be camouflaged. The results have to be evaluated by means of statistics and probability calculus". **Randomization** is not clearly addressed, but subsequent publications make it likely that alternating procedures, for example based on day of birth, were used.

In an article published in 1934, Martini again explained his methodology of therapeutic trials and defended himself against the arguments that had been raised against his ideas [2].

In 1957 he published in the Deutsche Medizinische Wochenschrift his ideas about double-blind trials [3]. He rejected the method of double-blindness as he was not convinced that the results of such trials were superior to the single-blind trials. In 1961 Martini was chairman of an international seminar in the field of drug trials in Berlin.

Martini was a highly esteemed physician and had among his patients many personalities of the political scene in Bonn. During the time of national socialism he was able to avoid involvement. In 1948 he was president of the first postwar "Internistenkongress" (annual meeting of the German Society of Internal Medicine) in Wiesbaden. In 1964 he died in his country house in the Eifel near Bonn.

H.J. DENGLER

Matched Analysis

On grounds of both validity and efficiency, the appropriate analysis of data involving category matching mandates the use of stratified analysis methods based on the strata used in the matching process [6] (*see* **Stratification**). Two important methods for analyzing category matched (or, more generally, stratified) data are the **Mantel–Haenszel** procedure [9] and **conditional logistic regression** (see [1], Chapter 7, and [5], Chapter 20).

The Mantel–Haenszel (MH) test statistic [9] is the most widely used and recommended method for testing for overall association in a stratified analysis. And, as we will see, the MH test statistic for stratified data analysis is based on the (central) **hypergeometric distribution**. For dichotomous disease and exposure variables (the setting for this presentation), the MH testing procedure involves a one **degree-of-freedom** (continuity-corrected) **chi-squared statistic** of the general form

$$\chi^2_{\mathrm{MH}} = \frac{[|A - \mathrm{E}_0(A)| - 1/2]^2}{\mathrm{var}_0(A)}, \qquad (1)$$

where A is the random variable denoting the total number (over all strata) of diseased subjects in each stratum who are exposed (i.e. the total number of "exposed cases"), $\mathrm{E}_0(A)$ is the expected total number of exposed cases under the **null hypothesis** of no **association** between exposure and disease, and $\mathrm{var}_0(A)$ is the **variance** of the total number of exposed cases under the same null hypothesis.

Suppose that there are G strata defined by the matching process, with the gth stratum having the structure given in Table 1.

The four marginal frequencies n_{1g}, n_{0g}, m_{1g}, and m_{0g} in the gth stratum convey no information about the strength of the association between exposure and disease in that stratum, but rather indicate only the "amount of information" in that stratum.

Table 1 Data layout for the gth stratum ($g = 1, 2, \ldots, G$)

	E	$\overline{E}$	
D	A_g	B_g	m_{1g}
$\overline{D}$	C_g	D_g	m_{0g}
	n_{1g}	n_{0g}	n_g

Consequently, the four marginal frequencies within each stratum may be assumed (with no compromise to validity) to be "fixed" for analysis purposes, even though the sampling scheme actually used may not have imposed such constraints on the margins of these G **2 × 2 tables**.

Conditional on these fixed margins for all strata, it is sufficient to focus entirely on the "A_g cell", namely, the number of exposed cases in the gth stratum, $g = 1, 2, \ldots, G$. The test statistic (1) is then a conditional test since properties of the **random variable** $A = \sum_{g=1}^{G} A_g$ are based on the condition that the four margins in each stratum are fixed. More specifically, assuming fixed margins and no exposure-disease association, A_g is a (central) hypergeometric random variable, so that

$$\mathrm{E}_0(A) = \sum_{g=1}^{G} \frac{(n_{1g}m_{1g})}{n_g} \quad \text{and}$$

$$\mathrm{var}_0(A) = \sum_{g=1}^{G} \frac{(n_{1g}n_{0g}m_{1g}m_{0g})}{(n_g - 1)n_g^2}.$$

Finally, some algebra can be used to write expression (1) in the form

$$\chi^2_{\mathrm{MH}} = \frac{\left[\left|\sum_{g=1}^{G}(A_g D_g - B_g C_g)/n_g\right| - 1/2\right]^2}{\sum_{g=1}^{G}(n_{1g}n_{0g}m_{1g}m_{0g})/(n_g - 1)n_g^2}; \qquad (2)$$

under the null hypothesis of no exposure–disease association, it can be shown that the test statistic (2) has, for "large samples", an approximate chi-square distribution with 1 df.

It is very important to stress that the "large samples" assumption for the test statistic (2) pertains to the pooled information over all G strata, rather than to stratum-specific numbers. Consequently, in the use of the Mantel–Haenszel test statistic (2), it is permissible to have relatively small numbers in each stratum as long as the total number of subjects on the margins over all strata is sufficiently large. Without going into detail, this form of **robustness** to sparse stratum-specific data accrues due to the assumption of fixed stratum-specific margins, an assumption that maintains validity at only a slight cost in efficiency.

Specific criteria for appropriate sample sizes to maintain the validity of the chi-squared approximation for (2) have been proposed by Mantel & Fleiss [8]. They recommend using (2) provided that the quantities

$$\mathrm{E}_0(A) - \left[\sum_{g=1}^{G} \max(0, m_{1g} - n_{0g})\right] \quad \text{and}$$

$$\left[\sum_{g=1}^{G} \min(n_{1g}, m_{1g})\right] - \mathrm{E}_0(A)$$

both exceed 5 in value.

It is important to mention that the use of the Mantel–Haenszel test statistic (2) should be avoided when there is evidence of strong **effect modification** in the data, as would be reflected by widely varying stratum-specific estimated **odds ratios** $\widehat{\mathrm{OR}}_g = A_g D_g / B_g C_g$, $g = 1, 2, \ldots, G$. Because of the structure of the numerator in (2), the value of (2) can be very small (suggesting no exposure–disease association) when, in fact, some stratum-specific estimated odds ratios are significantly greater than 1 and some are significantly less than 1. Indeed, claims of optimal statistical properties for the Mantel–Haenszel test [11] are valid only in the situation where stratum-specific population odds ratios all have the same value. Tests for lack of uniformity of stratum-specific odds ratios are discussed in Chapter 4 of [1].

Given the assumption of a common population odds ratio for all strata, it makes sense to compute a summary estimator of this common odds ratio; such an estimator is typically a weighted average of the G stratum-specific estimated odds ratios. Mantel & Haenszel [9] proposed several such summary estimators for use in **case–control studies**. The most notable of these is the $\widehat{\mathrm{mOR}}$, which is defined as

$$\widehat{\mathrm{mOR}} = \left[\sum_{g=1}^{G} (A_g D_g)/n_g\right] \Bigg/ \left[\sum_{g=1}^{G} (B_g C_g / n_g)\right]$$

$$= \sum_{g=1}^{G} W_g(\widehat{\mathrm{OR}}_g) \Bigg/ \sum_{g=1}^{G} W_g, \qquad (3)$$

where $W_g = B_g C_g / n_g$. An interesting property of $\widehat{\mathrm{mOR}}$ is that it equals unity only when expression (2) is zero, a property that is not shared by other summary estimators (see [5], Chapter 17). Another advantage of the $\widehat{\mathrm{mOR}}$ over other summary estimators is that it can be used without alteration when there are zero frequencies within the body of some of the stratum-specific tables.

For certain types of matched data, expressions (2) and (3) have simple structures. As one example, for a matched pairs case–control study where each stratum (or pair) consists of one case and one control, then expression (2) reduces to $(b - c)^2/(b + c)$ apart from continuity correction, and expression (3) equals b/c, where b is the number of strata where the case is exposed and the control is not, and c is the number of strata where the control is exposed and the case is not. For the special case of R-to-1 matching, see either Chapter 5 in [1] or Chapter 18 in [5]. For **confidence interval** methods based on (3) in case–control studies with multiple matching, see [3], [12], and [13]. Finally, some generalizations of the Mantel–Haenszel test have been developed for situations where the exposure variable is **nominal** with several categories [9] and where the exposure variable is ordinal (*see* **Measurement Scale**) in nature [2, 7].

A more general and flexible method for the analysis of matched (or, in general, stratified) data is conditional logistic regression (*see* **Logistic Regression, Conditional**). This multivariable modeling procedure is specifically designed to be used when there are small stratum-specific sample sizes. Hence, it is ideally suited for the analysis of matched study designs or to similar situations involving very fine stratification; in fact, its use in these situations is mandatory to avoid **biased** estimates of important odds ratio parameters. In contrast to stratified data analysis methods, conditional logistic regression methods do not require all variables to be categorized; for example, continuous exposure, **confounding**, and effect-modifying variables can be treated as such. In addition, it is theoretically possible to consider simultaneously in one model several exposure variables and to examine potential confounding and effect modification effects due to **covariates** not involved in the matching process.

Suppose we consider the case–control format, with $\mathbf{x}_{1g}, \mathbf{x}_{2g}, \ldots, \mathbf{x}_{m_g g}$ denoting the observed data vectors for the total of $m_g = (m_{1g} + m_{0g})$ cases and controls in the gth stratum, $g = 1, 2, \ldots, G$. Without loss of generality, we arrange these data vectors so that the first m_{1g} vectors belong to the m_{1g} cases in the gth stratum. For a dichotomous response variable

D with $D = 1$ signifying a case and $D = 0$ signifying a control, consider fitting by conditional logistic regression the logistic model

$$\text{logit}[\Pr(D_{lg} = 1)] = \alpha_g + \boldsymbol{\beta}'\mathbf{x}_{lg},$$
$$l = 1, 2, \ldots, m_g \quad \text{and} \quad g = 1, 2, \ldots, G.$$

Then, the contribution from the gth stratum to the full conditional **likelihood** has the structure

$$\text{CL}_g = \prod_{l=1}^{m_{1g}} \exp(\boldsymbol{\beta}'\mathbf{x}_{lg}) \Bigg/ \sum_u \left[\prod_{l=1}^{m_{1g}} \exp(\boldsymbol{\beta}'\mathbf{x}_{ulg}) \right], \tag{4}$$

where the sum $\sum_u$ in the denominator is over all partitions of the set of integers $\{1, 2, \ldots, m_g\}$ into two subsets, the first of which contains m_{1g} elements; there are $m_g!/m_{1g}!m_{0g}!$ such partitions. Thus, CL_g is the conditional probability that the first m_{1g} of the m_g data vectors $\mathbf{x}_{1g}, \mathbf{x}_{2g}, \ldots, \mathbf{x}_{m_g g}$ go with the cases (as they actually do) considering all possible arrangements of these m_g data vectors; in other words, CL_g is the conditional probability of the observed data. The full conditional likelihood CL is then equal to $\text{CL} = \prod_{g=1}^{G} \text{CL}_g$, and standard **maximum likelihood methods** can be used to estimate and to make **inferences** about the elements of $\boldsymbol{\beta}$.

It is important to note that the conditional likelihood CL based on (4) depends only on $\boldsymbol{\beta}$, the parameter vector of interest. The **nuisance parameters** $\alpha_1, \alpha_2, \ldots, \alpha_G$ indexing the matching strata have been eliminated via this permutation procedure, thus precluding the need to estimate unnecessarily an often large number of parameters that provide no information about important exposure–disease odds ratio parameters of interest. In addition, precisely the same likelihood CL is obtained regardless of whether we consider the data to have arisen from a follow-up study or from a case–control study. Also, CL has precisely the structure of Cox's **partial likelihood** [4], based on the **proportional hazards model**, for analyzing follow-up study data. However, an important distinction is that each stratum-specific set in the denominator of CL, instead of involving *all* persons in the study who are disease-free at the time each incident case is identified, consists only of the m_{0g} controls specifically associated with (e.g. sampled at the same time as) the m_{1g} cases.

As an illustration of the conditional likelihood approach for matched data, consider a matched case–control study involving G cases, where the gth case is individually matched to R_g controls on one or more variables. Then, $m_{1g} = 1, m_{0g} = R_g, m_g = (R_g + 1)$, and the conditional likelihood CL takes the specific form

$$\prod_{g=1}^{G} \left[1 + \sum_{l=2}^{R_g+1} \exp[\boldsymbol{\beta}'(\mathbf{x}_{lg} - \mathbf{x}_{1g})] \right]^{-1}. \tag{5}$$

Given the structure of this expression, if any of the elements of $\mathbf{x}$ are matching variables, taking the same value for each member of a matched set, then their contribution to the likelihood is zero and the corresponding elements of $\boldsymbol{\beta}$ cannot be estimated. However, by incorporating such matching variables in the model as **interaction** terms with exposure factors, one can model the variation in odds ratios across matched sets.

Finally, to appreciate that these conditional likelihood methods do, in fact, yield recognizable results in well-known special cases, consider the simple matched pairs case–control study considered earlier, where $R_g = 1$ for all g and where there is a single dichotomous exposure variable. With $e^{\boldsymbol{\beta}} = \text{EOR}$, the exposure odds ratio parameter, it can be shown that (5) is proportional to

$$\left[\frac{\text{EOR}}{(1 + \text{EOR})} \right]^b \left[\frac{1}{(1 + \text{EOR})} \right]^c.$$

By differentiating the logarithm of the above expression with respect to EOR, equating it to zero, and solving, one finds that the conditional maximum likelihood estimator of EOR is $\widehat{\text{mOR}} = b/c$, the ratio of discordant pairs. In contrast, the unconditional maximum likelihood estimator of EOR is $(b/c)^2$, which dramatically illustrates the potential bias associated with the use of unconditional likelihood methods for finely stratified data. While not as extreme as illustrated here, the bias of unconditional likelihood methods is found in many other sparse data situations [10]. These findings emphasize the need to consider the use of conditional likelihood methods when fitting logistic models involving many strata and/or other nuisance parameters to data sets of limited size.

Matched Pairs With Categorical Data

Matched pairs with categorical data arise when two measurements of the same categorical variable are obtained from each independent experimental unit. The repeated measurements might be obtained at two time points, for example, if a patient's condition is categorized as "good" or "poor" at diagnosis and then again six months after diagnosis. In other applications, the variable of interest might be measured under two different conditions. As an example, a patient's response to treatment, categorized as satisfactory or unsatisfactory, might be evaluated following treatment with the standard therapy and then again following treatment with a new therapy. The repeated measurements could also be obtained from each member of a matched set. In a matched **case–control study**, for example, each independent experimental unit consists of a case (individual with a specified disease or condition) and a control (individual without the disease or condition) individually matched to the case by factors such as age, sex, residence, employer, etc.

Such data can be displayed in a two-way **contingency table**. Table 1 shows the general layout when two measurements of a categorical response with I categories are obtained from each experimental unit. In this table, n_{ij} is the observed frequency in the ith row and jth column of the table, n_{i+} and n_{+j} denote the row and column marginal frequencies, respectively, and n is the total number of independent experimental units. The data layout displayed in Table 1 is one example of a **square contingency table**. The possible types of response variables include **polytomous data**, **ordered categorical data**, and, for the special case of $I = 2$, **binary data**.

Table 1 Two-way contingency table for matched pairs with categorical data

First measurement of response	Second measurement of response					
	1	...	j	...	I	Total
1	n_{11}	...	n_{1j}	...	n_{1I}	n_{1+}
⋮	⋮	⋱	⋮	⋱	⋮	⋮
i	n_{i1}	...	n_{ij}	...	n_{iI}	n_{i+}
⋮	⋮	⋱	⋮	⋱	⋮	⋮
I	n_{I1}	...	n_{Ij}	...	n_{II}	n_{I+}
Total	n_{+1}	...	n_{+j}	...	n_{+I}	n

Statistical Inference

Statistical inference for matched pairs with categorical data focuses generally on comparing the marginal distributions of the two correlated responses (*see* **Marginal Models**). Let π_{ij} denote the probability of being in the ith row and jth column, for $i, j = 1, \ldots, I$, and let π_{i+} and π_{+j} denote the corresponding row and column marginal probabilities. The hypothesis of marginal homogeneity is

$$\pi_{i+} = \pi_{+i}, \quad i = 1, \ldots, I.$$

The hypothesis of symmetry,

$$\pi_{ij} = \pi_{ji}, \quad i \neq j,$$

is also sometimes of interest. Other hypotheses include **quasi-symmetry** and **quasi-independence**.

Binary Response

When $I = 2$, the hypothesis of symmetry implies marginal homogeneity, and vice versa. In this situation marginal homogeneity is assessed using the **McNemar test**. This test is a special case of the general class of **Mantel–Haenszel methods**. If the sample size n is small, **exact tests for categorical data**, specifically, the exact one-sample test for the success probability of the **binomial distribution**, should be used.

*Polytomous Response (see **Polytomous Data**)*

Let $d_i = n_{i+} - n_{+i}$ and let $\mathbf{d}' = (d_1, \ldots, d_{I-1})$. Stuart [25] proposed a test of marginal homogeneity using the statistic

$$W_0 = \mathbf{d}' \mathbf{V}_0^{-1} \mathbf{d},$$

where $\mathbf{V}_0$, the sample **covariance matrix** under the null hypothesis of marginal homogeneity, has diagonal elements $n_{i+} + n_{+i} - 2n_{ii}$ and offdiagonal elements $-(n_{ij} + n_{ji})$. The asymptotic null distribution of W_0 is χ^2 with $I - 1\,\mathrm{df}\,(\chi^2_{I-1})$. For

2 × 2 tables, the test based on W_0 is identical to McNemar's test. For $I \times I$ tables, Stuart's statistic is the $I - 1$ df general association statistic from the class of Mantel–Haenszel methods.

Bhapkar [4] considered the statistic $W = \mathbf{d}'\mathbf{V}^{-1}\mathbf{d}$, where $\mathbf{V}_0$ is replaced with the unrestricted sample covariance matrix estimator $\mathbf{V}$, which has diagonal elements $n_{i+} + n_{+i} - 2n_{ii} - (n_{i+} - n_{+i})^2$ and off-diagonal elements $-(n_{ij} + n_{ji}) - (n_{i+} - n_{+i})(n_{j+} - n_{+j})$. The statistic W is asymptotically optimal, as shown by Wald [26], and can be computed using weighted **least squares** methodology for the analysis of categorical data [10] (*see* **Categorical Data Analysis**). Ireland et al. [11] noted that $W = W_0/(1 - W_0/n)$.

Although maximum likelihood estimators of the cell probabilities under the hypothesis of marginal homogeneity cannot be expressed in closed form, likelihood methods can also be used to test marginal homogeneity. Madansky [19] gave the generalized maximum **likelihood ratio test** comparing the likelihood maximized under the hypothesis of marginal homogeneity to the likelihood maximized in the unrestricted case. The likelihood ratio test is also presented by Plackett [22, pp. 79–80], who uses the approach of Wedderburn [27]. Firth & Treat [8] and Lipsitz [16] describe how to conduct this test using standard statistical software.

An alternative likelihood-based approach tests marginal homogeneity in the context of the model for quasi symmetry by comparing the maximized likelihoods for the symmetry and quasi-symmetry models (see, for example, Agresti [2, pp. 358–359]). While this test can be carried out using standard software for fitting a **loglinear model**, it is conditional on the model of quasi-symmetry holding.

For polytomous responses ($I > 2$), the hypotheses of marginal homogeneity and symmetry are not equivalent. Under the null hypothesis of symmetry, the expected count in the (i, j) cell, with $i \neq j$, is estimated by $(n_{ij} + n_{ji})/2$. Substituting the estimated expected cell counts into the usual formula for the Pearson χ^2 test, Bowker [5] derived the statistic

$$X^2 = \sum_{i<j} \frac{(n_{ij} - n_{ji})^2}{n_{ij} + n_{ji}}.$$

Under the null hypothesis of symmetry, X^2 is approximately $\chi^2_{I(I-1)/2}$. When $I = 2$, this test is identical to McNemar's test.

A likelihood-ratio test can also be used. The test statistic is

$$G^2 = 2 \sum_{i \neq j} n_{ij} \log \left(\frac{2n_{ij}}{n_{ij} + n_{ji}} \right).$$

Since the hypothesis of symmetry has a loglinear model representation, G^2 can be computed using standard software for fitting loglinear models.

*Ordered Categorical Response (see **Ordered Categorical Data**)*

The tests of marginal homogeneity described in the previous section use $I - 1$ df to compare the I pairs of marginal proportions. For ordered categorical variables, alternative tests that use the additional information provided in the ordering of the categories are more powerful for certain types of departures from the null hypothesis.

One approach is to compare marginal mean scores instead of marginal distributions. Given a set of scores that are appropriately assigned to the categories according to the alternative one wishes to detect, 1 df tests of marginal homogeneity analogous to the Stuart and Bhapkar tests can be carried out. The corresponding Stuart-type statistic (using the null covariance matrix estimator $\mathbf{V}_0$) is the Mantel–Haenszel mean score statistic; this test is discussed in White et al. [28]. If marginal rank scores are assigned, the statistic is equivalent to the Friedman [9] test obtained from a two-way rank analysis of variance with subjects as blocks (*see* **Ranks**). Agresti [1, Section 2.3] discusses the corresponding Bhapkar-type statistic (using the unrestricted covariance matrix estimator $\mathbf{V}$) and gives additional references; this test can be computed using weighted least squares methodology for the analysis of categorical data (*see* **Categorical Data Analysis**).

Another approach to testing marginal homogeneity for ordered classifications is based on the conditional symmetry model [20; 2, pp. 361–364]. This loglinear model has only one more parameter than the symmetry model. When conditional symmetry holds, a 1 df chi-square statistic for testing marginal homogeneity is the difference between the likelihood-ratio lack-of-fit statistics for the symmetry and conditional symmetry models. Agresti [1] mentions additional methods useful in the analysis of ordered categorical responses.

Example

Table 2 displays the cross-classification of right eye and left eye unaided distant vision grade in 7477 women employees, aged 30–39 years, in British Royal Ordnance factories during 1943–1946. The outcome variable of interest is an ordered categorical variable with four levels. These data, first quoted by Stuart [24], have been analyzed by numerous authors.

First, treating the categories as nominal rather than ordered, the tests of marginal homogeneity give χ^2 statistics of 11.957, 11.976, and 11.986 for Stuart's W_0, Bhapkar's W, and Madansky's likelihood-ratio statistic, respectively. With respect to the χ^2_3 null distribution, all are significant at $\alpha = 0.01$. The alternative likelihood-based approach of testing marginal homogeneity in the context of the quasi-symmetry model gives a likelihood-ratio statistic of $19.250 - 7.274 = 11.976$, also with 3 df. The values 19.250 and 7.274 are the likelihood-ratio statistics for symmetry (6 df) and quasi-symmetry (3 df), respectively. Bowker's test for symmetry gives $X^2 = 19.107$, which agrees closely with the corresponding value from the likelihood-ratio test.

If one treats the categories as ordered, the use of equally-spaced scores for the levels gives χ^2 statistics of 11.947 (Mantel–Haenszel mean score) and 11.97 (weighted least squares). The Friedman statistic (Mantel–Haenszel mean score test using rank scores) is 11.885. With respect to their asymptotic χ^2_1 null distributions, all three of these criteria are significant at $\alpha = 0.001$.

The likelihood-ratio lack-of-fit statistic from the conditional symmetry model is 7.35 with 5 df. Since this model provides a satisfactory fit to the data ($P = 0.2$), the difference between the likelihood-ratio statistics from the symmetry and conditional symmetry models also tests marginal homogeneity. The value of the statistic is $19.250 - 7.35 = 11.9$, which is also significant at $\alpha = 0.001$.

Table 2 Right eye and left eye unaided distance vision of 7477 women

Grade of right eye	Grade of left eye				
	Highest	Second	Third	Lowest	Total
Highest	1520	266	124	66	1976
Second	234	1512	432	78	2256
Third	117	362	1772	205	2456
Lowest	36	82	179	492	789
Total	1907	2222	2507	841	7477

Related Topics

The above methods are useful in analyzing matched pairs from a single population. In some situations there may be multiple populations defined by additional covariates of interest. If all covariates are categorical with a sufficiently large sample size in each covariate strata, a wide variety of types of regression models can be fitted using the general weighted least squares approach [10], which is described specifically for correlated responses by Koch et al. [13] and others. This methodology is applicable for binary, polytomous, and ordered categorical variables. A major shortcoming, however, is that this method fails if there are continuous covariates and/or small stratum-specific sample sizes.

Maximum likelihood regression models for matched pairs with binary data are discussed by Cox & Snell [7], Lipsitz et al. [18], and other authors. Breslow & Day [6] focus specifically on the use of conditional logistic regression (*see* **Logistic Regression, Conditional**), in the analysis of matched case–control studies. The **generalized estimating equations** (GEE) procedure of Liang & Zeger [14] and its extensions can also be used to analyze matched binary outcomes with covariates. Generalizations of the GEE methodology to polytomous and ordered categorical outcomes have also been studied [3, 12, 15, 17, 21, 23].

Matching, Probabilistic

Record linkage is usually concerned with establishing which records relate to the same individual. In the widest sense, record linkage is virtually universal in organizations that process information about people, and is usually achieved via some form of personal identifier, such as a case reference number in a hospital or a national insurance number in a state benefit system. When such unique personal identifiers are not available or feasible, record linkage must make the best possible use of the personal identifiers which are present, such as name, date of birth, area of residence, and so on. Probability matching is the key technique to have been developed to maximize the accuracy of linkage decisions based on the level of agreement and disagreement between the identifiers on different records [9].

Whenever such personal identifiers as name or date of birth are recorded or are transcribed other than electronically, it is possible that different information will be entered on different records relating to the same person (*see* **Data Management and Coordination**). Such discrepancies can arise for a wide range of reasons. Some discrepancies involve error or uncertainty: a name or date may be misheard, the person involved may not be clear about an item of identification, different names may be used in different contexts (formal versus informal), or data may be misread or miskeyed during transfer from one record to another. Other discrepancies reflect changes in circumstances such as a change of name (especially when women get married) or a change of residence.

Whatever the reason for such discrepancies, their presence means that a reliance upon exact correspondence of identifiers to establish that records belong to the same individual will usually lead to a large number of links being missed. For example, in the centrally held linked data set of hospital discharge records in Scotland, there is a discrepancy rate of an order of magnitude of 2%–3% for each of the identifiers first initial; surname; and day, month, and year of birth. Thus an insistence that all five of these identifiers matched exactly would involve losing 10–15% of true matches. Probability matching allows us to link records despite the existence of such discrepancies in identifying information. In Scotland, relatively straightforward methods of probability matching have produced an accuracy of around 99% on such data [6].

Probability matching translates the level of agreement and disagreement between each item of identifying information on two records – for example, both have first initial "J" or there is a discrepancy of one day in the day of birth – into a mathematical score or probability weight, which can be aggregated across all items to produce a relative probability that the two records belong to the same individual. Put more simply, when two items of identifying information are the same on two records, this increases the probability that they belong to the same person. When they are not the same, this decreases the probability. Probability matching puts these almost tautologic observations into systematic form and quantifies their implications [13].

Thus a very simple insight lies at the heart of probability matching. The skill and complexity of the technique lies in adapting the application of this insight to the precise characteristics of the records to be linked. Success in probability matching comes from staying close to the data and being guided by the emergent properties of each linkage.

This is very much the philosophy of Howard Newcombe, who is the founding father of probability matching, having first developed the technique in Canada in the 1950s [2, 14], and who has been involved in its progress ever since. The torch was taken up by the Oxford Record Linkage System in the 1960s [1] and by Scotland from the 1970s onwards [5, 6]. In the past ten years there has been a burgeoning of interest and a wider spread of probability matching techniques.

The statistical formalization of the theory of probability matching has tended to follow in the wake of its practical development. Thus Fellegi & Sunter [3] formalized the theory underlying Newcombe's early work. There is some debate about the importance of statistical formalization for the progress of probability matching [12]. This account, while accepting the importance of statistical formalization in confirming the validity of the technique, follows Newcombe in stressing the empirical and pragmatic aspects. We are primarily interested in the practical application of the technique to achieve the most accurate and efficient results.

The assumption that record linkage is about linking records belonging to the same individuals is

purely for clarity of exposition. The field of application is much wider of course; including, for example, the linkage of mothers to babies or linkages between the records of different members of families in general.

The Elements of Record Linkage Using Probability Matching

Record linkage using probability matching can be seen as involving three elements or stages. The first involves bringing pairs of records together to be compared. The second involves calculating the probability weight for each pair of records. The third involves making the linkage decision based upon the probability weights. Most attention has tended to focus on the second of these phases, the calculation of probability weights. The other elements are just as important and may well be where improvements will be concentrated in the future.

Bringing Records Together

It is normally not feasible to calculate probability weights for all the pairs of records in the data to be linked. For example, the one million Scottish hospital discharge records for a year contain approximately 500 000 000 000 pairs of records. The computing resources that are usually available would not permit probability weights for all of these pairs to be calculated.

We must restrict the number of pairs of records to be compared. This has traditionally been done by using some form of **blocking**, whereby only those pairs of records that share at least one common set of identifying items are compared [4]. By doing this, we run the risk that records which do belong to the same person will not be compared. The trick is to achieve the necessary reduction in pair comparisons while minimizing the number of links missed because the necessary comparisons were not carried out. For example, a common set of blocking criteria is as follows: compare only those records that share the same compressed surname (see below) and first initial, or that share the same date of birth. Pairs of records that differ both in terms of surname or initial and date of birth would not be compared. In a UK context, well under 0.5% of true links would generally be missed by such a blocking configuration.

Traditionally such blocking has been achieved by sorting the files involved to bring together records sharing the specified identifiers. Thus in terms of the blocking criteria outlined above, the files would be sorted by compressed surname and first initial. All records having these identifiers would be compared. Then the files would be sorted by date of birth. All records containing the same date of birth would be compared. Usually, at least one further sort is required to reconcile matches made in the two separate passes through the data.

When data volumes become large, this method has the disadvantage that no matter how few records are being added to an existing linked file, all the records involved must be sorted several times. Thus for example, the main Scottish linked data set contains 14 million linked records. Linking in an additional month's data or even an external data set such as a survey of 10 000 individuals would require sorting the entire file several times. This is extremely time consuming and is not feasible on a routine, frequent basis.

In Scotland, this problem has been solved by indexing incoming or "newcomer" records in memory [7]. The record numbers of all newcomer records sharing the same day and month of birth, for example, are stored in the same row of an array indexed by month and day of birth. The existing or catalog file is read through sequentially. Each catalog record can thus be directed for comparison to the newcomer records sharing its month and day of birth. The same principle can be applied to any numeric element of an identifier, such as the numeric element of a compressed surname. Thus the blocking usually achieved by sorting is mimicked in memory. Each of the newcomer records retains information about the catalog record with which it has achieved the highest probability weight. The major advantage of this technique is that the larger of the two files does not need to be sorted at all. A methodologic implication of the method is that each newcomer record is allowed to link to only one record already in the linked file. This may have advantages (see below).

The development of techniques of rapid direct access by any kind of key (not just numeric) inherent in the development of **database** management software should allow the generalization of such methods of selective comparison. Much more flexibility will be possible in the definition of the subset of pairs of records for which probability weights are to be calculated.

Calculating the Probability Weights

This is the aspect of record linkage which has been best documented, especially by Newcombe [9]. The key to the calculation of probability weights is the **odds ratio**. An odds ratio is calculated for every outcome of the comparison between two identifiers; for example, both records have first initial "J" or the day of birth is one day different. The odds ratio is simply the ratio between the frequency of a given outcome in pairs of records that relate to the same person and the frequency of a given outcome in pairs of records that do not belong to the same person. The odds ratio expresses mathematically how much a given outcome increases or decreases the probability that two records belong to the same person.

Let us take as an example, agreement of month of birth (e.g. both records have month of birth June).

The top line of the odds ratio is the frequency of agreement of month of birth in two records belonging to the same person. This depends upon how much miscoding takes place. Let us say that there is a miscoding of month of birth in one or another record for 3% of the time. Thus the top line of the odds ratio is 97%, meaning that for 97% of the time there is random agreement of month of birth in two records belonging to the same person.

What is the frequency of agreement of month of birth among records not belonging to the same person? This is broadly equivalent to asking how often is there random agreement of month of birth. There are 12 months in the year, so there will random agreement 1/12, or 8.3%, of the time.

The odds ratio for agreement of month of birth is thus 97% divided by 8.3%, or roughly 11.6. Agreement of month of birth thus increases the probability that two records belong to the same person 11.6 times.

This accords with common sense. The more uncommon an identifier is, the greater will be the odds ratio given by agreement. Agreement of the less common first initial "Z" will give a much higher odds ratio than agreement of the more common initial "J". The same principle can be applied to disagreement and levels of disagreement.

The odds ratios from different identifiers can be combined by multiplication to give the overall odds ratio derived from the agreement and disagreement of all identifiers to be compared for two records. Because of the clumsiness involved in multiplying odds, they are usually converted to logarithms to base 2 or binit weights, which can then be added and subtracted.

The most important principle in combining weights for different identifiers is the assumption of independence. Weights must only be given for independent sources of information. It would be illegitimate, for example, to give full weights both for area of residence and general practitioner, since these are highly correlated. Weights can, however, be made conditional; for example, different weights for the initials of men and women [9].

How do we obtain the frequencies of the outcomes in the first place? This tends to be a process combining a priori knowledge, **bootstrapping**, and common sense. A first linkage can be carried out using weights borrowed from previous similar linkages or worked out a priori (e.g. agreement of month of birth at around odds ratio 12). This first linkage can be used to produce files of pairs which do and do not belong to the same person. These "linked and unlinked" files can be used for more precise empirical derivation of odds ratios for a further linkage, and so on. A valuable feature of probability matching is its **robustness** in the face of imperfections in the probability weights assigned to outcomes. As long as weights are broadly correct, the linkage will work.

The final refinement of weights will usually take place after inspection of a sample of the weights close to the decision threshold alongside the pairs of records that generated them. Features of the linkage will usually emerge which could not have been anticipated in advance. To paraphrase Newcombe, linkage is an empirical, iterative and above all common-sense procedure [13].

A Brief Note on Name Compression. Discrepant spelling of surname is one of the most common aspects of mismatching identifiers in two records belonging to the same person. Various methods have been proposed for dealing with this, but a commonly used solution is to combine the method of Soundex codes, whereby similar sounding consonants are brought together and vowels are largely ignored, with the NYSIIS name compression algorithm, whereby other commonly miscoded elements of surnames are brought together. The resulting Soundex/NYSIIS codes are treated like any other identifier [9].

Making the Linkage Decision

The Linkage Threshold. The probability weights calculated by the methods outlined above do not represent absolute odds that the records concerned belong to the same person. They are relative odds that serve to order the pairs in a particular linkage according to the likelihood that they belong to the same person.

A useful diagnostic output in any linkage is a **frequency distribution** of the probability weights achieved by the pair comparisons. This is usually, but not always, bimodal. The bimodal distribution is produced by the superimposition of the weight distribution for pairs of records which do belong to the same person on the distribution for pairs which do not belong to the same person.

The decision threshold for linkage is usually determined by clerical inspection of a sample of pair comparisons across the weight range. The linkage decision can be made either completely automatically or can use supplementary clerical checking. If automatic linkage is chosen, a single threshold is chosen based on the sample checking. If a pair scores above the threshold, the records are linked. If a pair scores below the threshold, the records are not linked. If supplementary clerical checking is involved, then two thresholds are used to define a "gray zone" within which pairs will be clerically checked to make the final decision. Above the higher threshold, links are accepted automatically. Below the lower threshold links are rejected automatically. Within the "gray zone", human judgment is used to make the final decision.

The conversion of relative odds to absolute odds depends upon several factors, including the way in which the linkage is structured. Structuring the linkage to optimize the "terms of conversion" of relative odds to absolute odds is one of the most important aspects of designing a linkage.

The absolute odds required for acceptance that two records belong to the same individual depends upon the purpose of the linkage and the relative cost of a **false positive** link (linking two records which do not belong to the same person) compared with a **false negative** link (failing to link two records which do belong to the same person). For most statistical purposes, a best estimate linkage is required, and the decision threshold will be set at absolute odds of 50/50. For administrative purposes, it may be vitally important that wrong links are not made, while it is less crucial that links are missed. The decision threshold would thus be set at relatively high absolute odds. Where the purpose of the linkage is simply to trawl for potential candidates for linkage – the links themselves being established by other means – a relatively low threshold would be set.

Converting Relative Odds to Absolute Odds: the Importance of Context. As a first step in converting relative odds into absolute odds, Newcombe [9] has proposed numeric rules relating to two files: one a search file and the other a file being searched. Proposition A is that the higher is the proportion of records in the search file for which there exists a linked record in the file being searched, the better will be the conversion factor between relative and absolute odds. Proposition B is that the larger is the file being searched, the worse will be the conversion factor between relative and absolute odds.

These numeric considerations in converting absolute odds to relative odds show that the meaning of a given probability weight depends upon the wider context of the linkage, and in particular on the relationships between the records in the files to be linked [10].

This is a crucial insight, the wider implications of which must be drawn out. In designing a linkage, it is important to structure the linkage so as to take maximum advantage of the structures of the files involved and the relationships between them. For example, are the relationships between the records in two files one-to-one, one-to-many, or many-to-many? How much confidence do we have in previous linkages that may have been carried out on the files involved? How confident are we that a file to be linked already contains only one record per person?

For example, if we want to link to each other a set of hospital discharge records, we have no a priori knowledge of how many records belong to each person. Our best bet is to do a conventional internal linkage and inspect all resulting pairs in setting a threshold. In this case we have relatively little leverage to improve the terms of conversion between relative odds and absolute odds.

However, if we are linking a file of hospital discharge records to a file of death records (*see* **Death Certification**), we can obtain some "structural leverage". Death only occurs once, and assuming that this is reflected in there being only one death record

per person in the file of death records, the linkage becomes many-to-one. Each hospital discharge record should link to only one death record. The terms of conversion from relative to absolute odds can be improved by only retaining, for each hospital discharge record, the best (highest weight) link which is achieved to a death record. Similarly, at the other end of the life cycle, if we are linking babies to mothers, assuming that the mothers' records themselves have been correctly linked, we should allow each baby to link to only one mother.

The most powerful leverage occurs when there is a close to a one-to-one relationship between the files to be linked. For example, as groundwork for the creation of a unique patient identifier for the Scottish population it was necessary to link the regionally operated Community Health Index (CHI) to the National Health Service Central Register (NHSCR) in Scotland. Because both files had close to 100% population coverage, there was a very high a priori probability that there existed an NHSCR record for every CHI record, thus maximizing the conversion factor in terms of Newcombe's rules. Again, by applying the best-link principle, whereby only the highest weighted link for each CHI record was accepted, a massive degree of leverage was obtained. Administratively acceptable links (involving very high absolute odds of linkage) were achieved at low relative odds [8].

Summary

Record linkage using probability matching may be implemented in a very simple and straightforward way or it may involve a highly complex and delicate **algorithm**. However it is done, it is based on simple and initially intuitive insight. Success in record linkage comes from adapting the basic principle of probability matching to the precise characteristics of the data involved – both in terms of making best use of the identifiers available and in terms of structuring the linkage to obtain the greatest leverage from the relationships between the records involved.

Implications

Record linkage using probability matching is an extremely powerful tool, and will become increasingly powerful as techniques improve and computing hardware considerations become less restrictive. Because of its ability to bring together information in ways which were not part of the original intent when the data were first collected, it can be seen as posing a threat in terms of data **confidentiality** and individual privacy.

At all times, the benefits that record linkage using probability matching may bring for patient administration and medical research must be balanced against the dangers that it poses [11]. Careful monitoring and supervision are required.

Matching

Before discussing the procedure known as matching, it is necessary to provide some background and motivation for its use. In epidemiologic studies, it is typically the situation that valid **estimation** of the strength of the relationship between a response variable D of interest (e.g. the presence, $D = 1$, or not, $D = 0$, of some particular disease) and an independent variable E of interest (e.g. the presence, $E = 1$, or not, $E = 0$, of some exposure) necessitates the consideration of so-called **confounding** factors (*see* **Confounder**). Ignoring or inappropriately accounting for the effects of confounding factors can often lead to invalid (i.e. statistically inconsistent) and inefficient estimation of the true exposure–disease association of interest.

As a simple example, suppose that the dichotomous response (or disease) variable D of interest is the presence or absence of lung cancer and that the dichotomous independent (or exposure) variable E of interest is the presence or absence of a history of occupational exposure to asbestos. Then, a dichotomous variable C such as cigarette smoking status (e.g. evidence, $C = 1$, or not, $C = 0$, of a history of smoking), which is an established risk factor for the development of lung cancer, will be a confounder if, *in the data under consideration*, its distribution among the group of study subjects with a history of occupational exposure to asbestos (the "exposed group") is different from its distribution among the group of study subjects who do not have a history of occupationally related asbestos exposure (the "unexposed group"). If C is, in fact, a confounder in the data under consideration, then appropriate adjustment for C *at the analysis stage* (e.g. by **stratification** methods or, equivalently, by multivariable modeling) would be needed. In our particular example involving the three dichotomous variables D, E, and C, one could fit the **logistic regression** model $\text{logit}\,[\Pr(D = 1)] = \beta_0 + \beta_1 E + \gamma_1 C$ by appropriate **likelihood** methods to obtain an adjusted (for C) estimated **odds ratio** $\exp(\hat{\beta}_1)$ and to obtain a corresponding **interval estimator** for the population E–D odds ratio $\exp(\beta_1)$. Here, we are assuming that C is not an **effect modifier** (i.e. there is no **interaction** between E and C), so that it is not necessary to include the product term EC in the above model; we will make this no interaction assumption in our discussion to follow.

However, adjustment for C at the analysis stage can be problematic. For example, if almost all of the study subjects with a history of smoking have lung cancer (i.e. are "cases"), and if a large proportion of the study subjects with no smoking history are "noncases", then such stratum-specific imbalances can lead to poor statistical efficiency in the point and interval estimation of the odds ratio parameter $\exp(\beta_1)$. In more realistic situations where there are typically several confounders to consider simultaneously, distributional imbalances in strata defined by combinations of levels of these confounders can severely compromise the reliability of multivariable modeling analyses.

Design Options: Restriction and Matching

By using appropriate strategies at the *design stage* of a study, it is often possible to avoid many of the confounder-related distributional imbalance problems mentioned earlier. For example, consider a potentially confounding variable such as gender. One way to avoid completely any possible problems associated with an analysis stage adjustment for the variable gender is to decide, at the design stage, to restrict the study so that it involves either only males or only females. This simple study design option is called (*total*) *restriction* because the potential confounder is completely restricted to have exactly the same value for every study subject. Clearly, the disadvantage of (total) restriction is the lack of generalizability of the study results; in our example, by employing (total) restriction with respect to gender, the study conclusions would necessarily only pertain either to males or to females.

Matching, in contrast to total restriction, is a form of *partial restriction* on study subject selection, partial in the sense that only the so-called "referent (or comparison) group", and not the "index group", is chosen subject to certain restrictions. More specifically, for follow-up studies (*see* **Cohort Study**), once the index group of exposed ($E = 1$) subjects is randomly selected from the population of interest, the referent group of unexposed ($E = 0$) subjects is then chosen to be similar to the exposed group with respect to the distributions of one or more potentially confounding factors. For **case–control studies**, once the

index group of diseased ($D = 1$) subjects is chosen at random from the population of interest, the referent group of nondiseased ($D = 0$) subjects is picked to be similar to the cases with respect to the distributions of one or more potentially confounding factors. We use the word "similar", rather than "identical", because the index and matched referent groups will generally not have exactly the same confounder distributions after matching; the degree of similarity will depend on the type and the extent of matching employed.

To discuss types of matching schemes, we need to distinguish between matching on continuous variables (e.g. age, weight, cholesterol level) and matching on categorical variables (e.g. gender, race). Matching on a continuous variable (say, X) necessitates the specification of a rule for deciding when an index subject's value (say, X_1) and a referent subject's value (say, X_0) are "close enough" to declare that the two subjects are "matched" on X. In so-called "caliper matching", one specifies a caliper (or tolerance) value C and declares the index and referent subjects to be matched if $|X_1 - X_0| \leq C$.

The smaller is C, the tighter will be the match on X, but, correspondingly, the harder it will be to find index–referent pairs to satisfy such a stringent matching criterion [8, 9].

Since, in standard epidemiologic practice, variables are generally categorized for matching purposes (e.g. note that caliper matching defines categories of width C), we will henceforth focus on so called *category (or frequency) matching*. In particular, index and referent subjects are said to be matched on a categorized potential confounder if they are in the same category of that variable. In the realistic situation where category matching involves several potential confounding variables, index and referent subjects are said to be matched when they are in the same category for each and every one of the categorized matching variables under consideration. For example, suppose that there are three categorized matching variables of interest: age in four categories (30–39, 40–49, 50–59, and 60–69), race (black, white, and other), and gender (male and female). Then, there will be 24 strata defined by the various combinations of these three matching variables, with, for example, one stratum consisting of black females between the ages of 40 and 49.

In general, then, matching can be considered to be pre (or design stage)-stratification, as opposed to **post** (or analysis stage)-**stratification**, with the goal of such matching being to form strata that are sufficiently balanced to permit valid, stable, and efficient statistical analyses. Once matching is employed at the design stage, it is mandatory at the analysis stage to take the matching into account via the use of appropriate stratified analysis methods [5]. Such **categorical data analysis** procedures include the approach of **Mantel & Haenszel** [6] and the use of conditional logistic regression methods [1, 4] (*see* **Logistic Regression, Conditional**; **Matched Analysis**).

Types of Matching Schemes

There are various types of matching schemes that can be used. One of the more popular matching schemes, especially in case–control studies, is known as *pair matching*. Pair matching refers to the special situation when each stratum is assumed, for analysis purposes, to contain exactly one index subject and one referent subject. However, this assumption will generally lead to an inefficient stratified analysis when the pairing is artificial and unnecessary. For example, for a stratum of cases and controls consisting of black females between the ages of 40 and 49, any case in that stratum could theoretically be paired with any control without altering the basic within-stratum structure. Retaining this "random" pairing in the analysis is clearly unwarranted, and such an "overmatched analysis" generally leads to some loss in statistical efficiency [2]. In contrast, the term "**overmatching**" commonly refers to an undesirable design-stage strategy of matching on variables that make the cases and controls too much alike with respect to exposure status. Such variables are generally of two types, namely, so-called "intervening variables" that are intermediate in the causal pathway between exposure and disease and variables that are (at best) very weak risk factors for the disease in question but are nevertheless highly correlated with exposure status [10]. Such overmatching can sometimes lead to a meaningful loss in statistical efficiency, especially in case–control studies (see "Discussion" below).

A generalization of pair matching is a procedure known as R-to-1 matching, where each stratum is considered to contain one index subject and exactly R referent subjects. Miettinen [7] and others have shown that there is little to gain statistically by taking $R > 4$. For example, when comparing R-to-1

matching with pair matching ($R = 1$) in case–control studies, Ury [11] has shown that the **Pitman efficiency** of the Mantel–Haenszel test for stratified data is $2R/(R + 1)$, so that the Pitman efficiency only increases from 1.600 for $R = 4$ to 1.667 when $R = 5$.

In the most general category matching situation, a particular stratum (say, the gth of G strata) may contain R_g referent subjects and S_g index subjects, giving a *matching ratio* of R_g/S_g (which is not necessarily an integer). If this matching ratio varies with g, then we have a *variable matching ratio plan*. If the matching ratio does not vary over the strata (e.g. as with R-to-1 matching), then we have a *fixed matching ratio plan*. With either plan, the appropriate data analysis would still appropriately accumulate stratum-specific information; and, in terms of statistical efficiency, a fixed matching ratio plan is usually somewhat better.

Advantages and Disadvantages of Category Matching

Some of the *positive aspects* of category matching in epidemiologic studies are as follows:

1. Category matching a set of referent subjects to a **random sample** of index subjects can often lead to a more statistically efficient analysis than can be obtained by choosing the same number of referent subjects by random sampling. This efficiency advantage will tend to occur when the matching variables are well-established determinants of the response variable (e.g. are important risk factors for the disease under study) and are expected to be quite differentially distributed between the exposed and unexposed groups in the observed data (i.e. are anticipated to be strong confounders). For more detailed discussion, see Kupper et al. [5] and Karon & Kupper [3].
2. Matching on a variable like neighborhood of residence can lead to efficient adjustment for the potentially confounding effects of a wide range of social and economic factors that would be difficult, if not impossible, to measure and hence to control.
3. Matching can often lead to savings in time and money. For example, when the cases in a case–control study are chosen from records in different hospitals or in different companies within some industry, it is preferable, for reasons of simplicity and convenience in data collection (and also possibly on validity and efficiency grounds), to choose controls for each case from that same set of hospital or company records.
4. Matching in the selection of the referent group with respect to a given set of potential confounders does not preclude controlling for other nonmatched confounders at the analysis stage via multivariable modeling procedures like conditional logistic regression. In this regard, a recommended strategy would be to match only on important risk factors considered a priori to be highly likely to manifest themselves as strong confounders in the data, and to adjust (if necessary) for other factors at the analysis stage.

Some possible *negative aspects* of category matching in epidemiologic studies are the following:

1. Category matching can be a costly enterprise, both with regard to the *direct* costs of time and labor required to find the appropriate matches and the *indirect* costs (in terms of information loss) owing to the discarding of available referents not able to satisfy possibly stringent matching criteria.
2. When employing category matching, simultaneous recruitment of cases and controls can be problematic since there is no way to know in advance exactly how many controls will be needed to meet sample size requirements in different matching strata defined by the sample of cases. To circumvent this problem, a new "randomized recruitment" method for matching has been developed [12, 13].
3. The referent group chosen by category matching ends up being more like the index group than like the underlying population of referents being sampled. In particular, matching generally precludes the evaluation of the underlying population relationships between the matching variables and exposure status in follow-up studies or between the matching factors and disease status in case–control studies.
4. If the strata defined by the category matching process are wide (so that there is room for the matching factors each to vary sufficiently in value within particular strata), it is possible that stratum-specific residual confounding due to the matching factors can still be present.

Appropriate adjustment for such stratum-specific residual confounding at the analysis stage can be accomplished using multivariable modeling procedures.

Discussion

In summary, category matching on potential confounders can be a fruitful design-based strategy in both follow-up and case–control studies when reliable information, based on knowledge of the disease process under study and previous research findings, indicates that such variables are well-established disease determinants (i.e. are strong risk factors) expected to be quite differentially distributed between exposed and unexposed groups if matching is not employed (e.g. under random sampling of the referent group).

As a word of caution, the use of matching requires more care in case–control studies than in follow-up studies. Since exposure information is collected *after* the occurrence of disease in case–control studies, indiscriminate *overmatching* of controls to cases simultaneously on several factors can lead to a substantial loss in efficiency relative to random sampling of the control group. For example, consider a pair-matched case–control study involving n case–control pairs, where a is the number of pairs where both the case and control are exposed, b is the number of pairs where the case is exposed and the control is not, c is the number of pairs where the control is exposed and the case is not, and d is the number of pairs where neither the case nor the control is exposed. Then, the Mantel–Haenszel test statistic [6] takes the form $(b-c)^2/(b+c)$, and the appropriate odds ratio estimator is b/c (namely, the ratio of discordant pairs). Hence, the effective sample size in such a study is the total number of discordant pairs $(b+c)$, not n. If the matching variables are each correlated with the exposure variable, then overmatching generally increases the number of uninformative pairs in the observed data, namely $(a+d)$, thus leading to a (possibly substantial) loss in efficiency. Thus, in case–control studies especially, the best policy is to consider as candidate matching variables only well-established strong risk factors for the disease in question. As mentioned earlier, matching either on intervening variables or on very weak risk factors highly correlated with exposure status should be avoided.

Maternal Mortality

Maternal mortality claims the lives of some 585 000 women a year, 99% of them in the developing world. It is the main cause of death among young women aged 15–19, and the third or fourth most common cause in women of childbearing age, generally defined as 15–49. The differences between the developed and the developing world in levels of maternal mortality are greater than for any other indicator of public health: in developed countries a woman has a lifetime risk of maternal death of 1 in 1800: in developing countries this risk is 1 in 48. However, the risks range from 1 in 4000 in the industrialized of countries of northern Europe, to 1 in 12 in eastern and western Africa [1]. Maternal mortality also has severe consequences for the health of children: in developing countries the baby born to a woman who dies in childbirth rarely survives, and her older children face much greater risks of death [7].

Definition of Maternal Mortality

A maternal death is the death of a woman while pregnant, or within 42 days of the termination of pregnancy, irrespective of the duration and site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes [9]. This classification therefore includes deaths from abortion, spontaneous or induced, or from an ectopic pregnancy, but not deaths in pregnancy or the postpartum period caused by violence or accidents.

The distinction between causes related to, or aggravated by, pregnancy or its management gives rise to two other definitions: "direct" and "indirect" obstetric deaths. Direct obstetric deaths are those related to complications of pregnancy, labor or in the 42-day postpartum period (the puerperium), from interventions, or from incorrect treatment or omissions in treatment. Indirect obstetric deaths are those resulting from a pre-existing disease, or one that developed during pregnancy, and that is aggravated by pregnancy. Before 1975, deaths from indirect causes were not classified as maternal deaths.

Causes of Maternal Deaths

On the evidence of a few good community-based studies, direct causes account for the majority–80%–of maternal deaths. In turn, five major causes account for 80% of these direct maternal deaths. Although there is some variation in their relative importance among regions, the distribution of the five causes at global level is as follows: hemorrhage (25%); sepsis (15%); unsafe abortion (13%); eclampsia (8%) and obstructed labor (7%). Indirect causes of maternal death, such as anemia, malaria, cardiovascular disease, hepatitis, and diabetes, account for the remaining 20% of all maternal deaths [1] (*see* **Cause of Death, Underlying and Multiple**).

Sources of Data on Maternal Mortality

Gathering data on maternal mortality is difficult and expensive – and often beyond the resources of the very countries in which the problem is greatest. The chief sources of information are vital registration systems, health services data, and population-based surveys (*see* **Administrative Databases**; **Surveys, Health and Morbidity**; **Vital Statistics, Overview**).

Few developing countries have registration systems to provide information on the numbers of deaths (*see* **Death Certification**). Those that do can rarely provide information on the cause of death, or require that death certificates note pregnancy status. Moreover, in countries where induced abortion is illegal, official statistics seldom fully reflect deaths from this cause. Health service statistics suffer from **selection bias**: women who die in pregnancy or childbirth in health facilities often differ in important health and socioeconomic characteristics from pregnant women in the broader community. It is also difficult to define the appropriate catchment area of a hospital (*see* **Hospital Market Area**) for the derivation of ratios and rates. **Population-based studies**, therefore, have been used increasingly to gather information. Their most important drawback is expense: maternal mortality is a rare event compared with **infant mortality**, for example, and sample sizes need to be very large to obtain reliable estimates. Costs are somewhat lower where questions are added to **censuses** or surveys: the "sisterhood method", for example, has yielded useful

information on maternal mortality by asking adult respondents whether any sisters have died in their childbearing years. The most reliable data, however, where vital registration is incomplete or lacking, are obtained from studies that identify all deaths to women of reproductive age (reproductive age mortality surveys, or RAMOS). Interviewers consult many community sources and then, on the basis of symptoms described by family members and health care providers, classify the deaths as maternal or otherwise. Very few countries have been able to afford these studies.

Given these problems, but faced with the need to measure progress in reducing maternal mortality, the **World Health Organization** (WHO) and the United Nations International Children's Emergency Fund (UNICEF) have recently developed new estimates of maternal mortality [10]. They used country data where available, adjusted for undercount and **misclassification**, and developed a model to predict values for countries with no reliable national data. At the global level, the new estimates represent a significant upward revision of the annual number of maternal deaths – an increase of 80 000 over the figure of just over 500 000 in use for the past 10 years.

Measuring Maternal Mortality

The three most common measures of maternal mortality are the lifetime risk, the maternal mortality rate, and the maternal mortality ratio. The ratio is the number of maternal deaths per 100 000 live births during a certain time period, and is, therefore, a measure of the risks women face when they are pregnant, generally called obstetric risk. However, in order to run this risk, women must be pregnant. The lifetime risk and the maternal mortality rate take account of fertility: they measure both obstetric risk, and the frequency with which women are exposed to that risk through pregnancy. This is seen most easily in the maternal mortality rate: the number of maternal deaths per 100 000 women of reproductive age during a certain time period. The following equation demonstrates the relationship [2]:

$$\text{maternal mortality rate} = \text{maternal mortality ratio} \times \text{general fertility rate}$$

$$\frac{\text{maternal deaths}}{\text{women } 15\text{–}49} = \frac{\text{maternal deaths}}{\text{live births}} \times \frac{\text{live births}}{\text{women } 15\text{–}49}.$$

In using data on maternal mortality it is important to note how the maternal mortality rate is defined. Historically, it was defined as the number of maternal deaths per 100 000 live births, i.e. the definition of the ratio given above, and this is still the definition used in the tenth revision of the **International Classification of Diseases** published by WHO in 1992 in order to provide consistency with previous editions [9]. However, in its analytical work on maternal mortality WHO also distinguishes between the rate and the ratio using the definitions given above [1, 10], as exemplified in Table 1. The distinction is important for directing attention to appropriate interventions.

Table 1 Measures of maternal mortality in developed and developing countries, 1990

	Maternal mortality ratio (maternal deaths per 100 000 live births)	Number of maternal deaths	Lifetime risk[a] of maternal death (1 in:)
World	430	585 000	60
More developed regions	27	4000	1800
Less developed regions	480	582 000	48

Sources: [1, Table 2; 10].

[a]Lifetime risk devised by Roger Rochat, Emory University School of Medicine, USA. Calculated as $1 - (1 - \text{MMR})^{(1.2\text{TFR})}$], where the maternal mortality ratio (MMR) is expressed as a decimal and the total fertility rate (TFR) is adjusted by 1.2 to allow for pregnancies not ending in live births.

The other measure of maternal mortality that also takes into account both the risks within pregnancy and the risks of pregnancy is lifetime risk. In fact, this is the more commonly used indicator of international disparity, conveying graphically the risks of pregnancy in countries with high fertility. Table 1 presents the regional differences in maternal mortality ratios and lifetime risk by region.

Wide though the differences in maternal mortality ratios are, they are much less than the differences in lifetime risk: the risks women face in pregnancy and childbirth are compounded by the frequency with which they face those risks.

Actions to Reduce Maternal Mortality

It follows that maternal mortality can be reduced by interventions that reduce fertility, and that reduce obstetric risk (*see* **Reproduction**). Reductions in the total number of pregnancies result in fewer women at risk of a maternal death: a comparison of maternal mortality in Bali, Indonesia, and Menoufia, Egypt in the 1980s provides a telling example. The maternal mortality ratio in Bali was 718: in Menoufia it was 190–3.8 times as high. Yet the maternal mortality rate of 69 in Bali was only 1.5 times as high as the rate of 45 in Menoufia – because fertility was lower in Bali [3]. Changes in fertility, closely associated with the adoption of family planning, therefore have an important impact on the maternal mortality rate (and on lifetime risk).

Changes in fertility can also affect the maternal mortality ratio by reducing the number of high-risk pregnancies – pregnancies that are unwanted and that may lead women to run the risk of unsafe abortion, or pregnancies in women of older age, or who have had four or more previous births, or whose last birth occurred less than two years previously. These women are often the first to use family planning services, when available. In Bali, contraceptive use was higher, and fertility rates lower among older women than in Menoufia. However, since, in general, most births occur to women at "safe" ages and parities, the majority of maternal deaths do too. Thus, the chief reductions in the maternal mortality ratio are to be achieved by reducing the risks in pregnancy.

Underlying the immediate medical causes of maternal death are many factors contributing to the risk of maternal death. Women's socioeconomic status is a powerful determinant of their health status–and of their access to health services. Socioeconomic status also affects fertility, and the risk of maternal death: women with no, or little, primary education have more children than women with secondary and higher education (*see* **Social Classifications**). Raising women's status is necessary to improving maternal health, but is a long-term objective. In the short term, interventions to reduce the number of obstetric complications, and the number of deaths among women who develop complications, are essential.

Basic Maternal Care

Women need care throughout pregnancy, delivery, and in the postpartum period. Antenatal care is necessary to inform women on how to take care of themselves throughout pregnancy and childbirth, how to recognize danger signals, and what to do should complications arise. It is also necessary to treat conditions that can lead to complications, such as anemia, or which are aggravated by pregnancy, such as malaria and viral hepatitis. Health facilities providing antenatal care, however, need to be linked closely with facilities able to deal with complications that may arise: it is doubtful whether antenatal care that is not part of a more comprehensive system contributes to maternal mortality reduction [6]. Care in delivery should include attendance by trained personnel, in clean conditions to prevent sepsis, and, again, with access to health facilities and providers with the skills, equipment, and drugs to prevent, detect, and manage complications during birth, and during the postpartum period. A recent review and **meta-analysis** (synthesis of findings) of studies of maternal mortality in developing countries indicates that care in the postpartum period is essential: 60% of maternal deaths occurred in the postpartum period [5]. Almost half of postpartum deaths – 45% – occurred in the first 24 hours after delivery, and nearly three-quarters within the first week. The time of death varied according to cause: most postpartum deaths from hemorrhage and pregnancy-induced hypertension (eclampsia) occurred during the first day and week after delivery: most postpartum deaths from sepsis occurred in the second week and later.

Essential Obstetric Care and Emergency Obstetric Care

While basic maternal care meets the needs of all women whose pregnancies, labor, or delivery are uncomplicated, or who are able to return to this care when a complication has been successfully treated, an estimated one-third to one-half of pregnant women develop obstetric complications, and an estimated 15% develop complications that require emergency care. Both essential obstetric care for all complications, and emergency care, have been known by the acronym EOC, giving rise to some confusion. The Inter-Agency Group (IAG) on safe motherhood, comprised of representatives of several of the UN agencies and nongovernmental organizations active in the field of reproductive health, recommends differentiating between these terms by use of the acronym ECOC for Essential Care of Obstetric Complications, and EMCOC for Emergency Care for Obstetric Complications. The obstetric functions provided by ECOC include the functions necessary for EMCOC and, according to the IAG, should be available to all pregnant women with problems, including complications of unsafe abortion. ECOC comprises: surgical obstetrics; anesthesia and medical treatment; blood replacement and manual procedures; labor monitoring, management of problem pregnancies, and neonatal special care (statement developed at the IAG meeting, February 1996).

Maternal Health

Reductions in maternal mortality cannot be equated with improvements in maternal health. They may even be associated with increases in maternal morbidity – the disabilities suffered by women as a result of pregnancy, childbirth, and abortion, or the exacerbation of existing health problems by pregnancy. It has been estimated that for every woman who dies in pregnancy, another 15 survive but suffer long-term consequences [8]. It is also important to recognize that maternal health is part of women's health more broadly defined: this might seem a truism, but some are concerned that emphasis on maternal mortality has stressed women's maternal roles to the exclusion of recognition of other influences on women's health that also, though more indirectly, would improve maternal health [6]. In a slightly different vein, others worry that the drive to measure mortality, and the impact of programs on mortality, may divert resources that would be better deployed in strengthening implementation of those programs. They argue for developing indicators that measure progress in increasing the availability, quality and utilization of maternity services, thus contributing to improved maternal health more generally [4]. The new estimates and methodology developed by WHO and UNICEF, should help to reduce this pressure to produce ratios and **rates**. It is generally agreed, however, that investments in maternal health services, including family planning, provide significant health benefits to women at low cost and are essential components of basic health care. Work [11] on the burden of death and disability caused by various diseases, and on the health benefits and costs of interventions, found prenatal and delivery care and family planning to be among the most cost-effective of health interventions (*see* **Health Economics**).

J. NASSIM

Mathematical Biology, Overview

Mathematical biology has become a flourishing field in which real mathematics combines with real biology. The field is represented by numerous refereed journals, including *Journal of Mathematical Biology, Bulletin of Mathematical Biology, Biomathematics, IMA Journal of Mathematics Applied in Medicine and Biology, Journal of Theoretical Biology, Mathematical Biosciences, Biological Cybernetics*, and *Theoretical Population Biology*. In addition, there are frequent biological articles in *Biophysical Journal* and *SIAM Journal of Applied Mathematics*, and occasional mathematical articles in *Journal of Neurophysiology*, and even *Journal of Molecular Biology*. Lecture note series include *Lecture Notes in Biomathematics* and *Lectures on Mathematics in the Life Sciences*. There are also a number of good recent general textbooks [4, 8, 14], an excellent collection of mathematically sophisticated research papers [12], a survey of applications and unsolved problems in biomedical imaging [3], and important monographs on computational biology [23], stochastic models of carcinogenesis [22], and cardiac arrhythmias [25]. Medical applications include tomographic imaging, genetic linkage analysis, cardiac arrhythmias, epidemic diseases and control strategies, carcinogenesis, and tumor chemotherapy. A recent conference was reviewed in *Science* [6]. This list is necessarily incomplete, but it may be useful for beginning reading in the field.

Mathematical biology consists, not of the mathematics of living things, but of the mathematics of *models* of living things; and choosing the level of simplification and the nature of the abstraction is perhaps the modeler's most distinctive contribution. Mathematical skill and biological knowledge are necessary conditions for success in modeling, but the art of selecting the essential ingredients of complex and elusive phenomena goes beyond them.

> Simplification in mathematical modeling is both a blessing and a curse. The curse is the partial loss of predictive power that comes from whatever lack of correspondence there may be between the model and the real world. The blessing is the insight that comes from the process of pruning away unnecessary detail and leaving behind only what is essential. ... The models presented here are in the nature of metaphors, and these metaphors will have served their purpose if they have helped the reader to see through the bewildering complexity of living systems to the underlying simplicity of certain biological processes and functions (Hoppensteadt and Peskin [8, p. 3]).

It is natural, in this era of fast computation, to want to build as much realism as possible into biological models, and rely on the power of the computer to approximate the complex systems of equations that result and make quantitative predictions that can be tested against experimental data. While not minimizing the practical utility of computer **simulation**, e.g. in cardiac pacemaker design or in predicting the course of epidemics, it may be that the most distinctive contribution of mathematics to biology lies in the opposite direction: simplifying to the point where it is possible to prove *theorems* about the model, and not only to compute with it. The computational route may yield a model that gives good predictions, but is just as impenetrable to understanding as the original biological system, whereas, when one proves a theorem about a model, that theorem is likely to give insight into the underlying biology. Proving nontrivial theorems about models that are adequate "metaphors," to use Hoppensteadt & Peskin's term, is the summit of mathematical biology, but it is ascended only occasionally, and such achievements are worthy to be celebrated. This article delves into the reasoning processes of five good examples, and shows, through them, several different ways that mathematical reasoning can enhance our understanding of biological systems. The five papers are selected as illustrations, without any attempt at a historical review of the place of each in its field.

Neurons with Excitatory Interactions can Oscillate in Phase Opposition

It is well known that neurons with excitatory interactions can synchronize each other, and that neurons with *inhibitory* interactions can entrain each other to oscillate with opposite phases, but what Kopell & Somers show is that excitatory coupling can lead to phase opposition as well [11]. They use singular perturbation theory to study a neuronal model of the relaxation oscillator type (but quite general in form), in which there is a fast-activating current

x and a slow-activating current y, governed by the equations $\varepsilon\dot{x} = F(x, y)$, $\dot{y} = G(x, y)$, the singular limit being taken as $\varepsilon \to 0$. The *nullclines* (loci in the x, y plane of $F = 0$ and $G = 0$) are assumed to be sigmoidal (for the slow current) and cubic (for the fast current). With x on the horizontal axis and y on the vertical axis, the cubic nullcline has three branches: left (descending), middle (ascending), and right (descending), and the two nullclines intersect along the middle branch of the cubic. When ε is small, the neuron's periodic trajectory descends the left branch to its minimum, jumps horizontally to the right branch, ascends the left branch to its maximum, and jumps horizontally back to the left branch. Mutual excitatory coupling between a pair of neurons is modeled by assuming that, when neuron 1 is on its right branch (high x), neuron 2's cubic nullcline is shifted upward on the y axis, and vice versa.

The fundamental condition that must be met for an antiphase solution is that the time to *ascend* the original cubic nullcline is less than the time to *descend* the shifted cubic nullcline. Kopell & Somers reparameterize the slow current (substituting z for y) in such a way that $\mathrm{d}z/\mathrm{d}t$ is constant and positive on the left branch of the unshifted cubic nullcline, $z = 0$ corresponding to the leftward jump point, and $z = 1$ to the minimum. Now suppose that neuron 1 starts just at the point of a jump to the right branch, while neuron 2 is at some $z \in (0, 1)$. Neuron 2 will immediately follow in jumping to the left branch of the shifted cubic nullcline, because neuron 1 is on its right branch. If the fundamental condition is satisfied, then there are z close enough to 0 that neuron 1 will jump back to the left branch before neuron 2 has completed its descent to the minimum, so neuron 2 will end up, after this pair of jumps, back on its original nullcline at a new position $E(z)$. Kopell & Somers prove that, if the fundamental condition holds, and in addition $E(0) > 0$ and $0 \leq E'(z) < 1$, then there is a stable antiphase solution. Furthermore, the antiphase solution persists in the nonsingular case $\varepsilon > 0$.

Kopell & Somers then show that the hypotheses of the theorem hold for several commonly used models of neuronal firing, including the Morris–Lecar equations. This system, which was first analyzed from a qualitative dynamics point of view by Rinzel & Ermentrout [17], is a simplified model of excitable membranes that captures many of their important features. It postulates voltage-gated Ca^{2+} (fast) and K^+ (slow) channels, and has nullclines on the (x, y) phase plane of the cubic and sigmoid types described above. The model has three equilibria [5]: a stable rest point, an unstable node, and a saddle point. The unstable manifold of the saddle point, which contains the rest point, forms an attracting invariant loop. The system generates action potentials in a realistic manner.

It turns out that it is possible for both antiphase and the more typical in-phase oscillations to be stable under the same excitatory coupling conditions. Arrays of bistable oscillators with nearest-neighbor coupling may show "fractured synchrony", i.e. domains within which activity is synchronous, while neighboring domains are in phase opposition [19, Figure 14].

Mutation Rates can be Estimated from Gene Polymorphisms

Mutation rates refer to the history of a population over an extended time, whereas gene **polymorphisms** refer to a cross-section at one time. Using the method of "coalescence", Kimmel & Chakraborty are able to make inferences about genetic history from the present state of the population [9]. Short segments of DNA are often repeated in the genome, and when the units of these "tandem repeats" are 2–6 nucleotides long, they are called "microsatellites". Mutations occur relatively frequently in the repeat length; they can cause expansion or contraction. Kimmel & Chakraborty use the Wright–Fisher model (*see* **Population Genetics**) for genetic evolution without selection in a population of constant size N, a model that ignores diploidy, and treats the $2N$ chromosomes of the $(k + 1)$th generation as if they were sampled uniformly and independently, with replacement, from the $2N$ chromosomes of the kth generation. That is equivalent to the number of copies of each chromosome in the $(k + 1)$th generation having a symmetric **multinomial distribution** [10]. Let each chromosome have a probability ν per generation of a mutation at a given locus (regarded as a **Poisson process**), and let the size U of that mutation (replacing an allele of size X by an allele of size $X + U$) be a **random variable** independent of the time of the mutation.

Under the Wright–Fisher model, any two chromosomes selected from the current generation, if followed backward in their parentage, eventually "coalesce", i.e. have a common parent, and the time T (going backward from the current generation) when coalescence occurs is approximately **exponentially distributed** with parameter $1/2N$, if N is large [10, p. 36].

Now imagine that two chromosomes are drawn at random from the current population, with repeat lengths X_i and X_j at a given locus. Since mutations can occur on either branch of the coalescence tree, the number n of mutations since the two chromosomes had a common ancestor is Poisson-distributed with parameter $2\nu T$. Since the probability **generating function** (pgf) for the **Poisson distribution** with parameter $2\nu t$ is $\exp[2\nu t(s-1)]$ and the exponential density at $T = t$ is $(1/2N)\exp(-t/2N)$, the pgf $\mu(s) = \mathrm{E}(s^n)$ for the number of mutation events is

$$\mu(s) = \frac{1}{2N}\int_0^\infty \exp\left(-\frac{t}{2N}\right)\exp[2\nu t(s-1)]\,\mathrm{d}t = \frac{1}{1-4N\nu(s-1)}.$$

So far, we have taken into account the random processes determining the time to coalescence and the number of mutations since coalescence, but not the random size of the mutation $X \to X + U$. Kimmel & Chakraborty [9] allow an arbitrary function $\varphi(s)$ for the pgf of the mutation size, since its probability distribution is currently an active area of research [18]. Since any mutation has an equal probability of affecting X_i or X_j, its effect on $X_i - X_j$ has pgf $\psi(s) = \frac{1}{2}[\varphi(s) + \varphi(1/s)]$. We now have a compound distribution for $X_i - X_j$, i.e. a random number n of mutations with pgf $\mu(s)$, each step contributing a random amount to the size difference with pgf $\psi(s)$. The pgf of $X_i - X_j$ is, therefore, found by composition:

$$\lambda(s) = \mu \circ \psi = \frac{1}{1-4N\nu[\psi(s)-1]}.$$

The variance of $X_i - X_j$ is found by differentiating $\lambda(s)$ twice and setting $s = 1$; it is $4\nu N\psi''$. This quantity may also be expressed as $4\nu N E(\hat{U}^2)$, by introducing the symmetrized random variable $\hat{U}$, with the probability distribution $\Pr(\hat{U} = n, n \in \mathbb{Z}) = \frac{1}{2}(p_n + p_{-n})$, where $p_n = \Pr(U = n)$. An empirically convenient measure of variability is the probability of homozygosity $\Pr(X_i = X_j)$, which is p_0 in the Laurent expansion of $\lambda(s) = \sum_{k\in\mathbb{Z}} p_k s^k$. p_0 can be evaluated by means of the Cauchy integral formula,

$$p_0 = \frac{1}{2\pi i}\oint_{|s|=1} \frac{\lambda(s)}{s}\,\mathrm{d}s.$$

The SIR Model for Epidemics has Chaotic Solutions

The existence of **chaos** in models for epidemics has been debated many times, and found in some computer simulations [15], but Glendinning & Perry [7] are able to give a definitive answer, at least in a simple case (the SIR model), using Melnikov's method. The SIR model for the spread of diseases is highly simplified, but captures important features of epidemics (*see* **Epidemic Models, Deterministic**). S stands for the proportion of *susceptible* individuals, I for *infected*, and R for *recovered*. The equations of the model are:

$$\dot{S} = -B(I,t)S + \mu - \mu S,$$
$$\dot{I} = B(I,t)S - (\gamma + \mu)I,$$
$$\dot{R} = \gamma I - \mu R,$$

where $S + I + R$, representing the total population, is set equal to 1. μ is the birth(= death) rate (all newborns are assumed susceptible); γ is the rate of recovery (transition to a permanently immune state). Glendinning & Perry [7] take $B(I,t) = \beta(t)I^2$, and assume that $\beta(t)$ has the form $\beta_0(1 + \beta_1 \sin\omega t)$. The sinusoidal term might arise from the annual school calendar, or from long-term cyclical variation in social or environmental factors. Choosing an exponent of $I > 1$ is not implausible, because there might be a threshold for the concentration of viruses in the environment to become infectious, or individuals could harbor low-level infections that increase susceptibility, without becoming infectious [13, p. 200]. The dynamics may be thought of as taking place on the cylinder $(I, R, t) \in \mathbb{R} \times \mathbb{R} \times S^1$, since the forcing term is periodic in t. Consider a Poincaré section at a fixed time (modulo $2\pi/\omega$). If S and R are given at a certain time in one period, then the equations predict what S and R will be at that time in the next period. Thus we have a map f of the (S, R)

plane into itself. "Chaos" can be defined in this way [24, Section 4.11 and Proposition 4.2.7]: there exists a compact and invariant set Λ in the Poincaré section such that:

1. Λ contains periodic points of all orders, and the periodic points are dense in Λ
2. there also exist, in Λ, an uncountably infinite number of points (S, R) such that an orbit started at (S, R) never repeats itself
3. there exists at least one starting point (S', R') in Λ from which the orbit comes arbitrarily close to every point in Λ
4. the Poincaré map has "sensitive dependence on initial conditions" on Λ, which means that $\exists\, \varepsilon > 0$ such that, for every $(S, R) \in \Lambda$, there are points arbitrarily close to (S, R) that eventually separate from (S, R) by at least ε.

This harvest of dynamics is reaped simply by proving that the map f has a saddle point y whose stable and unstable manifolds intersect transversely (i.e. they cross, other than at y) [24, Section 4.4]. (By the *stable manifold* is meant the set of points that approach y under successive iteration by f; by the *unstable manifold* is meant the set of points that approach y under backwards iteration by f. These will both be smooth curves.)

The key step is demonstrating that the stable and unstable manifolds cross. Melnikov's method [24, Section 4.5] deals with the case where the flow is governed by an arbitrarily small periodic perturbation of a Hamiltonian system: $\dot{q} = \partial H/\partial p$, $\dot{p} = -\partial H/\partial q$. The unperturbed system is assumed to have a *homoclinic orbit* $[q^0(t), p^0(t)](-\infty < t < \infty)$ such that $\lim_{t\to\infty} q^0(t) = y$ and $\lim_{t\to\infty} q^0(t) = y$. The interior of the homoclinic orbit is assumed to be filled with a continuous family of periodic orbits. Let $\vec{F}(q, p)$ be the unperturbed flow, and $\vec{G}(q, p, t, \varepsilon)$ be the perturbation, both smoothly varying in all their arguments. The Melnikov function is defined as

$$M(t) = \int_{-\infty}^{\infty} \vec{F}[q^0(s-t), p^0(s-t)] \times \vec{G}[q^0(s-t), p^0(s-t), t]\,\mathrm{d}s,$$

$\times$ standing for the vector cross-product. If $M(t_0) = 0$ for some t_0, and $\mathrm{d}M/\mathrm{d}t|_{t_0} \neq 0$, then the stable and unstable manifolds of y will intersect transversely for sufficiently small ε. Conversely, if $M(t)$ is always $\neq 0$, the stable and unstable manifolds will not intersect. The computational utility of Melnikov's formula is that the integral is carried out on the unperturbed orbits. After elaborate transformations, Glendinning & Perry are able to cast the equations of the SIR model into the form of a Hamiltonian unperturbed system and a perturbation. The Melnikov conditions are indeed satisfied, but only if the periodic term is on a very long time scale, not, for example, the annual scale that we expect in epidemics.

Hydrostatic Forces Determine the Geometry of the Aortic Valve

The objective of this theory was to derive the geometric form of the aortic valve of the heart from the hydrostatic forces acting on it when it balloons out to block the retrograde flow of blood into the heart [16]. The valve consists of three pockets, arranged as 120° sectors of a circle, meeting in the middle when the valve closes under retrograde flow. The fibers of each leaflet are suspended from the two points where the sector boundary meets the circumference, called *commissural points*. The intrinsic coordinates of the valve surface, (u, v), are defined so that the curves $v = \text{const.}$ are the fibers, $v = 0$ being the free edge. u measures arc length along the fibers, $u = 0$ marking the midline. The Cartesian coordinates in space, $\mathbf{X} = (x, y, z)$, are chosen so that the $z = 0$ plane contains the three commissural points (each pair suspending one of the valve leaflets), and $x = y = z = 0$ is the center of the circle through the three points. The equation of the leaflet surface, $\mathbf{X}(u, v)$, is regarded as unknown, to be determined by mechanical equilibrium under hydrostatic forces. $T(u, v)$ is the tension in the fibers, and p_0 is the pressure load applied to the leaflet, assumed uniform. The equations of equilibrium are

$$\frac{\partial}{\partial u}\left(T\frac{\partial \mathbf{X}}{\partial u}\right) + p_0\left(\frac{\partial \mathbf{X}}{\partial u} \times \frac{\partial \mathbf{X}}{\partial v}\right) = 0. \qquad (1)$$

Peskin & McQueen [16] prove that: (i) $T(u, v)$ is independent of u (the tension is constant along each fiber); (ii) the fibers are geodesics on the surface of the valve leaflet; and (iii) the u, v coordinate curves are orthogonal. By a change of variables $\mathrm{d}V/\mathrm{d}v = T(v)/p_0$, equalizing the force per unit of V, (1) transforms into

$$\frac{\partial \mathbf{X}}{\partial V} = \frac{\partial \mathbf{X}}{\partial u} \times \frac{\partial^2 \mathbf{X}}{\partial u^2}. \qquad (2)$$

Peskin & McQueen make use of a remarkable analogy between (2) and the equations of vortex dynamics in moving fluids. They think of V as a *time* variable, so that (2) can be regarded as describing the filling-out of the leaflet by a single fiber, sweeping across the leaflet as V increases, moving in the direction of its binormal at each point. Eq. (2) is the same as the "self-induction approximation" in hydrodynamics for the motion of a line vortex, i.e. its motion under the influence of the velocity field it itself generates. The geometry problem becomes an initial-value problem: starting with $\mathbf{X}(u, 0)$, defined at the free edge of the leaflet, propagate $\mathbf{X}(u, V)$ forward in the "time" variable V, toward the circumference where the leaflet is suspended. The free edge $\mathbf{X}(u, 0)$ looks like a hyperbola when projected onto the x, y plane, and like a cubic when projected onto the x, z plane. To carry out the computations, they use a method developed by Buttke [2] for approximating the motion of a line vortex in a three-dimensional incompressible, isentropic fluid. According to the numerical solution, the fibers are not uniformly spread over the leaflet, but are gathered in bundles formed by the rolling up of the leaflet surface, just as vortex lines tend to kink as they move in a fluid. This result was unexpected, but it agrees very well with the observed anatomy of the aortic valve leaflet. Peskin & McQueen describe their surprise at the degree of agreement between theory and observation:

> When this work was undertaken, our goal was to produce a smooth array of fibers that would function as an aortic valve ... We were aware of the complicated branching structure of the collagen fibers that support the actual valve, but we thought of such a structure as being "too biologic" to be modeled within the present framework...Imagine our astonishment, then, when the result first appeared on the workstation screen! These results show that considerations of mechanical equilibrium determine the anatomy of the aortic valve in a much more detailed way than we had dared to hope [16, p. H326].

Knot Topology Establishes the Mechanism of Tn3 Resolvase

Tn3 resolvase is an enzyme that catalyzes recombination of duplex DNA at specific sites, i.e. the cutting of both strands of two DNA molecules and reattachment of the cut ends of the first molecule to the cut ends of the second, and vice versa [20]. DNA-binding proteins form the template, or *synaptosome*, to which the recombining partners attach. The Tn3 resolvase, a representative example of a major family of these recombinases, acts on closed circular DNA. Its function is in DNA transposition, moving a segment of DNA from one position to another. It is called a *topoisomerase*, because its action changes the topology of the molecule. From the topologic changes it induces, Sumners was able, in a brilliant analysis, to deduce its mechanism of action [21]. He treated the DNA attached to the synaptosome according to Conway's theory of *rational tangles* [1, Section 2.3]. A tangle is a circular region in the projection plane of a knot or link, such that the knot or link crosses the circumference at exactly four points (called NW, NE, SW, SE). A few examples will clarify the idea. The (∞) tangle is just two vertical strings, and the (0) tangle is two horizontal strings. The (3) tangle is made by winding two horizontal strings around each other so that they make three left-handed twists. (In the case of DNA, such twists are "supercoiled", since the primary structure is already coiled.) To make a (3, 2) tangle out of a (3) tangle, first reflect the (3) tangle along the NW–SE diagonal, than make two twists of the free horizontal ends. The process can be continued to make tangles with more indices. The *sum* of two tangles is formed simply by joining the NE end of the first to the NW end of the second, and the SE end of the first to the SW end of the second. From a tangle, a knot or link can be formed by the "numerator construction", which consists of connecting the NW end to the NE end, and the SW end to the SE end. Conway proves that the *continued fraction* derived from a tangle, for example $n + 1/[m + (1/l)]$ from the tangle (l, m, n), characterizes the knot formed by the numerator construction, in the sense that two knots formed from tangles are equivalent if and only if their continued fractions have the same value.

Closely following the biology of the recombination process, Sumners assumes that the DNA strands on the synaptosome form a tangle in Conway's sense, and furthermore that the synaptosome tangle is the sum of two tangles, O_b and P, P representing the two "parental" segments, lying parallel on the synaptosome, that are to be cut and recombined, and O_b representing the rest of the (possibly twisted) DNA that is bound to the synaptosome, but not involved directly in recombination. The actual DNA molecule, before and after recombination, is assumed to be derived by

the numerator construction $N(\cdot)$ from the tangle. The original substrate, in Conway's notation, is $N(O_b + P)$, and it is topologically just a circle. After recombination, the product is $N(O_b + R)$. Whereas P is the (0) tangle (two parallel horizontal strands), R is either the (1) tangle or the (-1) tangle (one twist, formed when the strands are cut and recombine). Sumners takes advantage of the fact that occasionally two or three recombination events occur. Then, according to this model, the products should be $N(O_b + 2R)$ and $N(O_b + 3R)$, respectively. Since the topology of the products in each case is known experimentally, the equations can be solved for the tangles O_b and R. $N(O_b + R)$ is known to be a Hopf link (the simplest two-component link, two circles passed through one another), $N(O_b + 2R)$ is a figure of eight knot, and $N(O_b + 3R)$ is a Whitehead link (two circles joined so that one becomes a figure eight). Sumners proves, on the basis of this information, that R must consist of one left-handed twist, and O_b must consist of three left-handed twists in the vertical direction. In other words, the DNA is supercoiled on the synaptosome, in addition to being prepared for cutting. The *pièce de résistance* of this work is being able to predict, on the basis of the model derived from $N(O_b + jR)$, $j = 1, 2, 3$, what kind of knot $N(O_b + 4R)$ will be. Quadruple recombination is rare, but it does occur; the prediction is a knot called 6_2, a six-crossing composite knot, which agrees with experiment.

Conclusion

Each of these five studies illuminates one of the values of proving theorems in mathematical biology. Kopell & Somers [11] (first section) achieve two things. They predict a new phenomenon – oscillation in phase opposition by neurons coupled through excitatory interactions. They also exhibit the mechanism of that effect, through their analysis of the singular solution. Kimmel & Chakraborty's work [9] on estimation of mutation rate from microsatellite polymorphisms (second section) shows how mathematical reasoning can connect two qualitatively distinct phenomena, in this case one stretched out over the history of the population, and the other observed in a cross-section at a single time. Glendinning & Perry's study [7] of chaos in the SIR model for epidemics (third section) is important, not because the chaotic regime is expected to occur under typical circumstances, but because it resolves a question about dynamics that no amount of computer simulation could ever settle, being necessarily confined to a finite time period, a finite number of starting points, and finite precision. Peskin & McQueen's demonstration [16] that equilibrium under hydrostatic forces can account for the geometry of the aortic valve (fourth section), apart from the fascination of its reasoning, shows how isomorphism in formal structure sometimes makes it possible for a large body of mathematical knowledge to be translated and applied in a new area. In this case, methods from vortex hydrodynamics could be used to study the equations of shape of a body in equilibrium. Finally, Sumners' elegant application [21] of knot theory in DNA biochemistry (fifth section) illustrates how mathematical proof can, at least occasionally, give a definitive answer to a question of mechanism. Each of the selected papers also illustrates the crucial step of formulating a model rich enough to capture the phenomena, yet simple enough to be tractable. Mathematical analysis in biology will remain a subtle art, but when theorems can be proved about realistic models, they are likely to shed valuable light on biologic mechanisms.

STEVEN MATTHYSSE

Matrix Algebra

The algebra that we learn when teenagers has letters of the alphabet, each representing a number. For example: a father and son are x and y years old, respectively, and their total age is 70. In a decade the father will be twice as old as the son. Hence $x + y = 70$ and $x + 10 = 2(y + 10)$, and so $x = 50$ and $y = 20$.

In contrast, matrix algebra is the algebra of letters each representing many numbers, with those numbers always arrayed in the form of a rectangle (or square). An example is

$$\mathbf{X} = \begin{bmatrix} 9 & 0 & 7 & t \\ u^2 + v & -3 & 6.1 & 5^3 \end{bmatrix}.$$

General Description

A *matrix* is a rectangular array of numbers, which can be any mixture of numbers that are complex, real, zero, positive, negative, decimal, fractions, or algebraic expressions. When none of them is complex (i.e. involving $\sqrt{-1}$), the matrix is said to be *real*. And because statistics deals with data, which are real numbers (especially biological data), almost all of this article applies to real matrices. Each number in a matrix is called an *element*: in being some representation of a single number it is called a *scalar*, to contrast with a matrix which represents many numbers.

Elements are always set out in rows and columns with the number of rows and columns being called the *order* (or *dimension*) of the matrix. Thus, the illustrated $\mathbf{X}$ has order 2×4 ("two by four") with the number of rows being mentioned first. Sometimes the order is used as a subscript to the matrix symbol; for example, $\mathbf{X}_{2\times4}$. In this encyclopedia the widespread custom is used of denoting matrices by bold face, capital, roman letters.

Elements of a matrix can be represented by letters, having subscripts to denote location (row and column) in the matrix. Thus, a matrix $\mathbf{A}$ might be represented as

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}.$$

The first subscript indicates row, and the second column; for example, a_{23} is in row 2 and column 3. More briefly, we can write

$$\mathbf{A} = \{a_{ij}\} \quad \text{for } i = 1, 2, 3 \text{ and } j = 1, 2, 3.$$

When $\mathbf{B}$ has r rows and c columns,

$$\mathbf{B} = \{b_{ij}\} \quad \text{for } i = 1, 2, \ldots, r \text{ and } j = 1, 2, \ldots, c.$$

A more compact form is

$$\mathbf{B} = \left\{{}_{\mathrm{m}}\ b_{ij}\right\}_{i=1,\,j=1}^{r\quad\ c},$$

the m indicating that it is a matrix. The element in the first row and first column (e.g. a_{11} in $\mathbf{A}$ and the 9 in $\mathbf{X}$) is called the *leading element*.

By virtue of a matrix being a rectangular array there are many special forms, the first two of which are square matrices and vectors.

Square Matrices

1. Square matrices have the same number of rows as columns. $\mathbf{A}$ is an example.
2. Elements on the diagonal from upper left to lower right, those with both subscripts the same, are *diagonal elements*; they constitute *the diagonal of the matrix*.
3. Elements immediately below the diagonal constitute the *sub-diagonal*.
4. Elements not on the diagonal are *off-diagonal elements*.
5. When all off-diagonal elements are zero, and at least some diagonal elements are nonzero, the matrix is a *diagonal matrix*.
6. When all elements below (above) the diagonal are zero the matrix is said to be *upper (lower) triangular*.

Vectors

When a matrix has only one column it is a *column vector* or, more usually, just *vector*; and it shall here be denoted by a bold face, lower case, roman letter, usually from the last part of the alphabet; for example,

$$\mathbf{x} = \begin{bmatrix} 1 \\ 7 \\ -4 \\ 0 \end{bmatrix}.$$

When a matrix has only one row it is called a *row vector*. The notation is similar to that for a column vector, except for a superscript prime:

$$\mathbf{y}' = [0 \quad -4 \quad 9 \quad 12 \quad 37].$$

A column vector is a matrix of order $r \times 1$ when it has r elements; its transpose, a row vector, has order $1 \times r$. For both vectors, r is often called the *order* of the vector.

Basic Operations

A minimal requirement for matrix algebra is to define the arithmetic operations. Moreover, the rectangular nature of matrices begets numerous operations that do not exist for scalars; for example, changing rows into columns, and columns into rows.

The Transpose of a Matrix

Changing $\mathbf{A}$ so that its rows become columns (and hence its columns become rows) gives a matrix called the *transpose* of $\mathbf{A}$, traditionally written as $\mathbf{A}'$ (and sometimes today as $\mathbf{A}^{\mathrm{T}}$). Thus for

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 & 4 \\ 6 & 1 & -2 & 5 \end{bmatrix}, \qquad \mathbf{A}' = \begin{bmatrix} 1 & 6 \\ 2 & 1 \\ 3 & -2 \\ 4 & 5 \end{bmatrix}.$$

Note that the transpose of $\mathbf{A}'$ is $\mathbf{A}$: $(\mathbf{A}')' = \mathbf{A}$. Also, the transpose of a column vector is a row vector (and vice versa):

$$[1 \quad 2 \quad 3]' = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}.$$

This explains the use of $\mathbf{y}'$ at the end of the preceding section.

Partitioned Matrices

The rows and columns of a matrix can be partitioned into a representation that is a matrix of matrices of smaller orders:

$$\mathbf{K} = \left[\begin{array}{cc|cc} 1 & 2 & 3 & 4 \\ 6 & 8 & 4 & 0 \\ 9 & 8 & 1 & 2 \\ \hline 6 & 8 & 3 & 9 \\ 4 & 1 & 6 & 1 \end{array}\right] = \begin{bmatrix} \mathbf{K}_{11} & \mathbf{K}_{12} \\ \mathbf{K}_{21} & \mathbf{K}_{22} \end{bmatrix}, \quad \text{for}$$

$$\mathbf{K}_{11} = \begin{bmatrix} 1 & 2 \\ 6 & 8 \\ 9 & 8 \end{bmatrix},$$

and so on. $\mathbf{K}$ is a *partitioned* matrix; the $\mathbf{K}$s with subscripts are *submatrices* of $\mathbf{K}$.

In transposing a partitioned matrix, not only is the matrix of submatrices transposed, but each submatrix is also transposed. Thus

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix}' = \begin{bmatrix} \mathbf{A}' & \mathbf{C}' \\ \mathbf{B}' & \mathbf{D}' \end{bmatrix}.$$

A matrix can also be partitioned into its columns (or its rows); for example,

$$\mathbf{K} = [\mathbf{k}_1 \quad \mathbf{k}_2 \quad \mathbf{k}_3 \quad \mathbf{k}_4],$$

where each of the subscripted $\mathbf{k}$s is a column of $\mathbf{K}$.

The Trace of a Matrix

The trace of a matrix is defined only for a square matrix; and *trace* of $\mathbf{A}$ is the sum of the diagonal elements of $\mathbf{A}$, often written as $\mathrm{tr}(\mathbf{A})$. Note that $\mathrm{tr}(\mathbf{A}) = \mathrm{tr}(\mathbf{A}')$, and $\mathrm{tr}(\text{scalar}) = \text{scalar}$.

Addition and Subtraction

Addition and subtraction are defined only for matrices of the same order, whereupon the matrices are said to be *conformable* for addition and subtraction. Then, for $\mathbf{A} = \{a_{ij}\}$ and $\mathbf{B} = \{b_{ij}\}$,

$$\mathbf{A} + \mathbf{B} = \{a_{ij} + b_{ij}\}.$$

If two matrices do not have the same order their sum and difference do not exist. Note the properties

$$(\mathbf{A} \pm \mathbf{B})' = \mathbf{A}' \pm \mathbf{B}'$$

and

$$\mathrm{tr}(\mathbf{A} \pm \mathbf{B}) = \mathrm{tr}(\mathbf{A}) \pm \mathrm{tr}(\mathbf{B}).$$

Scalar Multiplication

For λ being a scalar, $\lambda\mathbf{A}$ is $\mathbf{A}$ with every element multiplied by λ. Thus, for $\mathbf{A} = \{a_{ij}\}$, $\lambda\mathbf{A} = \{\lambda a_{ij}\}$.

Equality and Null Matrices

Two matrices are equal only when they are equal element by element. Thus, for

$$\mathbf{A} = \begin{bmatrix} 1 & 2 \\ 6 & 8 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 1 & 2 \\ 6 & 8 \end{bmatrix} \text{ and } \mathbf{C} = \begin{bmatrix} 1 & 2 \\ 5 & 8 \end{bmatrix},$$

$\mathbf{A} = \mathbf{B}$, but $\mathbf{A} \neq \mathbf{C}$. Furthermore,

$$\mathbf{A} - \mathbf{B} = \begin{bmatrix} 1-1 & 2-2 \\ 6-6 & 8-8 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} = \mathbf{0}.$$

Any matrix having every element zero is a *null matrix*. It is a zero of matrix algebra: note that it is *a* zero not *the* zero, because null matrices can be of any order.

Multiplication

Multiplication of matrices differs greatly from that of scalars. First of all, **AB** and **BA** can, and often do, differ. To distinguish between the two, **AB** is described as **B** *pre-multiplied* by **A** (or as **A** *post-multiplied* by **B**).

The *inner product* of two vectors is a row vector post-multiplied by a column vector, with both vectors having the same number of elements; for example,

$$[1 \quad 7 \quad 2] \begin{bmatrix} 3 \\ 5 \\ 9 \end{bmatrix} = 1(3) + 7(5) + 2(9) = 56.$$

Thus for $\mathbf{x}' = \{x_i\}_{i=1}^{n}$ and $y' = \{y_i\}_{i=1}^{n}$,

$$\mathbf{x}'\mathbf{y} = \sum_{i=1}^{n} x_i y_i.$$

In contrast, an *outer product* is a column vector post-multiplied by a row vector

$$\mathbf{x}\mathbf{y}' = \{_{\mathrm{m}}\ x_i y_j\}.$$

In this case, the vectors can be of different orders. Note that an inner product is a scalar, whereas an outer product is a matrix.

The product **AB** exists only when **A** has as many columns as **B** has rows; and then **A** and **B** are described as being *conformable for the product* **AB**, whereupon

$$\mathbf{A}_{r\times c}\mathbf{B}_{c\times t} = \mathbf{P}_{r\times t}.$$

In **P**, the element in row i and column j is the inner product of row i of **A** and column j of **B**:

$$\mathbf{P}_{r\times t} = \{p_{ij}\} = \left\{ \sum_{k=1}^{c} a_{ik} b_{kj} \right\} \quad \text{for } i = 1, \ldots, r$$

and $j = 1, \ldots, t$.

A simple numerical example of this is

$$\begin{bmatrix} 1 & 0 \\ 2 & -1 \end{bmatrix} \begin{bmatrix} 3 & 4 & 7 \\ -5 & 6 & 8 \end{bmatrix}$$

$$= \begin{bmatrix} [1 \quad 0] \begin{bmatrix} 3 \\ -5 \end{bmatrix} & [1 \quad 0] \begin{bmatrix} 4 \\ 6 \end{bmatrix} & [1 \quad 0] \begin{bmatrix} 7 \\ 8 \end{bmatrix} \\ [2 \quad -1] \begin{bmatrix} 3 \\ -5 \end{bmatrix} & [2 \quad -1] \begin{bmatrix} 4 \\ 6 \end{bmatrix} & [2 \quad -1] \begin{bmatrix} 7 \\ 8 \end{bmatrix} \end{bmatrix}$$

$$= \begin{bmatrix} 1(3) + 0(-5) & 1(4) + 0(6) & 1(7) + 0(8) \\ 2(3) + (-1)(-5) & 2(4) + (-1)6 & 2(7) + (-1)8 \end{bmatrix}$$

$$= \begin{bmatrix} 3 & 4 & 7 \\ 11 & 2 & 6 \end{bmatrix}.$$

Important consequences of this definition of multiplication are that **AB** exists only for $\mathbf{A}_{r\times c}$ and $\mathbf{B}_{c\times t}$; both **AB** and **BA** exist only for $\mathbf{A}_{r\times c}$ and $\mathbf{B}_{c\times r}$, but they will be of different orders (and so not equal) unless $r = c$. Even then, **AB** and **BA** are not necessarily equal. For example,

$$\begin{bmatrix} 1 & 0 \\ 2 & -1 \end{bmatrix} \begin{bmatrix} 3 & 4 \\ -5 & 6 \end{bmatrix} = \begin{bmatrix} 3 & 4 \\ 11 & 2 \end{bmatrix},$$

$$\text{but } \begin{bmatrix} 3 & 4 \\ -5 & 6 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 2 & -1 \end{bmatrix} = \begin{bmatrix} 11 & -4 \\ 7 & -6 \end{bmatrix}.$$

Products with Null Matrices

Every product of a matrix with a null matrix is a null matrix: but those null matrices are not necessarily of the same order. Thus, $\mathbf{0}_{3\times 2}\mathbf{A}_{2\times 5} = \mathbf{0}_{3\times 5}$ and $\mathbf{A}_{2\times 5}\mathbf{0}_{5\times 6} = \mathbf{0}_{2\times 6}$.

Products with Diagonal Matrices

Pre-(post-)multiplying **A** by a diagonal matrix **D** multiplies each row (column) of **A** by the corresponding diagonal element of **D**.

Identity Matrices

If every diagonal element of a diagonal matrix is a one the matrix is called an *identity* matrix, **I**; pre- or

post-multiplication of $\mathbf{A}$ by an identity matrix yields $\mathbf{A}$. Thus $\mathbf{I}$-matrices are the unities of matrix algebra.

Transposing a Product

The transpose of a product is the product of the transposed matrices in reverse order. Thus

$$(\mathbf{AB})' = \mathbf{B}'\mathbf{A}' \quad \text{and} \quad (\mathbf{XAY})' = \mathbf{Y}'\mathbf{A}'\mathbf{X}'.$$

Trace of a Product

The trace of a product equals the trace of cyclic permutations of that product: $\text{tr}(\mathbf{AB}) = \text{tr}(\mathbf{BA})$ and $\text{tr}(\mathbf{ABC}) = \text{tr}(\mathbf{CAB}) = \text{tr}(\mathbf{BCA})$, but these three do not equal the trace of $\mathbf{ACB}$.

Powers of Matrices

Only square matrices have powers: $\mathbf{A}_{2\times 4}\mathbf{A}_{2\times 4}$ does not exist. $\mathbf{A}_{4\times 4}\mathbf{A}_{4\times 4}$ written as $\mathbf{A}^2_{4\times 4}$ does.

Hadamard Products

The (i, j)th element of $\mathbf{AB}$ is $\sum_k a_{ik}b_{kj}$. But there are other ways of defining a product. One is the *Hadamard product*, defined as

$$\mathbf{A} \cdot \mathbf{B} = \{a_{ij}b_{ij}\}.$$

Thus, the (i, j)th element of the Hadamard product is the product of the (i, j)th elements of $\mathbf{A}$ and $\mathbf{B}$ – which must have the same order.

Direct Products

There is also the direct product

$$\mathbf{A} \otimes \mathbf{B} = \{_{\text{m}}\ a_{ij}\mathbf{B}\}.$$

When $\mathbf{A}$ has order $p \times q$ and $\mathbf{B}$ has order $r \times s$, $\mathbf{A} \otimes \mathbf{B}$ has order $pr \times qs$. For example,

$$\begin{bmatrix} 3 & 4 \\ 2 & 1 \end{bmatrix} \otimes [6 \quad 7 \quad 8] = \begin{bmatrix} 3[6 & 7 & 8] & 4[6 & 7 & 8] \\ 2[6 & 7 & 8] & 1[6 & 7 & 8] \end{bmatrix}$$
$$= \begin{bmatrix} 18 & 21 & 24 & 24 & 28 & 32 \\ 12 & 14 & 16 & 6 & 7 & 8 \end{bmatrix}.$$

Laws of Algebra

Provided that conformability requirements are met, the following equalities hold:

$$(\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + \mathbf{B} + \mathbf{C},$$
$$(\mathbf{AB})\mathbf{C} = \mathbf{A}(\mathbf{BC}) = \mathbf{ABC},$$
$$\mathbf{A}(\mathbf{B} + \mathbf{C}) = \mathbf{AB} + \mathbf{AC},$$
$$\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}.$$

This last equality is the commutative law of addition. In contrast, its mate, the commutative law of multiplication, does not generally hold for matrices; that is, $\mathbf{AB}$ and $\mathbf{BA}$ are not usually equal. Indeed, there are situations in which one exists and the other does not; and when they do both exist they can be of different orders; and even when they both exist and are of the same order (for which $\mathbf{A}$ and $\mathbf{B}$ must be square and of the same order) they are not necessarily equal.

Contrasts with Scalar Algebra

The following results illustrate differences in the algebra of matrices compared with that of scalars:

1. $\mathbf{AX} + \mathbf{BX} = (\mathbf{A} + \mathbf{B})\mathbf{X} \neq \mathbf{X}(\mathbf{A} + \mathbf{B})$;
2. $\mathbf{XP} + \mathbf{QX}$ does *not* have $\mathbf{X}$ as a factor;
3. $\mathbf{AB} = \mathbf{0}$ does not imply that $\mathbf{A}$ or $\mathbf{B}$ are $\mathbf{0}$, nor does it imply that $\mathbf{BA}$ is $\mathbf{0}$;
4. $\mathbf{Y}^2 = \mathbf{0}$ defines $\mathbf{Y}$ as *nilpotent* and does *not* imply that $\mathbf{Y}$ is $\mathbf{0}$
5. $\mathbf{Z}^2 = \mathbf{I}$ does *not* imply that $\mathbf{Z}$ is $\pm\mathbf{I}$;
6. $\mathbf{Q}^2 = \mathbf{Q}$ defines $\mathbf{Q}$ as *idempotent* without implying that $\mathbf{Q} = \mathbf{0}$ or $\mathbf{I}$.

Examples of these last four features are as follows:

$$\mathbf{AB} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}\begin{bmatrix} 1 & 1 \\ -1 & -1 \end{bmatrix} = \mathbf{0},$$
$$\mathbf{BA} = \begin{bmatrix} 1 & 1 \\ -1 & -1 \end{bmatrix}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} = \begin{bmatrix} 2 & 2 \\ -2 & -2 \end{bmatrix},$$
$$\mathbf{Y}^2 = \begin{bmatrix} 1 & 1 \\ -1 & -1 \end{bmatrix}^2 = \mathbf{0},$$
$$\mathbf{Z}^2 = \begin{bmatrix} 1 & 0 \\ 4 & -1 \end{bmatrix}^2 = \mathbf{I},$$

and

$$\mathbf{Q}^2 = \begin{bmatrix} 3 & -2 \\ 3 & -2 \end{bmatrix}^2 = \mathbf{Q}.$$

One may be tempted to think of these examples as pathologic cases. To some extent they are, born of the need to have illustrations that occupy minimum space; but they serve as stern warnings that what can be done in scalar algebra does not always carry over to matrix algebra.

Special Matrices

Square matrices and vectors have already been mentioned as special forms of matrices. There are many others, some arising from their intrinsic properties, and others from the applications in which they arose. Just a few of the more commonly occurring ones are mentioned here.

Symmetric Matrices

$\mathbf{A}$ is defined as being symmetric when $\mathbf{A}' = \mathbf{A}$. That can occur only when $\mathbf{A}$ is square. Its rows are then mirror images of its columns:

$$\begin{bmatrix} 1 & 7 & 0 \\ 7 & 2 & -3 \\ 0 & -3 & 9 \end{bmatrix}' = \begin{bmatrix} 1 & 7 & 0 \\ 7 & 2 & -3 \\ 0 & -3 & 9 \end{bmatrix};$$

and $a_{ij} = a_{ji}$.

$\mathbf{BB}'$ and $\mathbf{B}'\mathbf{B}$ are both symmetric. This is true for any $\mathbf{B}$. Then $\mathbf{BB}'$ (and $\mathbf{B}'\mathbf{B}$) have diagonal elements that are sums of squares of elements of rows (columns) of $\mathbf{B}$: and

$$\text{tr}(\mathbf{BB}') = \text{tr}(\mathbf{B}'\mathbf{B}) = \sum_i \sum_j b_{ij}^2.$$

When $\mathbf{B}$ is real, $\mathbf{BB}' = \mathbf{0}$ and $\text{tr}(\mathbf{BB}') = 0$ each imply that $\mathbf{B} = \mathbf{0}$.

Elementary Vectors

Columns of identity matrices are *elementary vectors*, represented as $e_i^{(n)}$, the ith column in $\mathbf{I}$ of order n.

Skew-Symmetric Matrices

$\mathbf{A}' = -\mathbf{A}$ defines $\mathbf{A}$ as *skew-symmetric*.

Summing Vectors

A vector having every element a one (1.0) is a *summing vector*, often denoted as $\mathbf{1}$. It is so named because $\mathbf{1}'\mathbf{x}$ is the sum of all elements in $\mathbf{x}$.

Matrices having Every Element Unity

$\mathbf{J}_{p\times k} = \mathbf{1}_p\mathbf{1}_k'$ is a matrix having every element being 1.0. Its most frequent occurrence in statistics is when it is square: $\mathbf{J}_n = \mathbf{1}_n\mathbf{1}_n'$. A useful variant is $\overline{\mathbf{J}}_\mathbf{n} = (1/n)\mathbf{J}_n$. Then,

$$\mathbf{C}_n = \mathbf{I}_n - \overline{\mathbf{J}}_n$$

is a *centering matrix*, with

$$\mathbf{C}_n\mathbf{x} = \{x_i - \overline{x}\} \quad \text{and} \quad \mathbf{x}'\mathbf{C}_n\mathbf{x} = \sum_{i=1}^{n}(x_i - \overline{x})^2,$$

for $\overline{x} = \sum_{i=1}^n x_i/n = \mathbf{1}'\mathbf{x}/n$.

Probability Transition Matrices

When elements of a matrix $\mathbf{P}$ are probabilities that add to unity over each row, $\mathbf{P1} = \mathbf{1}$. Then $\mathbf{P}^k\mathbf{1} = \mathbf{1}$ for any positive integer k, and $\mathbf{P}$ is called a *probability transition matrix*. It is *doubly stochastic* if $\mathbf{1}'\mathbf{P} = \mathbf{1}'$ (or, equivalently, $\mathbf{P}'\mathbf{1} = \mathbf{1}$), meaning that column sums are also unity.

Idempotent Matrices

$\mathbf{A}$ is *idempotent* when $\mathbf{A}^2 = \mathbf{A}$; then $\mathbf{I} - \mathbf{A}$ is also idempotent (but $\mathbf{A} - \mathbf{I}$ is not).

Orthogonality

1. The *norm* of a real vector $\mathbf{x}$ is $(\mathbf{x}'\mathbf{x})^{1/2}$.
2. $\mathbf{x}$ is a *unit vector* when $\mathbf{x}'\mathbf{x} = 1$.
3. $\mathbf{u} = \mathbf{x}/(\mathbf{x}'\mathbf{x})^{1/2}$, known as normalized $\mathbf{x}$, is always a unit vector when $\mathbf{x}$ is real.

Nonnull vectors $\mathbf{x}$ and $\mathbf{y}$ are *orthogonal vectors* when $\mathbf{x}'\mathbf{y} = 0$ $(= \mathbf{y}'\mathbf{x})$ (*see* **Orthogonality**).

Vectors $\mathbf{v}$ and $\mathbf{w}$ are *orthonormal vectors* when they are orthogonal $(\mathbf{v}'\mathbf{w} = 0)$ and each is a unit vector $(\mathbf{v}'\mathbf{v} = 1$ and $\mathbf{w}'\mathbf{w} = 1)$.

A collection of vectors of the same order is said to be an *orthogonal set of vectors* when they are pairwise orthonormal.

When $\mathbf{P}_{r\times c}$ has rows that are an orthonormal set, $\mathbf{PP}' = \mathbf{I}$. If $\mathbf{P}$ is square with orthonormal rows (columns), then its columns (rows) are also orthonormal, $\mathbf{PP}' = \mathbf{I} = \mathbf{P}'\mathbf{P}$ and $\mathbf{P}$ is an *orthogonal matrix*.

Certain special forms of orthogonal matrices go by the names Helmert, Givens, and Householder. The latter, for example, is $\mathbf{I} - \mathbf{2hh}'$ when $\mathbf{h}'\mathbf{h} = 1$.

Quadratic Forms

$\mathbf{x}'\mathbf{A}\mathbf{x}$ is a *quadratic form*, in which $\mathbf{A}$ can always be (taken as) symmetric. $\mathbf{x}'\mathbf{A}\mathbf{x}$ is a homogeneous second-order function of the elements of $\mathbf{x}$:

$$\mathbf{x}'\mathbf{A}\mathbf{x} = \sum_i x_i^2 a_{ii} + \sum x_i x_j a_{ij} = \sum_i x_i^2 a_{ii} + \sum_{j \neq i} x_i x_j (a_{ij} + a_{ji}),$$

and on taking $\mathbf{A} = \mathbf{A}'$, that is, $a_{ij} = a_{ji}$,

$$\mathbf{x}'\mathbf{A}\mathbf{x} = \sum_i x_i^2 a_{ii} + 2 \sum_{j>i} x_i x_j a_{ij}.$$

If $\mathbf{x}'\mathbf{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq \mathbf{0}$, $\mathbf{x}'\mathbf{A}\mathbf{x}$ is called a *positive definite (p.d.) quadratic form*, and $\mathbf{A}$ $(= \mathbf{A}')$ is a *p.d. matrix*. If $\mathbf{x}'\mathbf{A}\mathbf{x} \geq 0$ for all $\mathbf{x} \neq \mathbf{0}$ *and* $\mathbf{x}'\mathbf{A}\mathbf{x} = \mathbf{0}$ for some $\mathbf{x} \neq \mathbf{0}$, then $\mathbf{x}'\mathbf{A}\mathbf{x}$ and $\mathbf{A}$ are *positive semidefinite* (p.s.d.). The classes of quadratic forms and matrices that include those which are p.d. and p.s.d. are called *nonnegative definite* (n.n.d.).

Determinants

Definition

Associated with any square matrix $\mathbf{A}_{n \times n}$ is its determinant $|\mathbf{A}|$. It is a scalar, an n-order, homogeneous polynomial function of the elements. Two easy examples are for $\mathbf{A}$ of order 2 and 3:

$$|\mathbf{X}| = \begin{vmatrix} a_1 & a_2 \\ b_1 & b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

and

$$|\mathbf{Y}| = \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix} = a_1 b_2 c_3 + a_2 b_3 c_1 + a_3 b_1 c_2 - a_3 b_2 c_1 - a_1 b_3 c_2 - a_2 b_1 c_3.$$

For $\mathbf{A}$ of order n, the definition is more difficult: $|\mathbf{A}|$ is the sum of the n different terms that are each a signed product of one element from every row and column of $\mathbf{A}$. In writing $|\mathbf{A}|$ with the rows being $\mathbf{a}', \mathbf{b}', \mathbf{c}', \ldots$, a product written in alphabetic order has sign equal to $(-1)^p$, with p being the sum of the number of reverse sequences of the subscripts. For example, $a_2 b_3 c_1$ in the preceding $|\mathbf{Y}|$ has $p = 2$ because 2, 1 and 3, 1 are reverse sequences; hence, the sign for $a_2 b_3 c_1$ is $(-1)^2 = +1$. For $a_3 b_2 c_1$ there are three reverse sequences, 3, 2 and 3, 1 and 2, 1 and so the sign is $(-1)^3 = -1$.

Minors and Cofactors

Deleting from $|\mathbf{A}|$ the row and column containing a_{ij} leaves a determinant of order $n - 1$ that is called the *minor*, $|\mathbf{M}_{ij}|$, of a_{ij} in $|\mathbf{A}|$. Also $(-1)^{i+j}|\mathbf{M}_{ij}|$, the *signed minor*, is called the *cofactor* of a_{ij} in $|\mathbf{A}| : c_{ij} = (-1)^{i+j}|\mathbf{M}_{ij}|$. Then

$$|\mathbf{A}| = \sum_{i=1}^{n} a_{ij} c_{ij} \quad \text{for all } j \quad \text{and}$$

$$|\mathbf{A}| = \sum_{j=1}^{n} a_{ij} c_{ij} \quad \text{for all } i,$$

but

$$0 = \sum_{i=1}^{n} a_{ij} c_{ij'} \quad \text{for all } j \neq j' \quad \text{and}$$

$$0 = \sum_{j=1}^{n} a_{ij} c_{i'j} \quad \text{for all } i \neq i'.$$

Calculation

Computers now handle the calculation of determinants. Numerous available shortcuts and associated properties of determinants are detailed in the literature, which was especially rich on this subject up through the 1930s. Searle [4] deals with a few of these topics.

Some Properties Useful for Statistics

1. $|\mathbf{A}'| = |\mathbf{A}|$.
2. $|\mathbf{A}^k| = (|\mathbf{A}|)^k$, for integer k.
3. $|\mathbf{A}\mathbf{B}| = |\mathbf{A}||\mathbf{B}|$.
4. $|\mathbf{A}| = +1$, for orthogonal $\mathbf{A}$ (i.e. $\mathbf{A}'\mathbf{A} = \mathbf{I} = \mathbf{A}\mathbf{A}'$).
5. $|\mathbf{A}| = 0$, for idempotent $\mathbf{A}$ (i.e. $\mathbf{A}^2 = \mathbf{A}$), except for $\mathbf{A} = \mathbf{I}$.
6. $|\mathbf{I}| = 1$.
7. $|\lambda \mathbf{A}_{n \times n}| = \lambda^n |\mathbf{A}|$, for scalar λ.

Inverse Matrices

Existence

In matrix arithmetic, the very definition of multiplication precludes any obvious definition of division. Indeed, there is no such thing as matrix division; *division by a matrix does not exist*. Instead, multiplication by an inverse matrix is used, similar to the scalar equivalence of dividing by six (for example) being identical to multiplying by $1/6 = 6^{-1}$, the inverse of six: and

$$(6^{-1})6 = 1 = 6(6^{-1}).$$

There is one big difference: whereas every scalar different from zero has an inverse, not every nonnull matrix does.

Suppose that $\mathbf{A}$ has an inverse. Denote it by $\mathbf{A}^{-1}$, as is customary. Then with $\mathbf{I}$ being a "one" of matrix algebra, the matrix analogy of scalars is $(\mathbf{A}^{-1})\mathbf{A} = \mathbf{I} = \mathbf{A}(\mathbf{A}^{-1})$, where the parentheses are solely for emphasis, the usual writing being

$$\mathbf{A}^{-1}\mathbf{A} = \mathbf{I} = \mathbf{A}\mathbf{A}^{-1}.$$

This requirement demands that two conditions must be satisfied in order for $\mathbf{A}^{-1}$ to exist:

(i) $\mathbf{A}$ must be square;
(ii) $|\mathbf{A}| \neq 0$.

If either or both (i) and (ii) are not satisfied, $\mathbf{A}$ has no inverse; note, particularly, that every nonsquare matrix has no inverse.

When, for $\mathbf{A}$ square, $|\mathbf{A}| \neq 0$, $\mathbf{A}$ is called *nonsingular*, and if $|\mathbf{A}| = 0$ then $\mathbf{A}$ is called *singular*.

Form

The general form of $\mathbf{A}^{-1}$ is

$$\mathbf{A}^{-1} = \frac{1}{|\mathbf{A}|}\left[\begin{array}{c}\text{the matrix that is } \mathbf{A} \\ \text{with every element} \\ \text{replaced by its cofactor}\end{array}\right]^{\text{transposed}}$$

and $|\mathbf{A}|\mathbf{A}^{-1}$ is called the *adjugate* or *adjoint* of $\mathbf{A}$.

Some Basic Properties

1. $\mathbf{A}^{-1}$ is unique (for given $\mathbf{A}$).
2. $|\mathbf{A}^{-1}| = 1/|\mathbf{A}|$.
3. $\mathbf{A}^{-1}$ is nonsingular.
4. $(\mathbf{A}^{-1})^{-1} = \mathbf{A}$.
5. $(\mathbf{A}')^{-1} = (\mathbf{A}^{-1})'$.
6. $\mathbf{A}' = \mathbf{A} \Rightarrow (\mathbf{A}^{-1})' = \mathbf{A}^{-1}$.
7. $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$.

In all of these results, and whenever an inverse is used, one must always be certain that the matrix satisfies (i) and (ii) above; namely, squareness and nonzero determinant.

Four Special Cases

Denote a diagonal matrix having all its diagonal elements $\lambda_1, \ldots, \lambda_n$ nonzero by

$$\mathbf{D} = \{_{\mathrm{d}}\ \lambda_i\}_{i=1}^{n};$$

then,

$$\mathbf{D}^{-1} = \{_{\mathrm{d}}\ 1/\lambda_i\}_{i=1}^{n}, \quad \mathbf{I}^{-1} = \mathbf{I},$$

$$(a\mathbf{I}_n + b\mathbf{J}_n)^{-1} = \frac{1}{a}\left(\mathbf{I}_n - \frac{b}{a+nb}\mathbf{J}_n\right),$$

$$\mathbf{PP}' = \mathbf{I} = \mathbf{P}'\mathbf{P} \quad \text{implies} \quad \mathbf{P}^{-1} = \mathbf{P}'.$$

Algebra with Inverses

Compared with using division in scalar algebra, one has to be much more careful in using inverses in matrix algebra. This is because one never divides by a matrix; instead, in dealing with equations, one multiplies by an inverse. For example, given $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{AX} = \mathbf{B}$, the equation can be pre-multiplied, on both sides, by $\mathbf{A}^{-1}$ (provided that it exists) to obtain $\mathbf{A}^{-1}\mathbf{AX} = \mathbf{A}^{-1}\mathbf{B}$ and thus $\mathbf{IX} = \mathbf{A}^{-1}\mathbf{B}$ or $\mathbf{X} = \mathbf{A}^{-1}\mathbf{B}$. Note that $\mathbf{X}$ does not equal $\mathbf{BA}^{-1}$. Provided that conformability is satisfied, one could post-multiply $\mathbf{AX} = \mathbf{B}$ by $\mathbf{A}^{-1}$ and obtain $\mathbf{AXA}^{-1} = \mathbf{BA}^{-1}$; but that is it. No further simplification occurs.

Suppose that we have $\mathbf{P}$, $\mathbf{Q}$ and $\mathbf{K}$ such that $\mathbf{PK} = \mathbf{QK}$. This leads to $\mathbf{P} = \mathbf{Q}$ *only* if $\mathbf{K}^{-1}$ exists.

Inverses can also be used in factoring; for example, $\mathbf{R} + \mathbf{RST} = \mathbf{R}(\mathbf{I} + \mathbf{ST}) = \mathbf{R}(\mathbf{T}^{-1} + \mathbf{S})\mathbf{T}$, provided that $\mathbf{T}^{-1}$ exists.

Verifying the form of a particular inverse is often achieved by the following argument. Suppose that it is postulated that $\mathbf{A}$ inverse is $\mathbf{Q}$. Verifying this can be achieved by considering the product $\mathbf{AQ}$. If that can be shown to be equal to $\mathbf{I}$, thus $\mathbf{AQ} = \mathbf{I}$, then

$\mathbf{A}^{-1}\mathbf{AQ} = \mathbf{A}^{-1}\mathbf{I}$; that is, $\mathbf{Q} = \mathbf{A}^{-1}$. For example, suppose that $\mathbf{A}$ is $(\mathbf{I} + \mathbf{XY})$ and $\mathbf{Q}$ is $\mathbf{I} - \mathbf{X}(\mathbf{I} + \mathbf{YX})^{-1}\mathbf{Y}$. Then $\mathbf{A}^{-1}$ is shown to be $\mathbf{Q}$ by considering $\mathbf{AQ}$:

$$\begin{aligned}\mathbf{AQ} &= (\mathbf{I} + \mathbf{XY})[\mathbf{I} - \mathbf{X}(\mathbf{I} + \mathbf{YX})^{-1}\mathbf{Y}] \\ &= \mathbf{I} + \mathbf{XY} - (\mathbf{I} + \mathbf{XY})\mathbf{X}(\mathbf{I} + \mathbf{YX})^{-1}\mathbf{Y} \\ &= \mathbf{I} + \mathbf{XY} - (\mathbf{X} + \mathbf{XYX})(\mathbf{I} + \mathbf{YX})^{-1}\mathbf{Y} \\ &= \mathbf{I} + \mathbf{XY} - \mathbf{X}(\mathbf{I} + \mathbf{YX})(\mathbf{I} + \mathbf{YX})^{-1}\mathbf{Y} \\ &= \mathbf{I} + \mathbf{XY} - \mathbf{XY} \\ &= \mathbf{I},\end{aligned}$$

and so $\mathbf{A}^{-1} = \mathbf{Q}$.

Computers and Inverses

The arithmetic required for calculating an inverse matrix can be voluminous. Fortunately, computers have eased this situation enormously and many **software** packages include reliable routines for doing the arithmetic. Nevertheless, there are cases in which rounding error can lead to erroneous results; thankfully, this occurs very seldom, and software often handles it satisfactorily.

Rank

Linear Dependence and Independence of Vectors

$$\mathbf{Xa} = [\mathbf{x}_1 \quad \mathbf{x}_2 \quad \ldots \quad \mathbf{x}_c]\begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_i \\ \vdots \\ a_c \end{bmatrix} = \sum_{i=1}^{c} a_i \mathbf{x}_i$$

is a vector. It is a *linear combination* of the vectors $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_c$.

If, for a given $\mathbf{X}$ (with all columns nonnull), a nonnull vector $\mathbf{a}$ exists such that $\mathbf{Xa} = \mathbf{0}$, then the columns of $\mathbf{X}$ are said to be a set of *linearly dependent vectors*. If no such $\mathbf{a}$ exists, the columns are *linearly independent vectors*. These definitions exclude null vectors.

A Definition of Rank

If c columns are linearly dependent, there is always a smaller number of them that are linearly independent. In fact, there may be several sets of less than c columns that are linearly independent, with those sets not necessarily all having the same number of columns. The greatest number of columns in such a set is called the *rank of* $\mathbf{A}$, often denoted $\mathrm{r}(\mathbf{A})$. Thus, $\mathrm{r}(\mathbf{A})$ is the largest number of linearly independent columns available from $\mathbf{A}$. The "largest" is usually omitted. Thus, $\mathrm{r}(\mathbf{A})$ is the number of linearly independent columns in $\mathbf{A}$.

Some Properties and Consequences

Rank is an important and exceedingly useful concept in matrix algebra, with widespread applications. A list of some of the properties of rank follows:

1. The numbers of linearly independent rows and columns in a matrix are the same, $\mathrm{r}(\mathbf{A})$.
2. $\mathrm{r}(\mathbf{0}) = 0$.
3. $\mathrm{r}(\mathbf{A}_{p\times q}) \leq p$ and $\mathrm{r}(\mathbf{A}_{p\times q}) \leq q$.
4. $\mathrm{r}(\mathbf{A}_{n\times n}) \leq n$.
5. $\mathrm{r}(\mathbf{A}_{n\times n}) < n \Leftrightarrow \mathbf{A}$ is singular, $|\mathbf{A}| = \mathbf{0}$, with $\mathbf{A}^{-1}$ not existing.
6. $\mathrm{r}(\mathbf{A}_{n\times n}) = n \Leftrightarrow \mathbf{A}$ is nonsingular, $|\mathbf{A}| \neq \mathbf{0}$, with $\mathbf{A}^{-1}$ existing: $\mathbf{A}$ is said to be of *full rank*.
7. $\mathrm{r}(\mathbf{A}_{p\times q}) = p < q$ means that $\mathbf{A}$ has *full row rank*.
8. $\mathrm{r}(\mathbf{A}_{p\times q}) = q < p$ means that $\mathbf{A}$ has *full column rank*.
9. $\mathbf{A}_{p\times q}$ having rank r can always be expressed as $\mathbf{A}_{p\times q} = \mathbf{K}_{p\times r}\mathbf{L}_{r\times q}$, where $\mathbf{K}$ has full column rank r and $\mathbf{L}$ has full row rank r.
10. $\mathrm{r}(\mathbf{AB}) \leq$ lesser of $\mathrm{r}(\mathbf{A})$ and $\mathrm{r}(\mathbf{B})$.
11. $\mathrm{r}(\mathbf{A}) = \mathrm{tr}(\mathbf{A})$ for idempotent $\mathbf{A}$.
12. $\mathrm{r}(\mathbf{A}) = \mathrm{r}(\mathbf{A}')$.
13. $\mathrm{r}(\mathbf{A}) = \mathrm{r}(\mathbf{AA}')$.
14. $\mathrm{r}(\mathbf{A}) = \mathrm{r}(\mathbf{TA})$ for nonsingular $\mathbf{T}$.
15. $\mathrm{r}(\mathbf{A}^{-1}) = \mathrm{r}(\mathbf{A}) = n$ for $\mathbf{A}_{n\times n}$.

Left and Right Inverses

For given $\mathbf{A}_{r\times c}$, there exists:

1. $\mathbf{A}^{-1}$, the inverse of $\mathbf{A}$, such that $\mathbf{A}^{-1}\mathbf{A} = \mathbf{I} = \mathbf{AA}^{-1}$ if and only if $\mathbf{A}$ is square, with $|\mathbf{A}| \neq 0$;
2. $\mathbf{L}_{c\times r}$, a *left inverse* of $\mathbf{A}$, such that $\mathbf{LA} = \mathbf{I}_c$ (and $\mathbf{AL} \neq \mathbf{I}_r$) only if $\mathbf{A}$ has full column rank;
3. $\mathbf{R}_{c\times r}$, a *right inverse* of $\mathbf{A}$, such that $\mathbf{AR} = \mathbf{I}_r$ (and $\mathbf{RA} \neq \mathbf{I}_c$) only if $\mathbf{A}$ has full row rank;
4. neither an $\mathbf{A}^{-1}$, $\mathbf{L}$, nor $\mathbf{R}$ of (1), (2), or (3) – for example, any matrix having at least one null row and one null column.

Only when $\mathbf{A}^{-1}$ exists does $\mathbf{A}$ have both an $\mathbf{L}$ and an $\mathbf{R}$; and they both equal $\mathbf{A}^{-1}$. Otherwise, if $\mathbf{A}$ has full column (row) rank it has left (right) inverses of many values.

Vector Spaces

Since a vector of order n has n elements, it can be considered as a point in n-space, which is denoted R^n. Consider a set of vectors S, in R^n. Suppose, for every pair of vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ in S, that both the sum $\mathbf{x}_i + \mathbf{x}_j$ and the vectors $a\mathbf{x}_i$ and $b\mathbf{x}_i$ for any scalars a and b are in S; then S is a *vector space*.

Suppose that every vector in the vector space S can be expressed as a linear combination of the set of t vectors, $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_t$. Then that set *spans*, or *generates*, S and is called a *spanning* set of S. If those t vectors are also linearly independent, they are said to be a *basis* for S, and the number of such vectors is the *dimension* of S, $\dim(S)$.

There are many vector spaces of order n; and each of them usually has several bases.

Range and Null Spaces

$\mathbf{A}$ of rank r has r linearly independent columns. All vectors that are linear combinations of those columns form a vector space. It is known as the *column space* of $\mathbf{A}$, the *range* of $\mathbf{A}$, or the *manifold* of $\mathbf{A}$, often denoted by $\mathcal{R}(\mathbf{A})$. Clearly, $r = \mathrm{r}(\mathbf{A}) = \dim[\mathcal{R}(\mathbf{A})]$.

The space defined by the many vectors $\mathbf{x}$ for which $\mathbf{Ax} = \mathbf{0}$ (with $\mathbf{A}$ being rectangular, or square and singular) is the *null space* of $\mathbf{A}$, denoted $\mathcal{N}(\mathbf{A})$. Its dimension is the *nullity* of $\mathbf{A}$: $\mathrm{nullity}(\mathbf{A}) = \dim[\mathcal{N}(\mathbf{A})]$.

Equivalent and Congruent Canonical Forms

Elementary Operators

Three particular adaptations of identity matrices are *elementary operators; each is an identity matrix* with (i) two rows (or columns) interchanged, or (ii) λ in place of a one in the diagonal, or (iii) λ in place of a zero in an off-diagonal element. These and all products of any numbers of them are nonsingular.

Equivalent Canonical Form

For any $\mathbf{A}_{p\times q}$, of rank r, there always exists a $\mathbf{P}$ and a $\mathbf{Q}$, each a product of elementary operators, such that

$$\mathbf{P}_{p\times p}\mathbf{A}_{p\times q}\mathbf{Q}_{q\times q} = \begin{bmatrix} \mathbf{I}_{r\times r} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} = \mathbf{K}, \text{ say.}$$

$\mathbf{K}$ is the *equivalent canonical form* of $\mathbf{A}$; or the *canonical form under equivalence* of $\mathbf{A}$. Because $\mathbf{P}$ and $\mathbf{Q}$ are products of elementary operators, they are nonsingular, and so the equation $\mathbf{PAQ} = \mathbf{K}$ leads to $\mathbf{A} = \mathbf{P}^{-1}\mathbf{K}\mathbf{Q}^{-1}$. If $\mathbf{A}$ is nonsingular, $\mathbf{K} = \mathbf{I}$ and $\mathbf{A}^{-1} = \mathbf{QP}$.

Congruent Canonical Form

When $\mathbf{A}$ is symmetric (and hence square), the $\mathbf{Q}$ of $\mathbf{PAQ}$ can be $\mathbf{P}'$, giving

$$\mathbf{PAP}' = \begin{pmatrix} \mathbf{I}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} = \mathbf{C},$$

known as the *congruent canonical form* of $\mathbf{A}$ or the *canonical form under congruence*.

En route to deriving $\mathbf{C}$, one can obtain the form

$$\mathbf{P}_*\mathbf{AP}_*' = \begin{pmatrix} \mathbf{D}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} = \mathbf{C}_*,$$

where $\mathbf{D}_r$ is a diagonal matrix of order and rank r. For $\mathbf{A}$ being real, $\mathbf{P}_*$ will be real; but if $\mathbf{D}_r$ has negative elements, $\mathbf{P}$ in obtaining $\mathbf{C}$ will be complex. For $\mathbf{A}$ being nonnegative definite, elements of $\mathbf{D}_r$ are always positive and $\mathbf{P}$ is always real.

Utility: Sums of Squares

The utility of these canonical forms is their existence. For each $\mathbf{A}$ there are many values of $\mathbf{P}$ (and $\mathbf{Q}$) but usually not any one of them is of particular interest. It is the fact that they exist that is important, and that provides the means for establishing other useful results. For example, consider the quadratic form $q = \mathbf{x}'\mathbf{Ax}$ with $\mathbf{A} = \mathbf{A}'$ of rank r. Then there is a $\mathbf{P}$ such that $\mathbf{PAP}' = \mathbf{C}$. Thus, $q = \mathbf{x}'\mathbf{P}^{-1}\mathbf{PAP}'(\mathbf{P}')^{-1}\mathbf{x}$, and letting $\mathbf{y} = (\mathbf{P}')^{-1}\mathbf{x}$ gives $q = \mathbf{y}'\mathbf{Cy}$ which, because

$$\mathbf{C} = \begin{pmatrix} \mathbf{I}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix},$$

becomes $q = \sum_{i=1}^{r} y_i^2$. Thus, without knowing $\mathbf{P}$ except for its existence and nonsingularity, we can show that a quadratic form can always be expressed as a sum of r squared terms, where r is the rank of the (symmetric) matrix $\mathbf{A}$ of the quadratic form. That

is a result of great importance in considering the distribution of quadratic forms of normally distributed random variables.

Generalized Inverses

Definition

For any nonnull matrix $\mathbf{A}$, there is a unique matrix $\mathbf{M}$ satisfying:

(i) $\mathbf{AMA} = \mathbf{A}$;
(ii) $\mathbf{MAM} = \mathbf{M}$;
(iii) $(\mathbf{AM})' = \mathbf{AM}$; and
(iv) $(\mathbf{MA})' = \mathbf{MA}$.

These are the *Penrose* conditions and $\mathbf{M}$ is the *Moore–Penrose inverse*. Whereas $\mathbf{M}$ is unique, there are (with one exception) many matrices $\mathbf{G}$ satisfying

$$\mathbf{AGA} = \mathbf{A},$$

which is condition (i). Each matrix $\mathbf{G}$ satisfying $\mathbf{AGA} = \mathbf{A}$ is called a *generalized inverse* of $\mathbf{A}$, and if it also satisfies $\mathbf{GAG} = \mathbf{G}$ it is a *reflexive generalized inverse*. The exception is when $\mathbf{A}$ is nonsingular: there is then only one $\mathbf{G}$; namely, $\mathbf{G} = \mathbf{A}^{-1}$.

Arbitrariness

That there are many matrices $\mathbf{G}$ can be illustrated by showing ways in which from one $\mathbf{G}$ others can be obtained. Thus, if $\mathbf{A}$ is partitioned as

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix},$$

where $\mathbf{A}_{11}$ is nonsingular with the same rank as $\mathbf{A}$, then

$$\mathbf{G} = \begin{bmatrix} \mathbf{A}_{11}^{-1} - \mathbf{U}\mathbf{A}_{21}\mathbf{A}_{11}^{-1} - \mathbf{A}_{11}^{-1}\mathbf{A}_{12}\mathbf{V} - \mathbf{A}_{11}^{-1}\mathbf{A}_{12}\mathbf{W}\mathbf{A}_{21}\mathbf{A}_{11}^{-1} & \mathbf{U} \\ \mathbf{V} & \mathbf{W} \end{bmatrix}$$

is a generalized inverse of $\mathbf{A}$ for any values of $\mathbf{U}$, $\mathbf{V}$ and $\mathbf{W}$. This can be used to show that a generalized inverse of a symmetric matrix is not necessarily symmetric; and that of a singular matrix is not necessarily singular [[4], p. 219].

A simpler illustration of arbitrariness is that if $\mathbf{G}$ is a generalized inverse of $\mathbf{A}$ then so is

$$\mathbf{G}^* = \mathbf{GAG} + (\mathbf{I} - \mathbf{GA})\mathbf{S} + \mathbf{T}(\mathbf{I} - \mathbf{AG}),$$

for any values of $\mathbf{S}$ and $\mathbf{T}$.

Generalized Inverses of $\boldsymbol{X'X}$

The matrix $\mathbf{X}'\mathbf{X}$ plays an important role in statistics, usually involving a generalized inverse thereof, which has several useful properties. Thus, for $\mathbf{G}$ satisfying

$$\mathbf{X}'\mathbf{X}\mathbf{G}\mathbf{X}'\mathbf{X} = \mathbf{X}'\mathbf{X},$$

$\mathbf{G}'$ is also a generalized inverse of $\mathbf{X}'\mathbf{X}$ (and $\mathbf{G}$ is not necessarily symmetric). Also,

1. $\mathbf{X}\mathbf{G}\mathbf{X}'\mathbf{X} = \mathbf{X}$;
2. $\mathbf{X}\mathbf{G}\mathbf{X}'$ is invariant to $\mathbf{G}$;
3. $\mathbf{X}\mathbf{G}\mathbf{X}'$ is symmetric, whether or not $\mathbf{G}$ is;
4. $\mathbf{X}\mathbf{G}\mathbf{X}' = \mathbf{X}\mathbf{X}^+$ for $\mathbf{X}^+$ being the Moore–Penrose inverse of $\mathbf{X}$.

Solving Linear Equations

A Single Solution

Given $\mathbf{A}$ and $\mathbf{y}$, the equations $\mathbf{Ax} = \mathbf{y}$ are linear in the unknowns, the elements of $\mathbf{x}$. When $\mathbf{A}$ is nonsingular, the equations are solved uniquely, as $\mathbf{x} = \mathbf{A}^{-1}\mathbf{y}$. But for singular or rectangular $\mathbf{A}$, solutions involve using a generalized inverse of $\mathbf{A}$. The following results apply.

First, equations $\mathbf{Ax} = \mathbf{y}$ are said to be *consistent* when any linear relationships existing among rows of $\mathbf{A}$ also exist among elements of $\mathbf{y}$. Only then do solutions exist. Secondly, for singular or rectangular $\mathbf{A}$ there will be many solutions for $\mathbf{x}$, except when $\mathbf{A}$ has full column rank, whereupon there is only one solution, $\mathbf{x} = (\mathbf{A}'\mathbf{A})^{-1}\mathbf{A}'\mathbf{y}$: and this includes, of course, the case of nonsingular $\mathbf{A}$.

Many Solutions

When $\mathbf{A}$ has less than full column rank, there are many solutions. They are characterized as follows, with $\mathbf{G}$ being a generalized inverse satisfying $\mathbf{AGA} = \mathbf{A}$.

1. $\tilde{\mathbf{x}} = \mathbf{G}\mathbf{y}$ is a solution if and only if $\mathbf{AGA} = \mathbf{A}$.
2. Letting $\mathbf{G}$ take all its possible values in $\tilde{\mathbf{x}} = \mathbf{G}\mathbf{y}$ (for $\mathbf{y} \neq \mathbf{0}$) generates all possible solutions.
3. $\tilde{\mathbf{x}} = \mathbf{G}\mathbf{y} + (\mathbf{I} - \mathbf{GA})\mathbf{z}$ is a solution for any arbitrary $\mathbf{z}$ of the same order as $\mathbf{x}$.
4. For a given $\mathbf{G}$, letting $\mathbf{z}$ take all possible values in $\tilde{\mathbf{x}} = \mathbf{G}\mathbf{y} + (\mathbf{I} - \mathbf{GA})\mathbf{z}$ generates all possible solutions.

5. When $\tilde{\mathbf{x}}_1, \tilde{\mathbf{x}}_2, \ldots, \tilde{\mathbf{x}}_t$ are any solutions, $\sum_{i=1}^{t} \lambda_i \tilde{\mathbf{x}}_i$ is a solution (with $\mathbf{y} \neq \mathbf{0}$) if and only if $\sum_{i=1}^{t} \lambda_i = 1$; this condition is not needed when $\mathbf{y} = \mathbf{0}$.
6. For $\mathbf{A}_{p\times q}$ and $\mathbf{y} \neq \mathbf{0}$ there are $q - r(\mathbf{A}) + 1 - \delta_{\mathbf{y},\mathbf{0}}$ linearly independent solutions, where $\delta_{\mathbf{y},\mathbf{0}} = 1$ when $\mathbf{y} = \mathbf{0}$ and zero otherwise.
7. The value of $\mathbf{k}'\tilde{\mathbf{x}}$ is invariant to $\tilde{\mathbf{x}}$ if and only if $\mathbf{k}' = \mathbf{k}'\mathbf{G}\mathbf{A}$.
8. When $\mathbf{y} = \mathbf{0}$, solutions are orthogonal to rows of $\mathbf{A}$; and solutions orthogonal to each other can always be derived. The vector space spanned by the solutions, sometimes called the *solution space*, is the *orthogonal complement* of the row space of $\mathbf{A}$.

Partitioned Matrices

Some results for partitioned matrices used in statistics are as follows.

Orthogonality

If $\mathbf{P} = [\mathbf{A} \quad \mathbf{B}]$ is orthogonal,

$$\mathbf{P}\mathbf{P}' = \mathbf{I} \Rightarrow [\mathbf{A} \quad \mathbf{B}]\begin{bmatrix}\mathbf{A}'\\ \mathbf{B}'\end{bmatrix} = \mathbf{I} \Rightarrow \mathbf{A}\mathbf{A}' + \mathbf{B}\mathbf{B}' = \mathbf{I},$$

$$\mathbf{P}'\mathbf{P} = \mathbf{I} \Rightarrow \begin{bmatrix}\mathbf{A}'\\ \mathbf{B}'\end{bmatrix}[\mathbf{A} \quad \mathbf{B}] = \mathbf{I} \Rightarrow \begin{bmatrix}\mathbf{A}'\mathbf{A} & \mathbf{A}'\mathbf{B}\\ \mathbf{B}'\mathbf{A} & \mathbf{B}'\mathbf{B}\end{bmatrix}$$

$$= \begin{bmatrix}\mathbf{I} & \mathbf{0}\\ \mathbf{0} & \mathbf{I}\end{bmatrix} \Rightarrow \mathbf{A}'\mathbf{A} = \mathbf{I}, \qquad \mathbf{A}'\mathbf{B} = \mathbf{0}$$

$$\text{and} \quad \mathbf{B}'\mathbf{B} = \mathbf{I}.$$

Note that $\mathbf{A}\mathbf{A}'$ and $\mathbf{B}\mathbf{B}'$ are not identity matrices.

Determinants

$$\begin{vmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{vmatrix} = |\mathbf{A}||\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}| = |\mathbf{D}||\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C}|,$$

provided that $\mathbf{A}^{-1}$ and $\mathbf{D}^{-1}$ exist, where needed.

Inverses

$$\begin{bmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{bmatrix}^{-1} = \begin{bmatrix}\mathbf{A}^{-1} & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix} + \begin{bmatrix}-\mathbf{A}^{-1}\mathbf{B}\\ \mathbf{I}\end{bmatrix} \times (\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})^{-1}[-\mathbf{C}\mathbf{A}^{-1} \quad \mathbf{I}]$$

$$= \begin{bmatrix}\mathbf{0} & \mathbf{0}\\ \mathbf{0} & \mathbf{D}^{-1}\end{bmatrix} + \begin{bmatrix}\mathbf{I}\\ -\mathbf{D}^{-1}\mathbf{C}\end{bmatrix} \times (\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})^{-1}[\mathbf{I} \quad -\mathbf{B}\mathbf{D}^{-1}],$$

again provided that $\mathbf{A}^{-1}$ and $\mathbf{D}^{-1}$ exist as needed.

Schur Complements

In

$$\begin{bmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{bmatrix}$$

the *Schur complement* of $\mathbf{A}$ is $\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B}$ and that of $\mathbf{D}$ is $\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C}$. The inverse of one involves that of the other:

$$(\mathbf{D} - \mathbf{C}\mathbf{A}^{-1}\mathbf{B})^{-1} = \mathbf{D}^{-1} + \mathbf{D}^{-1}\mathbf{C} \times (\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})^{-1}\mathbf{B}\mathbf{D}^{-1}.$$

This result also applies when the two minus signs are changed to plus, and the plus to minus. It also has some useful special cases; for example,

$$(\mathbf{D} \pm \lambda\mathbf{t}\mathbf{t}')^{-1} = \mathbf{D}^{-1} \mp \frac{\mathbf{D}^{-1}\mathbf{t}\mathbf{t}'\mathbf{D}^{-1}}{(\lambda^{-1} \pm \mathbf{t}'\mathbf{D}^{-1}\mathbf{t})}.$$

Generalized Inverses

By analogy with expressions for the inverse, one might expect (with $\mathbf{A}^-$ being a generalized inverse of $\mathbf{A}$)

$$\tilde{\mathbf{Q}} = \begin{bmatrix}\mathbf{A}^- & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix} + \begin{bmatrix}-\mathbf{A}^-\\ \mathbf{I}\end{bmatrix} \times (\mathbf{D} - \mathbf{C}\mathbf{A}^-\mathbf{B})^-[-\mathbf{C}\mathbf{A}^- \quad \mathbf{I}]$$

to be a generalized inverse of

$$\mathbf{Q} = \begin{bmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C} & \mathbf{D}\end{bmatrix}.$$

It is, if and only if $\mathrm{r}(\mathbf{Q}) = \mathrm{r}(\mathbf{A}) + \mathrm{r}(\mathbf{D} - \mathbf{C}\mathbf{A}^-\mathbf{B})$. Satisfying this rank condition depends upon $\mathbf{A}^-$. For some values of $\mathbf{A}^-$ the condition will be satisfied and for others it will not. Only when it is satisfied will $\tilde{\mathbf{Q}}$ be a generalized inverse of $\mathbf{Q}$.

Direct Sums

The direct sum of matrices $\mathbf{A}$ and $\mathbf{B}$, each of any order, is defined as

$$\mathbf{A} \oplus \mathbf{B} = \begin{bmatrix} \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \mathbf{B} \end{bmatrix}.$$

Extension to the direct sum of more than two matrices is straightforward.

Provided that the needed conformability requirements are met,

$$(\mathbf{A} \oplus \mathbf{B}) + (\mathbf{C} \oplus \mathbf{D}) = (\mathbf{A} + \mathbf{C}) \oplus (\mathbf{B} + \mathbf{D}),$$

$$(\mathbf{P} \oplus \mathbf{Q})(\mathbf{L} \oplus \mathbf{M}) = \mathbf{PL} \oplus \mathbf{QM},$$

and

$$(\mathbf{X} \oplus \mathbf{Y})^{-1} = \mathbf{X}^{-1} \oplus \mathbf{Y}^{-1}.$$

Direct Products

The *direct product* of two matrices, each of any order, is defined as

$$\mathbf{A}_{p\times q} \otimes \mathbf{B}_{m\times n} = \begin{bmatrix} a_{11}\mathbf{B} & \dots & a_{1q}\mathbf{B} \\ \vdots & & \\ a_{p1}\mathbf{B} & \dots & a_{pq}\mathbf{B} \end{bmatrix}_{pm\times qn} = \{_{\mathrm{m}}\ a_{ij}\mathbf{B}\}_{i=1,j=1}^{p\quad q}.$$

It is sometimes called the *Kronecker product*. Some properties follow – assuming that conformability requirements are met:

1. $\mathbf{x}' \otimes \mathbf{y} = \mathbf{y}\mathbf{x}' = \mathbf{y} \otimes \mathbf{x}'$;
2. $\lambda \otimes \mathbf{A} = \lambda\mathbf{A} = \mathbf{A} \otimes \lambda$;
3. $(\mathbf{A} \otimes \mathbf{B})' = \mathbf{A}' \otimes \mathbf{B}'$, *not* $\mathbf{B}' \otimes \mathbf{A}'$;
4. $(\mathbf{A} \otimes \mathbf{B})(\mathbf{X} \otimes \mathbf{Y}) = \mathbf{AX} \otimes \mathbf{BY}$;
5. $(\mathbf{P} \otimes \mathbf{Q})^{-1} = \mathbf{P}^{-1} \otimes \mathbf{Q}^{-1}$, *not* $\mathbf{Q}^{-1} \otimes \mathbf{P}^{-1}$;
6. $[\mathbf{A}_1 \quad \mathbf{A}_2] \otimes \mathbf{B} = [\mathbf{A}_1 \otimes \mathbf{B} \quad \mathbf{A}_2 \otimes \mathbf{B}]$, $\mathbf{A} \otimes [\mathbf{B}_1 \quad \mathbf{B}_2] \neq [\mathbf{A} \otimes \mathbf{B}_1 \mathbf{A} \otimes \mathbf{B}_2]$;
7. $\mathrm{r}(\mathbf{A} \otimes \mathbf{B}) = \mathrm{r}(\mathbf{A})\mathrm{r}(\mathbf{B})$;
8. $\mathrm{tr}(\mathbf{A} \otimes \mathbf{B}) = \mathrm{tr}(\mathbf{A})\mathrm{tr}(\mathbf{B})$;
9. $|\mathbf{A}_{p\times p} \otimes \mathbf{B}_{m\times m}| = |\mathbf{A}|^m |\mathbf{B}|^p$.

Sometimes $\mathbf{A} \otimes \mathbf{B} = \{a_{ij}\mathbf{B}\}$ as defined above is called the *right direct product*, to distinguish it from $\mathbf{B} \otimes \mathbf{A}$, which is then called the *left direct product*; and on rare occasions $\{a_{ij}\mathbf{B}\}$ will be found defined as $\mathbf{B} \otimes \mathbf{A}$.

Eigenvalues and Eigenvectors

The equation

$$\mathbf{Au} = \lambda\mathbf{u}, \text{ i.e. } (\mathbf{A} - \lambda\mathbf{I})\mathbf{u} = \mathbf{0},$$

has solutions for $\mathbf{u}$ provided that $\mathbf{A} - \lambda\mathbf{I}$ is singular. This occurs when

$$|\mathbf{A} - \lambda\mathbf{I}| = \mathbf{0}.$$

This is called the *characteristic equation* of $\mathbf{A}$; for $\mathbf{A}_{n\times n}$ it is a polynomial of order n and therefore has n solutions for λ. Those solutions are the **eigenvalues** (or *eigenroots*) of $\mathbf{A}$. They can be real or complex, positive or negative, or zero. For each eigenvalue, λ_* say, a corresponding value of $\mathbf{u}$ can be obtained from solving the equations $(\mathbf{A} - \lambda_*\mathbf{I})\mathbf{u} = \mathbf{0}$, as

$$\mathbf{u}_* = [\mathbf{I} - (\mathbf{A} - \lambda_*\mathbf{I})^-(\mathbf{A} - \lambda_*\mathbf{I})]\mathbf{z}$$

for arbitrary $\mathbf{z}$. (Searle [4, Section 11.4] has details.) $\mathbf{u}_*$ is the **eigenvector** corresponding to λ_*.

Numerical Example

For

$$\mathbf{A} = \begin{bmatrix} 2 & 2 & 0 \\ 2 & 1 & 1 \\ -7 & 2 & -3 \end{bmatrix},$$

the characteristic equation $|\mathbf{A} - \lambda\mathbf{I}| = 0$ reduces to $(\lambda - 1)(\lambda - 3)(\lambda + 4) = 0$, so that the eigenvalues are 1, 3, and -4. For $\lambda_* = 1$ the eigenvector, from the equation for $\mathbf{u}_*$,

$$\begin{aligned} \mathbf{u}_* &= \left[\mathbf{I} - \begin{pmatrix} 1 & 2 & 0 \\ 2 & 0 & 1 \\ -7 & 2 & -4 \end{pmatrix}^- \begin{pmatrix} 1 & 2 & 0 \\ 2 & 0 & 1 \\ -7 & 2 & -4 \end{pmatrix}\right] \begin{bmatrix} z_1 \\ z_2 \\ z_3 \end{bmatrix} \\ &= \left[\mathbf{I} + \tfrac{1}{4}\begin{pmatrix} 0 & -2 & 0 \\ -2 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} 1 & 2 & 0 \\ 2 & 0 & 1 \\ -7 & 2 & -4 \end{pmatrix}\right] \begin{bmatrix} z_1 \\ z_2 \\ z_3 \end{bmatrix} \\ &= \left[\mathbf{I} + \tfrac{1}{4}\begin{pmatrix} -4 & 0 & -2 \\ 0 & -4 & 1 \\ 0 & 0 & 0 \end{pmatrix}\right] \begin{bmatrix} z_1 \\ z_2 \\ z_3 \end{bmatrix} \\ &= \begin{bmatrix} 0 & 0 & -\frac{1}{2} \\ 0 & 0 & \frac{1}{4} \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \\ z_3 \end{bmatrix} = \begin{bmatrix} -\frac{1}{2}z_3 \\ \frac{1}{4}z_3 \\ z_3 \end{bmatrix} \quad \text{for any } z_3 \neq 0. \end{aligned}$$

Similarly, for $\lambda_* = 3$,

$$\mathbf{u}_* = \left[\mathbf{I} - \begin{pmatrix} -1 & 2 & 0 \\ 2 & -2 & 1 \\ -7 & 2 & -3 \end{pmatrix}^- \begin{pmatrix} -1 & 2 & 0 \\ 2 & -2 & 1 \\ -7 & 2 & -3 \end{pmatrix}\right] \mathbf{z}$$

$$= \left[\mathbf{I} - \frac{1}{2}\begin{pmatrix} -2 & -2 & 0 \\ -2 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} -1 & 2 & 0 \\ 2 & -2 & 1 \\ -7 & 2 & -3 \end{pmatrix}\right]\mathbf{z}$$

$$= \left[\mathbf{I} - \frac{1}{2}\begin{pmatrix} -2 & 0 & -2 \\ 0 & -2 & -1 \\ 0 & 0 & 0 \end{pmatrix}\right]\mathbf{z} = \begin{bmatrix} 0 & 0 & -1 \\ 0 & 0 & -\frac{1}{2} \\ 0 & 0 & 1 \end{bmatrix}\mathbf{z}$$

$$= \begin{bmatrix} -z_3 \\ -\frac{1}{2}z_3 \\ z_3 \end{bmatrix}.$$

The case of $\lambda_* = -4$ is left to the reader.

Properties of Eigenvalues

See **Eigenvalue**.

Properties of Eigenvectors

See **Eigenvector**.

Some Summaries

Orthogonal Matrices

Any two of (i) $\mathbf{A}$ being square, (ii) $\mathbf{A}\mathbf{A}' = \mathbf{I}$, and (iii) $\mathbf{A}'\mathbf{A} = \mathbf{I}$ imply the third; and define $\mathbf{A}$ as being orthogonal. The properties of orthogonal $\mathbf{A}$ include the following

1. Rows (columns) are orthonormal;
2. $|\mathbf{A}| = \pm 1$;
3. λ being an eigenroot of $\mathbf{A}$ implies that $1/\lambda$ is also;
4. $\mathbf{AB}$ is orthogonal when $\mathbf{A}$ and $\mathbf{B}$ are.

Idempotent Matrices

Idempotent $\mathbf{A}$ of order n has the following properties:

1. $\mathbf{A}^2 = \mathbf{A}$;
2. $\mathbf{A}$ is singular, unless $\mathbf{A} = \mathbf{I}$;
3. $\mathrm{r}(\mathbf{A}) = \mathrm{tr}(\mathbf{A})$;
4. $\mathbf{I} - \mathbf{A}$ is idempotent, with $\mathrm{r}(\mathbf{I} - \mathbf{A}) = n - \mathrm{r}(\mathbf{A})$;
5. If $\mathbf{A}$ is also symmetric (but not $\mathbf{I}$) it is positive semidefinite, and can be expressed as $\mathbf{A} = \mathbf{L}\mathbf{L}'$ for $\mathbf{L}'\mathbf{L} = \mathbf{I}$;
6. For idempotent $\mathbf{A}$ and $\mathbf{B}$, $\mathbf{AB}$ is idempotent if $\mathbf{AB} = \mathbf{BA}$;
7. $\mathrm{r}(\mathbf{A})$ eigenvalues of $\mathbf{A}$ are 1.0, and $n - \mathrm{r}(\mathbf{A})$ are 0;
8. There is a $\mathbf{U}$ such that
$$\mathbf{U}^{-1}\mathbf{A}\mathbf{U} = \begin{bmatrix} \mathbf{I}_{\mathrm{r}(\mathbf{A})} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix};$$
9. $\mathbf{P} = \mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'$ is idempotent, and is very useful in statistics.

Matrices $a\mathbf{I} + b\mathbf{J}$

The matrix $a\mathbf{I} + b\mathbf{J}$ for $\mathbf{J} = \mathbf{1}\mathbf{1}'$ occurs in a number of analysis of variance situations in statistics. When of order n it has the following properties:

$$(a_1\mathbf{I} + b_1\mathbf{J})(a_2\mathbf{I} + b_2\mathbf{J}) = a_1a_2\mathbf{I} + (a_1b_2 + a_2b_1 + nb_1b_2)\mathbf{J},$$

$$(a\mathbf{I} + b\mathbf{J})^{-1} = \frac{1}{a}\left(\mathbf{I} - \frac{b}{a+nb}\mathbf{J}\right),$$

$$|a\mathbf{I} + b\mathbf{J}| = a^{n-1}(a + nb).$$

Eigenvalues are a, $n-1$ times, and $a + nb$ once.

Nonnegative Definite Matrices

If $\mathbf{A}$ is nonnegative definite (n.n.d.):

1. $\mathbf{x}'\mathbf{A}\mathbf{x} \geq 0$, for all $\mathbf{x} \neq 0$;
2. $\mathbf{A}$ is assumed to be symmetric, because otherwise it can be replaced by $\frac{1}{2}(\mathbf{A} + \mathbf{A}')$;
3. $|\mathbf{A}| \geq 0$;
4. Diagonal elements of $\mathbf{A}$ are ≥ 0;
5. Principal leading minors are ≥ 0;
6. Eigenvalues are ≥ 0;
7. For $\mathbf{A}$ is positive definite (p.d.), all the above ≥ 0 symbols become > 0;
8. For real $\mathbf{X}$, $\mathbf{X}'\mathbf{X}$ is n.n.d.

For real $\mathbf{X}$ of full column rank:

1. $\mathbf{X}'\mathbf{X}$ is p.d.;
2. $(\mathbf{X}'\mathbf{X})^{-1}$ exists;
3. $\mathbf{X}\mathbf{X}'$ has Moore–Penrose inverse $\mathbf{X}(\mathbf{X}'\mathbf{X})^{-2}\mathbf{X}'$.

Canonical and Other Forms

For any matrix $\mathbf{A}_{p\times q}$ of rank r:

1. Equivalent canonical form:
$$\mathbf{P}\mathbf{A}\mathbf{Q} = \begin{bmatrix} \mathbf{I}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \mathbf{P} \text{ and } \mathbf{Q} \text{ nonsingular.}$$

2. Similar canonical form:

$$\mathbf{AU} = \mathbf{UD}\{\lambda\},$$

where $\mathbf{D}\{\lambda\}$ is the diagonal matrix of eigenvalues; and $\mathbf{U}$ is the matrix of corresponding eigenvectors. $\mathbf{U}^{-1}$ exists when the diagonability theorem is satisfied (*see* **Eigenvector**), and then

$$\mathbf{U}^{-1}\mathbf{AU} = \mathbf{D}\{\lambda\}.$$

3. Singular-valued decomposition:

$$\mathbf{A} = \mathbf{L}\begin{bmatrix} \boldsymbol{\Delta}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}\mathbf{M}',$$

where $\mathbf{L}$ and $\mathbf{M}$ are each orthogonal, and $\boldsymbol{\Delta}_r = (\boldsymbol{\Delta}^2)^{1/2}$, where

$$\mathbf{L}'\mathbf{AA}'\mathbf{L} = \begin{bmatrix} \boldsymbol{\Delta}^2 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad \text{and}$$

$$\mathbf{M}'\mathbf{A}'\mathbf{AM} = \begin{bmatrix} \boldsymbol{\Delta}^2 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix},$$

with $\boldsymbol{\Delta}^2$ being the diagonal matrix of the (positive) eigenroots of $\mathbf{A}'\mathbf{A}$ (or, equivalently, of $\mathbf{AA}'$).

For symmetric $\mathbf{A}$ of order p and rank r:

4. Diagonal form:

$$\mathbf{PAP}' = \begin{bmatrix} \mathbf{D}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \text{with } \mathbf{D}_r \text{ diagonal, order } r.$$

When $\mathbf{A}$ is n.n.d., elements of $\mathbf{D}_r$ are positive.

5. Congruent canonical form:

$$\mathbf{RAR}' = \begin{bmatrix} \mathbf{I}_r & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \text{for } \mathbf{R} \text{ possibly complex.}$$

When $\mathbf{A}$ is n.n.d., $\mathbf{R}$ is real.

6. Orthogonal similar canonical form:

$$\mathbf{U}'\mathbf{AU} = \mathbf{D}\{\lambda\},$$

with $\mathbf{U}$ being orthogonal and $\mathbf{U}^{-1} = \mathbf{U}'$.

7. Spectral decomposition:

$$\mathbf{A} = \sum_i \lambda_i \mathbf{u}_i \mathbf{u}_i',$$

for λ_i being an eigenvalue and $\mathbf{u}_i$ its corresponding eigenvector.

Solving Equations by Iteration

Current computing facilities provide numerous methods of arithmetically solving equations which cannot be solved algebraically. Matrix notation permits succinct description of one of these methods.

For n equations in n unknowns, represented by $\mathbf{x}$, let the equations be

$$\mathbf{f}(\mathbf{x}) = \mathbf{0}, \tag{1}$$

and define

$$\mathbf{G}(\mathbf{x}) = \{g_{ij}(\mathbf{x})\} = \left\{\frac{\partial}{\partial x_j} f_i(\mathbf{x})\right\} \quad \text{for}$$

$$i, j = 1, \ldots, n. \tag{2}$$

Suppose that $\mathbf{x}_r$ is an approximate solution for $\mathbf{x}$ to $\mathbf{f}(\mathbf{x}) = \mathbf{0}$. Then an improved approximation is $\mathbf{x}_{r+1}$ for

$$\mathbf{f}(\mathbf{x}_{r+1}) = \mathbf{f}(\mathbf{x}_r) + \mathbf{G}(\mathbf{x}_r)\boldsymbol{\Delta}_r, \tag{3}$$

where

$$\boldsymbol{\Delta}_r = \mathbf{x}_{r+1} - \mathbf{x}_r. \tag{4}$$

Were $\mathbf{x}_{r+1}$ to be a solution to (1) then $\mathbf{f}(\mathbf{x}_{r+1})$ would be $\mathbf{0}$ and (3) would yield

$$\boldsymbol{\Delta}_r = -[\mathbf{G}(\mathbf{x}_r)]^{-1}\mathbf{f}(\mathbf{x}_r), \tag{5}$$

and with this, (4) gives

$$\mathbf{x}_{r+1} = \boldsymbol{\Delta}_r + \mathbf{x}_r. \tag{6}$$

In this way, (5) and (6) provide an iterative procedure for calculating a solution: for some initial value $\mathbf{x}_0$, use (5) to obtain $\boldsymbol{\Delta}_0$ and then (6) to obtain $\mathbf{x}_1$; and back to (5) to obtain $\boldsymbol{\Delta}_1$, and so on.

Differential Calculus with Matrices

A number of situations in statistics involve maximizing or minimizing a function: for example, maximum likelihood estimation, least squares estimation, minimum variance procedures, minimizing loss functions, and so on. In many cases, differentiation of matrix expressions is involved, for which the following results are often useful.

Differentiating with Respect to a Scalar

Suppose that the elements of $\mathbf{A} = \{a_{ij}\}$ are functions of a scalar x. Then

$$\frac{\partial \mathbf{A}}{\partial x} = \left\{ \frac{\partial a_{ij}}{\partial x} \right\},$$

$$\frac{\partial \mathbf{A}^{-1}}{\partial x} = -\mathbf{A}^{-1} \frac{\partial \mathbf{A}}{\partial x} \mathbf{A}^{-1},$$

$$\mathbf{A} \frac{\partial \mathbf{A}^{-}}{\partial x} \mathbf{A} = -\mathbf{A}\mathbf{A}^{-} \frac{\partial \mathbf{A}}{\partial x} \mathbf{A}^{-}\mathbf{A},$$

where $\mathbf{A}^{-}$ is a generalized inverse of $\mathbf{A}$, satisfying $\mathbf{A}\mathbf{A}^{-}\mathbf{A} = \mathbf{A}$. Also,

$$\mathbf{A} \frac{\partial (\mathbf{A}'\mathbf{A})^{-}}{\partial x} \mathbf{A}' = -\mathbf{A}(\mathbf{A}'\mathbf{A})^{-} \frac{\partial (\mathbf{A}'\mathbf{A})}{\partial x} (\mathbf{A}'\mathbf{A})^{-}\mathbf{A}'.$$

Also, for $\mathbf{A} = \mathbf{A}'$ and elements of $\mathbf{T}$ not involving x,

$$\mathbf{P} = \mathbf{T}(\mathbf{T}'\mathbf{A}\mathbf{T})^{-1}\mathbf{T}' \text{ has } \frac{\partial \mathbf{P}}{\partial x} = -\mathbf{P} \frac{\partial \mathbf{A}}{\partial x} \mathbf{P}.$$

Differentiating with Respect to Elements of a Vector

The basis of differentiating with respect to elements of $\mathbf{x}$ is defining what is meant by $\partial/\partial\mathbf{x}$. This is important, because the definition determines the form of its various applications, and because not all writers use the same definition. Any presentation of this topic should therefore start by defining $\partial/\partial\mathbf{x}$.

A widely used convention is that, for $\mathbf{x}$ being a column vector, $\partial/\partial\mathbf{x}$ is also: thus, for $\mathbf{x} = [x_1 \ldots x_n]'$, we define

$$\mathbf{x} = \{_{\mathrm{c}}\ x_i\}_{i=1}^{n} \quad \text{and} \quad \frac{\partial}{\partial \mathbf{x}} = \left\{ {}_{\mathrm{c}} \frac{\partial}{\partial x_i} \right\}_{i=1}^{n}.$$

Thus $\partial/\partial\mathbf{x}$ is a vector of differential operators. With this definition come the following basic results:

$$\frac{\partial}{\partial \mathbf{x}}(\mathbf{a}'\mathbf{x}) = \frac{\partial}{\partial \mathbf{x}}(\mathbf{x}'\mathbf{a}) = \mathbf{a} \quad \text{and} \quad \frac{\partial}{\partial \mathbf{x}}(\mathbf{x}'\mathbf{A}) = \mathbf{A}.$$

Then, in order to maintain feasible matrix dimensions, the convention is adopted that

$$\frac{\partial}{\partial \mathbf{x}}(\mathbf{A}\mathbf{x}) = \frac{\partial}{\partial \mathbf{x}}(\mathbf{x}'\mathbf{A}'),$$

and so

$$\frac{\partial}{\partial \mathbf{x}}(\mathbf{A}\mathbf{x}) = \mathbf{A}'.$$

This leads to

$$\frac{\partial}{\partial \mathbf{x}}(\mathbf{x}'\mathbf{A}\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{A}'\mathbf{x} \quad \text{for } \mathbf{A} \text{ not symmetric,}$$

$$= 2\mathbf{A}\mathbf{x} \quad \text{for } \mathbf{A} \text{ symmetric.}$$

Differentiating with Respect to Elements of a Matrix

Again, the basic definition is important: for scalar θ and $\mathbf{X}_{p\times q}$,

$$\frac{\partial \theta}{\partial \mathbf{X}} = \left\{ {}_{\mathrm{m}} \frac{\partial \theta}{\partial x_{ij}} \right\}_{i=1\ j=1}^{p \quad q}.$$

For $\mathbf{X}$ having functionally unrelated elements,

$$\frac{\partial}{\partial \mathbf{X}}[\mathrm{tr}(\mathbf{X}\mathbf{A})] = \mathbf{A}'.$$

But for symmetric $\mathbf{X}$,

$$\frac{\partial}{\partial \mathbf{X}}[\mathrm{tr}(\mathbf{X}\mathbf{A})] = \mathbf{A} + \mathbf{A}' - \mathrm{diag}(\mathbf{A}),$$

where $\mathrm{diag}(\mathbf{A})$ is the diagonal matrix of the diagonal elements of $\mathbf{A}$. Of course, these results also apply to $\mathrm{tr}(\mathbf{A}\mathbf{X}) = \mathrm{tr}(\mathbf{X}\mathbf{A})$.

Differentiating Determinants

Let x_{ij} be the (i, j)th element of $\mathbf{X}$, and let $|\mathbf{X}_{ij}|$ be its cofactor in $|\mathbf{X}|$. Then, for $\mathbf{X}$ having functionally unrelated elements:

$$\frac{\partial |\mathbf{X}|}{\partial x_{ij}} = |\mathbf{X}_{ij}|, \qquad \frac{\partial |\mathbf{X}|}{\partial \mathbf{X}} = |\mathbf{X}|(\mathbf{X}^{-1})',$$

and

$$\frac{\partial}{\partial \mathbf{X}} \log |\mathbf{X}| = (\mathbf{X}^{-1})'.$$

For symmetric $\mathbf{X}$, comparable results are

$$\frac{\partial |\mathbf{X}|}{\partial \mathbf{x}_{ij}} = (2 - \delta_{ij})|\mathbf{X}_{ij}|,$$

where $\delta_{ij} = 0$ except when $i = j$, and then $\delta_{ii} = 1$,

$$\frac{\partial |\mathbf{X}|}{\partial \mathbf{X}} = |\mathbf{X}|[2\mathbf{X}^{-1} - \mathrm{diag}(\mathbf{X}^{-1})],$$

and

$$\frac{\partial}{\partial \mathbf{X}} \log |\mathbf{X}| = 2\mathbf{X}^{-1} - \mathrm{diag}(\mathbf{X}^{-1}).$$

Finally, for any nonsingular $\mathbf{X}$, symmetric or not,

$$\frac{\partial}{\partial \mathbf{y}} \log |\mathbf{X}| = \operatorname{tr}\left(\mathbf{X}^{-1} \frac{\partial \mathbf{X}}{\partial \mathbf{y}}\right).$$

Jacobians

When $\mathbf{y}$ is a vector of n differentiable functions of the n elements of $\mathbf{x}$, such that the transformation of $\mathbf{x}$ to $\mathbf{y}$, to be denoted $\mathbf{x} \to \mathbf{y}$, is 1-to-1, then the matrix

$$\mathbf{J}_{\mathbf{x}\to\mathbf{y}} = \left(\frac{\partial \mathbf{x}}{\partial \mathbf{y}}\right) = \left\{ \underset{\mathrm{m}}{\frac{\partial x_j}{\partial y_i}} \right\}_{i=1 \;\; j=1}^{n \quad n}$$

is the *Jacobian matrix* of $\mathbf{x} \to \mathbf{y}$. For example, if $\mathbf{y} = \mathbf{A}\mathbf{x}$,

$$\mathbf{J}_{\mathbf{x}\to\mathbf{y}} = \left[\frac{\partial (\mathbf{A}^{-1}\mathbf{y})'}{\partial \mathbf{y}}\right] = (\mathbf{A}^{-1})'.$$

$||\mathbf{J}_{\mathbf{x}\to\mathbf{y}}||$, the positive value of the determinant of $\mathbf{J}_{\mathbf{x}\to\mathbf{y}}$, is called the *Jacobian* of $\mathbf{x} \to \mathbf{y}$. It is needed when using $\mathbf{x} \to \mathbf{y}$ on an integral such as

$$\varphi = \int \mathrm{f}(\mathbf{x})\, \mathrm{d}\mathbf{x},$$

where $\mathrm{f}(\mathbf{x})$ is a scalar function of elements of $\mathbf{x}$. If $\mathbf{x} \to \mathbf{y}$ is $\mathbf{y} = g(\mathbf{x})$, then

$$\varphi = \int \mathrm{f}(g^{-1}[y])||\mathbf{J}_{\mathbf{x}\to\mathbf{y}}||\, \mathrm{d}\mathbf{y}.$$

With the identity $||\mathbf{J}_{\mathbf{x}\to\mathbf{y}}|| \equiv 1/||\mathbf{J}_{\mathbf{y}\to\mathbf{x}}||$, with elements of $\mathbf{J}_{\mathbf{y}\to\mathbf{x}}$ sometimes being easier to derive than those of $\mathbf{J}_{\mathbf{x}\to\mathbf{y}}$, and when notation other than $\mathbf{x}$ and $\mathbf{y}$ is the context, confusion easily arises as to whether φ involves $\mathbf{J}_{\mathbf{x}\to\mathbf{y}}$ or $\mathbf{J}_{\mathbf{y}\to\mathbf{x}}$. Fortunately, there is a mnemonic that clarifies the situation. Defining the transformation as old $\to$ new, one always uses $\mathbf{J}_{\mathrm{old}\to\mathrm{new}}$, abbreviated to $\mathbf{J}_{\mathrm{o}\to\mathrm{n}}$. In the latter the subscripts are always in the sequence "on", not "no". This always works.

Vec and Vech Operators

Vec and vech are operators that vectorize a matrix. It can be done in various ways, the most useful of which is stacking the columns of a matrix one under the other. For $\mathbf{X}_{p\times q}$, the resulting column is denoted vec $\mathbf{X}$, a column of order pq. For example,

$$\mathbf{X} = \begin{bmatrix} 1 & 2 & 3 \\ a & b & c \end{bmatrix} \text{ gives } \operatorname{vec} \mathbf{X} = \begin{bmatrix} 1 \\ a \\ 2 \\ b \\ 3 \\ c \end{bmatrix}.$$

Three useful properties are as follows:

$$\begin{aligned} \operatorname{vec}(\mathbf{ABC}) &= (\mathbf{C}' \otimes \mathbf{A})\operatorname{vec} \mathbf{B}, \\ \operatorname{tr}(\mathbf{AB}) &= (\operatorname{vec} \mathbf{A}')'\operatorname{vec} \mathbf{B}, \\ \operatorname{tr}(\mathbf{AZ}'\mathbf{BZC}) &= \operatorname{tr}[\mathbf{Z}'(\mathbf{BZCA})] \\ &= (\operatorname{vec} \mathbf{Z})'\operatorname{vec}(\mathbf{BZCA}) \\ &= (\operatorname{vec} \mathbf{Z})'(\mathbf{A}'\mathbf{C}' \otimes \mathbf{B})\operatorname{vec} \mathbf{Z}. \end{aligned}$$

The operator vech $\mathbf{X}$ is defined for $\mathbf{X}$ being symmetric. It has the columns of $\mathbf{X}$, starting at the diagonal elements, stacked one under the other. For example,

$$\mathbf{X} = \begin{bmatrix} 1 & 2 & 3 \\ 2 & x & y \\ 3 & y & \alpha \end{bmatrix} \text{ has } \operatorname{vech} \mathbf{X} = \begin{bmatrix} 1 \\ 2 \\ 3 \\ x \\ y \\ \alpha \end{bmatrix}.$$

Henderson & Searle [1, 2] give some history and numerous details.

A particular use of vec and vech is in calculating $||\mathbf{J}_{\mathbf{X}\to\mathbf{Y}}||$. This is the positive value of the determinant of

$$\mathbf{J}_{\mathbf{X}\to\mathbf{Y}} = \frac{\partial (\operatorname{vec} \mathbf{X})'}{\partial (\operatorname{vec} \mathbf{Y})'},$$

and if $\mathbf{X}$ and $\mathbf{Y}$ are both symmetric, vec is replaced by vech.

Matrices having Complex Numbers as Elements

Because statistics almost always deals with real numbers (e.g. data) and not complex numbers that involve $i = \sqrt{-1}$, most of this article deals with real matrices, those having no complex numbers as elements. Nevertheless, since many texts do deal with

matrices of complex numbers, a few basic definitions are given here.

In scalar arithmetic the complex number $a - ib$ is called the *complex conjugate* of $a + ib$, and the two numbers are a *conjugate pair*. Likewise with matrices, $\overline{\mathbf{M}} = \mathbf{A} - i\mathbf{B}$ is the *complex conjugate* of $\mathbf{M} = \mathbf{A} + i\mathbf{B}$, with $\mathbf{M}$ and $\overline{\mathbf{M}}$ being a *conjugate pair*. $\mathbf{M}$ is said to be *Hermitian* when $\overline{\mathbf{M}}' = \mathbf{M}$; and $\mathbf{M}$ is *unitary* if $\overline{\mathbf{M}}'\mathbf{M} = \mathbf{I}$. Thus, being Hermitian is the complex counterpart of being symmetric, as is unitary of orthogonal.

Some Matrix Usage in Statistics

The development and description of statistical methodology benefits enormously from the use of matrices. The following examples briefly illustrate some of the widely used situations in which matrix notation so efficiently encapsulates a multitude of results.

Means and Variances

$\mathbf{x}$ being a vector of random variables with mean $\boldsymbol{\mu}$ implies that $\mathrm{E}(\mathbf{x}) = \boldsymbol{\mu}$, where E represents expectation. Then, because the ith element of $\mathbf{x}$ has a variance, σ_i^2, and each pair of elements, the ith and jth say, have a covariance, σ_{ij}, these variances and covariances can be arrayed in a symmetric matrix, called the **variance–covariance matrix**, for which we use the symbol $\boldsymbol{\Sigma}$. For example, for $\mathbf{x}$ of order 3,

$$\boldsymbol{\Sigma} = \mathrm{var}(\mathbf{x}) = \begin{bmatrix} \sigma_1^2 & \sigma_{12} & \sigma_{13} \\ \sigma_{12} & \sigma_2^2 & \sigma_{23} \\ \sigma_{13} & \sigma_{23} & \sigma_3^2 \end{bmatrix}.$$

A more general expression is

$$\boldsymbol{\Sigma} = \mathrm{var}(\mathbf{x}) = \mathrm{E}(\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})'.$$

For a linear change of variables, from $\mathbf{x}$ to $\mathbf{y} = \mathbf{T}\mathbf{x}$, the mean vector and the variance–covariance matrix are easily established as

$$\mathrm{E}(\mathbf{y}) = \mathrm{E}(\mathbf{T}\mathbf{x}) = \mathbf{T}\mathrm{E}(\mathbf{x}) = \mathbf{T}\boldsymbol{\mu}$$

and

$$\begin{aligned} \mathrm{var}(\mathbf{y}) = \mathrm{var}(\mathbf{T}\mathbf{x}) &= \mathrm{E}(\mathbf{T}\mathbf{x} - \mathbf{T}\boldsymbol{\mu})(\mathbf{T}\mathbf{x} - \mathbf{T}\boldsymbol{\mu})' \\ &= \mathrm{E}\mathbf{T}(\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})'\mathbf{T}' = \mathbf{T}\boldsymbol{\Sigma}\mathbf{T}'. \end{aligned}$$

Suppose that $\mathbf{T}$ is a row vector, $\mathbf{t}'$. Then, because a variance is never negative, $\mathrm{var}(\mathbf{t}'\mathbf{y}) = \mathbf{t}'\boldsymbol{\Sigma}\mathbf{t} \geq 0$ and so $\boldsymbol{\Sigma}$ is n.n.d.

Correlation

A **correlation** matrix, $\mathbf{P}$ say, is a matrix with 1.0 as its diagonal elements and correlations $\rho_{ij} = \sigma_{ij}/(\sigma_i^2\sigma_j^2)^{1/2}$ (for $i \neq j$) as its off-diagonal elements. Define $\mathbf{D}$ as the diagonal matrix of the σ_i^2 terms. Then $\mathbf{P} = \mathbf{D}^{-1/2}\boldsymbol{\Sigma}\mathbf{D}^{-1/2}$.

A frequently used form of $\boldsymbol{\Sigma}$ is one which has σ^2 for all diagonal elements (variances) and $\rho\sigma^2$ for all off-diagonal elements (covariances). Then,

$$\boldsymbol{\Sigma} = \sigma^2\mathbf{P} \quad \text{for} \quad \mathbf{P} = (1 - \rho)\mathbf{I} + \rho\mathbf{J},$$

and, for order k,

$$|\boldsymbol{\Sigma}| = \sigma^{2k}(1 - \rho)^{k-1}(1 - \rho + k\rho).$$

Since $\boldsymbol{\Sigma}$ is n.n.d., $|\boldsymbol{\Sigma}| \geq 0$, which implies that $1 + (k - 1)\rho \geq 0$; that is, $\rho \geq -1/(k - 1)$. This is a consequence that one would not be inclined to anticipate on assuming the same covariance, $\rho\,\sigma^2$, between each pair of variables.

Sums of Squares and Products

For a column vector $\mathbf{x}_j$, the jth column of $\mathbf{X}$, the sum of squares of its elements x_{ij} is $\sum_i x_{ij}^2 = \mathbf{x}_j'\mathbf{x}_j$; and $\sum_i x_{ij}x_{ij'} = \mathbf{x}_j'\mathbf{x}_{j'}$. Thus, $\mathbf{X}'\mathbf{X} = \{_{\mathrm{m}}\, \mathbf{x}_j'\mathbf{x}_{j'}\}$ is a matrix of these sums of squares and products.

For $\mathbf{x}_j$ having n elements, define $\mathbf{C}_n = \mathbf{I}_n - \overline{\mathbf{J}}_n$, the centering matrix of order n. Then, $\mathbf{X}'\mathbf{C}_n\mathbf{X}$ has terms $\sum_i (x_{ij} - \overline{x}_{\cdot j})^2$ in its diagonal and terms $\sum_i (x_{ij} - \overline{x}_{\cdot j})(x_{ij'} - \overline{x}_{\cdot j'})$ as its off-diagonal elements, with $\overline{x}_{\cdot j} = 1_n'\mathbf{x}_j/n$. It is the matrix of sums of squares and products corrected for the mean.

If $\boldsymbol{\Delta}$ is defined as the diagonal matrix of the diagonal elements of $\mathbf{X}'\mathbf{C}\mathbf{X}$, then the correlation matrix $\mathbf{P} = \mathbf{D}^{-1/2}\boldsymbol{\Sigma}\mathbf{D}^{-1/2}$ described earlier is estimated by $\mathbf{R} = \boldsymbol{\Delta}^{-1/2}\mathbf{X}'\mathbf{C}\mathbf{X}\boldsymbol{\Delta}^{-1/2}$.

The Multivariate Normal Distribution

The density function of a normally distributed random variable x having mean μ and variance σ^2 is $\{\exp[-\frac{1}{2}(x - \mu)^2/\sigma^2]\}/(2\pi\sigma^2)^{1/2}$. The counterpart of this for a vector $\mathbf{x}$ of random variables

distributed $N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, means that this x has mean $\boldsymbol{\mu}$ and variance–covariance matrix $\boldsymbol{\Sigma}$, with a **multivariate normal distribution**, which is $\{\exp[-\frac{1}{2}(\mathbf{x}-\boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu})]\}/(|2\pi\boldsymbol{\Sigma}|)^{1/2}$. The **moment generating function** of linear combinations $\mathbf{Kx}$ of $\mathbf{x}$ is $\exp(\mathbf{t}'\mathbf{K}\boldsymbol{\mu} + \frac{1}{2}\mathbf{t}'\mathbf{K}\boldsymbol{\Sigma}\mathbf{K}'\mathbf{t})$.

A very neat consequence of using matrices is the derivation of marginal and conditional distributions in the multivariate normal distribution $\mathbf{x} \sim N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. It stems from partitioning $\mathbf{x}$, $\boldsymbol{\mu}$, and $\boldsymbol{\Sigma}$ as

$$\mathbf{x} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix}, \qquad \boldsymbol{\mu} = \begin{bmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{bmatrix} \quad \text{and}$$

$$\boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{bmatrix}$$

with $\boldsymbol{\Sigma}_{21} = (\boldsymbol{\Sigma}_{12})'$. Then a marginal distribution is

$$\mathbf{x}_1 \sim N(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_{11})$$

and a conditional distribution is

$$\mathbf{x}_1|\mathbf{x}_2 \sim N[\boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}(\mathbf{x}_2 - \boldsymbol{\mu}_2), \boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}].$$

Details are available in Searle [3, Section 2.4f].

Quadratic Forms

Every sum of squares is a homogeneous second-degree function of data. It can therefore be represented as a quadratic form $\mathbf{x}'\mathbf{Ax}$ for $\mathbf{x}$ being the vector of data and $\mathbf{A}$ being symmetric. A variety of properties pertaining to $\mathbf{x}'\mathbf{Ax}$ are then available for whatever sums of squares one is interested in. Some of these properties for $\mathbf{x} \sim N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ are as follows:

1. $E(\mathbf{x}'\mathbf{Ax}) = \text{tr}(\mathbf{A}\boldsymbol{\Sigma}) + \boldsymbol{\mu}'\mathbf{A}\boldsymbol{\mu}$ (normality is not needed for this result);
2. $\text{var}(\mathbf{x}'\mathbf{Ax}) = 2\text{tr}(\mathbf{A}\boldsymbol{\Sigma})^2 + 4\boldsymbol{\mu}'\mathbf{A}\boldsymbol{\Sigma}\mathbf{A}\boldsymbol{\mu}$;
3. $\mathbf{x}'\mathbf{Ax}$ has a (noncentral) **chi-square distribution** if and only if $\mathbf{A}\boldsymbol{\Sigma}$ is idempotent;
4. $\mathbf{x}'\mathbf{Ax}$ and $\mathbf{Lx}$ are stochastically independent if and only if $\mathbf{L}\boldsymbol{\Sigma}\mathbf{A} = \mathbf{0}$;
5. $\mathbf{x}'\mathbf{Ax}$ and $\mathbf{x}'\mathbf{Bx}$ are stochastically independent if and only if $\mathbf{B}\boldsymbol{\Sigma}\mathbf{A} = \mathbf{0}$ or, equivalently, $\mathbf{A}\boldsymbol{\Sigma}\mathbf{B} = \mathbf{0}$.

Regression and Linear Models

There is an enormous volume of literature on these topics, most of it using matrix algebra. Only a minute sampling of it is given here.

Consider a vector of data $\mathbf{y}$, modeled as having expected value $E(\mathbf{y}) = \mathbf{X}\boldsymbol{\beta}$ with $\mathbf{X}$ being known and $\boldsymbol{\beta}$ being a vector of unknown parameters. Defining $\boldsymbol{\varepsilon}$ as $\mathbf{y} - E(\mathbf{y})$, a vector of residuals leads to modeling $\mathbf{y}$ as $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$. **Least squares** estimation of $\boldsymbol{\beta}$ dictates minimizing $(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$ with respect to $\boldsymbol{\beta}$ and taking the resulting value of $\boldsymbol{\beta}$, say $\hat{\boldsymbol{\beta}}$, as the estimator of $\boldsymbol{\beta}$. This leads to the equations $\mathbf{X}'\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}'\mathbf{y}$. In regression (*see* **Multiple Linear Regression**) $\mathbf{X}$ almost always has full column rank, so that $\mathbf{X}'\mathbf{X}$ is nonsingular and hence $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}$. But with many more **general linear models** $(\mathbf{X}'\mathbf{X})^{-1}$ does not exist and a generalized inverse $(\mathbf{X}'\mathbf{X})^{-}$ has to be used. In that case there are many solutions for $\hat{\boldsymbol{\beta}}$, and to indicate this they can be denoted by $\boldsymbol{\beta}^o$. Thus, $\boldsymbol{\beta}^o = (\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{y}$.

Since $\boldsymbol{\beta}^o$ becomes $\hat{\boldsymbol{\beta}}$ when $(\mathbf{X}'\mathbf{X})^{-1}$ exists, the properties of $\hat{\boldsymbol{\beta}}$ are included among those of $\boldsymbol{\beta}^o$, just a few of which are as follows:

1. There are many solutions, $\boldsymbol{\beta}^o$, but for each of them $\hat{\mathbf{y}} = \mathbf{X}\boldsymbol{\beta}^o = \mathbf{X}(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{y}$ is the same, because $\mathbf{X}(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'$ is invariant to $(\mathbf{X}'\mathbf{X})^{-}$.
2. $E(\boldsymbol{\beta}^o) \neq \boldsymbol{\beta}$, but $E(\mathbf{X}\boldsymbol{\beta}^o) = \mathbf{X}\boldsymbol{\beta}$.
3. The residual sum of squares

$$\text{SSE} = (\mathbf{y} - \hat{\mathbf{y}})'(\mathbf{y} - \hat{\mathbf{y}}) = \mathbf{y}'\mathbf{y} - \mathbf{y}'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{y}$$

is invariant to $(\mathbf{X}'\mathbf{X})^{-}$. Because it can be expressed as $\text{SSE} = \mathbf{y}'[\mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}']\mathbf{y}$, with the matrix being idempotent, the expected value of SSE for $\mathbf{y} \sim N(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I}_N)$ is $E(\text{SSE}) = [N - r(\mathbf{X})]\sigma^2$. Also, SSE/σ^2 has a chi-square distribution. Moreover, the sum of squares due to fitting the model is $\mathbf{y}'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{y}$; it too has a (noncentral) chi-square distribution, and it is stochastically independent of SSE.

Readers whose appetite has been whetted by this introduction to regression and linear models will find plenty of books and papers to satiate their hunger.

Matrix Computations

Much of the development and formulation of the mathematical and statistical models that biostatisticians use relies heavily on matrix notation (*see* **Matrix Algebra**). For example, matrix notation is often the preferred way to describe the mathematics underlying many of the procedures in statistical packages (*see* **Software, Biostatistical**). Routines are now widely available that implement standard matrix operations including matrix multiplication and the solution of systems of linear equations, facilitating computer implementation of matrix formulas presented in the literature. Some knowledge of the alternative available **algorithms** is helpful both for implementers of matrix formulas and for users of existing statistical package implementations. In the following we comment on some alternative widely used approaches to linear **least squares** and related calculations.

Areas where matrix computations have a large place include **regression** methods, **multivariate analysis**, **maximum likelihood** estimation, **robust** estimation, smoothing, and **optimization**. Linear matrix computational methods are more generally important because nonlinear problems are frequently handled by solving a sequence of linearized problems. Numerical linear algebra is, effectively, another name for matrix computations.

Modern numerical matrix algebra gains much of its power from the use of a relatively small number of matrix decompositions, whose numerical properties are well understood. Major aims are guaranteed accuracy, speed of computation (efficiency), and the ability to handle all inputs [6, 7, 9]. The article [9] discusses several topics that we omit or only mention in passing.

Implementing Matrix Computations

Matrix computations must reckon with the finite precision of computer arithmetic. Most common computers now implement the IEEE standard for **floating point arithmetic**, which has around seven decimal digits single-precision and around 16 decimal digit double-precision arithmetic. The double-precision standard is a sound basis on which to build accurate and reliable algorithms.

Technical accuracy and efficiency issues are reasons for providing expert "black box" implementations of what might appear simple calculations such as $||\mathbf{x}|| = (\mathbf{x}'\mathbf{x})^{1/2}$ and matrix multiplication. Specifications for sets of lower-level routines have been established in the **numerical analysis** literature, where they are known as BLAS (basic linear algebra subroutines) [1]. The BLAS, or other such lower-level routines, then make effective building blocks in the creation of higher-level routines.

Understanding Matrix Methods

There are often, in matrix computations just as elsewhere, several different ways to solve the same problem. Knowledge of matrix algorithms may allow the substitution of one algorithm for another when required. For example, a published formula may involve a matrix operation not found in available software. Additional information that is required from a routine may be available, for someone who understands the algorithm, as an adaptation of existing output.

Often it is helpful to know what accuracy can reasonably be expected from a calculation. When results from different algorithms for the same problem differ numerically (perhaps in decimal places after the third or fourth), which is more accurate? What characteristics of input data may lead to such differences in accuracy? Knowledge of the algorithm may be even more important when a calculation fails.

Matrix Inversion

The use of matrix inverses is a convenience in writing down matrix formulas. However, direct implementation of such formulas rarely leads to algorithms that are optimal for practical computation. For example, solving $\mathbf{Sb} = \mathbf{c}$ for $\mathbf{b}$ is preferable to forming $\mathbf{S}^{-1}$ and computing $\mathbf{b} = \mathbf{S}^{-1}\mathbf{c}$. Avoiding unnecessary matrix inversion reduces computational effort, leading to a small improvement in precision. There is a choice of default actions where the inverse does not exist. Later in this article we illustrate approaches which avoid the explicit calculations of matrix inverses.

Linear Least Squares

Linear **least squares** has been the context for much of the discussion of statistical matrix computations. As

well as being important for linear least squares, the matrix computations we describe are important building blocks for many other statistical computations.

We consider the contrived example

$$(\mathbf{X}|\mathbf{y}) = \left[\begin{array}{rrr|r} 1 & 7 & 8 & 6 \\ 1 & -3 & 4 & 4 \\ 1 & 2 & 2 & 0 \\ 1 & 2 & 2 & 6 \\ 1 & 7 & 6 & 5 \\ 1 & 2 & 4 & 7 \\ 1 & -3 & 2 & 3 \\ 1 & 2 & 4 & 1 \\ 1 & 2 & 4 & 4 \end{array}\right].$$

Given $\mathbf{X}(n \times p)$ and $\mathbf{y}(n \times 1)$, least squares calculations determine $\mathbf{b}(p \times 1)$ such that

$$(\mathbf{y} - \mathbf{Xb})'(\mathbf{y} - \mathbf{Xb}) = ||\mathbf{y} - \mathbf{Xb}||^2 \qquad (1)$$

is a minimum. In the example above one minimizes the sum of squares $[6 - (b_1 + 7b_2 + 8b_3)]^2 + [4 - (b_1 - 3b_2 + 4b_3)]^2 + \cdots$

Algebraically, the linear least squares problem (1) is equivalent to solving what are called the normal equations, i.e.

$$\mathbf{X}'\mathbf{Xb} = \mathbf{X}'\mathbf{y}. \qquad (2)$$

If $\mathbf{S} = \mathbf{X}'\mathbf{X}$ is singular, theoretical arguments show that the normal equations are consistent, but rather than just one solution there are an infinity of solutions. An example appears below in the section on linear dependencies.

We describe and contrast two approaches to the linear least squares problem, one of which forms and solves the normal equations, while the other (the QR method) avoids formation of the normal equations.

A Normal Equation Approach

An effective way to solve the normal equations is to use the Cholesky algorithm, which modifies Gaussian elimination to take advantage of the symmetry of the normal equation matrix of coefficients. Diagrammatically, the steps are

$$(\mathbf{X}|\mathbf{y}) \rightarrow \begin{pmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{y} \\ (\mathbf{X}'\mathbf{y})' & \mathbf{y}'\mathbf{y} \end{pmatrix} \rightarrow \begin{pmatrix} \mathbf{R} & \mathbf{d} \\ \mathbf{0}' & r_{yy} \end{pmatrix}. \qquad (3)$$

The normal equations $\mathbf{X}'\mathbf{Xb} = \mathbf{X}'\mathbf{y}$ reduce to $\mathbf{Rb} = \mathbf{d}$, where $\mathbf{R}$ is $p \times p$ upper triangular, i.e. below diagonal elements are zero. (It might also be described as right triangular, which perhaps justifies the symbol $\mathbf{R}$.) It is convenient to take $\mathbf{R}$ to be the upper triangular matrix which is formed by the Cholesky decomposition of $\mathbf{X}'\mathbf{X}$, i.e. $\mathbf{R}'\mathbf{R} = \mathbf{X}'\mathbf{X}$. On the right-hand side of (3), $\mathbf{R}$ is augmented with an additional row and column, to form an array which is the Cholesky decomposition of $(\mathbf{X}|\mathbf{y})'(\mathbf{X}|\mathbf{y})$.

For our numerical example the system of equations $\mathbf{Rb} = \mathbf{d}$ is

$$\begin{pmatrix} 3 & 6 & 12 \\ 0 & 10 & 4 \\ 0 & 0 & 4 \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix} = \begin{pmatrix} 12 \\ 2 \\ 2 \end{pmatrix}.$$

Calculations are completed by solving first for b_3 $\left(=\frac{1}{2}\right)$, then for $b_2(=0)$ in terms of b_3, and finally for $b_1(=2)$ in terms of b_2 and b_3.

The QR Method for Linear Least Squares

Our description will emphasize points of contact with the normal equations approach. The QR method omits the intermediate step in (3). It determines

$$\mathbf{Q}(\mathbf{X}|\mathbf{y}) = \begin{pmatrix} \mathbf{R} & \mathbf{d} \\ \mathbf{0} & \mathbf{z} \end{pmatrix}, \qquad (4)$$

where $\mathbf{Q}(n \times n)$ is a product of orthogonal matrices and is hence orthogonal, i.e. $\mathbf{Q}'\mathbf{Q} = \mathbf{QQ}' = \mathbf{I} = \text{diag}(1, \ldots, 1)$. The vector $\mathbf{z}$ is $(n - p) \times 1$. If we insist that $\mathbf{R}$ have positive diagonal elements, then it is algebraically identical to the matrix $\mathbf{R}$ formed by the Cholesky decomposition of $\mathbf{X}'\mathbf{X}$. The quantity $\mathbf{z}'\mathbf{z}$ is the sum of squares of residuals from the regression, and equals r_{yy}^2.

Other Methods for Least Squares

Other methods for least squares include the once popular Gauss–Jordan scheme, which calculates $(\mathbf{X}'\mathbf{X})^{-1}$ as well as $\mathbf{b}$. There are in addition a range of iterative methods for least squares, which have found particular application in large sparse problems [3, 6, 9].

Linear Dependencies

In the data set

$$(\mathbf{X}|\mathbf{y}) = \left[\begin{array}{ccc|c} 1 & -2 & -4 & -1 \\ 1 & 1 & -1 & 0 \\ 1 & 2 & 0 & 4 \\ 1 & 5 & 3 & 7 \end{array}\right],$$

the third column is the difference between the second column and twice the first column. Linear dependencies, of which this is a trivial example, arise in least squares problems when one or more variables are a linear combination of earlier variables. The normal equations are

$$\begin{pmatrix} 4 & 6 & -2 \\ 6 & 34 & 22 \\ -2 & 22 & 26 \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix} = \begin{pmatrix} 10 \\ 45 \\ 25 \end{pmatrix}.$$

The matrix of coefficients $\mathbf{S} = \mathbf{X}'\mathbf{X}$ is, because the coefficients in row 3 are the difference between row 2 and twice row 1, *singular*. Hence $\mathbf{S}^{-1}$ does not exist. Nevertheless the coefficients are, because from normal equations, consistent. With b_3 chosen arbitrarily, $b_2 = 1.2 - b_3$ and $b_1 = 0.7 + 2b_3$. Such nonunique solutions occur when one variable or term in a model is a linear combination of other terms.

In **analysis of variance** applications, dependencies may arise because there are inadequate data to allow the estimation of one or more parameters associated with main effects or interactions. Alternately, one or more **explanatory** variables may be an exact linear combination of other terms in the model, and a decision is needed on which terms to include. Dependencies may be a result of an unanticipated feature of the input data, or of a mistake in the data.

Dependencies are, when working with observational data on a large number of variables, surprisingly common. They may be a huge source of frustration, especially if the program responds by exiting with an uninformative error message. Sensible default actions, and information on the coefficients of the linear relation, may be a huge help. Where column i of $\mathbf{X}$ is a linear combination of earlier columns, an easy device which will allow calculations to continue is to set b_i to zero, effectively deleting column i of $\mathbf{X}$. It would be useful to have criteria for detecting instances where a near singularity may make results nonsensical or hard to interpret. Regrettably, there are no effective simple criteria that will cover all circumstances.

Normal Equations vs. QR

At a fixed level of numerical precision the QR decomposition will solve a wider range of problems than normal equation methods. The difference is marked when there are strong dependencies between the columns of $\mathbf{X}$, leading to a large **standard error** for one or more elements of $\mathbf{b}$. A consequence of large standard error(s) is that the additional numerical precision is unlikely to be statistically meaningful.

The solution of the normal equations retains very nearly the accuracy of $\mathbf{X}'\mathbf{X}$ and $\mathbf{X}'\mathbf{y}$. Where $\mathbf{X}$ has an initial column of ones, precision may be assisted by expressing values in remaining columns as differences from the column mean, prior to forming $\mathbf{X}'\mathbf{X}$ and $\mathbf{X}'\mathbf{y}$. Careful implementations of normal equation methods take this precaution. The precision of $\mathbf{X}'\mathbf{X}$ and $\mathbf{X}'\mathbf{y}$ is then equivalent to that of an accurately formed correlation matrix. In applications in the biological and social sciences, where differences from the mean are rarely accurate to more than two or three significant digits, this seems adequate precision.

Caution may nevertheless advise use of the QR method except in those applications – unbalanced analysis of variance, for example – where columns of $\mathbf{X}$ are unlikely to be highly correlated. There is a helpful discussion in [5] which compares the normal equation method with QR (see also [6]).

QR Algorithms

Another name for the QR method is orthogonal reduction to upper triangular form. Available algorithms for QR include Householder and modified Gram–Schmidt (MGS), which proceed columnwise, and the Givens algorithm, which operates on new rows one at a time to incorporate them into the current version of $\mathbf{R}$. We discuss these in more detail below. Elements of $\mathbf{Q}$ are unlikely to be stored explicitly; instead, key quantities are stored from which $\mathbf{Q}$ can be reconstructed as required.

Algorithms for QR factorization effectively form rows of $\mathbf{R}$ as linear combinations of rows of $\mathbf{X}$ rather than as linear combinations of rows of $\mathbf{X}'\mathbf{X}$. They avoid the loss of accuracy which, in normal equation methods, may occur in the formation of $\mathbf{X}'\mathbf{X}$ and $\mathbf{X}'\mathbf{y}$.

There is some additional computational cost. When p is much smaller than n, use of QR approximately doubles the number of multiplications and divisions compared with using the normal equations.

Various diagnostic and other information that may be required for least squares modeling may be computed straightforwardly from submatrices of **Q**. Examples include leverage statistics (*see* **Diagnostics**), and the variance–**covariance matrix** of **residuals**. Brief details appear in a later section.

Some Key Matrix Methods

Here we discuss in more detail several algorithms that have major importance in statistical computation, including algorithms mentioned above. We emphasize the connections between algorithms which, to first appearance, are quite different.

Cholesky Decomposition

Given a positive definite matrix **S**, perhaps formed as $\mathbf{X'X}$, the Cholesky decomposition determines an upper triangular matrix **R** such that $\mathbf{S} = \mathbf{R'R}$. Equivalently, one may form $\mathbf{S} = \mathbf{U'DU}$, where **D** is diagonal and **U** is upper triangular with unit diagonal.

Several algorithms are available, which differ in the order in which they form elements of **R**. In the version we now describe, elements in the first row of **R** are formed as

$$r_{11} = \sqrt{s_{11}}, \qquad r_{1j} = r_{11}^{-1} s_{1j}, \quad j = 1, \ldots, p.$$

Then, for $i = 2, \ldots, p$, calculate

$$s_{ij}^{(i-1)} = s_{ij} - \sum_{k=1}^{i-1} r_{ki} r_{kj}, \quad j = i, \ldots, p,$$

and

$$r_{ii} = [s_{ii}^{(i-1)}]^{1/2}, \quad \text{if } (i < p)\ r_{ij} = r_{ii}^{-1} s_{ij}^{(i-1)}, \quad j = i+1, \ldots, p.$$

Note that if **X** has an initial column of ones and remaining columns are centered by expressing values as differences from the column mean, then $1 - s_{ii}^{-1} s_{ii}^{(i-1)}$ is the squared multiple correlation measuring the dependence of column k of **X** on earlier columns. Where $r_{ii} = 0$, all elements in that row may be set to zero.

The Cholesky decomposition may be used in solving the generalized weighted least squares problem, where **W** is a positive-definite symmetric weighting matrix. Observe that if **U** is upper triangular such that $\mathbf{U'U} = \mathbf{W}$, then

$$(\mathbf{y} - \mathbf{Xb})'\mathbf{W}(\mathbf{y} - \mathbf{Xb}) = (\mathbf{y}^* - \mathbf{X}^*\mathbf{b})'(\mathbf{y}^* - \mathbf{X}^*\mathbf{b}),$$

where $\mathbf{y}^* = \mathbf{Uy}, \mathbf{X}^* = \mathbf{UX}$. This is now in the form of (1).

Simulation from a **multivariate normal distribution** with $p \times p$ variance–covariance matrix $\mathbf{\Sigma} = \mathbf{R'R}$ may be handled by setting $\mathbf{u} = \mathbf{R'x}$, where elements of **x** are independent normal random deviates each with mean 0 and variance 1.

The Householder QR Algorithm

The Householder QR algorithm has wide application apart from least squares. It is, for example, used in forming the singular value decomposition, which we describe below. It is usually motivated by describing the matrix **Q** of (4) as a product of Householder *reflections*

$$\mathbf{I} - \frac{2\mathbf{w}_i \mathbf{w}_i'}{\tau_i}, \quad i = 1, \ldots, p,$$

where $\tau_i = ||\mathbf{w}_i||^2$. The first reflection reduces to zero elements all elements except the first in the initial column of **X**, replacing the first row of **X** by the first row of **R**. The second takes the matrix so formed and reduces to zero all elements below the second row in its second column, replacing the second row of this matrix with the second row of **R**. In the adaptation of the Householder method, for which we give algebraic details, one or more rows of **R** may differ from the result of applying Householder reflections by a change of sign of all elements in the row [8]. This simplifies the detailed algebraic description and simplifies the algorithm.

Let $\mathbf{x}_j^{(k-1)}$ $(j \geq k)$ be the result of applying rotations $1, \ldots, k-1$ to column j of **X**, but with elements $1, \ldots, k-1$ set to zero when $k > 1$. Then

$$r_{kk} = \left\| \mathbf{x}_k^{(k-1)} \right\|, \qquad r_{kj} = r_{kk}^{-1} \left(\mathbf{x}_k^{(k-1)} \right)' \mathbf{x}_j^{(k-1)}, \quad j > k. \tag{5}$$

For elements in rows after the kth we use

$$\mathbf{x}_j^{(k)} = \mathbf{x}_j^{(k-1)} - \alpha_k^{-1}\left(x_{kj}^{(k-1)}\mathrm{sgn}\left(x_{kk}^{(k-1)}\right) + r_{kj}\right)\mathbf{x}_k^{(k-1)}, \quad j > k,$$

where $\alpha_k = |x_{kk}| + r_{kk}$.

Where a column is a linear combination of earlier columns, this leads to $r_{ii} = 0$. The easiest way to deal with this is to move any such column to the final column position. More generally, the columns of $\mathbf{X}$ may be permuted so that columns which are highly dependent on earlier columns are taken last – a device known as *pivoting*. The initial order of columns can, if this is required, be restored when calculations are complete. Additional orthogonal rotations may be required to recover the matrix $\mathbf{R}$ that corresponds to the original ordering.

The Modified Gram–Schmidt QR Algorithm

If the variant of Householder just described is applied to a matrix $\mathbf{X}$ which is augmented with p initial rows of zeros, this leads, essentially, to the modified **Gram–Schmidt** (MGS) algorithm [8]. The MGS algorithm may be described in terms of residuals from repeated regressions. This statistical interpretation is a main reason for mentioning it here.

Let $\mathbf{e}_j^{(k-1)}$ be the vector of residuals when the column j, $j \geq k$, of $\mathbf{X}$ is regressed on columns $1, \ldots, k-1$. Then the MGS algorithm forms

$$r_{kk} = \left\|\mathbf{e}_k^{(k-1)}\right\|, \qquad r_{kj} = r_{kk}^{-1}\left(\mathbf{e}_k^{(k-1)}\right)'\mathbf{e}_j^{(k-1)}.$$

Thus the MGS algorithm uses least squares vectors of residuals to form elements of $\mathbf{R}$. For details see [3, 6–8, 10, 11].

The Givens QR Algorithm

This algorithm operates on $\mathbf{X}$ one row at a time, where Householder and modified Gram–Schmidt operate on columns. It is useful where the QR decomposition must from time to time be updated as new data become available.

The matrix $\mathbf{R}$ is filled initially with zeros. Planar rotations,

$$\begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix}, \tag{6}$$

then rotate rows of $\mathbf{X}$, one at a time, into the upper triangular array. Thus $\mathbf{R}$ is sequentially updated as each new row of $\mathbf{X}$ is rotated into the upper triangular scheme. The rotations which operate on row k ($k > p$) of $\mathbf{X}$ replace y_k with z_k, where z_k^2 is the increase in the residual sum of squares when row k is included. The planar rotations in the Givens QR algorithm are often called Givens rotations.

Another use for planar rotations is to remove rows that were earlier included, i.e. to *downdate* $\mathbf{R}$. A stable algorithm requires access to the matrix $\mathbf{Q}$ [3, 6]. The algorithm in [4] is as stable as possible when $\mathbf{Q}$ is not available.

Orthogonalization of the Columns of X

One way to view the QR method is that it reduces the problem of minimizing $||\mathbf{y} - \mathbf{X}\mathbf{b}||$ to that of minimizing $||\mathbf{y} - \mathbf{X}^*\mathbf{b}^*||$, where $\mathbf{X}^* = \mathbf{X}\mathbf{R}^{-1}$ and $\mathbf{b}^* = \mathbf{R}\mathbf{b}$. It replaces $\mathbf{X}$ by a matrix $\mathbf{X}^*$ the columns of which are orthogonal, i.e. $(\mathbf{X}^*)'\mathbf{X}^*$ is the matrix $\mathbf{I} = \mathrm{diag}(1, \ldots, 1)$.

Let

$$\mathbf{Q} = \begin{pmatrix} \mathbf{Q}_1 \\ \mathbf{Q}_2 \end{pmatrix}, \tag{7}$$

where $\mathbf{Q}_1$ is $p \times n$ and $\mathbf{Q}_2$ is $(n-p) \times n$. Then it may be shown that $\mathbf{Q}_1' = \mathbf{X}\mathbf{R}^{-1}$. Thus, if $\mathbf{Q}$ is available, the matrix $\mathbf{X}^* = \mathbf{X}\mathbf{R}^{-1}$ can be extracted as a submatrix.

Orthogonal Polynomials

Low-order **polynomial** functions are frequently used to provide simple curvilinear models for data. If the covariate $\mathbf{x}$ has elements x_i, $i = 1, \ldots, n$, then calculations can in principle be handled as a least squares calculation in which $\mathbf{X}$ has its (i, j)th element equal to x_i^{j-1}, $i = 1, \ldots, n$; $j = 1, \ldots, p$. This natural representation of the problem produces a matrix $\mathbf{X}$ the columns of which are likely to be strongly **correlated**. This gives coefficients which are strongly correlated, with standard errors which are inflated by amounts which depend on the correlations.

The QR method may be used as discussed in (7) to form the matrix $\mathbf{X}^*$ with orthogonal columns. The first column of $\mathbf{X}^*$ is a constant, the second is a multiple of $\mathbf{x} - \overline{x}$, the third involves terms up to degree two in $\mathbf{x}$, and so on. Even better is

to use recurrence formulas for systems of orthogonal polynomials to generate the columns of $\mathbf{X}^*$ (*see* **Orthogonality**). Such use of orthogonal polynomials gives independent and often more interpretable regression coefficients and avoids numerical instability (*see* **Polynomial Approximation**).

The Deletion and Addition of Columns

Removal of a column of $\mathbf{X}$ is achieved by removing the corresponding column from $\mathbf{R}$ and using a series of Givens rotations to reduce the resulting matrix to upper triangular form. The addition of a further column $\mathbf{x}_{p+1}$ to $\mathbf{X}$ is likewise straightforward, providing $\mathbf{Q}$ is available. A further QR reduction is used to reduce $(\mathbf{R}, \mathbf{Q}\mathbf{x}_{p+1})$ to upper triangular form.

Singular Value Decomposition (SVD)

This decomposition finds application in principal components analysis and in many different related multivariate calculations. It offers yet another approach to least squares calculations [6]. Given an $n \times p$ matrix $\mathbf{X}$, it forms

$$\mathbf{X} = \mathbf{UGV}',$$

where $\mathbf{U}$ is $n \times n$ orthogonal, $\mathbf{V}$ is $p \times p$ orthogonal, and $\mathbf{G}$ is $n \times p$ with its only nonzero elements on the uppermost diagonal, namely the singular values.

One or more singular values that are close to zero indicates that $\mathbf{X}$ is near singular, with the relevant linear relations given by the corresponding columns of $\mathbf{V}$. Note that the singular values of $\mathbf{X}'\mathbf{X}$ are the squares of those of $\mathbf{X}$. The Golub–Kahan algorithm for the singular value decomposition first uses Householder reflections to reduce $\mathbf{X}$ to upper bidiagonal form, i.e. all elements are zero except those on the diagonal or in positions immediately above the diagonal. Repeated planar rotations, (6), then reduce the above diagonal elements to zero [6].

Methods for Singular Matrices

Here we examine several technical issues that arise when matrices are singular or close to singular.

Distance from Singularity

Assume that $\mathbf{X}$ has an initial column of ones and that remaining columns are centered. A statistically motivated measure of the distance of column k of $\mathbf{X}$ from a linear combination of all other columns is the inverse $(s_{kk}s^{kk})^{-1}$ of the *variance inflation factor* $s_{kk}s^{kk}$, where s_{kk} and s^{kk} are the kth diagonal elements of $\mathbf{X}'\mathbf{X}$ and $(\mathbf{X}'\mathbf{X})^{-1}$, respectively. This variance inflation factor is the amount by which the standard error of b_k is multiplied because of correlation between column k of $\mathbf{X}$ and other columns. Note the relationship

$$s_{kk}s^{kk} = \left(1 - R^2_{k|1,\ldots,k-1,k+1,\ldots,p}\right)^{-1}, \qquad (8)$$

with the squared multiple correlation $R^2_{k|1,\ldots,k-1,k+1,\ldots,p}$ measuring the dependence of explanatory variable k upon other explanatory variables.

Which are the Linear Dependencies?

Let $\mathbf{r}_k^{(k-1)}$ consist of elements 1 to $k-1$ in column k of $\mathbf{R}$. Let $\mathbf{R}_{11}^{(k-1)}$ be the leading $(k-1) \times (k-1)$ submatrix of $\mathbf{R}$. Then the vector of coefficients in the least squares regression of column k of $\mathbf{X}$ on earlier columns is found by solving for $\mathbf{h}$ in

$$\mathbf{R}_{11}^{(k-1)}\mathbf{h} = \mathbf{r}_k^{(k-1)}.$$

(If $r_{ii} = 0$ for one or more $i < k$, then set $h_i = 0$.)

Suppose that m diagonal elements of $\mathbf{R}$ are zero. Then by determining all such vectors $\mathbf{h}$ we can construct a matrix $\mathbf{H}(p \times m)$ with maximum rank m such that

$$\mathbf{XH} = \mathbf{0}. \qquad (9)$$

Columns of $\mathbf{H}$ have the form $(h_1, h_2, \ldots, h_{k-1}, -1, 0, \ldots, 0)'$. The columns of $\mathbf{H}$ are a basis for the orthogonal complement of the row space of $\mathbf{X}$. The general solution to the least squares problem is $\tilde{\mathbf{b}} = \mathbf{b} + \mathbf{Hc}$, where $\mathbf{c}$ is arbitrary. One way to make $\tilde{\mathbf{b}}$ unique is to choose $\mathbf{c}$ so that $\tilde{\mathbf{b}}$ has minimum length, which is itself a least squares problem [8], pp. 106–107, 119. The easiest choice is $\mathbf{c} = \mathbf{0}$.

A Reflexive g-inverse of $\boldsymbol{R}$

Let $\mathbf{R}^-$ be obtained from $\mathbf{R}$ by replacing zero diagonal elements r_{ii} with 1, inverting the resulting matrix, and then placing zeros in the rows and columns where $r_{ii} = 0$. Then

$$\mathbf{RR}^-\mathbf{R} = \mathbf{R}, \mathbf{R}^-\mathbf{RR}^- = \mathbf{R}^-,$$

which are the conditions for $\mathbf{R}^-$ to be a *reflexive g-inverse* of $\mathbf{R}$. The matrix $\mathbf{R}^-$ may be used in the calculation of variances and covariances of regression coefficients that correspond to the choice $\mathbf{c} = \mathbf{0}$ above.

Applications

We give a few examples where an elegant alternative to matrix inversion reduces computational effort. In part our aim is to move away from an exclusive focus on least squares.

Leverages and Standard Errors of Residuals

In least squares, the matrix $\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$ may be calculated as $\mathbf{X}\mathbf{R}^{-1}(\mathbf{X}\mathbf{R}^{-1})'$. If $(\mathbf{X}\mathbf{R}^{-1})'$ is not already available, it may be determined by solving for columns of $\mathbf{Q}_1$ in the lower triangular system of equations $\mathbf{R}'\mathbf{Q}_1 = \mathbf{X}'$ (cf. (7)). The leverage statistic h_i, which is the ith diagonal element of $\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$, may be calculated as the sum of squares of elements of the ith column of $\mathbf{Q}_1$. Note also that $\mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}' = \mathbf{Q}_2'\mathbf{Q}_2$. Thus $\mathbf{Q}_2$ may be used in calculating the variance–covariance matrix of residuals.

Partial Sums of Squares and Products

We show how to form partial correlations between columns of $\mathbf{Y}$ $(n \times q)$, conditional on columns of $\mathbf{X}$ $(n \times p)$. Let $\mathbf{Z} = \mathbf{(1, X, Y)}$, where $\mathbf{1}$ is a column of ones. Now use the QR algorithm to form

$$\mathbf{QZ} = \begin{pmatrix} \sqrt{n} & \mathbf{u}_1' & \mathbf{u}_2' \\ \mathbf{0} & \mathbf{R}_{XX} & \mathbf{R}_{XY} \\ \mathbf{0} & \mathbf{0} & \mathbf{R}_{YY} \end{pmatrix}, \qquad (10)$$

where $\mathbf{u}_1'$ is $1 \times p$, $\mathbf{u}_2'$ is $1 \times q$, $\mathbf{R}_{XX}$ is $p \times p$, $\mathbf{R}_{XY}$ is $p \times q$, and $\mathbf{R}_{YY}$ is $q \times q$.

Then $\mathbf{R}_{YY}'\mathbf{R}_{YY}$ is the matrix of sums of squares and products of the q vectors of residuals from the regressions of columns of $\mathbf{Y}$ on columns of $\mathbf{X}$. The corresponding matrix of partial correlations is $\mathbf{D}^{-1/2}\mathbf{R}_{YY}'\mathbf{R}_{YY}\mathbf{D}^{-1/2}$, where $\mathbf{D}^{-1/2}$ is the diagonal matrix whose elements are the inverses of the square roots of the diagonal elements of $\mathbf{R}_{YY}'\mathbf{R}_{YY}$.

Canonical Correlation

We assume the orthogonal reduction in (10) above. Then computations may be handled by solving the symmetric eigenproblem

$$|\mathbf{R}_{XY}'\mathbf{R}_{XY} - \lambda\mathbf{R}_{YY}'\mathbf{R}_{YY}| = \mathbf{0}. \qquad (11)$$

This may be rewritten as

$$|(\mathbf{R}_{XY}\mathbf{R}_{YY}^{-1})'\mathbf{R}_{XY}\mathbf{R}_{YY}^{-1} - \lambda\mathbf{1}| = \mathbf{0},$$

which can be solved by finding the singular value decomposition of $\mathbf{R}_{XY}\mathbf{R}_{YY}^{-1}$. The **canonical correlations** ϕ_i, where i runs from 1 to min [rank $(\mathbf{R}_{XX})$, rank $(\mathbf{R}_{YY})$], are given by

$$\phi_i^2 = \frac{\lambda_i}{1 + \lambda_i}$$

([8], pp. 200–202, 206–208; *see* **Eigenvalue**; **Eigenvector**).

Canonical Variate Analysis

Canonical variate analysis provides a perspective on **multivariate analysis of variance**. Let $\mathbf{Z} = (\mathbf{X}, \mathbf{Y})$, where now columns of $\mathbf{Z}$ specify the groups to which observations belong. Again the orthogonal reduction of $\mathbf{Z}$ to upper triangular form is an effective starting point for further calculations, leading to an eigenproblem of the same form as for canonical correlation [8], pp. 202–203, 208–210.

Matrix Condition Numbers

A matrix *condition number* κ for a matrix $\mathbf{S}$ provides an indication of the relative sensitivity of $\mathbf{Sd}$ or $\mathbf{S}^{-1}\mathbf{d}$ to small relative changes in the elements of $\mathbf{d}$. One possibility is the *spectral condition number* κ_2, which is the ratio $\lambda_{\max}/\lambda_{\min}$ of the largest to smallest eigenvalue of $\mathbf{S}$.

Let $k = \log_{10}\kappa_2(\mathbf{S})$. In general one can expect to lose k digits of accuracy when solving the linear system

$$\mathbf{Sx} = \mathbf{d}$$

for $\mathbf{x}$, or in computing the inverse of $\mathbf{S}$. Note that $\kappa_2(\mathbf{S}) \geq 1$, which means that relative error can never be expected to decrease in solving a linear system. A matrix whose condition number is no more than

10 or 100 is, from a computational perspective, well-conditioned.

Numerical and Statistical Measures of Conditioning

Let κ_2 be the spectral condition number of the correlation matrix derived from $\mathbf{X}'\mathbf{X}$. Then

$$\max_{1\le i\le p}(s_{ii}s^{ii}) \le \kappa_2 \le \sum_{i=1}^{p} s_{ii}s^{ii},$$

where s_{ii} and s^{ii} are defined as in (8). This makes a connection between statistical and numerical measures of conditioning [2, 8], p. 211. The quantity $s_{ii}s^{ii}$ has the benefit that, unlike matrix condition numbers such as κ_2, it is independent of scale.

Note that determination of the minimum value $\min_{\mathbf{b}} ||\mathbf{y} - \mathbf{X}\mathbf{b}||^2$ is well-conditioned, even if $\mathbf{X}$ is singular.

Components of Larger Computations

The notes on computational methods in [5] demonstrate extensive use of matrix calculations as building blocks for a wide variety of other statistical calculations, analysis of variance with multiple error strata (*see* **Multilevel Models**), **generalized linear models** (GLMs), **generalized additive models** (GAMs), local regression smoothing (loess) (*see* **Graphical Displays**), and **nonparametric regression**; see also [11]. New complications are inevitable as matrix computational methods are used to extend the range of models available to statisticians. In models where a variance–covariance structure must be estimated, the notion of a singularity has subtleties beyond those of ordinary least squares.

Software

Many statistical packages allow the user to specify calculations as a sequence of matrix operations. SAS (in the IML Interactive Matrix Language module), SPSS (MATRIX language), STATA, **S-PLUS, R**, and Genstat are some of the statistical systems which have extensive matrix computational abilities. Statistical packages have generally stayed with normal equation methods. S-PLUS and R make extensive use of modern methods such as QR. Note also the extensive modern matrix abilities in the mathematically oriented languages of MATLAB, Gauss, and Mathematica. MATLAB has been used extensively by numerical analysts [7].

The FORTRAN subroutine package LAPACK [1], and earlier packages LINPACK, and EISPACK from which LAPACK is derived, provide high-quality software to perform calculations referred to in this article. These packages are publicly available from the NETLIB online database, and are also part of the NAG and IMSL subroutine libraries.

Maximum Likelihood

The term "maximum likelihood" refers to a general method of **estimation** with important historical and practical significance for biostatistics. Consider a sample $y_1, y_2, \ldots, y_n$ drawn independently from a distribution with density or probability function $f(y;\theta)$ with an unknown vector parameter θ (*see* **Random Variable**). The **likelihood** function is defined as

$$L(\theta) = \prod_{i=1}^{n} f(y_i;\theta).$$

The maximum likelihood estimate (MLE) is the value $\theta = \hat{\theta}$ which maximizes $L(\theta)$ over the set of all possible values for θ. In practice, it is usually more convenient to maximize the logarithm of the likelihood function, $l(\theta) = \ln L(\theta)$. From calculus, it follows that $\hat{\theta}$ satisfies the score equation $\partial l/\partial\theta = 0$.

Early references to the method of maximum likelihood are attributed to **Gauss**, **Laplace**, and **Edgeworth** [4]. However, the prominent English statistician **R. A. Fisher** is unquestionably responsible for popularizing the technique and for identifying many of its statistical properties [3].

The method has a strong heuristic appeal: choose as your parameter estimate the one which makes the observed data seem most likely. As it turns out, it is often the best estimate possible, particularly in **large samples**. Inference is made easy by the fact that maximum likelihood estimates are **consistent** and asymptotically **normal** under broad regularity assumptions, with a variance that can be estimated from the observed or expected **information matrix**. The MLE is also invariant under one-to-one **transformations** of the parameters, so to obtain the MLE of a transformation of the original parameters, one need only apply the transformation to the original MLE.

Optimal Properties

The following is a list of the most important properties of the MLE in large samples (i.e. $n \to \infty$):

1. *Consistency*. The MLE **converges in probability** to the true value of the parameter.
2. *Asymptotic normality*. The distribution of $n^{1/2}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta})$ converges to a normal distribution with zero mean and a covariance matrix which is the inverse of the information matrix $\mathbf{I}$. From a practical point of view it is more convenient to say that $\hat{\boldsymbol{\theta}}$ is approximately distributed as $\mathrm{N}(\boldsymbol{\theta}, \mathbf{I}^{-1}/n)$.
3. *Asymptotic efficiency*. The MLE is the best asymptotically normal (**BAN**) estimate in terms of its variance in large samples. Put more precisely, if $\tilde{\boldsymbol{\theta}}$ is another estimate such that $n^{1/2}(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta}) \xrightarrow{\mathscr{L}} \mathrm{N}(\boldsymbol{\theta}, \mathbf{C})$, where $\mathbf{C}$ is a fixed matrix, then $\mathbf{C} \geq \mathbf{I}^{-1}/n$ in the sense that $\mathbf{C} - \mathbf{I}^{-1}/n$ is a positive semidefinite matrix.

Regularity Conditions

It is important to be aware of the general regularity conditions for the optimal properties of the MLE. Most advanced statistics texts have a discussion of these conditions [1, 5], with the classic reference being Cramér [2]. The following three conditions are commonly given:

1. The observed data points $y_1, y_2, \ldots, y_n$ are independently and identically distributed (iid) according to a density or probability function $f(y;\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ has finite dimension m. This condition is less restrictive than it may seem, given that y_i may be a vector. In fact, the method of maximum likelihood is popular and appropriate for many regression problems where the distributions of the data points are not identical, and many texts give less restrictive assumptions.
2. The underlying density or probability function is identifiable, i.e. $f(y;\boldsymbol{\theta}_1) = f(y;\boldsymbol{\theta}_2)$ for all y implies that $\boldsymbol{\theta}_1 = \boldsymbol{\theta}_2$.
3. The density is "smooth" in the sense that f has derivatives up to the third order with finite expectation, and the information matrix

$$\mathbf{I} = E_\theta\left[\frac{\partial^2 \ln f(y;\theta)}{\partial\theta_j \partial\theta_k}\right], \quad j,k = 1,\ldots,m$$

exists and is nonsingular. The latter conditions ensure that the asymptotic covariance matrix exists.

These conditions are satisfied for many models of interest to biostatisticians, such as the **binomial**, normal, and **Poisson** distributions.

Maximum Likelihood Calculations

Maximum likelihood estimation involves finding a global maximum of a function of one or several parameters. For certain models, the solution can be expressed as a simple function of the data. However, more often the solution must be posed as a nonlinear **optimization** problem. Typically, it involves solving a system of nonlinear equations.

The main methods in use today are the Newton–Raphson (NR) or quasi-Newton (QN) methods, and the Fisher scoring (FS) algorithm [6]. The NR algorithm is based on an approximation of the log likelihood by a quadratic function through a Taylor series expansion of the score functions. To implement the NR algorithm, one has to provide second-order derivatives for the log likelihood function – the so-called Hessian matrix. Initial values for the parameters are updated and the process is repeated until convergence is obtained. If the initial value for parameters is close enough to the maximum, the NR algorithm usually converges quickly. However, if the initial value is poorly chosen it may fail. In particular, the Hessian matrix can become non-positive-definite. Upon convergence, at the final iteration, the inverse of the Hessian matrix provides an approximation to the asymptotic covariance of the MLE. In the QN algorithm only first derivatives are used, and the second derivatives are estimated based on results from previous iterations. The QN algorithm involves line search methods, i.e. maximization of the log likelihood along a given ray in the parameter space.

The difference between the NR and FS algorithms is that the latter uses the expectation of the Hessian matrix rather than the Hessian matrix itself as in the NR algorithm. There are two versions of the FS algorithm. In the first version the expectation of the Hessian is approximated as the sum of cross-products of first derivatives. In the second version, the exact calculated information matrix is used. Thus, to use this version of the FS algorithm one has to have a formula for the information matrix as a function of the parameters calculated prior to the maximization procedure.

Other methods are sometimes used for maximum likelihood estimation. One that deserves special mention is the **EM (expectation–maximization) algorithm**. Certain likelihoods may be thought as involving **missing data**, with the most notable example being **random effects** models. The EM method works in this setting by maximizing the expectation of the log-likelihood iteratively for the complete data. This may aid in difficult maximization problems by taking advantage of simple closed-form solutions available for the "M" stage. Other advantages of the EM algorithm include its natural statistical interpretation and its property of producing an increasing sequence of log likelihood values in the specified parameter space. The principal drawback is that it may be relatively slow.

Examples

Estimation of a Proportion

We observe the occurrence of a certain event for n individuals, where y_i is 1 if the event occurs and 0 otherwise. It can be assumed that events are independent among individuals and have the same probability of occurrence θ. The likelihood can be written as

$$\begin{aligned} L(\theta) &= \prod_{i=1}^{n} \theta^{y_i}(1-\theta)^{1-y_i} \\ &= \theta^m(1-\theta)^{n-m}, \end{aligned}$$

where m is the number of events observed among the n individuals. The log likelihood is

$$l(\theta) = m\ln(\theta) + (n-m)\ln(1-\theta). \qquad (1)$$

To find the maximum, we consider the following score equation:

$$\frac{\mathrm{d}l}{\mathrm{d}\theta} = \frac{m}{\theta} - \frac{n-m}{1-\theta} = 0, \qquad (2)$$

which has the unique solution $\hat{\theta} = m/n$.

Logistic Regression

Logistic regression may be viewed as a continuation of the previous example where the probability of the event occurring depends on some other factor. For instance, y could be an indicator of heart disease and x could denote the weight of an individual. We can model the relationship between y and x as the logistic function of the conditional probability of disease,

$$\Pr(y = 1|x) = \frac{\exp(\alpha + \beta x)}{1 + \exp(\alpha + \beta x)}, \qquad (3)$$

or, equivalently,

$$\ln \frac{\Pr(y = 1|x)}{1 - \Pr(y = 1|x)} = \alpha + \beta x.$$

Here $\theta = (\alpha, \beta)'$. The assumption is that the log **odds ratio** for the occurrence of disease is linear in the covariate, and β is sometimes referred to as the "log odds" parameter.

Now let $(y_1, x_1), (y_2, x_2), \ldots, (y_n, x_n)$ be values for the disease status and weight of a sample of n individuals. Technically speaking, to write down the likelihood we have to assume that x has a certain distribution which may contain unknown parameters. However, maximum likelihood inference for the logistic regression parameters is not affected by the assumption concerning the distribution of x as long as it does not depend on the parameters α and β. In fact, the values for x_i may be considered as fixed, known constants, and as long as the design matrix (*see* **Experimental Design**) is of full rank, maximum likelihood estimation is valid. The log likelihood is

$$\begin{aligned} l(\alpha, \beta) &= \sum_{i=1}^{n} y_i \ln \Pr(y = 1|x_i) \\ &\quad + \sum_{i=1}^{n} (1 - y_i) \ln[1 - \Pr(y = 1|x_i)] \\ &= \sum_{i=1}^{n} y_i \ln \frac{\exp(\alpha + \beta x_i)}{1 + \exp(\alpha + \beta x_i)} \\ &\quad + \sum_{i=1}^{n} (1 - y_i) \ln \frac{1}{1 + \exp(\alpha + \beta x_i)} \\ &= \alpha n + \beta \sum_{i=1}^{n} y_i x_i - \sum_{i=1}^{n} \ln[1 + \exp(\alpha + \beta x_i)]. \end{aligned}$$

A typical graph of the likelihood function is shown in Figure 1. The maximum of the log likelihood is found as the solution to the score equations

$$\frac{\partial l}{\partial \alpha} = n - \sum_{i=1}^{n} \frac{1}{1 + \exp(\alpha + \beta x_i)} = 0$$

and

$$\frac{\partial l}{\partial \beta} = \sum_{i=1}^{n} y_i x_i - \sum_{i=1}^{n} \frac{\exp(\alpha + \beta x_i)}{1 + \exp(\alpha + \beta x_i)} x_i = 0.$$

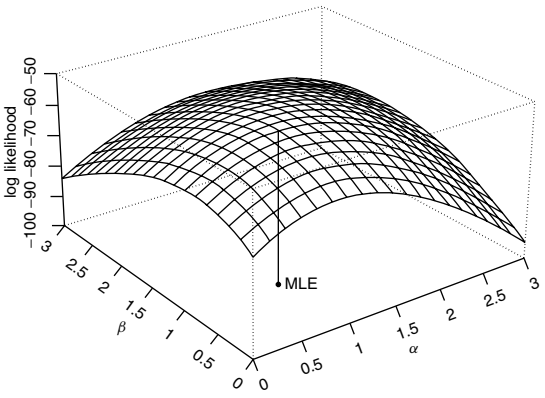

Figure 1 An example of the log likelihood surface and MLE in logistic regression

This system of nonlinear equations must be solved iteratively, e.g. by the Newton–Raphson algorithm.

Discussion and Extensions

In theory, the method of maximum likelihood is very simple: determine an appropriate sampling distribution for the data, write down the likelihood as a function of the unknown parameters, and solve for the estimate. Of course, in practice it is not always so easy. Solutions to the likelihood score equations usually must be arrived at by numerical methods, and may be computationally intensive or inaccurate. For some models and data sets it may be difficult to demonstrate that the likelihood has a unique global maximum. Many small-sample MLEs can be shown to be **biased**. The presence of **nuisance parameters** can exacerbate the computational difficulties. Often the MLE is quite non **robust** to **outliers** and, unlike competing general methods such as **least squares** and the **method of moments**, computation of the MLE requires that the distribution of the data be completely parameterized. Uniformly **minimum variance unbiased** (UMVU) **estimation** theory and **Bayesian methods** compete with maximum likelihood estimation with regard to optimal properties, but also require complete specification of the distribution, and may be even harder to implement.

To overcome some of the difficulties of maximum likelihood estimation, modified methods have been proposed such as **restricted maximum likelihood**, conditional likelihood (*see* **Conditionality Principle**), **pseudo-likelihood, quasi-likelihood**, **partial**

likelihood, and M-estimation (*see* **Robustness**). These methods were all inspired by the powerful heuristic appeal and conceptual simplicity of the original formulation of the method of maximum likelihood.

TOR D. TOSTESON & EUGENE DEMIDENKO

Maxwell, Albert Ernest

Born: July 7, 1916, in Rockmount, Co. Cavan, Ireland.
Died: 1996, in Leeds, UK.

Albert Ernest Maxwell was educated at the Royal School, Cavan and at Trinity College, Dublin, where he developed interests in psychology and mathematics. After graduating, 'Max' as he was invariably known to his colleagues, became a mathematics teacher at St Patrick's Cathedral School, Dublin. After only three years, at the age of 25, he was appointed Headmaster. His attempt to understand the behavioral problems of some of his pupils renewed his interest in psychology, a subject he eventually pursued more seriously at the University of Edinburgh where he was awarded a doctorate in 1950.

In 1952 Max left schoolteaching to take up the post of lecturer in statistics at the Institute of Psychiatry, a postgraduate school of the University of London. He was to spend the rest of his working life at the Institute, retiring in 1978 as Professor of Psychological Statistics.

For a number of years Max was a member of the Psychology Department of the Institute, collaborating and advising Professor Hans Eysenck, but he was eventually rewarded with the Headship of his own Biometrics Unit, which had responsibility for helping Institute researchers on all aspects of statistical design and analysis.

Max's main area of expertise was in **multivariate analysis**, particularly **factor analysis**, where his collaboration with Dr D. Lawley resulted in an important account of the mathematical theory behind the technique [1].

Max's teaching skills (no doubt learnt whilst a schoolmaster in Co. Cavan) were legendry and many psychologists obtained a firm grasp of statistical methods from his numerous lecture courses and a number of useful textbooks including [2].

BRIAN S. EVERITT

McKendrick, Anderson Gray

Born: 1876
Died: 1943

McKendrick made important contributions to the mathematical theory of epidemics. He served as a lieutenant-colonel in the Indian Medical Service, and later became Curator of the College of Physicians at Edinburgh. In 1914 [2], he gave the solution of the general homogeneous birth process (*see* **Stochastic Processes**), and this was followed in 1926 by a major paper [3] on stochastic epidemics (*see* **Epidemic Models, Stochastic**). He then turned to deterministic models (*see* **Epidemic Models, Deterministic**), in a series of papers with W.O. Kermack, which included the celebrated Threshold Theorem (*see* **Epidemic Thresholds**). His work is described in some detail in [1].

McNemar Test

The McNemar test arose in the context of psychology in which two correlated dichotomous responses were to be compared. One example of this test would be an indication of a response or no response under two experimental conditions. The original paper was by McNemar [7]; see also [8].

Armitage and Berry [1] give an example in which we have two culture media and wish to determine if they are equally effective in detecting tubercle bacilli in sputum specimens. The two media, evaluated for the same sample of 50 specimens, give cell counts of positive and negative results, as given in Table 1.

This can be regarded as a single multinomial table in which the cell probabilities, denoted by $\{\pi_{ij}\}$, add to 1. If the two media have the same ability to detect the bacilli, the null hypothesis takes the form $\pi_{i+} = \pi_{+i}$, i.e. that the marginal proportions are the same. This is easily seen to be equivalent to $\pi_{12} = \pi_{21}$. Since only these probabilities are of interest, the hypothesis can be tested referring only to the counts in these off-diagonal cells. Let the cell counts be denoted by $\{n_{ij}\}$. The (uncorrected) test statistic is given by

$$X^2 = \frac{(n_{12} - n_{21})^2}{n_{12} + n_{21}},$$

which (asymptotically) has a **chi-square distribution** with 1 **degree of freedom** (df). In this case $X^2 = (12 - 2)^2/(12 + 2) = 7.14$. The test is equivalent to the binomial test that the proportion is 0.5, given that the observation lies in one of the off-diagonal cells. It has also been suggested that a continuity corrected test be used. This is equivalent to the continuity correction for the binomial test. The corrected form is $X^2 = (|12 - 2| - 1)^2/(12 + 2) = 5.79$. In this case, both statistics are significant at the $\alpha = 0.05$ level.

Table 1

		Medium B		
		+	−	Total
Medium A	+	20	12	32
	−	2	16	18
Total		22	28	50

Examples of this procedure also arise in diagnostic imaging studies when the investigator wishes to determine if a new method provides better diagnostic **sensitivity** and **specificity** than a standard method. In this situation, there are several options: one may compare only the sensitivity (diagnostic performance when the patients have the condition), or the specificity (diagnostic performance when the patients do not have the condition); it is sometimes suggested that the accuracy (proportion correct) be compared, but this comparison is quite sensitive to the proportion of positive and negative subjects, and is not recommended. For the comparison of sensitivity or specificity, a McNemar test can be formed, and the 1 df test can be made. This provides two tests, which may be contradictory in the sense that one test may have higher sensitivity while the other has higher specificity. The two tests may be combined by adding the χ^2 to get a 2 df test. This gives an overall test of common performance [3].

In diagnostic test comparisons, it is important to note that the investigators may be artificially imposing a two-category result on the data. For example, in diagnosing recurrent cancer, the outcomes might be "negative", "resectable", or "not resectable", and the implications of imposing two categories are unclear. In such a case, it seems relevant to examine the 3×3 matrix of categorizations, and use a procedure which formally tests for marginal symmetry. In addition, some misclassifications are more serious than others. This would imply that a weighted procedure might be used. Tests for this are referenced in [6].

The McNemar test can be generalized to equivalence testing [5]. Conditional logistic regression (*see* **Logistic Regression, Conditional**) can be used to adjust for covariates.

Sample size computations are based on comparing a binomial proportion to 0.5. These calculations give the number of discordant pairs (those not represented on the main diagonal). It is then required to determine what fraction of discordant pairs is likely to arise. Various methods have been proposed recently for this (e.g. [4] and [2]).

Mean Deviation

The mean deviation d of a data set $x_1, \ldots, x_n$ is defined as

$$d = \frac{1}{n} \sum_{i=1}^{n} |x_i - m|, \tag{1}$$

where m is a location measure, most often the arithmetic **mean**, $\overline{x}$, most naturally the sample **median**, med (which minimizes d over all values of m), or, if known, a population location measure, such as the **expectation** or the median of the population.

It is also called mean absolute deviation (or average deviation), and the mean deviation from the mean is also called mean absolute error (MAE).

Its probabilistic counterpart for a random variable X is the first absolute **moment** with respect to (usually) the expectation (if it exists),

$$\delta = \mathrm{E}(|X - \mathrm{E}X|). \tag{2}$$

The mean deviation is thus a measure of scale or dispersion, like the **standard deviation** (sd) or the **range**, or the median (absolute) deviation (MAD) $= \mathrm{med}_i(|x_i - \mathrm{med}_j x_j|)$ (the median, not mean, of the absolute differences from the sample median). In general, they all estimate different quantities; but, for example, for large samples from the normal distribution, one can give conversion factors:

$$d = \left(\frac{2}{\pi}\right)^{1/2} \mathrm{sd} \approx 0.7979 \ \mathrm{sd}$$

and

$$\mathrm{MAD} \approx 0.6745 \ \mathrm{sd} \approx 0.8453 \ d. \tag{3}$$

The mean deviation is the **maximum likelihood estimator** of the scale parameter δ (and is therefore asymptotically **efficient**) for the double-exponential distribution with density $f_{\mu,\delta}(x) = (2\delta)^{-1} \exp(-|x - \mu|/\delta)$ (μ arbitrary, $\delta > 0$). (The corresponding estimator for μ is the median.)

Around 1900, mean deviation and standard deviation were the two most commonly used scale estimators. Both were usually converted into the *probable error* (the error that would be surpassed with probability one-half) according to the above Eqs (3), with MAD replaced by probable error. The MAD, although the direct (and **nonparametric**) estimate of the probable error, apparently was never used then as an estimator (perhaps because of its low efficiency near the normal distribution, and without awareness of its good **robustness** properties).

In 1920, Fisher [2] proved and stressed the optimality of the standard deviation under strictly normal data and showed that the mean deviation in this case has an **asymptotic relative efficiency** of only $1/(\pi - 2) \approx 88\%$, causing the mean deviation to fall into oblivion. The astronomer Eddington [1, p. 147; 2, footnote, p. 762] maintained that the mean deviation was the better (more accurate) scale measure according to (astronomical) practical experience. There is no contradiction – both were right; real data are never exactly normal. In 1960, Tukey ([[6], inserts], with more details and a correction given by Huber [5, p. 3]) showed that less than 0.2% of a very mild form of contamination of a normal distribution suffice to render d better than sd, while for about 5% contamination (a common frequency of gross errors) of the same mild type, d is twice as efficient as sd.

A key to better understanding of these and other facts about the mean deviation is provided by the concepts of robustness theory (the stability theory of statistical procedures). If we add a single observation (e.g. a gross error) in any point x to a large sample with (estimated) parameters m and d, the standardized change of d in the limit of $n \to \infty$ is given by the influence curve or influence function [3]

$$\mathrm{IF}(x) = |x - m| - d, \tag{4}$$

which increases only linearly with x, while the IF for sd increases quadratically, implying a much higher sensitivity to "dirt" in the tails of the observed distribution (*see* **Robustness**). However, both functions are unbounded; in fact, a single **outlier** moving to infinity carries both estimates to infinity. Hence neither should be used. We say, that their *breakdown point* [3] is zero. By contrast, the MAD tolerates about 50% gross errors before it gives arbitrarily false values; its breakdown point is 50%. There are other scale estimators with positive breakdown point and generally higher efficiency than the MAD (e.g. **trimmed** variances, or Huber's scale estimators – cf. [5]). Using sd or d after (some functioning form of) rejection of outliers prevents the worst, but this approach is a complex procedure usually not well understood, and is less efficient than other robust scale estimators (cf. [4]); nevertheless, it might often be the simplest practical solution.

FRANK HAMPEL

Mean Square Error

If $\hat{\theta} = \hat{\theta}(Y_1, \ldots, Y_n)$ is an estimator of a parameter θ based on a **random sample** of size n, then the mean square(d) error (MSE) of the estimator is defined as the expected value of the squared deviation of the estimator from the true value to be estimated:

$$\begin{aligned}\mathrm{MSE}(\hat{\theta}) &= \mathrm{E}[(\hat{\theta} - \theta)^2] \\ &= \int \cdots \int [\hat{\theta}(Y_1, \ldots, Y_n) - \theta]^2 \\ &\quad \times f(y_1; \theta) \ldots f(y_n; \theta) \partial y_1 \ldots \partial y_n,\end{aligned}$$

where $f(y;\theta)$ is the density upon which the sample is based. In general, for any estimator $\hat{\theta}$ of a parameter θ, the MSE can equivalently be defined as $\mathrm{E}[(\hat{\theta}) - \theta)^2] = \int (\hat{\theta} - \theta)^2 g(\hat{\theta}; \theta) \partial \hat{\theta}$, where $g(\hat{\theta};\theta)$ is the **sampling distribution** of the estimator $\hat{\theta}$. The MSE is a measure of the closeness of the estimator to the true value. From the following identity:

$$\begin{aligned}\mathrm{E}[(\hat{\theta} - \theta)^2] &= [\mathrm{E}(\hat{\theta}) - \theta]^2 + \mathrm{E}[\hat{\theta} - \mathrm{E}(\hat{\theta})]^2 \\ &= [\mathrm{bias}(\hat{\theta})]^2 + \mathrm{var}(\hat{\theta}),\end{aligned}$$

it is seen that the MSE is the sum of the squared **bias** plus the **variance** of the estimator. Thus, the MSE reflects both the bias of an estimator, i.e. how much its expected value differs systematically from the true value, as well as the precision (variance) of the estimator, which measures how much it varies about its expected value or mean due to sampling variability. A good estimator ideally will have a small MSE, reflecting both small bias and small variance. Choosing an estimator with a small MSE often entails a tradeoff between bias and variance.

Subset Selection in Regression and Prediction

Tradeoffs between bias and variance are illustrated in the problem of choosing the "best" set of predictor variables in multiple linear regression (*see* **Variable Selection**). Let y_i be a response measured on the ith individual in a sample of size n. The objective is to relate y_i to a set of p predictors (**explanatory** or independent variables) and to predict future values of y. The standard model writes $y_i = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_p x_{ip} + e_i$, where $x_{i1}, \ldots, x_{ip}$ are p predictors measured on subject i, $\beta_0, \beta_1, \ldots, \beta_p$ are unknown regression coefficients to be estimated, and $e_i, i = 1, \ldots, n$, are independent, identically distributed, residual errors having mean zero and variance σ^2. This model is expressed in matrix notation as $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$, where $\mathbf{Y}$ is the $n \times 1$ vector of responses, $\mathbf{X}$ is the $n \times (p+1)$ design matrix of rank $(p+1)$ whose ith row is $(1, x_{i1}, \ldots, x_{ip})$, $\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_p)'$, and $\mathbf{e}$ is the $n \times 1$ vector of errors. The **least squares** estimate of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}$, and for a given set of predictors $\mathbf{x} = (1, x_1, \ldots, x_p)'$, the usual predictor of y is $\hat{y} = \mathbf{x}'\hat{\boldsymbol{\beta}}$. This is an **unbiased** predictor, and the *mean squared error of prediction* (MSEP), is defined as $\mathrm{E}(\hat{y} - y)^2 = \sigma^2[1 + \mathbf{x}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}]$. The *mean squared error of the regression coefficients* is defined as $\mathrm{MSE}(\hat{\boldsymbol{\beta}}) = \mathrm{E}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})'$, which equals $\mathrm{var}(\hat{\boldsymbol{\beta}}) = \sigma^2(\mathbf{X}'\mathbf{X})^{-1}$. At times, an objective is to select the "best" subset for predicting y out of a potentially large number p of available predictor variables. Walls & Weeks [5] show that it is possible for the prediction based on a subset of variables to have a smaller MSEP. Partition $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2)$, where $\mathbf{X}_1$ is the set of variables included in the regression and $\mathbf{X}_2$ are excluded. Similarly, partition $\boldsymbol{\beta}' = (\boldsymbol{\beta}_1', \boldsymbol{\beta}_2')$ and $\mathbf{x}' = (\mathbf{x}_1', \mathbf{x}_2')$. The least squares estimate of $\boldsymbol{\beta}_1$ based on the subset $\mathbf{X}_1$ is $\tilde{\boldsymbol{\beta}}_1 = (\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{X}_1'\mathbf{y}$, with bias $\mathrm{E}(\tilde{\boldsymbol{\beta}}_1 - \boldsymbol{\beta}_1) = (\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{X}_1'\mathbf{X}_2\boldsymbol{\beta}_2$ and $\mathrm{MSE}(\tilde{\boldsymbol{\beta}}_1) = \sigma^2(\mathbf{X}_1'\mathbf{X}_1)^{-1} + (\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{X}_1'\mathbf{X}_2\boldsymbol{\beta}_2\boldsymbol{\beta}_2'\mathbf{X}_2'\mathbf{X}_1(\mathbf{X}_1'\mathbf{X}_1)^{-1}$. The predicted value of y based on $\mathbf{X}_1$, $\tilde{y} = \mathbf{x}_1'\tilde{\boldsymbol{\beta}}_1$, will generally be biased (the bias is nonzero unless $\mathbf{X}_1'\mathbf{X}_2\boldsymbol{\beta}_2 = \mathbf{0}$), and $\mathrm{MSEP}(\tilde{y}) = \sigma^2[1 + \mathbf{x}_1'(\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{x}_1] + \{[\mathbf{x}_2' - \mathbf{x}_1'(\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{X}_1'\mathbf{X}_2]\boldsymbol{\beta}_2\}^2$, which may be less than $\mathrm{MSEP}(\hat{y})$ based on the full model. In particular, Hocking [2] shows that if $\mathrm{var}(\hat{\boldsymbol{\beta}}_2) - \boldsymbol{\beta}_2\boldsymbol{\beta}_2'$ is positive definite, then (i) $\mathrm{MSE}(\hat{\boldsymbol{\beta}}_1) - \mathrm{MSE}(\tilde{\boldsymbol{\beta}}_1)$ is positive definite, and (ii) $\mathrm{MSEP}(\hat{y}) \geq \mathrm{MSEP}(\tilde{y})$, implying that the reduced model using the subset of variables in $\mathbf{X}_1$ is better in terms of mean squared error both for estimating the regression coefficients $\boldsymbol{\beta}_1$ as well as for predicting y. For example, excluding a single variable X_2 will result in a better estimate of $\boldsymbol{\beta}_1$ and a lower MSEP if $\mathrm{var}(\hat{\boldsymbol{\beta}}_2) > (\boldsymbol{\beta}_2)^2$, i.e. if the variance of the regression coefficient of $\boldsymbol{\beta}_2$ estimated in the full model exceeds the square of the true value of $\boldsymbol{\beta}_2$. Hocking [2] also proposes considering as a criterion the average decrease in predictive mean squared error

over the n points in the sample:

$$\frac{1}{n}\sum_{i=1}^{n}[\text{MSEP}(\hat{y}_i) - \text{MSEP}(\tilde{y}_i)]$$

and discusses how selecting a subset to maximize this criterion is closely related to the use of **Mallows' C_p** and the adjusted R^2 as criteria for subset selection in multiple regression.

The concept that a biased estimator may be preferable in terms of MSE to an unbiased estimator with a large variance also underlies the concept of **ridge regression** [3]. In situations where the p predictor variables are highly intercorrelated (i.e. the problem of **multicollinearity**), they suggest the biased "ridge regression" estimate $\hat{\boldsymbol{\beta}}_k = (\mathbf{X}'\mathbf{X} + k\mathbf{I})^{-1}\mathbf{X}'\mathbf{y}$, where the predictor variables in X have been standardized by subtracting their sample means and dividing by their standard deviations, and the constant k is determined by inspecting the "ridge trace" or plot of $\hat{\boldsymbol{\beta}}_k$ vs. k. For some choice of k, the ridge regression estimate will have smaller MSE than the least squares estimator. **Shrinkage estimators** derived from an **empirical Bayes** approach [1] also typically have a smaller MSE than the usual unbiased estimators. *See also* **James–Stein Estimator** [4].

MARK D. SCHLUCHTER

Mean

The mean is a central concept in both data analysis and statistical theory. The usual sample mean is an arithmetic average of a set of n numerical observations, $x_1, x_2, x_3, \ldots, x_n$,

$$\overline{x} = \frac{\sum_{i=1}^{n} x_i}{n}.$$

The sample mean is nearly universally denoted by the symbol, $\overline{x}$, and is the most commonly used measure of central tendency of a set of numerical data.

In probability, the population mean, expected value or **expectation** of a **random variable** is the analog of the arithmetic or sample mean, $\overline{x}$. In fact, the **law of large numbers** implies that, for an infinitely large sample of independent random variables drawn from a distribution, the sample mean, $\overline{x}$, is equal to the expected value or mean of the distribution.

In any data analysis the usefulness of a summary statistic, such as the mean, depends on the details of the physical or biological process measured and specific summary information needed from the data. The sample mean can often be modified to provide the appropriate summary information. These modifications and their probability model analogs provide a rich source of both theory and numerical description of data sets.

Often each numerical observation does not have equal weight or importance. For example, the numerical observations themselves may be means of subgroups with different numbers of observations in each subgroup. In this case a *weighted mean* or average is used:

$$\overline{x}_w = \frac{\sum_{i=1}^{n} w_i x_i}{\sum_{i=1}^{n} w_i},$$

where w_i is the weight of the ith numerical observation. In the example where each observation represents a subgroup, the weight should be the number of units in the subgroup. This kind of weighted average is found in **analysis of variance,** sample survey analysis, and other more specialized areas.

Weighting can sometimes correct for sampling bias. A special case is when the probability that a unit is sampled is proportional to the variable of interest – an example of size-biased sampling. In this, weighting each observation by $w_i = 1/x_i$ yields

$$\overline{x}_h = \frac{\sum_{i=1}^{n} \frac{1}{x_i} x_i}{\sum_{i=1}^{n} \frac{1}{x_i}} = \frac{1}{\frac{1}{n}\sum_{i=1}^{n} \frac{1}{x_i}},$$

which is called the *harmonic mean*. The harmonic mean is found by taking the average value of the reciprocal of the data, $1/x_i$, and then taking the reciprocal of the average value. The harmonic mean is well defined only for positive data, i.e. when all possible values of the data are greater than 0. For positive data the harmonic mean is always less than or equal to the arithmetic mean.

The *geometric mean* can be used when measurements from natural processes have a distribution that is not symmetric and is **skewed** to the right. For skewed data the sample mean is not an adequate description of the center of the data. Both the theory of the **lognormal** distribution and practical data analysis justify the use of a log transformation of the original data,

$$y_i = \ln x_i.$$

Often the log transformed data will have a nearly symmetric distribution. In this case

$$\overline{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$$

is a good measure of the center of the log transformed data. Transforming $\overline{y}$ back to the original scale of the data yields the geometric mean of x,

$$\mathrm{GM} = \exp \overline{y}.$$

Thus, the geometric mean, GM, is the antilog of the mean of the log transformed data. A mathematically equivalent way of expressing the geometric mean is as the nth root of the product of the n observations,

$$\mathrm{GM} = \left(\prod_{i=1}^{n} x_i\right)^{1/n}.$$

The geometric mean is only well defined for positive data. For positive data the following inequality

holds for geometric, harmonic, and sample (arithmetic) means:

$$\overline{x}_h \leq \mathrm{GM} \leq \overline{x}.$$

One straightforward way to obtain a measure of central tendency that does not depend on the extremes or tails of the data is to first remove or trim the data in both tails of the distribution and then compute the usual arithmetic mean using the remaining data. The result is referred to as a **trimmed** or Winsorized mean.

W. SMITH

Measurement Error in Epidemiologic Studies

This article is concerned with relating a response or outcome to an exposure and **confounders** in the presence of measurement error in one or more of the variables. We focus almost entirely on measurement error in a continuous or measured variable. When categorical variables (exposed or not exposed, case or control, quintiles of fat) are measured with error, they are said to be misclassified (*see* **Misclassification Error**). There are also many links in this topic with methods for handling missing data and with validation studies (*see* **Missing Data in Epidemiologic Studies**; **Validation Study**). For further details and a general overview of the topic, see [20]; [30] should be consulted for the linear model.

Before describing the problem, it is useful first to consider a number of specific examples that have had an impact on the development of the field:

1. Measurement error has long been a concern in relating error-prone predictors such as systolic blood pressure (SBP) to the development of coronary heart disease (CHD). That SBP is measured with error is well known, and estimates [23] suggest that approximately one-third of its observed variability is due to measurement error. The **Framingham Heart Study** is perhaps the best known **cohort study** in which the role of measurement error in SBP has been a concern for many years. MacMahon et al. [44] describe the important public health implications of properly accounting for the measurement error inherent in SBP. In an (as yet) unpublished paper, David Yanez, Richard Kronmal & Lynn Shemanski have discovered an example also in the CHD context where the failure to account properly for measurement error leads to misleading conclusions based on falsely detected statistical significance.
2. In measuring nutrient intake, measurement error has been a long-term concern, as has the impact of this error on the ability to detect nutritional factors leading to cancer, especially breast and colon cancer. Typical cohort studies measure diet by means of food frequency questionnaires which, while related to long-term diet, are known to have biases and measurement errors. Other instruments are in use in this field, including food records (essentially diaries), 24 h recalls and (for a limited number of variables such as total caloric intake) biomarkers. Measurement error in nutrient instruments can be very large, for example because of the daily and seasonal variability of an individual's diet, and the **biases** in and loss of **power** to detect nutrient–cancer relationships can be profound. There is still considerable controversy in this field (see [37], [54], and [41]). Because of the cost of cohort studies in nutrition, **case–control studies** are of considerable interest. However, nutrient intakes in case–control studies are measured after the development of disease in cases, and this might cause differential measurement error, a topic we discuss in some detail below (*see* **Nutritional Exposure Measures**).
3. There are a number of ongoing prospective and case–control studies of disease and serum hormone levels, and this is an area of considerable potential. Measurement error is a major concern here, due to within-individual variation of hormones, as well as various laboratory errors.
4. In measuring environmental risk factors (*see* **Environmental Epidemiology**), measurement error is a common problem. For example, measuring household lead levels is an error-prone process, not only because of laboratory and device error, but also because lead levels are inhomogeneous in both space and time, while measurement methods tend to be in fixed locations at fixed times. Because lead exposure has many possible media (air, dust, soil) with possibly correlated errors, the effects of measurement error can be large and complex.

Outline

This article consists of a series of major Sections, as follows:

1. We first outline the basic concepts of measurement error modeling, making particular distinction between **differential** and **nondifferential measurement error**. We also describe the ideas of functional and structural modeling, as well as indicating how the measurement error problem can be treated as a **missing data** problem.
2. Following the introductory concepts, we discuss the problem of measurement error as it pertains to

the **linear regression** model. Here we introduce the idea of attenuation of regression coefficients, and the biases in parameter estimates caused by measurement error. We also discuss **hypothesis testing**. In the simplest cases, measurement error causes an often large decrease in the power to detect significant effects, while, as indicated above, and as exhibited through the **analysis of covariance**, in an **observational study**, measurement error in a confounder can cause misleading **inferences** about exposure effects.

3. Having described the effects of measurement error on **estimation** and hypothesis testing, we turn to correcting for the effects due to measurement error. We first describe the two most common methods, known as regression calibration and SIMEX, and also a group of techniques called corrected score methods. We also describe the use of instrumental variables.
4. **Maximum likelihood** and **Bayesian** estimation form an important component of the measurement error problem, and are described in some detail. We define the **likelihood** function, and show the crucial difference in the likelihood function between the nondifferential and differential measurement error cases; see (13) and (14).
5. While most of the article is based on measurement error in predictors, there is an important literature on response error, which we also review.
6. Case–control studies are important in epidemiology. A distinguishing feature of case–control studies is that the measurement error may be differential. In the differential measurement error case, we indicate that a specific type of data is required, the validation data sets, in which the true predictor can be observed for a subset of the study participants. If the measurement error is nondifferential, then matters are much easier, and the famous result of Prentice & Pyke [55] on the analysis of case–control studies is shown to have an analogue in the measurement error context.
7. There is a significant and developing literature on measurement error in **survival analysis**, and we indicate two possible approaches to the problem.

Measurement error models have a common structure; we illustrate the terms using a breast cancer and nutrition example:

1. An underlying model for a response in terms of predictors, e.g. linear **regression**, **logistic regression**, **nonlinear regression**; see Carrell & Ruppert [14]. This is the model we would fit if all variables were observed without error. In what follows, we call Y the response. For example, in the breast cancer and nutrition example, Y is breast cancer incidence fit to covariables using logistic regression
2. A variable which is measured subject to error. This could be an exposure or a confounder. We call this variable X. It is often called the *error-prone* predictor or the *latent predictor*. In the breast cancer example, X is long-term nutrient intake
3. The observed value of the mismeasured variable. We call this W, e.g. nutrient intake measured from a food frequency questionnaire
4. Those predictors which for all practical purposes are measured without error, which we call Z, e.g. age, body mass index
5. We are interested in relating the response Y to the true predictors (Z, X). One method, often called the *naive* method, simply replaces the error-prone predictor X with its measured version W. This substitution typically leads to biases in parameter estimates and can lead to misleading inferences
6. The goal of measurement error modeling is to obtain nearly **unbiased** estimates of exposure effects and valid inferences. Attainment of this goal requires careful analysis. Substituting W for X, but making no adjustments in the usual fitting methods for this substitution, leads to estimates that are biased, sometimes seriously. In assessing measurement error, careful attention needs to be given to the type and nature of the error, and the sources of data which allow modeling of this error.

It should be obvious that one should design studies and instruments in such a way as best to lessen or to eliminate measurement error. In this article, we demonstrate some of the impacts of ignoring measurement error, ranging from bias in parameter estimates (Figure 1), to loss of power, requiring therefore much larger sample sizes to detect effects (Figure 2) to cases where the type I errors (*see* **Hypothesis Testing**) occur at higher rates than the usual 5% (Figure 3).

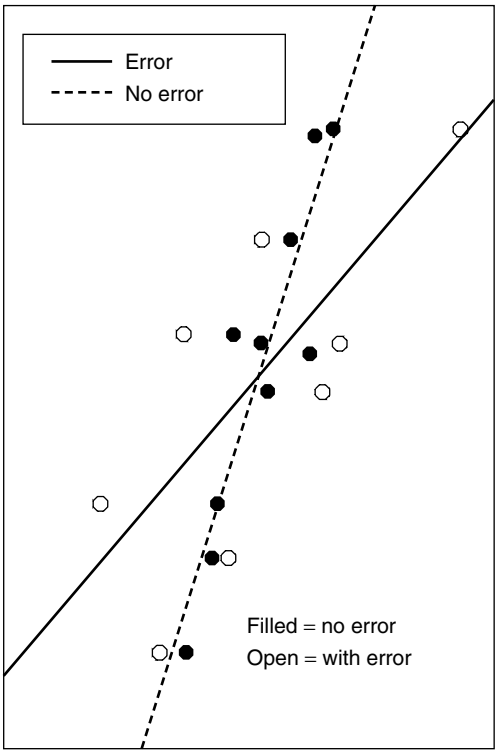

Figure 1 Illustration of additive measurement error model. The filled circles are the true (Y, X) data and the dashed (steeper) line is the least squares fit to these data. The open circles and solid (attenuated) line are the observed (Y, W) data and the associated least squares regression line. For these data $\sigma_x^2 = \delta_u^2 = 1$, $(\beta_0, \beta_x) = (0, 1)$ and $\sigma_\varepsilon^2 = 0.25$

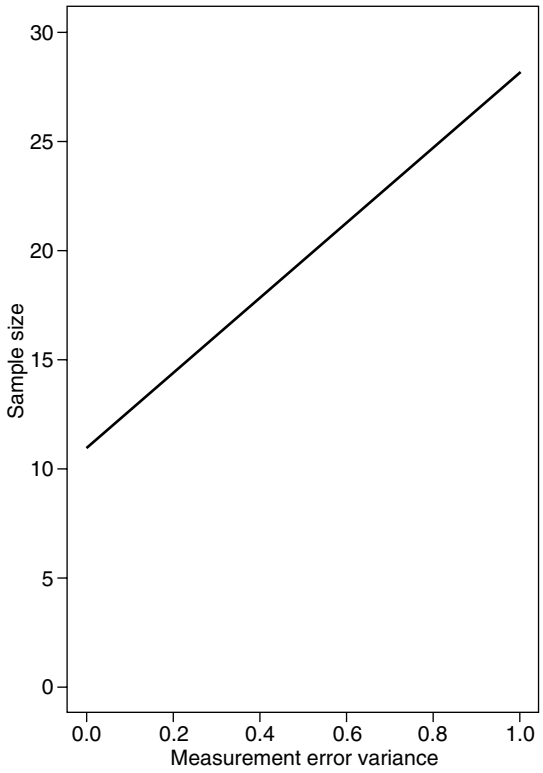

Figure 2 Sample size for 80% power in a one-sided test of level 5% in linear regression, as a function of the measurement error variance. Here the true slope = 0.75, the true variance of X is 1.0, and the true variance about the line is 1.0

Computer Programs

S-PLUS and SAS (*see* **Software, Biostatistical**) computer programs (on Solaris SPARC architecture and for Windows on PCs) which implement many of the methods described in this article (for major **generalized linear models** such as linear, logistic, probit, Poisson and gamma regression) are available at no cost on the World Wide Web at `http://stat.tamu.edu/qvf/qvf./html`.

Bootstrap standard errors are available. They have been developed by Raymond Carroll, Henrik Schmiedieche, and H. Joseph Newton.

A set of programs for **logistic regression** (in SAS and FORTRAN) is available from Professor Donna Spiegelman (e-mail `stdls@gauss.bwh.harvard.edu`). Interested readers should contact her for information concerning extension of these programs to **proportional hazards** and linear regression.

Iowa State University (Department of Statistics, Iowa State University, Ames IA 50011) distributes programs called EV-CARP for linear measurement error models at a cost of $300.

Models for Measurement Error

A fundamental prerequisite for analyzing a measurement error problem is specification of a model for the measurement error process. The *classical error model*, in its simplest form, is appropriate when an attempt is made to determine X directly, but one is unable to do so because of various errors in measurement. For example, consider systolic blood pressure (SBP), which is known to have strong daily

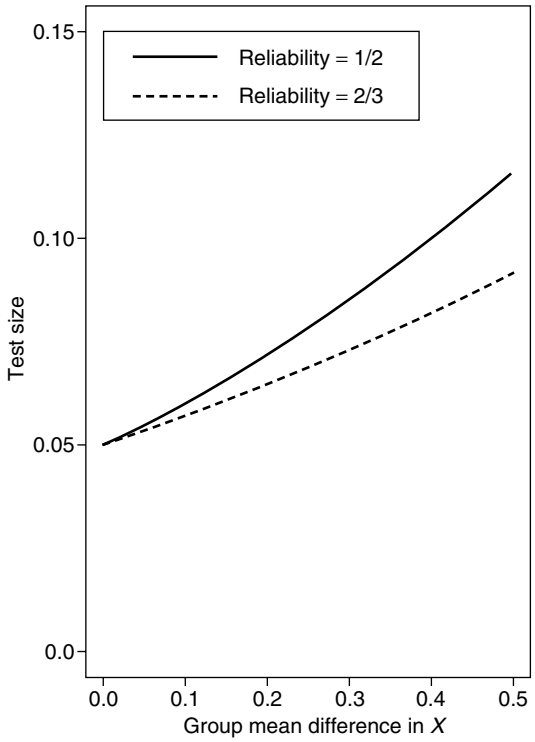

Figure 3 The actual level of a test for exposure effect with a highly predictive covariate measured with error, based on a sample of size $n = 20$. Here the true slope for the covariate $X = 1.0$, the true variance of X is 1.0, the true variance about the line is 1.0, and the reliability is either 2/3 (dashed line) or 1/2 (solid line). The term "Group mean difference in X" is the difference in the mean of X in the exposure group minus the mean of X in the control group

and seasonal variations. In trying to measure SBP, the various sources of error include simple machine recording error, administration error, time of day, and season of the year. In such a circumstance, it sometimes makes sense to hypothesize an unbiased **additive error model**, which we write as

$$\text{(the classic model) } W = X + U, \qquad (1)$$

where U, the error, is assumed to be independent of X. An alternative model, the *controlled variable or Berkson model* [6], is especially applicable to laboratory studies. As an example, consider the herbicide study of Rudemo et al. [61]. In that study, a nominal measured amount W of herbicide was applied to a plant. However, the actual amount X absorbed by the plant differed from W, e.g. because of potential errors in application. In this case,

$$\text{(the Berkson model) } X = W + U, \qquad (2)$$

where U, the error, is assumed to be independent of W.

Determining an appropriate error model to use in the data analysis depends upon the circumstances and the available data. For example, in the herbicide study, the measured concentration W is fixed by design and the true concentration X varies due to error, so that model (2) is appropriate. On the other hand, in the measurement of long-term systolic blood pressure, it is the true long-term blood pressure which is fixed for an individual, and the measured value which is perturbed by error, so model (1) should be used. Estimation and inference procedures have been developed both for error and controlled-variable models.

This hardly exhausts the possible error models. See [20] and [29] for more details and further examples with more complex structure.

Sources of Data

To perform a measurement error analysis, one needs information about the error structure. These data sources can be broken up into two main categories:

1. *internal* subsets of the primary data
2. *external* or independent studies.

Within each of these broad categories, there are three types of data, all of which might be available only in a random subsample of the data set in question:

1. *validation* data, in which X is observable directly
2. *replication* data, in which replicates of W are available
3. *instrumental* data, in which another variable T is observable in addition to W.

An internal validation data set is the ideal, because it can be used with all known analytical techniques, permits direct examination of the error structure and tests of critical error model assumptions, typically leads to much greater precision of estimation and inference, and has strong links to the well-developed

theory of missing data analysis (see below). We cannot express too forcefully that, if at all possible, one should obtain an internal validation data set.

With external validation data, one must assume that the error structure in those data also applies to the primary data (see below).

Replication data are used when it is impossible to measure X exactly, as, for example, when X represents long-term systolic average blood pressure or long-term average nutrient intake. Usually, one would make replicate measurements if there were good reason to believe that the replicated mean is a better estimate of X than a single observation, i.e. the classical error model is the target. In the classical error model (1), replication data can be used to estimate the **variance** of the measurement error, U.

Internal instrumental data sets containing a second measure T are useful for **instrumental variable** analysis, discussed briefly later in this article.

Transportability of Models and Parameters

In some studies, the measurement error process is not assessed directly, but instead is estimated from external data sets. We say that parameters of a model can be transported from one study to another if the model holds with the same parameter values in both studies. Typically, in applications only a subset of the model parameters need be transportable.

In many instances, approximately the same classical error model holds across different populations. For example, consider systolic blood pressure at two different clinical centers. Assuming similar levels of training for technicians making the measurements and a similar measurement protocol, it is reasonable to expect that the distribution of the error in the recorded measure is independent of the clinical center one enters, the technician making the measurement, and the value of X being measured. Thus, in classical error models it is often reasonable to assume that the error distribution is the same across different populations, i.e. transportable.

A common mistake is to transport a correction for measurement error from one study to the next. Such transportation is almost never appropriate. For instance, while the properties of errors of measurement may be reasonably transportable, the distribution of the true (or latent) predictor X is rarely transportable, since it depends so heavily on the population being sampled. Problems arise because corrections for measurement error involve not only the measurement error process but also the distribution of X. For example, systolic blood pressure measurements in the MRFIT study and the Framingham Heart Study may well have the same measurement error variance, but the distribution of true blood pressure X appears to differ substantially in the two studies, and the "correction for attenuation" described below cannot be transported from Framingham to MRFIT (see [17] for further details).

Is there an "Exact" Predictor?

We have based our discussion on the existence of an exact predictor X and measurement error models that provide information about this predictor. However, in practice, it is often the case that the definition of "exact" needs to be carefully considered prior to discussion of error models. In the measurement error literature the term "**gold standard**" is often used for the operationally defined exact predictor, though sometimes this term is used for an exact predictor that cannot be operationally defined. Using an operational definition for an "exact" predictor is often reasonable and justifiable on the grounds that it is the best one could ever possibly hope to accomplish. However, such definitions may be controversial. For example, consider the problem of relating breast cancer risk to the dietary intake of fat. One way to determine whether decreasing one's fat intake lowers the risk of developing breast cancer is to conduct a **clinical trial** in which members of the treatment group are encouraged to reduce fat intakes. If instead one uses observational prospective data, along with an operational definition of long-term intake, one should be aware that the results of a measurement error analysis could be invalid if true long-term intake and operational long-term intake differ in subtle ways.

Differential and Nondifferential Error

It is important to make a distinction between *differential* and *nondifferential* measurement error. Nondifferential measurement error occurs in a broad sense when one would not even bother with W if X were available, i.e. W has no information about the response other than what is available in X.

Nondifferential measurement error typically holds in **cohort studies**, but is often a suspect assumption in **case–control studies**.

Technically, measurement error is nondifferential if the distribution of Y given (X, Z, W) depends only on (X, Z). In this case W is said to be a *surrogate*. Measurement error is *differential* otherwise.

For instance, consider the Framingham example. The predictor of major interest is long-term systolic blood pressure, X, but we can only observe blood pressure on a single day, W. It seems plausible that a single day's blood pressure contributes essentially no information over and above that given by true long-term blood pressure, and hence that measurement error is nondifferential. The same remarks apply to the nutrition examples: measuring diet on a single day should not contribute information not already available in long-term diet.

Many problems can be analyzed plausibly assuming nondifferential measurement error, especially when the **covariate** measurements occur at a fixed point in time, and the response is measured at a later time, as is typical in cohort studies.

There are two exceptions that need to be kept in mind. First, in case–control studies, the disease response is obtained first, and then one measures antecedent exposures and other covariates. In nutrition studies, this ordering of measurement may well cause differential measurement error. For instance, here the true predictor would be long-term dietary intake before diagnosis, but the dietary interview data are obtained only after diagnosis. A woman who develops breast cancer may exaggerate her estimated fat intake, thus introducing **recall bias** (*see* **Bias in Case–Control Studies**). In such circumstances, estimated fat intake will be associated with disease status even after conditioning on true long-term diet before diagnosis.

When measurement error is nondifferential, one can estimate parameters in models for responses given true covariates even when the true covariates are not observable. This is not true when measurement error is differential, except for the linear model. With differential error, one must obtain a validation subsample in which both true covariate measurements and surrogate measurements are available. Most of this article focuses on nondifferential measurement error models. Differential models with a **validation study** are typically best analyzed by techniques for handling missing data (*see* **Missing Data in Epidemiologic Studies**; **Missing Data**; **Multiple Imputation Methods**).

Prediction

Prediction of a response is different from estimation and inference for parameters. If a predictor X is measured with error, and one wants to predict a response *based on the error-prone version* W of X, then, except for an important case discussed below, it makes little sense to worry about measurement error. The reason for this is quite simple. If one has an original set of data (Y, W) then one can fit a convenient model to Y as a function of W. Predicting Y from W is merely a matter of using this model for prediction. There is no need then for measurement error to play a role in the problem.

The one situation requiring that we model the measurement error occurs when we develop a **prediction** model using data from one population but we wish to predict in another population. A naive prediction model that ignores measurement error may not be transportable. This context often becomes quite complex, requiring a combination of missing data and measurement error techniques, and to the best of our knowledge has not been investigated in detail in the literature, an exception being [31].

Is Bias Always Towards the Null?

It is commonly thought that the effect of measurement error is to bias estimates of exposure effects "towards the null" (*see* **Bias Toward the Null**). Hence, one could ignore measurement error when testing the **null hypothesis** of no exposure effect, and one could assume that non-null estimates, if anything, underestimate the effect of exposure. This lovely and appealing folklore is sometimes true but, unfortunately, often wrong. We discuss this point in detail below. A numerical example has recently been provided to us by David Yanez, Richard Kronmal & Lynn Shemanski in a heart disease context with seven covariates and a baseline variable. They found that, while an analysis ignoring measurement error showed highly statistically significant effects in all variables, none of the effects was even close to being statistically significant when the analysis took measurement error into account.

Functional and Structural Models

The words *functional* and *structural* have important places in the area of measurement error models. They act as a shorthand terminology for the basic approach one uses to solve the problem. In *functional modeling* nothing is assumed about the Xs; they could be fixed constants (the usual definition) or random variables. In *structural modeling*, X is assumed to be random, and a parametric distribution (usually the **normal**) is assumed. There has traditionally been considerable concern in the measurement error literature about the **robustness** of estimation and inferences based upon structural models for unobservable variates. Fuller [30, p. 263] discusses this issue briefly in the classical **nonlinear regression** problem, and basically concludes that the results of structural modeling "may depend heavily on the (assumed) form of the X distribution". In probit regression, Carroll et al. [23] report that, if one assumes that X is normally distributed, and it really follows a **chi-square distribution** with one **degree of freedom**, then the effect on the likelihood estimate is "markedly negative"; see also [63]. Essentially all research workers in the measurement error field come to a common conclusion: likelihood methods can be of considerable value, but the possible nonrobustness of inference due to model **misspecification** is a vexing and difficult problem.

The issue of model robustness is hardly limited to measurement error modeling. Indeed, it pervades statistics, and has led to the rise of a variety of **semiparametric** and **nonparametric** techniques. From this general point of view, *functional modeling* may be thought of as a group of semiparametric techniques. Functional modeling uses parametric models for the response, but makes no assumptions about the distribution of the unobserved covariate.

There is no agreement in the statistical literature as to whether functional or structural modeling is more appropriate. Many researchers believe that one should make as few model assumptions as possible and favor functional modeling. The argument is that any extra efficiency gained by structural modeling is more than offset by the need to perform careful and often time-consuming **sensitivity analyses**. Other researchers believe that appropriate statistical analysis requires one to do one's best to model every feature of the data, and thus favor structural modeling.

We take a somewhat more relaxed view of these issues. There are many problems, e.g. linear and logistic regression with additive measurement error, where functional techniques are easily computed and fairly efficient, and we have a strong bias in such circumstances towards functional modeling. In other problems – for example, the segmented regression problem [38] – structural modeling clearly has an important role to play, and should not be neglected.

Measurement Error as a Missing Data Problem

From one perspective, measurement error models are special kinds of missing data problems, because the Xs, being mostly and often entirely unobservable, are obviously missing as well. Readers who are already familiar with linear measurement error models and functional modeling will be struck by the fact that most of the recent missing data literature has pursued likelihood and Bayesian methods, i.e. structural modeling approaches. Readers familiar with missing data analysis will also be interested to know that, in large part, the measurement error model literature has pursued functional modeling approaches. We feel that both functional and structural modeling approaches are useful in the measurement error context, and this article pursues both strategies.

The usual interpretation of the classical missing data problem [42] is that the values of some of the variables of interest may not be observable for all study participants. For example, a variable may be observed for 80% of the study participants, but unobserved for the other 20%. The techniques for analyzing missing data are continually evolving, but it is fair to say that most of the recent advances (**multiple imputation**, data augmentation, etc.) have been based on likelihood (and Bayesian) methods.

The classical measurement error problem discussed to this point is one in which one set of variables, which we call X, is *never* observable, i.e. always missing. As such, the classical measurement error model is an extreme form of a missing data problem, but with *supplemental information* about X in the form of a surrogate, which we call W. Part of the art in measurement error modeling concerns how the supplemental information is related to the unobservable covariate.

Because there is a formal connection between the two fields, and because missing data analysis has become increasingly parametric, it is important to consider likelihood and Bayesian analysis of measurement error models – topics taken up later in this article.

Linear Regression and the Effects of Measurement Error

A comprehensive account of linear measurement error models can be found in Fuller [30].

Many textbooks contain a brief description of measurement error in linear regression, usually focusing on **simple linear regression** and arriving at the conclusion that the effect of measurement error is to bias the slope estimate in the direction of 0. Bias of this nature is commonly referred to as *attenuation* or *attenuation to the null*.

In fact, though, even this simple conclusion has to be qualified, because it depends on the relationship between the measurement, W, and the true predictor, X, and possibly other variables in the regression model as well. In particular, the effect of measurement error depends upon the model under consideration and on the joint distribution of the measurement error and the other variables. In **multiple linear regression**, the effects of measurement error vary, depending on: (i) the regression model, be it additive or multiple regression; (ii) whether or not the predictor measured with error is univariate or **multivariate**; and (iii) the presence of bias in the measurement. The effects can range from the simple attenuation described above to situations where: (i) real effects are hidden; (ii) observed data exhibit relationships that are not present in the error-free data; and (iii) even the signs of estimated coefficients are reversed relative to the case with no measurement error.

The key point is that the measurement error distribution determines the effects of measurement error, and thus appropriate methods for correcting for the effects of measurement error depend on the measurement error distribution.

Simple Linear Regression with Additive Error: Regression to the Mean

We start with the simple linear regression model $Y = \beta_0 + \beta_x X + \varepsilon$, where the scalar X has mean μ_x and variance σ_x^2, and the error in the equation ε is independent of X, has mean zero, and variance σ_ε^2. The error model is additive as in (1). In this classical additive measurement error model, it is well known that an ordinary **least squares** regression ignoring measurement error produces an estimate not of β_x, but instead of $\beta_{x*} = \lambda\beta_x$, where

$$\lambda = \frac{\sigma_x^2}{\sigma_x^2 + \sigma_u^2} < 1. \tag{3}$$

Thus ordinary least squares regression of Y on W produces an estimator that is attenuated to 0. The attenuating factor, λ, is called the *reliability ratio*.

One would expect that, because W is an error-prone predictor, it has a weaker relationship with the response than does X. This can be seen both by the attenuation and also by the fact that the residual variance of this regression is increased, being not σ_ε^2 but instead

$$\begin{aligned}\mathrm{var}(Y|W) &= \text{residual variance of observed data} \\ &= \sigma_\varepsilon^2 + \lambda\beta_x^2\sigma_u^2.\end{aligned}$$

This facet of the problem is often ignored, but it is important. *Measurement error causes a double-whammy*: not only is the slope attenuated, but the data are more noisy, with an increased error about the line.

To illustrate the attenuation associated with the classical additive measurement error, the results of a small simulation are displayed in Figure 1.

Ten observations were generated with $\sigma_x^2 = \sigma_u^2 = 1$, $(\beta_0, \beta_x) = (0, 1)$, and $\sigma_\varepsilon^2 = 0.25$. The filled circles and steeper line depict the true but unobservable data (Y, X) and the regression line of Y on X. The empty circles and attenuated line depict the observed (Y, W) data and the linear regression of Y on W.

Figure 1 is indicative of a phenomenon called **regression to the mean**. Intuitively, what this means is that the extremes in the observed (W) data are *too* extreme, and that the true X is closer to the mean of the data. In fact, in normally distributed data, if X has a population mean μ_x, then having observed the fallible instrument, the best prediction of X is $\mu_x(1 - \lambda) + \lambda W$, where $\lambda < 1$ is defined in (3). The net effect is that the best (linear) predictor of X is always closer to the overall mean than any observed W.

The foregoing is one facet of regression to the mean. A more common definition is complementary. In a study participant with an unusually large observed W, if one repeats the measurement and obtains a second (replicated) measure, then this replicate is generally less (and often much less) than the original extreme value.

For instance, in a study of true long-term fat intake (X) using a 24 h recall instrument (W), if one focuses on the person with the highest reported fat intake, then (i) that person's true fat intake is most likely less than the observed intake, and (ii) if one repeats the 24 h recall instrument, then the new reported fat intake is likely to be less than the original reported fat intake.

The second part of the "double-whammy" is a loss of **power**. The following example is meant to illustrate this loss of power, and it is easiest to do this illustration in the special case that all variances are known. Suppose that one wants to test the null hypothesis H_0: $\beta_x = 0$ of zero slope against the one-sided alternative H_1: $\beta_x > 0$, using a test with a 5% level (type I error) which has power 80% to detect that the slope $\beta_x = 0.75$. With known variances, in the absence of measurement error, the required sample size is

$$n = \frac{(z_{0.95} + z_{0.80})^2 \sigma_\varepsilon^2}{\sigma_x^2 \beta_x^2},$$

where z_α is the usual α percentile of the normal distribution. With measurement error, the same formula applies, except that, with $\beta_x = 0.75$, one replaces σ_ε^2 by $\sigma_\varepsilon^2 + \lambda\beta_x^2\sigma_u^2$, σ_x^2 by $\sigma_x^2 + \sigma_u^2$, and β_x by $\lambda\beta_x$. In Figure 2, we plot the sample sizes as a function of the measurement error variance in the case that X has variance $\sigma_x^2 = 1$ and the error about the line has variance $\sigma_\varepsilon^2 = 1$. In the absence of measurement error, approximately 10 observations are required to obtain the desired power. However, if the measurement error variance $\sigma_u^2 = 1$ and thus the reliability $= 1/2$, then approximately 30 observations are required. Thus, measurement error causes a loss of power. In planning a study with a large measurement error in a covariate, one will typically require a much larger sample size to meet power goals than if there were no measurement error.

It is a common belief that the effect of measurement error is always to attenuate the slope of the regression line, but in fact attenuation depends critically on the assumed classical additive measurement error model. Very different results are obtained if measurement errors are differential. One example where this problem may arise is in dietary calibration studies. In a typical dietary calibration study, one is interested in the relationship between a self-administered food frequency questionnaire (FFQ, the value of Y) and usual (or long-term) dietary intake (the value of X) as measures of, for example, the percentage of calories from fat in a person's diet. FFQs are thought to be biased for usual intake, and in a calibration study researchers will obtain a second measure (the value of W), typically from a food diary, a 24h recall, or a short-term biomarker. In this context, it is often assumed that the diary, recall, or biomarker is unbiased for usual intake. If, as sometimes occurs, the FFQ and the diary/recall are given very nearly contemporaneously, it is unreasonable to assume that the error in the relationship between the FFQ and usual intake is uncorrelated with the error in the relationship between a diary–recall–biomarker and usual intake. This correlation has been demonstrated [29], and gives rise to differential error. It can be shown [20] that, if there is significant **correlation** between the measurement error and the error about the true line, then the regression of Y on W can have a slope biased away from the null. Thus, correction for bias induced by measurement error clearly depends on the nature, as well as the extent, of the measurement error.

Multiple Regression: Single Covariate Measured with Error

In multiple linear regression the effects of measurement error are more complicated, even for the classical additive error model.

We now consider the case where X is scalar, but there are additional covariates Z measured without error. In the linear model the mean is $\beta_0 + \beta_x X + \beta_z Z$. Under the usual conditions of independence of errors, the least squares regression estimator of the coefficient of W consistently estimates $\lambda_1\beta_x$, where

$$\lambda_1 = \frac{\sigma_{x|z}^2}{\sigma_{w|z}^2} = \frac{\sigma_{x|z}^2}{\sigma_{x|z}^2 + \sigma_u^2}, \tag{4}$$

and $\sigma_{w|z}^2$ and $\sigma_{x|z}^2$ are the (residual) variances of the regressions of W on Z and X on Z, respectively. Note that λ_1 is equal to the simple linear regression attenuation $\lambda = \sigma_x^2/(\sigma_x^2 + \sigma_u^2)$ only when X and Z are uncorrelated. *The basic point is that the attenuation depends on the relationships among the covariates.*

The problem of measurement-error-induced bias is not restricted to the regression coefficient of X. The coefficient of Z is also biased in general, unless Z is independent of X [19]. In fact, naive ordinary least

squares estimates not β_z but rather

$$\beta_{z*} = \beta_z + \beta_x(1 - \lambda_1)\gamma_z, \tag{5}$$

where γ_z is the coefficient of Z in the regression of X on Z.

This result has important consequences in epidemiology when interest centers on the effects of covariates measured without error. For example, consider the case that Z is a **binary** exposure variable (exposed or not) which is classified correctly, and X is an important confounder measured with significant error. Then Carroll et al. [19] show that ignoring measurement error produces a **consistent** estimate of the exposure effect only if the design is balanced, i.e. X has the same mean in both groups and is independent of treatment. With considerable imbalance, the naive analysis may lead to the conclusion that: (i) there is a treatment effect when none actually exists; and (ii) the effects are negative when they are actually positive, and vice versa. In most observational studies the confounder and the exposure are correlated (see [34] and [35]). Errors in measuring the confounders can produce very misleading results.

Multiple Covariates Measured with Error

If multiple covariates are measured with error, then the direction of the bias induced by this error does not follow any simple pattern. One may have attenuation, reverse-attenuation, changes of sign, or an observed positive effect even at a true null model. This is especially the case when the predictors measured with error are correlated or their errors are correlated. In such a problem, there really seems to be no substitute for a careful measurement error analysis.

Correcting for Bias

As we have just seen, the ordinary least squares estimator is typically biased under measurement error, and the direction and magnitude of the bias depends on the regression model and the measurement error distribution. We next describe two commonly used methods for eliminating bias.

In simple linear regression with the classical additive error model, we have seen in (3) that ordinary least squares is an estimate of $\lambda\beta_x$; recall that λ is called the reliability ratio. If the reliability ratio were known, then one could obtain a proper estimate of β_x simply by dividing the ordinary least squares slope by the reliability ratio.

Of course, the reliability ratio is rarely known in practice, and one has to estimate it. If $\hat{\sigma}_u^2$ is an estimate of the measurement error variance (this is discussed below), and if $\hat{\sigma}_w^2$ is the sample variance of the Ws, then a consistent estimate of the reliability ratio is $\hat{\lambda} = (\hat{\sigma}_w^2 - \hat{\sigma}_u^2)/\hat{\sigma}_w^2$. The resulting estimate is $\beta_{x*}/\hat{\lambda}$. In small samples the sampling distribution of this estimate is highly skewed, and in such cases a modified version of the **method of moments** estimator is recommended [30].

The **algorithm** described above is called the *method-of-moments* estimator. The terminology is apt, because ordinary least squares and the reliability ratio depend only on moments of the observed data.

The method-of-moments estimator can be constructed for the **general linear model**, as well as for simple linear regression. Consult the book by Fuller [30], especially Chapter 2.

Another well publicized method for linear regression in the presence of measurement error is *orthogonal regression*. It is fairly rare in epidemiologic situations that the model underlying orthogonal regression holds [15], and we will not discuss the method any further.

Bias vs. Variance

Estimates that do not account for measurement error are typically biased. Unfortunately, correcting for this bias often has a price. In particular, the resulting corrected estimator will be more variable than the biased estimator, and wider **confidence intervals** result. For example, Rosner et al. [60] describe a problem in logistic regression, where the response is the development of breast cancer, and the predictor measured with error is daily saturated fat intake. Ignoring measurement error, they obtained an estimated **odds ratio** for saturated fat of 0.92, with a 95% confidence interval from 0.80 to 1.05. The corrected estimated odds ratio was 0.83 with a confidence interval from 0.61 to 1.12, which is twice as wide as the previous interval.

Attenuation in General Problems

We have already seen that, with multiple covariates, even in linear regression the effects of measurement

error are complex, and not easily described. In this Section, we provide a brief overview of what happens in nonlinear models.

Consider a scalar covariate X measured with error, and suppose that there are no other covariates. In the classical error model for simple linear regression we have seen that the bias caused by measurement error is always in the form of attenuation, so that ordinary least squares preserves the sign of the regression coefficient asymptotically, but is biased towards zero. Attenuation is a consequence then of (i) the simple linear regression model and (ii) the classical additive error model. Without (i) and (ii), the effects of measurement error are more complex; we have already seen that attenuation may not hold if (ii) is violated.

In logistic regression, when X is measured with additive error, attenuation does not always occur, but it is typical and generally much like that of linear regression.

Dosemeci et al. [28] give an example of **misclassification error** that shows that trends are not always preserved under nondifferential measurement error. Suppose that 1348 subjects are exposed at no ($X = 0$), low ($X = 1$), and high ($X = 2$) levels to a harmful substance. Suppose that the chance of an adverse outcome is 1/2, 2/3, and 6/7 for no, low, and high exposures, while the chances of the exposures themselves are 0.0059347, 0.8902077, and 0.1038576, respectively. If true exposure could be ascertained, then the expected outcomes would be as in the section of Table 1 labeled "true". If we were to regress Y on the **dummy variables** X_1 indicating low exposure ($X_1 = 1$), and X_2 indicating high exposure ($X_2 = 1$), then the true logistic regression parameters for X_1 and X_2 would be $\log 2 = 0.69$ and $\log 6 = 1.79$, respectively, indicating that the two higher exposure levels have response rates higher than the response rate associated with the no-exposure level. The true data clearly indicate a harmful effect due to exposure.

Table 1 A hypothetical logistic regression example with nondifferential measurement error. The entries are the expected counts. The true logistic parameters for dummy variables low and high exposure are $\log 2$ and $\log 6$, respectively, while the observed coefficients for the error prone data are $\log 0.46$ and $\log 0.53$, respectively

Disease status	Exposure = none	Exposure = low	Exposure = high
True			
$Y = 1$	4	800	120
$Y = 0$	4	400	20
Observed			
$Y = 1$	52	480	392
$Y = 0$	12	240	172

Now suppose, however, that measurement error (in this case misclassification) occurs, so that 40% of those truly at high exposure are misclassified into the no-exposure group, and 40% of those truly at low exposure are misclassified into the high-exposure group. Let W be the resulting variable taking on the three observed levels of exposure, with corresponding dummy variables W_1 and W_2. This is a theoretical example, of course, and one can criticize it for not being particularly realistic, but it is an example of nondifferential measurement error. The observed data we expect to see using the surrogates W_1 and W_2 are also given in Table 1.

The observed logistic regression parameters for W_1 and W_2 are $\log 0.46 = -0.78$ and $\log 0.53 = -0.63$, respectively, indicating that the two higher exposure levels have response rates lower than the response rate associated with the no-exposure level. The observed data suggest a beneficial effect due to exposure, even though the exposure is harmful!

Hypothesis Testing

In this section, we discuss hypothesis tests concerning regression parameters. To keep the exposition simple, we focus on linear regression. However, the results hold in some generality, especially for logistic and **Poisson regression**. We assume nondifferential measurement error and the classical additive error model.

The simplest approach to hypothesis testing calculates the required test statistic from the parameter estimates obtained from a measurement error analysis and their estimated standard errors. Such tests are justified whenever the estimators themselves are justified. However, this approach to testing is only possible when the indicated methods of estimation are possible, and thus requires either knowledge of the measurement error variance, or the presence of validation data, or replicate measurements, or instrumental variables.

There are certain situations in which naive hypothesis tests are justified and thus can be performed

without additional data or information of any kind. Here "naive" means that we ignore measurement error and substitute W for X in a test that is valid when X is observed. This Section studies naive tests, describing when they are and are not acceptable.

We use the criterion of asymptotic validity to distinguish between acceptable and nonacceptable tests. We say a test is asymptotically valid if its type I error rate approaches its nominal level as the sample size increases. Asymptotic validity (which we shorten to validity) of a test is a minimal requirement for acceptability.

The main results on the validity of naive tests under nondifferential measurement error are as follows:

1. The naive test of no effects due to X is valid. This means that if one wants to test whether *all* components of X together have no effect, then it is valid to ignore nondifferential measurement error. Thus, for example, if X is the exposure, then a valid test of the null hypothesis for X is obtained by ignoring measurement error and performing the standard test for the problem at hand.
2. The naive test described above is also fully efficient if X is linearly related to W and Z, but not otherwise [79]. Thus, while in principle one can obtain additional power by a measurement error analysis, many times in practice the naive test of the null hypothesis for X is reasonably efficient.
3. In many problems, more than one covariate is measured with error. For example, suppose that the exposure and one of the confounders are measured with error. Generally, the naive test of the null hypothesis for the exposure is invalid, except under special circumstances, e.g. the exposure and confounder are statistically independent, as are their measurement errors.
4. In general, naive tests for Z are invalid, except possibly if Z is uncorrelated with X. Thus, if X is the exposure and Z is a confounder, then naive tests for significance of the exposure are valid, but they are not valid for testing the significance of the confounder. Somewhat more troubling, though, is the case when X is a confounder related to the exposure Z; here the naive test for the exposure is generally invalid, *even if exposure is measured without error*. We have mentioned this example previously in the case that the exposure is binary (see [19]).

The last point can be demonstrated in the **analysis of covariance**, in which Z is a binary exposure variable and X is a confounder with strong predictive ability. In the analysis of covariance, the model is

$$Y = \beta_0 + \beta_z Z + \beta_x X + \varepsilon,$$

where ε is the error about the line, with variance σ_ε^2. The binary indicator Z takes on the values ± 1, with 50% of the data being unexposed ($Z = -1$) and 50% of the data being exposed ($Z = 1$). Within the unexposed group, X has mean $-\theta/2$ and variance σ_x^2, while, within the exposed group, X has mean $\theta/2$ and variance σ_x^2. The difference between the means for X in the two groups is θ. In a randomized **clinical trial**, one would expect that $\theta = 0$, since **randomization** ensures that the population means of X are the same in the exposed and unexposed groups. In nonrandomized studies, one would expect that $\theta \neq 0$. Thus, the larger the value of θ, the more unbalanced is the study. In Figure 3, we plot the level (type I error) of the test for the exposure effect which ignores measurement error as a function of the difference in group means θ. This calculation is done for the case that $n = 20$ (10 exposed and 10 unexposed), $\sigma_\varepsilon^2 = 1, \sigma_x^2 = 1$, and $\beta_x = 1$, for reliability ratios $\dot{\lambda} = 1/2$ and $= 2/3$. The graph shows that if the means of the confounders are sufficiently different, then, instead of a type I error of 5%, the test for exposure effect which ignores measurement error in the *confounder* can have type I error rates higher than 10%, even for such small sample sizes.

Regression Calibration and SIMEX

We now describe two simple, generally applicable approaches to nondifferential measurement error analysis, regression calibration, and simulation extrapolation (SIMEX).

Regression Calibration

The basis of regression calibration is the replacement of X by the regression of X on (Z,W). After this approximation, one performs a standard analysis. This *regression calibration* algorithm was suggested as a general approach by Carroll & Stefanski [16] and

Gleser [33]. Prentice [52] pioneered the idea for the **proportional hazard** model, and a modification of it has been suggested for this topic by Clayton [25]; see below. Armstrong [4] suggests regression calibration for **generalized linear models**, and Fuller [30, pp. 261–262] briefly mentions the idea. Rosner et al. [59, 60] have developed the idea for **logistic regression** into a workable and popular methodology, complete with a good computer program. Because of the importance of their contribution to epidemiologic applications, regression calibration is often referred to as "Rosner's Method". Other interesting and important applications and methodology related to regression calibration include work by Whittemore [83], Pierce et al. [51], Liu & Liang [43], and Kuha [39]. In some special cases, regression calibration is equivalent to the classical method of moments bias correction.

The main justifications of the regression calibration approximation are that, for some models, e.g. **loglinear** mean models and **linear regression**, the regression calibration approximation is often exact except for a change in the intercept parameter. For logistic regression, in many cases the approximation is almost exact.

The Regression Calibration Algorithm. The regression calibration algorithm is what Pierce et al. [51] call a "replacement method":

1. Using replication, validation or instrumental data, estimate the regression of X on (Z,W) (see below). This is called the *calibration function*.
2. Replace the unobserved X by its estimate from the regression model, and then run a standard analysis to obtain parameter estimates.
3. Adjust the resulting standard errors to account for the estimation at the first step, using either the bootstrap or asymptotic methods [20].

The simplest form of regression calibration is the "correction for attenuation" used in linear regression. It is easiest to describe in the following situation:

1. X is a scalar.
2. The measurement error is additive, with estimated error variance $\hat{\sigma}_u^2$.

For estimating the effect of X, the regression calibration estimator is formed by three steps: (i) form the naive estimator by ignoring measurement error; (ii) let $\hat{\sigma}_{w|z}^2$ be the regression **mean square error** from a linear regression of W on Z (this is the sample variance of the Ws if there are no other covariates Z); (iii) the regression calibration estimator is defined by multiplying the naive estimator by $\hat{\sigma}_{w|z}^2/(\hat{\sigma}_{w|z}^2 - \hat{\sigma}_u^2)$.

Estimating the Calibration Function Parameters. With *internal validation data*, the simplest approach is to regress X on the other covariates (Z, W) in the validation data. While linear regression will be typical, it is not required.

In some problems, an *unbiased second instrument* T is available for a subset of the study participants. For instance, one might be interested in $X =$ caloric intake over a year, but have available only $T =$ the result of a biomarker experiment using a technique known as doubly labeled water over a 2 week period, which does not equal X because it does not take into account the variability of diet over a year. In this case one uses the regression of T on (Z,W) as the calibration function. This is the method used by Rosner et al. [59] in their analysis of the Nurses' Health Study.

Finally, in the classical additive error model, one often has merely a second measurement (a replicate) for a subset of the study population. One could treat this replicate as an unbiased second instrument and apply the method described in the previous paragraph. If the Ws are not too far from normally distributed, a more efficient method is to use the so-called best linear approximation to the calibration function (see [20, pp. 47–48]). This takes into account that some of the study participants do have a replicated W and hence use the data in a reasonably efficient fashion.

Suppose there are k_i replicate measurements of X_i, and that $\overline{W}_i$ is their mean. Replication enables us to estimate the measurement error **covariance matrix** σ_u^2 by the usual **variance components** analysis, as follows:

$$\hat{\sigma}_u^2 = \frac{\sum_{i=1}^{n}\sum_{j=1}^{k_i}(W_{ij} - \overline{W}_{i\cdot})^2}{\sum_{i=1}^{n}(k_i - 1)}. \qquad (6)$$

The calibration function is defined as follows. Suppose the observations are $(Z_i, \overline{W}_{i\cdot})$, where $\overline{W}_{i\cdot}$ is the

mean of k_i replicates. We use **analysis of variance** formulas. Let

$$\hat{\mu}_x = \hat{\mu}_w = \frac{\sum_{i=1}^{n} k_i \overline{W}_{i\cdot}}{\sum_{i=1}^{n} k_i}, \qquad \hat{\mu}_z = \overline{Z}_{\cdot},$$

$$\nu = \frac{\sum_{i=1}^{n} k_i - \sum_{i=1}^{n} k_i^2}{\sum_{i=1}^{n} k_i},$$

$$\hat{\sigma}_z^2 = (n-1)^{-1} \sum_{i=1}^{n} (Z_i - \overline{Z}_{\cdot})^2,$$

$$\hat{\sigma}_{xz} = \frac{\sum_{i=1}^{n} k_i (\overline{W}_{i\cdot} - \hat{\mu}_w)(Z_i - \overline{Z}_{\cdot})}{\nu},$$

$$\hat{\sigma}_x^2 = \frac{\left\{ \left[\sum_{i=1}^{n} k_i (\overline{W}_{i\cdot} - \hat{\mu}_w)^2 \right] - (n-1)\hat{\sigma}_u^2 \right\}}{\nu}.$$

The resulting estimated calibration function which is used to replace $\mathbf{X}$ in the standard analysis is

$$\hat{\mu}_w + (\hat{\sigma}_x^2, \hat{\sigma}_{xz}) \begin{bmatrix} \hat{\sigma}_x^2 + \hat{\sigma}_u^2/k_i & \hat{\sigma}_{xz} \\ \hat{\sigma}_{xz} & \hat{\sigma}_z^2 \end{bmatrix}^{-1} \begin{pmatrix} \overline{W}_{i\cdot} - \hat{\mu}_w \\ Z_i - \overline{Z}_{\cdot} \end{pmatrix}. \tag{7}$$

Expanded Regression Calibration Models. Rudemo et al. [61], Carroll & Stefanski [16] and Carroll et al. [20] all describe refinements to the regression calibration algorithm. Rudemo et al. [61] describe a bioassay problem (*see* **Biological Assay, Overview**) with a heteroscedastic Berkson error model. Racine-Poon et al. [56] describe a similar problem.

There is a long history of approximately consistent estimates in nonlinear problems, of which regression calibration and the SIMEX method are the most recent such methods. Readers should also consult Stefanski & Carroll [70], Stefanski [67], Amemiya & Fuller [3], and Whittemore & Keller [85] for other approaches.

The SIMEX Method

We now describe a method that shares the simplicity of regression calibration and is well suited to problems with additive or multiplicative measurement error. Simulation extrapolation (SIMEX) is a **simulation**-based method of estimating and reducing bias due to measurement error. SIMEX estimates are obtained by adding additional measurement error to the data in a resampling-like stage, establishing a trend of measurement error-induced bias vs. the variance of the added measurement error, and **extrapolating** this trend back to the case of no measurement error. The technique was proposed by Cook & Stefanski [26], and further developed by Carroll et al. [22] and Stefanski & Cook [73]. See also Stefanski, [68].

An integral component of SIMEX is a self-contained simulation study resulting in **graphical displays** that illustrate the effect of measurement error on parameter estimates and the need for bias correction. The graphical displays are especially useful when it is necessary to motivate or explain a measurement error model analysis.

This Section describes the basic idea of SIMEX, focusing on linear regression with additive measurement error. For this simple model the effect of measurement error on the least squares estimator is easily determined mathematically, as we have shown. *The key idea underlying SIMEX is the fact that the effect of measurement error on an estimator can also be determined experimentally via simulation*. If we regard measurement error as a factor whose influence on an estimator is to be determined, we are naturally led to consider simulation experiments in which the level of the measurement error, i.e. its variance, is varied intentionally.

The SIMEX Algorithm

Suppose that, in addition to the original data used to calculate the naive estimate $\hat{\beta}_{x,\text{naive}}$, there are $M-1$ additional data sets available, each with successively larger measurement error variances, say $(1+\zeta_m)\sigma_u^2$, where $0 = \zeta_1 < \zeta_2 < \cdots < \zeta_M$. Of course, the least squares estimate of slope from the mth data set ignoring measurement error, $\hat{\beta}_{x,m}$, consistently estimates $\beta_x \sigma_x^2 / [\sigma_x^2 + (1+\zeta_m)\sigma_u^2]$.

We can think of this problem as a nonlinear regression model, with dependent variable $\hat{\beta}_{x,m}$ and

independent variable ζ_m, having a mean function of the form

$$\mathcal{G}(\zeta) = \frac{\beta_x \sigma_x^2}{\sigma_x^2 + (1+\zeta)\sigma_u^2}, \zeta \geq 0.$$

The parameter of interest, β_x, is obtained from $\mathcal{G}(\zeta)$ by extrapolation to $\zeta = -1$. We describe the process schematically in Figure 4.

SIMEX imitates the procedure just described. In the *simulation step*, additional independent measurement errors with variance $\zeta_m \sigma_u^2$ are generated and added to the original data, thereby creating data sets with successively larger measurement error variances. For the mth data set, the total measurement error variance is $\sigma_u^2 + \zeta_m \sigma_u^2 = (1+\zeta_m)\sigma_u^2$. Next, estimates are obtained from each of the resulting contaminated data sets. The simulation and reestimation step is repeated a large number of times (to remove simulation variability) and the average value of the estimate for each level of contamination is calculated. These averages are plotted against the ζ values, and regression techniques are used to fit an extrapolant function to the averaged, error-contaminated estimates. Extrapolation back to the ideal case of no measurement error ($\zeta = -1$) yields the SIMEX estimate.

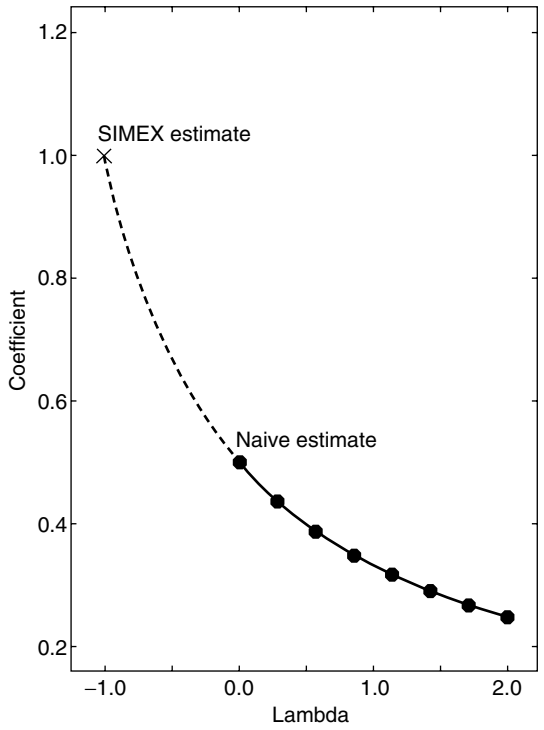

Figure 4 A generic plot of the effect of measurement error of size $(1+\zeta)\sigma_u^2$ on parameter estimates. The value of ζ is on the x-axis, while the value of the estimated coefficient is on the y-axis. The SIMEX estimate is an extrapolation to $\zeta = -1$. The naive estimate occurs at $\zeta = 0$

The first part of the algorithm is the simulation step. As described above, this involves using simulation to create additional data sets with increasingly large measurement error $(1+\zeta)\sigma_u^2$. For any $\zeta \geq 0$, define

$$W_{b,i}(\zeta) = W_i + \zeta^{1/2} U_{b,i}, \quad i = 1, \ldots, n, \quad b = 1, \ldots, B, \qquad (8)$$

where the computer-generated *pseudo-errors*, $\{U_{b,i}\}_{i=1}^n$, are mutually independent, independent of all the observed data, and identically distributed, normal random variables with mean 0 and variance σ_u^2.

Having generated the new predictors, we compute the resulting naive estimates, component by component. For each ζ, do this B times ($B = 100$ usually works fine) and compute their average, $\hat{\beta}(\zeta)$. It is the points $\{\hat{\beta}(\zeta_m), \zeta_m\}_1^M$ that are plotted as filled circles in Figure 4. This is the simulation component of SIMEX.

The extrapolation step of the proposal entails modeling each of the components of $\hat{\beta}(\zeta)$ as functions of ζ for $\zeta \geq 0$, and extrapolating the fitted models back to $\zeta = -1$. In Figure 4 the extrapolation is indicated by the dashed line and the SIMEX estimate is plotted as a cross. Carroll et al. [20] describe practical modifications of the algorithm, and how to estimate variances of parameters. Inference for SIMEX estimators can also be performed via the **bootstrap**. Because of the computational burden of the SIMEX estimator, the bootstrap requires considerably more computing time than do other methods. Without efficient implementation of the estimation scheme at each step, the SIMEX bootstrap may take an inconveniently long time to compute. On my computing system for measurement error models the implementation is efficient, and most bootstrap applications take little time.

We have described the SIMEX algorithm in terms of the additive measurement error model. However, SIMEX applies more generally.

For example, consider multiplicative error. Taking logarithms transforms the **multiplicative model** to the **additive model**. SIMEX works naturally here,

in that one performs the simulation step (8) on the logarithms of the Ws and not on the Ws themselves.

With replicates, one can also investigate the appropriateness of different **transformations**. For example, after transformation, the **standard deviation** of the intra-individual replicates should be uncorrelated with their mean, and one can find the transformation (logarithm, square root, etc.) which makes the two uncorrelated.

Example

To illustrate SIMEX, we use data from the Framingham Heart Study, correcting for bias due to measurement error in systolic blood pressure measurements. The Framingham study consists of a series of exams taken two years apart. We use Exam #3 as the baseline. There are 1615 men aged 31–65 in this data set, with the outcome, Y, indicating the occurrence of coronary heart disease (CHD) within an 8-year period following Exam #3; there were 128 such cases of CHD. Predictors employed in this example are the patient's age at Exam #2, smoking status at Exam #1, and serum cholesterol at Exams #2 and #3, in addition to systolic blood pressure (SBP) at Exam #3, the latter being the average of two measurements taken by different examiners during the same visit. In addition to the measurement error in SBP measurements, there is also measurement error in the cholesterol measurements. However, for this example we ignore the latter source of measurement error and illustrate the methods under the assumption that only SBP is measured with error.

The covariates measured without error, Z, are age, smoking status, and serum cholesterol, with $W = \log(\text{SBP} - 50)$. Implicitly, we are defining X as the long-term average of W. We illustrate the analyses for the case where W is the mean of the two transformed SBPs, and σ_u^2 is estimated using (6). The estimated linear model correction for attenuation, or inverse of the reliability ratio, is 1.16; if only one SBP measurement were used, the correction would be 1.33.

Figure 5 contains plots of the logistic regression coefficients $\hat{\Theta}(\zeta)$ for eight equally spaced values of ζ spanning [0, 2] (solid circles). For this example $B = 2000$. The points plotted at $\zeta = 0$ are the naive estimates $\hat{\Theta}_{\text{naive}}$. The nonlinear least-squares fits of $\mathcal{G}_{\text{RL}}(\lambda, \Gamma)$ to the components of $\{\hat{\Theta}(\zeta_m), \zeta_m\}_1^8$ (solid curves) are extrapolated to $\zeta = -1$ (dashed curves), resulting in the SIMEX estimators (crosses). The open circles are the SIMEX estimators that result from fitting quadratic extrapolants. To preserve clarity the quadratic extrapolants were not plotted. Note that the quadratic-extrapolant estimates are conservative relative to the rational linear-extrapolant estimates in the sense that they fall between the rational linear-extrapolant estimates and the naive estimates.

We have stated previously that the SIMEX plot displays the effect of measurement error on parameter estimates. This is especially noticeable in Figure 5. In each of the four graphs in Figure 5, the range of the ordinate corresponds to a one-standard-error confidence interval for the naive estimate constructed using the information standard errors. Thus Figure 5 illustrates the effect of measurement error relative to the variability in the naive estimate. It is apparent that the effect of measurement error is of practical importance only on the coefficient of $\log(\text{SBP} - 50)$.

Conditional and Corrected Scores for Functional Modeling

Regression calibration and SIMEX are easily applied general methods for nondifferential error. Although the resulting estimators are **consistent** in important special cases such as linear regression and loglinear mean models, they are only approximately consistent in general.

For certain generalized linear models and measurement error distributions there are easily applied functional methods that are fully (and not just approximately) consistent, and make no assumptions about the distribution of X.

We focus on the case of additive normally distributed measurement error with measurement error variance σ_u^2. Although the problem has this parametric error assumption, it also has a nonparametric component: no assumptions are made about the true predictors X.

Suppose for the sake of discussion that the measurement error variance σ_u^2 is known. In the functional model, the unobservable Xs are fixed constants, and hence the unknown parameters include the Xs. With additive normally distributed measurement error, one strategy is to maximize the joint density of the observed data with respect to all of the unknown parameters including the Xs. While this works for linear regression [32], it fails for more complex models

such as logistic regression. Indeed, the logistic regression functional maximum likelihood estimator is both inconsistent and difficult to compute [70]. An alternative approach is to change to the structural model and apply likelihood techniques (see below).

In this Section, we consider two functional methods, the conditional-score and corrected-score methods. We start with logistic and gamma–loglinear modeling as important examples for which these techniques apply. The conditional methods exploit

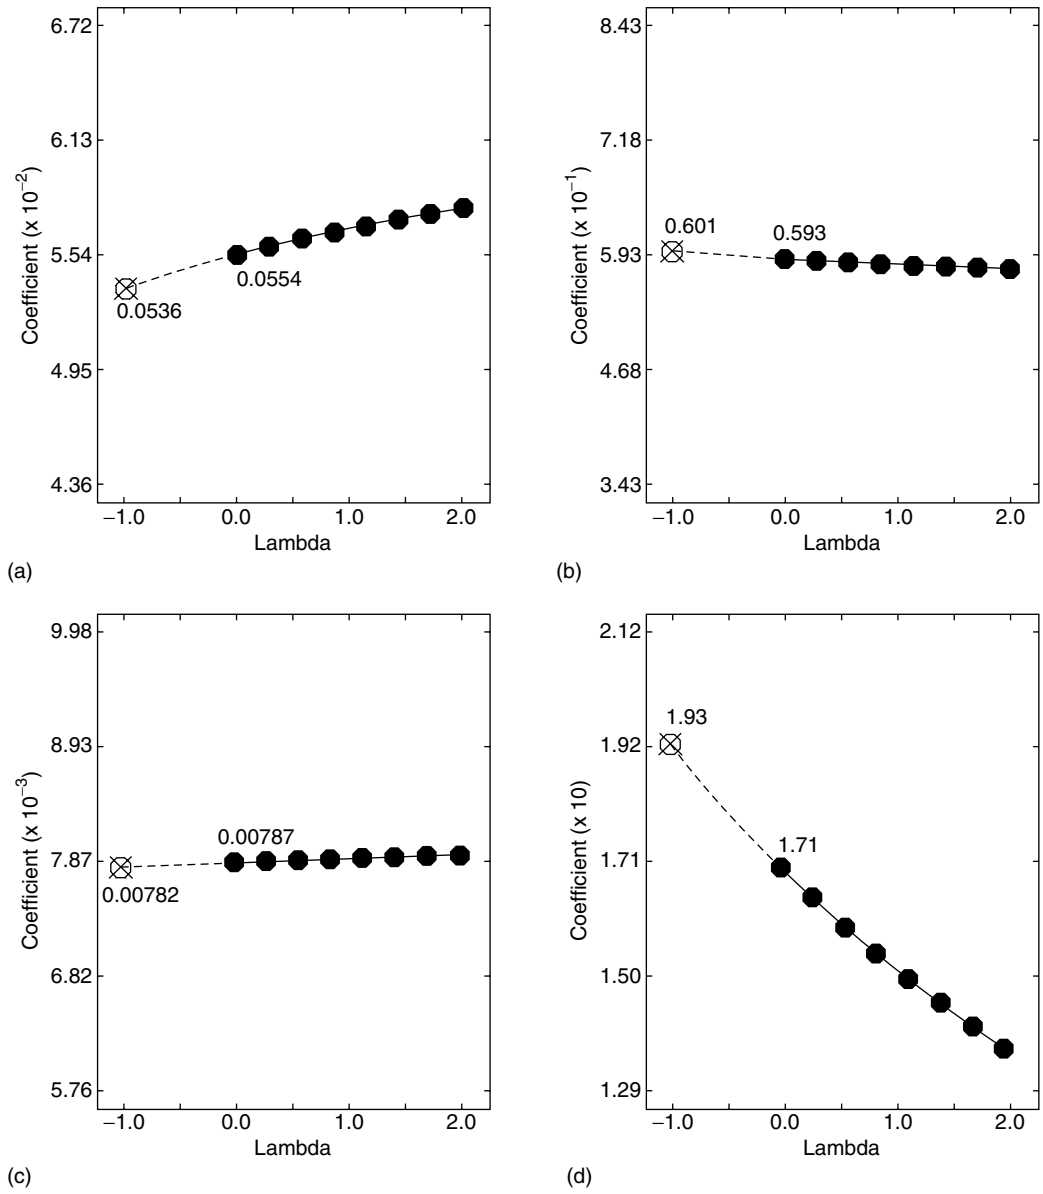

Figure 5 Coefficient extrapolation functions for the Framingham logistic regression modeling. The simulated estimates $\{\hat{\Theta}(\zeta_m), \zeta_m\}_1^8$ are plotted (solid circles) and the fitted rational linear extrapolant (solid line) is extrapolated to $\zeta = -1$ (dashed line), resulting in the SIMEX estimate (cross). Open circles indicate SIMEX estimates obtained with the quadratic extrapolant. (a) Age; (b) Smoking; (c) Cholesterol; (d) log(SBP − 50)

special structures in important models such as linear, logistic, Poisson loglinear, and gamma-inverse, and then use a traditional statistical device – conditioning on **sufficient statistics** – to obtain estimators. The corrected-score method effectively estimates the estimator one would use if there were no measurement error.

First consider the **multiple linear regression** model with mean $\beta_0 + \beta_x X + \beta_z Z$, and write the unknown regression parameter as $\Theta = (\beta_0, \beta_x, \beta_z)$. When the measurement error is additive with nondifferential measurement error variance Σ_{uu}, the usual **method-of-moments** regression estimator can be derived as the solution to the equation

$$\sum_{i=1}^{n} \psi_* (Y_i, Z_i, W_i, \Theta, \Sigma_{uu}) = 0, \qquad (9)$$

where

$$\psi_* (Y, Z, W, \Theta, \Sigma_{uu}) = (Y - \beta_0 - \beta_x^t X - \beta_z^t Z) \times \begin{pmatrix} 1 \\ Z \\ W \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \Sigma_{uu}\beta_x \end{pmatrix}$$

is the *corrected score* for linear regression. If Σ_{uu} is unknown, then one substitutes an estimate of it into (9) and solves for the regression parameters.

The key point to note here is that, in solving (9), we need know nothing about the Xs. This feature is common to all the methods in this Section.

Eq. (9) is an example of an **estimating equation** approach for estimating a set of unknown parameters. The reader can consult the Appendix of [20] for an overview of estimating equations, although this is unnecessary for the purpose of using the methods. Asymptotic standard errors for the estimators can be derived using either the bootstrap or the sandwich formula.

Logistic regression is best handled using the conditional-score method. For example, consider the usual linear-logistic model, where Y is binary and has success probability following the logistic model $H(\beta_0 + \beta_x X + \beta_z Z)$. The conditional score is

$$\psi_*(Y, Z, W, \Theta, \sigma_u^2) = \{Y - H[\beta_0 - \beta_x^t \Delta(\cdot) - 0.5\beta_x^t \sigma_u^2 \beta_x - \beta_z^t Z]\} \begin{pmatrix} 1 \\ Z \\ \Delta(\cdot) \end{pmatrix}, \qquad (10)$$

where $\Delta(\cdot) = \Delta(Y, W, \beta_x, \sigma_u^2) = W + Y\sigma_u^2\beta_x$. Eq. (10) is substituted into (9), and the resulting equation is solved numerically.

When Y has a **gamma distribution** with loglinear mean $\exp(\beta_0 + \beta_x X + \beta_z Z)$, it has a variance which is ϕ times the square of the mean. For this important example, the corrected-score estimator is obtained from the corrected score

$$\psi_*(Y, Z, W, \Theta, \sigma_u^2) = \begin{pmatrix} 1 \\ Z \\ W \end{pmatrix} - \exp[\Delta(Z, W, \Theta, \sigma_u^2)] \times \begin{pmatrix} Y \\ ZY \\ Y(W + 0.5\sigma_u^2\beta_x) \end{pmatrix}, \qquad (11)$$

where $\Delta(Z, W, \Theta, \sigma_u^2) = -\beta_0 - \beta_x^t W - \beta_z^t Z - 0.5\beta_x^t \sigma_u^2 \beta_x$.

Unbiased Score Functions via Conditioning

The conditional estimators of Stefanski & Carroll [71] and Nakamura [48] are discussed in detail in Carroll et al. [20, Chapter 6]. They apply to linear, logistic, Poisson loglinear, and gamma inverse regression [the mean is $1/(\beta_0 + \beta_x X + \beta_z Z)$]. Their methods have simple formulas for standard errors, although, of course, as usual, the bootstrap applies.

Exact Corrected Estimating Equations

Suppose that it is possible to find a function of the observed data, say $\psi_*(Y, Z, W, \Theta)$, having the property that

$$\mathrm{E}[\psi_*(Y, Z, W, \Theta)|Y, Z, X] = \psi(Y, Z, X, \Theta), \qquad (12)$$

for all Y, Z, X, and Θ. Then corrected score function estimators simply replace ψ by ψ_*. Corrected score functions satisfying (12) do not always exist, and finding them when they do is not always easy.

One useful class of models that admits corrected functions contains those models with log likelihoods of the form

$$\log[f(y|z, x, \Theta)] = \sum_{k=0}^{2} [c_k(y, z, \Theta)(\beta_x^t x)^k] + c_3(y, z, \Theta)\exp(\beta_x^t x);$$

see the examples given below. Then, using normal distribution **moment generating function** identities, the required function is

$$\psi_*(y, z, w, \Theta, \sigma_u^2) = \frac{\partial}{\partial \Theta^t}\left[\sum_{k=0}^{2}[c_k(y, z, \Theta)(\beta_x^t w)^k] - c_2(y, z, \Theta) \times \beta_x^t \sigma_u^2 \beta_x + c_3(y, z, \Theta)\exp(\beta_x^t w - 0.5\beta_x^t \sigma_u^2 \beta_x)\right].$$

Regression models in this class include:

1. normal linear with mean $= \eta$, variance $= \phi$, $c_0 = -(y - \beta_0 - \beta_z^t z)^2/(2\phi) - \log(\phi^{1/2})$, $c_1 = (y - \beta_0 - \beta_z^t z)/\phi$, $c_2 = -(2\phi)^{-1}$, $c_3 = 0$
2. Poisson with mean $= \exp(\eta)$, variance $= \exp(\eta)$, $c_0 = y(\beta_0 + \beta_z^t z) - \log y!$, $c_1 = y$, $c_2 = 0$, $c_3 = -\exp(\beta_0 + \beta_z^t z)$
3. gamma with mean $= \exp(\eta)$, variance $= \phi \exp(2\eta)$, $c_0 = -\phi^{-1}(\beta_0 + \beta_z^t z) + (\phi^{-1} - 1)\log y + \phi^{-1}\log(\phi^{-1}) - \log[\Gamma(\phi^{-1})]$, $c_1 = \phi^{-1}$, $c_2 = 0$, $c_3 = -\phi^{-1} y \exp(-\beta_0 - \beta_z^t z)$.

Comparison of Methods

The methods are applicable at the same time only in linear regression (where they are identical) and Poisson regression. For Poisson regression the corrected estimating equations are more convenient because they are explicit, whereas the conditional estimator involves numerical summation. For Poisson regression the conditional-score estimator is more efficient than the corrected-score estimator in some practical cases.

Instrumental Variables

We have assumed that it was possible to estimate the measurement error variance, say with replicate measurements or validation data. However, it is not always possible to obtain replicates or validation data, and thus direct estimation of the measurement error variance is sometimes impossible. In the absence of information about the measurement error variance, estimation of the regression model parameters is still possible provided the data contain an *instrumental variable* T, in addition to the unbiased measurement $W = X + U$.

There are three basic requirements that an **instrumental variable** must satisfy: (i) it must be correlated with X; (ii) it must be independent of $W - X$; and (iii) it must be a surrogate, i.e. subject to nondifferential measurement error.

One possible source of an instrumental variable is a second measurement of X obtained by an independent method. This second measurement need not be unbiased for X. Thus the assumption that a variable is an instrument is weaker than the assumption that it follows the classical additive error model.

Instrumental variable estimation in linear models is covered in depth by Fuller [30]. The work described here, outside the linear model, is based on that of Carroll & Stefanski [17] and Stefanski & Buzas [69]. Other pertinent references include [1], [2], and [13].

We have found that instrumental variables require a slightly different notation. For example, $\beta_{Y|\mathbf{1}ZX}$ is the coefficient of $\mathbf{1}$, i.e. the intercept, in the regression of Y on $\mathbf{1}$, Z, and X; $\beta_{Y|\mathbf{1}Z\mathbf{X}}$ is the coefficient of Z in the regression of Y on $\mathbf{1}$, Z, and X. This notation allows representation of subsets of coefficient vectors, e.g. $\boldsymbol{\beta}_{Y|\mathbf{1}Z\mathbf{X}} = (\beta_{Y|\mathbf{1}ZX}, \beta_{Y|\mathbf{1}Z\mathbf{X}})$ and $\boldsymbol{\beta}_{X|\mathbf{1}Z\mathbf{T}} = (\beta_{X|\mathbf{1}ZT}, \beta_{X|\mathbf{1}Z\mathbf{T}}, \beta_{X|\mathbf{1}Z\mathbf{T}})$.

Our analysis is based upon regression calibration in generalized linear models, e.g. linear, logistic, and Poisson regression. It might be useful simply to think of this Section as dealing with a class of important models, whose details of fitting are standard in many computer programs.

The approximate models and estimation algorithms are best described in terms of the composite vectors

$$\mathbf{X} = (\mathbf{1}, Z, X), \qquad \mathbf{W} = (\mathbf{1}, Z, W),$$
$$\mathbf{T} = (\mathbf{1}, Z, T).$$

Define $\boldsymbol{\beta}_{Y|\tilde{\mathbf{X}}} = (\beta_{Y|\mathbf{1}ZX}, \beta_{Y|\mathbf{1}Z\mathbf{X}}, \beta_{Y|\mathbf{1}Z\mathbf{X}})$.

We note here that, in addition to the assumptions stated previously, we will also assume that the regression of X on (Z, T, W) is approximately linear. This restricts the applicability of our methods somewhat, but is sufficiently general to encompass many potential applications.

The simplest instrumental variables estimator starts with a (possibly multivariate) regression of $\mathbf{W}$ on $\mathbf{T}$ to obtain $\hat{\beta}_{\mathbf{W}|\mathbf{T}}$. Then Y is regressed on the predicted values $\hat{\beta}_{\mathbf{W}|\mathbf{T}}\mathbf{T}$, which results in an estimator of $\boldsymbol{\beta}_{Y|\mathbf{X}}$.

This estimator is easily computed as it requires only linear regression of the components of **W** on **T**, and then the use of standard regression programs to regress Y on the "predictors" $\hat{\beta}_{\mathbf{W}|\mathbf{T}}\mathbf{T}$.

Carroll et al. [20] describe somewhat more elaborate methods of instrumental variable estimation, which can be more efficient than this simple method, especially if the number of components of T differs from the number of components of W.

This Section describes the use of likelihood methods in measurement error models. There have been a few examples in the literature based on likelihood. See [23], [63], [64], and [78] for probit regression, [84] for a Poisson model, [27], [62] and [81] in logistic regression, and [38] in a **change-point problem**. The relatively small literature belies the importance of the topic and the potential for further applications.

There are a number of important differences between likelihood methods and the methods described in previous Sections:

1. The previous methods are based on additive or multiplicative measurement error models, possibly after a transformation. Typically, few, if any, distributional assumptions are required. Likelihood methods require stronger distributional assumptions, but they can be applied to more general problems, including those with discrete covariates subject to **misclassification error**.
2. The likelihood for a fully specified parametric model can be used to obtain **likelihood ratio** confidence intervals. In methods not based on likelihoods, inference is based on bootstrapping or on normal approximations. In highly nonlinear problems, likelihood-based confidence intervals are generally more reliable than those derived from normal approximations.
3. Likelihood methods are often computationally more demanding, whereas the previous methods require little more than the use of standard statistical packages.
4. **Robustness** to modeling assumptions is a concern for both approaches, but is generally more difficult to understand with likelihood methods.
5. There is a belief that the simpler methods described previously perform just as well as likelihood methods for many statistical models, including the most common generalized linear models. There is little documentation as to whether the folklore is realistic. The only evidence that we know of is given for logistic regression by Stefanski & Carroll [72], who contrast the maximum likelihood estimate and a particular functional estimate. They find that the functional estimate is fairly efficient relative to the maximum likelihood estimate unless the measurement error is "large" or the logistic coefficient is "large". One should be aware, however, that their calculations indicate that there are situations where *properly parameterized* maximum likelihood estimates are considerably more efficient than estimates derived from functional modeling.

Likelihood Specification: Differential and Nondifferential Error

We consider here only the simplest problem in which X is not observable for all subjects, but there are sufficient data, either internal or external, to characterize the distribution of W given (X, Z) (with validation data, we are in the realm of missing data). To perform a likelihood analysis, one must specify a parametric model for every component of the data. Likelihood analysis starts with a model for the distribution of the response given the true predictors. The likelihood (density or mass) function of Y given (Z, X) will be called $f_{Y|Z,X}(y|z, x, \mathcal{B})$ here, and interest lies in estimating $\mathcal{B}$. For example, if Y is normally distributed with mean $\beta_0 + \beta_x X + \beta_z Z$ and variance σ^2, then $\mathcal{B} = (\beta_0, \beta_x, \beta_z, \sigma^2)$ and

$$f_{Y|Z,X}(y|z, x, \mathcal{B}) = \sigma^{-1}\phi[(y - \beta_0 + \beta_x x + \beta_z z)/\sigma],$$

where $\phi(v) = (2\pi)^{-1/2}\exp(-0.5v^2)$ is the standard normal density function. If Y follows a logistic regression model with mean $H(\beta_0 + \beta_x X + \beta_z Z)$, then $\mathcal{B} = (\beta_0, \beta_x, \beta_z)$ and

$$f_{Y|Z,X}(y|z, x, \mathcal{B}) = H^y(\beta_0 + \beta_x x + \beta_z z) \times [1 - H(\beta_0 + \beta_x x + \beta_z z)]^{1-y}.$$

A likelihood analysis starts with determination of the joint distribution of Y and W given Z, as these are the observed variates. There are three components required:

1. A model relating the response to the "true" covariates, see just above.

2. An error model, here called $f_{W|Z,X}(w|z, x, \tilde{\alpha}_1)$. In many applications, the error model does not depend on Z. For example, in the classical additive measurement error model (1) with normally distributed measurement error, σ_u^2 is the only component of $\tilde{\alpha}_1$, and the error model density is $\sigma_u^{-1}\phi[(w - x)/\sigma_u]$, where $\phi(\cdot)$ is the standard normal density function. In the classical error model with independent replicates, W consists of the k replicates, and $f_{W|Z,X}$ is the k-variate normal density function with mean zero, common variance σ_u^2, and zero correlation. A generalization of this error model that allows for correlations among the replicates has been studied [81]. In some application areas, error model structures are studied independently of their role in measurement error modeling, and one can use this research to estimate error models for the problem at hand.
3. A model for the distribution of the latent variable, here called $f_{X|Z}(x|z, \tilde{\alpha}_2)$. Specifying a model for the distribution of the true covariate X given all the other covariates, Z is more difficult. Difficulties arise because: (i) the distribution is usually not transportable, so that different studies yield very different models; and (ii) X is not observed.

Having hypothesized the various models, the likelihood of the observed data under nondifferential measurement error is

$$\begin{aligned} f_{Y,W|Z}(y, w|z, \mathcal{B}, \tilde{\alpha}_1, \tilde{\alpha}_2) &= \int f_{Y|Z,X}(y|z, x, \mathcal{B}) f_{W|Z,X}(w|z, x, \tilde{\alpha}_1) \\ &\quad \times f_{X|Z}(x|z, \tilde{\alpha}_2)\, \mathrm{d}\mu(x). \end{aligned} \tag{13}$$

The notation $\mathrm{d}\mu(x)$ indicates that the integrals are sums if X is discrete and integrals if X is continuous. The likelihood for the problem is just the product over the sample of these terms.

There is a significant difference between the likelihood function in the differential and nondifferential cases. This can be expressed in various ways, but the simplest is as follows. In general, and dropping parameters, the likelihood of the observed data is

$$f_{Y,W|Z}(y, w|z) = \int f_{Y,W,X|Z}(y, w, x|z)\, \mathrm{d}\mu(x).$$

Using standard conditioning arguments, this becomes

$$\begin{aligned} f_{Y,W|Z}(y, w|z) &= \int f_{W|Y,Z,X}(w|y, z, x) f_{Y|Z,X}(y|z, x) \\ &\quad \times f_{X|Z}(x|z)\, \mathrm{d}\mu(x) \\ &= \int f_{Y|Z,X}(y|z, x) f_{W|Y,Z,X}(w|y, z, x) \\ &\quad \times f_{X|Z}(x|z)\, \mathrm{d}\mu(x). \end{aligned} \tag{14}$$

Note that the only difference between (13) and (14) is in the error term. In the former, under nondifferential measurement error, W and Y are independent, so that $f_{W|Y,Z,X}(w|y, z, x) = f_{W|Z,X}(w|z, x)$.

What makes differential error so difficult is that, under differential measurement error, we must ascertain the distribution of W given the other covariates *and the response* Y. This is essentially impossible to do in practice unless one has a subset of the data in which all of (Y, Z, X, W) are observed, i.e. a *validation* data set (*see* **Validation Study**).

Numerical Computation of Likelihoods

Typically one maximizes the logarithm of the overall likelihood in the unknown parameters. There are two ways one can maximize the likelihood function. The most direct is to compute the likelihood function itself, and then use numerical optimization techniques to maximize the likelihood. Below we provide a few details about computing the likelihood function. The second general approach is to view the problem as a missing data problem, and then use missing data techniques (*see* **Missing Data**); see, for example, [42] and [75].

Computing the likelihood analytically is easy if X is discrete, as the conditional expectations are simply sums of terms. Likelihoods in which X has some continuous components can be computed using a number of different approaches. In some problems the log likelihood can be computed or very well approximated analytically. In most problems that we have encountered, X is a scalar or a 2×1 vector. In these cases, standard numerical methods such as Gaussian quadrature can be applied, although they are not always very good. When sufficient computing resources are available, the likelihood can be computed using **Monte Carlo** techniques.

Bayesian Methods

Bayesian estimation and inference in the measurement error problem is a promising approach under active development (*see* **Bayesian Methods**). Examples of this approach are given by Schmid &

Rosner [65], Richardson & Gilks [57], Stephens & Dellaportas [74], Müller & Roeder [47], Mallick & Gelfand [45], and Kuha [40].

Bayesian analysis of parametric models requires specifying a likelihood (as described above) and a **prior distribution** for the parameters, the latter representing knowledge about the parameters prior to data collection. The product of the prior and likelihood is the joint density of the data and the parameters. Using **Bayes' Theorem**, one can in principle obtain the posterior density, i.e. the conditional density of the parameters given the data. The posterior summarizes all of the information about the values of the parameters and is the basis for all Bayesian inference. For example, the mean, median, or mode of the posterior density are all suitable point estimators. A region with probability $1 - \alpha$ under the posterior is called a "credible set", and is a Bayesian analog to a confidence region.

Computing the posterior distribution is often a nontrivial problem, because it usually requires high-dimensional numerical integration. This computational problem is the subject of much recent research, with many major advances. The method currently receiving the most attention in the literature is the Gibbs sampler (see [66] and [24]; *see* **Markov Chain Monte Carlo**). Also, see Tanner [75] for a book-length introduction to modern methods for computing posterior distributions.

In the Bayesian approach with Gibbs sampling, the Xs are treated as "missing data" (they just happen to be missing for all study subjects unless there is a validation study!). The approach for the classical additive error model is:

1. Assuming nondifferential error, write the likelihood of Y given (X, Z), the likelihood of W given (X, Z), and the likelihood of X given Z depending on parameters, just as in a regular likelihood problem.
2. If X were observable, then the likelihood would be the product of the three terms given above.
3. Select a starting value for the parameters, e.g. from SIMEX.
4. Use a simulation approach to fill in the "missing" Xs, i.e. from the posterior distribution of X given the observed data and the current values of the parameters. In this step, it is rare that the posterior distribution is known exactly, and so one has to use a device such as the Metropolis–Hastings algorithm.
5. Now one has complete data, with Xs all filled in, and one uses simulation to draw a sample of parameters from the posterior distribution of the parameters given the observed data and the current Xs.
6. Repeat the process of generating X and the parameters. These multiple samples of parameters are used to evaluate features of the posterior distribution.

While the procedure is easy to write down, the computations may be difficult.

More importantly, though, is the need to consider the distribution of X given Z. As we emphasized above, the simplest structural approach assumes that X is normally distributed, but this is often a strong assumption. The popularity of functional methods lies in the fact that such methods require no distributional assumptions about the Xs. There is considerable current effort being made to circumvent the problem of model robustness by specifying a flexible distribution for X.

Mixture Modeling

When there are no covariates measured without error, the nonlinear measurement error problem can be viewed as a special case of what are called mixture problems (see [77]). The idea is to pretend that X has a distribution, but to estimate this distribution nonparametrically. Applications of nonparametric mixture methods to nonlinear measurement error models have only recently been described by Thomas et al. [76] and Roeder et al. [58].

An alternative formulation is to let X have a flexible distribution, which covers a wide range of possibilities including the normal distribution. The simplest such model is the mixture of normals, which has been applied by Wang et al. [81] and by Küchenhoff & Carroll [38].

Response Error

In preceding Sections we have focused exclusively on problems associated with measurement error in predictor variables. Here we consider problems that arise when a true response is measured with error. For example, in a study of factors affecting dietary intake of fat, e.g. sex, race, age, socioeconomic status,

etc., true long-term dietary intake is impossible to determine and instead it is necessary to use error-prone measures of long-term dietary intake. Wittes et al. [86] describe another example in which damage to the heart muscle caused by a myocardial infarction can be assessed accurately, but the procedure is expensive and invasive, and instead it is common practice to use the peak cardiac enzyme level in the bloodstream as a proxy for the true response.

For a binary response (case or control), see **Misclassification Error**.

The exclusive attention paid to predictor measurement error earlier in this article is explained by the fact that predictor measurement error is seldom ignorable, by which is meant that the usual method of analysis is statistically valid, whereas response measurement error is often ignorable when the response is continuous. Here, "ignorable" means that the model holding for the true response holds also for the proxy response with parameters unchanged, except that a measurement error variance component is added to the response variance. For example, in linear regression models with simple types of response measurement error, the response measurement error is **confounded** with equation error and the effect is simply to increase the variability of parameter estimates. Thus, response error is ignorable in these cases, although of course power will be lost. However, in more complicated regression models, certain types of response error are not ignorable and it is important to account for the response error explicitly in the regression analysis.

Although the details differ between methods for predictor error and response error, many of the basic ideas are similar. Throughout this section, the response proxy is denoted by S. We consider only the case of measurement error in the response, and not the more complex problem where both the response and some of the predictors are measured with error.

We first consider the analysis of the observed data when the response is subject to independent additive or multiplicative measurement error. Suppose that the proxy response S is unbiased for the true response. Then, in either case, the proxy response has the same mean (as a function of exposure and confounders) as the true response, although the variance structure differs. In models such as linear regression, or more generally for **quasi-likelihood** estimation, this means that the parameter estimates are consistent, but inferences may be affected. For example, in linear regression, additive, unbiased response error does not change the mean and simply increases the variance by a constant, so that there is no effect of measurement error other than loss of power. However, for multiplicative, unbiased response error, while the mean remains unchanged, the variances now are no longer constant, and hence inferences which pretend that the variances are constant would be affected. The usual solution is to use a robust covariance estimator, also known as the sandwich estimator (*see* **Generalized Estimating Equations**).

If the proxy response **S** is not unbiased for the true response, then a validation study is required to understand the nature of the bias and to correct for it. In a series of papers, Buonaccorsi [8, 9, 11] and Buonaccorsi & Tosteson [12] discuss the use of adjustments for a biased response. See Carroll et al. [20] for further details.

We call **S** a *surrogate response* if its distribution depends only on the true response and not otherwise on the covariates, i.e. the information about the surrogate response contained in the true response is the same no matter what the values of the covariates. In symbols, if $f_{S|Y,Z,X}(s|y,z,x,\gamma)$ denotes the density or mass function for S given (Y,Z,X), then $f_{S|Y,Z,X}(s|y,z,x,\gamma) = f_{S|Y}(s|y,\gamma)$. In both the additive and multiplicative error models, S is a surrogate. This definition of a surrogate response is the natural counterpart to a surrogate predictor, because it implies that all the information in the relationship between S and the predictors is explained by the underlying response. See Prentice [53] and Carroll et al. [20] for further details.

In general, i.e. for a possibly nonsurrogate response, the likelihood function for the observed response is

$$f_{S|Z,X}(s|z,x,\mathcal{B},\gamma) = \int f_{Y|Z,X}(y|z,x,\mathcal{B}) f_{S|Y,Z,X}(s|y,z,x,\gamma)\,\mathrm{d}\mu(y). \tag{15}$$

There are a number of implications of this formula:

1. If S is a surrogate, and if there is no relationship between the true response and the predictors, then neither is there one between the observed response and the predictors. Hence, if interest lies in determining whether *any of the predictors* contains any information about the response, then one can use naive hypothesis tests and

ignore response error. The resulting tests have an asymptotically correct level, but a decreased power relative to tests derived from true response data. This property of a surrogate is important in clinical trials; see Prentice [53] (*see* **Surrogate Endpoints**).

2. If S is *not* a surrogate, then there may be no relationship between the true response and the covariates, but the observed response may be related to the predictors. Hence, naive tests will not be valid in general if **S** is not a surrogate.

Note that one implication of (15) is that a likelihood analysis with mismeasured responses requires a model for the distribution of response error. Except for additive and multiplicative error, understanding such a model requires a validation study.

Case–Control Studies

A *case–control study* is one in which sampling is conditioned on the disease response; it is useful to think that the response is first observed and only later are the predictors observed. A similar design, *choice-based sampling*, is used in econometrics. We use case–control terminology and concentrate on logistic regression models. A distinguishing feature of case–control studies is that the measurement error may be differential.

Two-phase case–control designs, where X is observed on a subset of the data, have been studied by Breslow & Cain [7], Zhao & Lipsitz [87], Tosteson & Ware [80], and Carroll et al. [18], among others. These designs are significant because the validation, if done on both cases and controls, frees us from the nondifferential error assumption.

We assume that the data follow a logistic model in the underlying source population, although the results apply equally well to the more general models described by Weinberg & Wacholder [82]. For such models, Prentice & Pyke [55] and Weinberg & Wacholder [82] show that when analyzing a classical case–control study one can ignore the case–control sampling scheme entirely, at least for the purpose of estimating **relative risk**. Furthermore, these authors show that, if one *ignores the case–control sampling scheme and runs an ordinary logistic regression*, then the resulting relative risk estimates are consistent and the standard errors are asymptotically correct.

The effect of measurement error in logistic case–control studies is to bias the estimates. Carroll et al. [21] show that, for many problems, one can ignore the case–control study design and proceed to correct for the bias from measurement error as if one were analyzing a random sample from the source population. With nondifferential measurement error, this result applies to the methods we have described previously for prospective studies. Regression calibration needs a slight modification, namely that the regression calibration function should be estimated using the controls only.

Michalek & Tripathi [46], Armstrong et al. [5], and Buonaccorsi [10] consider the normal **discriminant** model. Satten & Kupper [62] have an interesting example of likelihood analysis for nondifferential error validation studies when the validation sampling is in the controls.

Survival Analysis

One of the earliest applications of the regression calibration method was discussed by Prentice [52] in the context of **survival analysis**. Further results in survival analysis were obtained by Pepe et al. [50], Clayton [25], Nakamura [49], and Hughes [36]. While the details differ in substantive ways, the ideas are the same as put forward in the rest of this article, and here we provide only a very brief overview in the case of covariates which do not depend on time.

Suppose that the instantaneous risk that the time T of an event equals t conditional on no events prior to time t and conditional on the true covariate X is denoted by

$$\psi(t, X) = \psi_0(t) \exp(\beta_x X), \tag{16}$$

where $\psi_0(t)$ is the baseline **hazard** function. When the baseline hazard is not specified, (16) is commonly called the **proportional hazards** assumption. When X is observable, it is well known that estimation of β_x is possible without specifying the form of the baseline hazard function.

If X is unobservable and instead we observe a surrogate W, then the induced hazard function is

$$\psi^*(t, W, \beta_x) = \psi_0(t)\mathrm{E}[\exp(\beta_x X)|T \geq t, W]. \tag{17}$$

The difficulty is that the expectation in (17) for the observed data depends upon the unknown baseline

hazard function ψ_0. Thus, the hazard function does not factor into a product of an arbitrary baseline hazard times a term that depends only on observed data and an unknown parameter, and the technology for proportional hazards regression cannot be applied without modification.

The problem simplifies when the event is rare, so that $T \geq t$ occurs with high probability for all t under consideration. As shown by Prentice [53] and others, under certain circumstances this leads to the regression calibration algorithm. The rare event assumption allows the hazard of the observed data to be approximated by

$$\psi^*(t, W, \beta_x) = \psi_0(t)\mathrm{E}[\exp(\beta_x X)|W]. \qquad (18)$$

The hazard function (18) requires a regression calibration formulation! If one specifies a model for the distribution of X given W, then (18) is in the form of a proportional hazards model (16), but with $\beta_x X$ replaced by $\log\{\mathrm{E}[\exp(\beta_x X)|W]\}$. An important special case leads directly to the standard regression calibration model, namely when X given W is normally distributed.

Clayton [25] proposed a modification of regression calibration which does not require events to be rare. At each time t_i, $i = 1, \ldots, k$, for which an event occurs, define the risk set $R_i \subseteq \{1, \ldots, n\}$ as the case numbers of those members of the study cohort for whom an event has not occurred and who were still under study just prior to t_i. If the Xs were observable, and if X_i is the covariate associated with the ith event, in the absence of ties the usual proportional hazards regression would maximize

$$\prod_{i=1}^{k} \frac{\exp(\beta_x X_i)}{\sum_{j \in R_i} \exp(\beta_x X_j)}.$$

Clayton basically suggests using regression calibration within each risk set. He assumes that the true values X within the ith risk set are normally distributed with mean μ_i and variance σ_x^2, and that within this risk set $W = X + U$, where U is normally distributed with mean zero and variance σ_u^2. Neither σ_x^2 nor σ_u^2 depend upon the risk set in his formulation.

Given an estimate $\hat{\sigma}_u^2$, one applies the usual regression calibration calculations to construct an estimate of $\hat{\sigma}_x^2$.

Clayton modifies regression calibration by using it within each risk set. Within each risk set, he applies the formula (7) for the best unbiased estimate of the Xs. Specifically, in the absence of replication, for any member of the ith risk set, the estimate of the true covariate X from an observed covariate W is

$$\hat{X} = \hat{\mu}_i + \frac{\hat{\sigma}_x^2}{\hat{\sigma}_x^2 + \hat{\sigma}_u^2}(W - \hat{\mu}_i),$$

where $\hat{\mu}_i$ is the sample mean of the Ws in the ith risk set.

As with regression calibration in general, the advantage of Clayton's method is that no new software need be developed, other than to calculate the means within risk sets.

RAYMOND J. CARROLL

Measurement Error in Survival Analysis

Introduction

Let $T \geq 0$ be a failure time variate (*see* **Survival Distributions and Their Characteristics**) and $Z = (Z_1', Z_2')'$, a corresponding **covariate** vector. Suppose first that the **hazard rate** for T given Z follows a **Cox regression** [9] model $\lambda(t; Z) = \lambda_0(t) \exp(Z'\beta)$, where λ_0 is an unspecified baseline hazard function and $\beta = (\beta_1', \beta_2')'$ is a corresponding parameter to be estimated. Failure times may be subject to right **censoring** by a variate C that is assumed to be independent of T given Z, so that one observes $X = T \wedge C$ and $\delta = I[X = T]$. On the basis of an independent random sample $(X_i, \delta_i, Z_i), i = 1, \ldots, n$ the standard "**partial likelihood**" estimator $\hat{\beta}$ solves $U(\hat{\beta}) = 0$ where

$$U(\beta) = \sum_{i=1}^{n} \int_0^\infty \{Z_i - \overline{Z}(\beta, t)\} \, \mathrm{d}N_i(t). \qquad (1)$$

In (1) $\mathrm{d}N_i(t) = 1$ if $(X_i = t, \delta_i = 1)$ and is zero otherwise, the covariate "average" $\overline{Z}$ is given by $\overline{Z}(\beta, t) = S^{(1)}(\beta, t)/S^{(0)}(\beta, t)$ where

$$S^{(j)}(\beta, t) = \sum_{i=1}^{n} Y_i(t) Z_i^j \exp(Z_i'\beta), \text{ for } j = 0, 1 \qquad (2)$$

and the "at risk" process Y_i is given by $Y_i(t) = I(X_i \geq t)$; see, for example, [3, 4, 13] for development of the asymptotic distribution theory for $\hat{\beta}$.

Suppose now that the component Z_1 of the regression vector is unavailable for some or all of the study population, whereas Z_2 and an error prone estimate W of Z_1 is routinely available. How then can the **relative risk** (hazard ratio) parameter β be estimated? This measurement error, or errors-in-variables problem arises in many application areas, in conjunction with failure time and other types of response variables. For example, in a **nutritional epidemiology** application, Z_1 may be comprised of an individual's long-term (e.g. 10 or 20 years) average daily intake of fat, along with dietary and nondietary **confounding** factors, while T is the time from entry into a **cohort study** until the diagnosis of a specific disease, such as coronary heart disease or colon cancer. The measured fat intake, a component of W in this context, may derive from self-reported food consumption over a short period of time (e.g. a few days or months) in which case the measured fat intake may differ from the theoretical quantity due to day-to-day or month-to-month variations in actual consumption, because of errors in dietary recording or recall, because of inaccuracies in the nutrient database used to estimate nutrient consumption from food consumption, or due to systematic self-report bias that may, for example, relate to "social desirability" characteristics.

If the variation in $W - Z_1$ is small compared to that for Z_1, one may simply be able to replace missing Z_1 values by corresponding W values in (1) and obtain estimates of β having little bias. See [12] for a study of bias in this context. Otherwise, a more careful approach is required. In the best of situations, a **validation** subsample can be obtained that includes (X, δ, Z, W), while only (X, δ, Z_2, W) is available on the remainder of the sample. Very commonly, however, only a **reliability** subsample consisting of repeat measures $W_1, W_2, \ldots$ of W can be obtained so that the data consist of $(X, \delta_1, Z_2, W_1, W_2, \ldots)$ on the reliability subsample and (X, δ, Z_2, W_1) on the remainder of the study cohort. It is often assumed that reliability sample measurement errors have mean zero and are independent of Z, each other, and other study subject characteristics, assumptions that are likely violated in the above nutritional epidemiology context.

While the focus of this entry is on estimation in the Cox model [9], there is also some work on estimation in an **additive hazards model** with covariate measurement error. This latter work will be described in the section "Measurement Error in the Additive Hazards Model".

Relative Risk Parameter Estimation with a Validation Subsample

Estimation of the Cox model regression parameter β in the presence of measurement error and a validation subsample is very closely connected to that of estimation with missing covariate data (*see* **Missing Data**). Specifically, W is said to be a **surrogate** for Z_1 if $\lambda(t; Z, W) = \lambda(t, Z) = \lambda_0(t) \exp(Z'\beta)$. Hence β may be estimated by Cox regression on (Z_1', Z_2', W') while regarding Z_1 to be sometimes missing, and

while requiring the regression coefficient for W to be zero. In fact, the surrogacy assumption can be checked by testing for a zero coefficient for W in such an analysis.

The hazard rate at time t for an "at risk" individual having Z_1 missing is given [21] by

$$\lambda_0(t)\mathrm{E}[\exp(Z'\beta)], \tag{3}$$

where the **expectation** is **conditional** on $(Z_2, W, T \geq t)$. The inclusion of $T \geq t$ in the conditioning event implies that this expectation is typically a complicated function of β and $\lambda_0(\cdot)$. If the probability that Z_1 is missing depends only on Z but not on (X, δ), then a "complete case" analysis that simply drops the observations having missing Z_1-values from (1) will typically yield **consistent estimators** of β, but may be quite inefficient. Toward more efficient estimation Zhou and Pepe [30] propose an "estimated partial likelihood" procedure wherein if Z_1, assumed to be discrete, is missing the expectation in (3) is replaced by a **nonparametric** estimate. This method allows the missingness rate to depend on (Z_2, W) but not on (X, δ, Z_1). Zhou and Wang [31] extended this method to continuous covariates using kernel estimation, though this extension may not be practical if the dimension of $\{Z_2, W\}$ is at all large. Lin and Ying [15] proposed an "approximate partial likelihood" procedure in which the summations leading to $\overline{Z}$ were restricted to individuals having Z_1 available. For components of $U(\beta)$ corresponding to Z_1, the overall summation was also restricted to individuals having known Z_1 values. This estimator can, but need not, improve upon the efficiency of the complete case estimator, and it requires a missing completely at random assumption (e.g. [17]); that is, the missingness probability is not allowed to depend on any aspect of (X, δ, Z, W).

An alternate simple procedure, referred to as regression **calibration** [6, 21], approximates the expectation in (3) by $\exp\{\mathrm{E}(Z_1|Z_2, W)'\beta_1 + Z_2'\beta_2\}$ and estimates $\mathrm{E}(Z_1|Z_2, W)$, typically using a simple **least-squares** procedure, using the validation subsample. This method is applicable if missingness depends only on $\{Z_2, W\}$. Because of the relative risk approximation, the resulting regression parameter estimates typically have some asymptotic bias. Wang et al. [27] develop the asymptotic theory for this estimator, along with a suitable variance estimator. In extensive **simulations**, they showed the bias to be surprisingly modest in situations of practical interest. The bias can be substantial, however, for large β values, depending somewhat on the censorship pattern. See [10] for some additional related approaches.

More comprehensive estimators of β generally require further modeling assumptions, either concerning the missingness probabilities, or the probability distribution for the covariates, or both. Chen and Little [7] consider a **nonparametric maximum likelihood** (NPML) procedure under which β and $\Lambda_0(t) = \int_0^t \lambda_0(u)\,\mathrm{d}u$ are chosen to maximize

$$L = \prod_{i=1}^{n} \left\{ \lambda_0(X_i)^{\delta_i} \int \exp(Z_i'\beta) \times \exp[-\exp(Z_i'\beta)\Lambda_0(X_i)]F(Z_i;\theta)\,\mathrm{d}Z_i \right\}, \tag{4}$$

where the integral for the ith term is over Z_{1i} given Z_{2i} if Z_{1i} is missing, and reduces to the integrand at Z_i if Z_{1i} is available, and F denotes the probability density for Z, which is allowed to depend on a fixed length parameter vector θ. These authors maximize L after approximating Λ_0 by a step function with jumps at the uncensored X values, and obtain asymptotic distribution theory building on the work of Murphy et al. [18]. This NPML method allows missingness rates to depend on observed data (X, δ, Z_2), though a stronger than usual independent censoring assumption is required in that the censoring time is required to be independent of T given the observed covariate, and hence is not allowed to depend on the potentially unavailable Z_1 value; see [29] for earlier related work.

The augmented **inverse probability weighted estimator** (AIPW) of Wang and Chen [26] avoids this stronger censorship condition through inverse probability weighting. Their estimator of β, building on the work of Robins et al. [23], solves an estimating equation (*see* **Estimating Functions**) of the form

$$\sum_{i=1}^{n} \left\{ \eta_i \hat{\pi}_i^{-1} \int_0^{\infty} [Z_i - \hat{Z}(\beta, t)]\,\mathrm{d}N_i(t) + B_i\beta) \right\} = 0, \tag{5}$$

where $\eta_i = 0$ if Z_{1i} is missing and $\eta_i = 1$ otherwise, $\hat{\pi}_i$ is an estimate of the probability that Z_{1i} is missing, derived from a separate modeling exercise, and both the estimated covariate averages $\hat{Z}$ and the "augmentation term" B_i involve expectations

over the distribution of Z_1 given (X, δ, Z_2, W). This procedure has a nice **robustness** property in that it will generally provide consistent estimators of β under a missing at random [17] assumption even if the missingness model is not correctly specified, provided the distribution of Z_1 given (X, δ, Z_2, W) is correctly specified; and it will generally provide consistent estimates of β even if the covariate distribution is misspecified, provided the missingness rates are correctly modeled as a function of (X, δ, Z, W).

Further study of the properties of the NPML and AIPW estimators is needed, but simulation studies to date [7, 26] suggest good efficiency relative to the other estimators mentioned. The efficiency of the NPML estimator seems particularly good, though a noticeable bias was detected in simulations [26] if censoring rates depend strongly on the missing Z_1.

Relative Risk Parameter Estimation with a Reliability Subsample

As noted above, it quite often happens that measurements of Z_1 are unavailable for the entire sampled cohort; that is, there is no validation subsample. In these circumstances, it is necessary to make error model assumptions to connect the covariate measurement W to the "true", but missing, covariate Z_1. Often a classical measurement model assumption

$$W = Z_1 + \varepsilon, \tag{6}$$

is made, where the additive error ε is assumed to be independent of Z and of the corresponding failure and censoring times, and ε is assumed to have mean zero and a variance σ^2. Repeat measurements $W_1, W_2, \ldots$ on some study subjects are needed to estimate σ^2, or other aspects of the error distribution. The error variates corresponding to multiple measurements on a study subject are usually assumed to be independent, as are the error variates across study subjects. The measurements $\{W_1, W_2, \ldots\}$ meeting these conditions are said to constitute a covariate reliability sample.

Before proceeding, it is important to note that (6) and its attendant assumptions may be oversimplified or inappropriate in many important circumstances. For example, in the nutritional epidemiology setting mentioned above, one might expect nutrient consumption from repeat self-reports of dietary intakes to include systematic bias (e.g. errors having different distributions depending on such characteristics as body mass, age, and ethnicity) as well as positive within-person **correlations**. In such settings it may be crucial to identify biomarkers, or other objective measures that plausibly adhere to (6). Such objective measures are likely too expensive to be practical in the entire cohort in an epidemiologic study, so that a more comprehensive measurement model may be needed that assumes (6) for the objective measure on a subset, along with a more flexible model for the self-report data. In effect, the objective measures data can then be used to calibrate the self-report data on the entire cohort; see [20, 22, 24] for related discussion.

Assuming a reliability sample adhering to (6) to be available Xie et al. [28] adapt the regression calibration approach to reliability sample data, and extend it by improving the approximation to the relative risk in (3) to $\exp\{\mathrm{E}(Z_1|Z_2, W_1, W_2, \ldots; T \geq t)'\beta_1 + Z_2'\beta_2\}$ leading to a recalibration within each risk set, prior to applying a partial likelihood estimation procedure. More specifically, simple **variance component** arguments lead to estimates of the mean and covariance of $(Z_1, \overline{W}, Z_2)$ at each failure time, where $\overline{W}$ is the average of W values available for an individual. A joint normality assumption for $(Z_1, \overline{W}, Z_2)$ then leads to an approximate estimator of $\mathrm{E}(Z_1|\overline{W}, Z_2, X \geq t)$ for use at time t in the partial likelihood function. Asymptotic distribution theory and a variance estimator were provided [28] for the "ordinary" regression calibration, and "risk set" regression calibration estimators under reliability sampling. Both estimators typically incorporate some asymptotic bias, but the recalibration within risk sets extends the set of configurations where the bias will be negligible; see [8] for related work.

Consistent estimation of Cox model parameters, if only a reliability sample adhering to (6) is available, is possible using a corrected score function approach (*see* **Likelihood**). This approach (e.g. [19]) involves replacing the terms in the (standardized) score function (1) by consistent estimates based on the reliability sample; see also [5]. Some corrected score proposals require distributional assumptions on Z_1 or ε to hold, but recent work by Huang and Wang [11] avoids distributional assumptions in either the true covariate, or the error variate for consistent estimation of β, assuming two or more W-values are available for each individual. Briefly, $n^{-1}U(\beta)$ from

(1) can be consistently estimated by

$$n^{-1}\sum_{i=1}^{n}\int_0^\infty \left\{\begin{pmatrix}\overline{W}_i\\ Z_{2i}\end{pmatrix} - \frac{\hat{S}^{(1)}(\beta,t)}{\hat{S}^{(0)}(\beta,t)}\right\} \mathrm{d}N_i(t), \quad (7)$$

where

$$\hat{S}^{(j)}(\beta,t) = \sum_{i=1}^{n} Y_i(t)\mathcal{A}_i\left[\begin{pmatrix}\tilde{W}_{1i}\\ Z_{2i}\end{pmatrix} \times \exp\left\{\begin{pmatrix}\overline{W}_{2i}\\ Z_{2i}\end{pmatrix}'\beta\right\}\right], \quad j=0,1$$

and the operator $\mathcal{A}_i$ is a summation over all distinct pairs of $\overline{W}_{1i}$ and $\tilde{W}_{2i}$ selected from the set of $\{W_{1i}, W_{2i}, \ldots\}$ of W-values available on the ith study subject. The independence of the error terms in (6) for these W-values implies that $n^{-1}\hat{S}^{(j)}(\beta,t)$ estimates the corresponding $n^{-1}S_j(\beta,t)$ aside from the factor $E(\mathrm{e}^{\varepsilon\beta_1})$, which cancels out of the ratio in (7). This factor, needs to be estimated to obtain a **cumulative hazard** estimator, requiring some further assumption. For example, an assumption of symmetry of the error distribution is sufficient for this purpose.

The corrected score regression parameter estimator of Huang and Wang [11] performed well in simulations reported by these authors. The lack of monotonicity of the **estimating function** (7), however, presents some numerical challenges that have yet to be fully addressed.

The methods described here can be generalized to allow time-varying regression coefficients; see [25] for an interesting illustration based on repeat measurements on a **time-dependent covariate**.

Measurement Error in the Additive Hazards Model

A fixed covariate form of the additive hazards model (Aalen [1, 2], Andersen et al. [3]) can be written

$$\lambda(t;Z) = \lambda_0(t) + Z'\beta, \quad (8)$$

with restriction to assure nonnegative hazard rates. This model also has substantial applied potential, especially if extended to allow time-varying covariates. It's linear form admits some convenient, noniterative procedures for β-estimation in the presence of covariate measurement error.

Aalen [1] notes that the form of (8) is retained, with attenuated regression coefficient, under a classical measurement error model (5). Kulich and Lin [14] consider a corrected score approach to estimation in (8), assuming a validation subsample to be available. If Z is always available, Lin and Ying [16] propose that β in (8) be estimated by the explicit quantity

$$\hat{\beta} = \left[\sum_{i=1}^{n}\int_0^\infty \{Z_i - \overline{Z}(0,t)\}^{\otimes 2} Y_i(t)\,\mathrm{d}t\right]^{-1} \times \sum_{i=1}^{n}\int_0^\infty \{Z_i - \overline{Z}(0,t)\}\,\mathrm{d}N_i(t), \quad (9)$$

where $a^{\otimes 2} = aa'$. Kulich and Lin [14] derive a corresponding class of explicit estimators of β when Z_1 is available only in a validation sample, while W and Z_2 are always available. Under assumptions on the form of the mean and variance of W given Z these authors develop an unbiased score contribution for each study subject, and a corresponding explicit class of regression parameter estimates that is indexed by a downweighting parameter for the nonvalidation subsample. At least in important special cases this downweighting parameter can be estimated in an optimal fashion, yielding an estimator that necessarily improves on the efficiency of the complete case estimator, often substantially. Estimation procedures under (8) with only a reliability sample evidently have yet to be presented.

ROSS L. PRENTICE

Measurement Scale

Many different types of variables occur in statistical investigations. Some are merely classifications, such as a diagnosis into one of three unrelated diseases. Sometimes the classifications have an order, for example the stages of cancer or the common categorization into mild, moderate, and severe. For other variables the order is everything – "preference" recorded on a visual analog scale is an example. Here there are no categorical groups, and yet one can say that one score corresponds to a greater preference than another. Yet other variables seem to impose more sophisticated mathematical relationships between the possible values. With temperature, for example, we can say not only that one temperature is larger than another, but also that the difference between a given pair of temperatures is larger than the difference between some other pair. And, for other variables, we can go even further: for weight or concentration or height we can say that one is twice the other, or half again as large as the other. And, of course, yet other variables are simply counts – the number of cells on a plate, for example.

In fact, many different classifications of variable types have been proposed, often motivated from the perspective of statistical analysis: the set of techniques needed to analyze one type of variable often differs from that needed to analyze another type. However, one classification in particular has had a major impact on statistics. This is the classification into *nominal, ordinal, interval*, and *ratio* scales proposed by the psychophysicist Stevens [18, 19].

Prior to Stevens' work, the emphasis in understanding measurement had been in the physical sciences. The problems there, at least at that stage and at least superficially, seemed more straightforward. Measurement involved assigning numbers to represent the properties of objects, where the objects satisfied (i) an order relationship and (ii) a physical process of addition. The latter is illustrated by the placing of two objects in one pan of a weighing scales, and balancing them by a third object in the other pan. In terms of weight, this third object corresponds to the "physical addition" of the first two. Such a physical addition process is nowadays called *concatenation*. In such situations the notion of "quantity" seems relatively straightforward. Axiom systems describing (i) and (ii), which the objects must satisfy in order for the relationships between them to be representable by order and addition of numbers, were developed by von Helmholtz [23] and Hölder [7]. Campbell [2], in particular, adopted this approach. Of course, even here things are not completely simple: physical concepts such as density are defined in terms of other concepts. They have thus been called "derived" measurements, with the directly measured ones being called "fundamental measurements". Moreover, and more importantly, densities do not physically add in the same way as weight: combine two samples of gas with different densities and the result is something with an intermediate density, not the sum of the densities.

However, in other scientific areas, notably psychology, things are even less clear. In particular, there is often no "physical addition operation" evident. Because of this, notions of measurement in psychology came under much criticism [3]. Stevens tackled these criticisms by pointing out that the numerical representation preserving the relationships between a set of empirical objects was not unique and that the alternative numerical representations are obviously related since they represent the same empirical system. To get from one legitimate numerical representation to another, some transformation or mapping is involved. Stevens suggested that different such mappings defined different *types* or *scales* of measurement. Thus, if any one-to-one mapping was allowed (that is, any mapping which preserved the unique identity of the classes of objects), then the measurement was on a *nominal* scale. For example, the appearance of a lesion may be classified into one of three distinct types. If any order-preserving mapping was allowed (that is, if any numerical representation which assigned numbers in the same order to the objects was allowed), then measurement was on an *ordinal* scale. For example, "severity" might be encoded so that any alternative encoding would be equally legitimate, provided it had the same order. If any linear transformation was allowed (that is, if rescaling the numbers by changing the units and then adding some constant resulted in an alternative numerical assignment which still preserved the relationships between objects), then the scale was *interval*. Body temperature is an example: this might be measured in degrees centigrade or degrees Fahrenheit, the two being related by a linear transformation. And, finally, if any change of

the units yielded an alternative, equally legitimate numerical assignment, then the scale was *ratio*, for example, changing the units of length from inches to centimeters. The physical measurements with which Campbell was concerned were of this last type; Stevens thus generalized the notions of measurement. In each case the class of transformations, which lead to another, equally legitimate, representation of the empirical system being modeled is called the class of *admissible* or *permissible* transformations. Mathematically, this class defines the scale being studied.

The notion of admissible transformations has implications for what statistical statements may sensibly be made using the data. If, for example, any numerical assignment which preserves the order of a set of values is equally legitimate, then comparing the arithmetic means of two groups is of dubious value: it may be possible to invert the relative order of the two means by a suitable choice of transformation. To illustrate, suppose that one numerical representation has the values $\{1, 5\}$ for the two objects in one group and $\{3, 4\}$ for the two objects in the other group. Then the mean, 3, of the first group is smaller than the mean, $3\frac{1}{2}$, of the second group. However, consider the alternative numerical assignment $\{1, 7\}$ for the members of the first group and $\{3, 4\}$ for the members of the second. This preserves the order of the numbers – the object which was previously assigned the smallest number has still been assigned the smallest number, and so on. But this new numerical assignment yields respective means of 4 and $3\frac{1}{2}$. Now the mean of the first group is larger than the mean of the second. In general, one's conclusions will be an artifact of one's choice of numerical assignment, and will not reflect any truth about the empirical reality. Thus it seems that statistical arguments must take account of scale type. However, the assumptions made by inferential statistical arguments are distributional, and not scale-specific. Indeed, given a set of numbers, no matter what their scale type, arbitrary statistical statements may be made about those numbers – one is able to compute a t statistic and carry out a t test whatever the scale type, and this might even seem a sensible thing to do if suitable distributional assumptions are satisfied. The tension between these two viewpoints has stimulated a major debate, running from the time of Campbell and Stevens right up to the present [5, 6, 15, 21, 22]. Its resolution is subtle and lies in awareness of the fact that the objective of statistical analysis is ultimately to make a statement about the empirical system being studied, and not simply about the numbers being used to represent that system. However, this needs to be tempered by the fact that statistical statements applied to what are apparently impermissible transformations of the data may lead to the detection of hitherto unsuspected structures in those data. It seems that if one wants to test strong theories, described in terms of numbers derived by a well-defined mapping from a well-understood empirical system, then the strictures imposed by the theory of scale types should be adhered to. But if one's theories are less stringently formalized, then the constraints of scale type are less important and, indeed, adhering to them may risk missing important discoveries (see [6] and the ensuing discussion).

The nominal, ordinal, interval, and ratio typology is an old one. Since its formulation a huge amount of work has been carried out, partly philosophical, concerned with relating measurement activities to scientific questions, and partly mathematical, concerned with developing axiom systems which an empirical system must obey if it is to be representable by a given numerical system. For reviews of this work see [8–10, 14, 17, 20]. One conclusion of this work has been to show that, for mappings to the real numbers, only certain types of scales can exist, and that Stevens' ordinal, interval, and ratio classification is closely related to this set. However, an interesting anomaly is that for mappings to rational numbers there is an infinite variety of scale types [1]. Since all data are recorded to only a finite number of digits, scientific mappings are in fact to only a subset of the rationals. Quite what the implication of this is, if any, remains to be seen.

Clearly, physical addition operations hold a central place in measurement theory. Such operations can be mapped to addition, so that very familiar numerical operations can be used. But they are not the only empirical relationships which can be mapped to addition. A completely different class of relationships arises in *conjoint measurement*. Suppose that the objects in the empirical system can be ordered according to attribute A, that each object can be described in terms of a pair of attributes (B, C), and that each of B and C can be ordered. Then, subject to certain conditions, it is possible to find numerical assignments such that the relationships between

objects can be represented by addition between the assigned numbers (see, for example, [11] and [13]).

So far we have described the aim of measurement as being to assign numbers according to a numerical system within which the relationships correspond to those between the empirical objects. This approach is termed *representational measurement theory*, and is by far the best developed. However, it is not adequate for all situations in which measurement is used. In particular, in many areas of psychology this approach seems to be inadequate, chiefly because it is not clear precisely what empirical system is being modeled. As a consequence, alternative theories have been developed. Chief amongst these is the *operational* approach. This takes the measurement operation as *defining* the attribute being measured. As a consequence, no notion of permissible transformations, and consequently of scale types, can arise. Yet a third theory, termed by Michell [12] the *classical* approach, takes as its starting point that numerical quantities of attributes exist, with the objective of measurement being the determination of the magnitude of these quantities. A key driving force for both the representational and classical approaches is the desire to characterize the relationship between the empirical system and the numerical system. In the operational approach, however, with the assumption of an underlying empirical reality not being necessary, the emphasis is on internal consistency and reproducibility. One might describe the aims of the representational, operational, and classical approaches as being, respectively, to assign, define, and discover numerical representations.

As will be apparent from the above and from the reference list at the end of this article, much of the debate about the fundamental concepts of measurement has occurred in the psychological literature. This is not surprising: in psychology of all disciplines, measurement is difficult. Rarely can the attributes being studied be directly observed, so that subtle indirect measurement procedures have to be devised. Naturally this stimulates debate about the precise nature of the measurement activity and what the resulting numbers actually mean. Earlier manifestations of measurement theory in physics, most notably in *dimensional analysis* [16], although useful, stimulated little debate about underlying principles. Measurement procedures in psychology involve constructing complex instruments which often require collecting many scores or numbers which need to be combined using sophisticated statistical techniques to yield a final measurement. Examples of such methods include **paired comparisons**, Guttman, Likert, and Thurstone scaling factor analysis, and item response theory [4] (*see* **Psychometrics, Overview**). Measurement procedures in medicine can be equally complex: a prime example being attempts to formulate **quality of life** scales.

DAVID J. HAND

Median Effective Dose

In biological experiments, the primary goal is to investigate the responses of biologic subjects to a stimulus administered at various levels (*see* **Stimulus–Response Studies**). Drugs, chemical compounds, toxicants, food preservatives, radiation, or specific environmental conditions are typical examples of stimuli. Biologic subjects can be human volunteers, animals, insects, microorganisms, or living tissue. In practice, however, it is impossible and difficult to measure the responses quantitatively. However, the responses of the units to the stimulus can be easily documented by the occurrence of some meaningful and well-defined events such as death, survival, convulsion, infection, eradication of infection, induction of estrus, or cure of disease. These responses are known as *quantal responses* (*see* **Binary Data**). As indicated by Ashford [4] and Morgan [48], a quantal response usually involves an irreversible process in organisms that either respond or do not respond. The corresponding experiments are called quantal biological assays or quantal bioassays [22, 23, 33, 70, 72, 73], (*see* **Biological Assay, Overview**). Biological assay not only plays an important role in the evaluation of pharmacological and toxicological effects of a chemical compound, but is also crucial for screening possible drug entities. Note that a quantal bioassay is closer to the *direct* bioassay than it is to the *indirect* quantitative bioassay.

Finney [23] defined the tolerance of a biological subject as the dose level just sufficient to produce predefined events (*see* **Quantal Response Models**). If the dose level given is lower than the tolerance of the subject, then the event will not occur. The subject will respond if the dose level administered is higher than the tolerance. However, the tolerance to a particular stimulus may be different from subject to subject owing to genetic, environmental, and other unknown factors. The resulting distribution of dose levels of a stimulus with respect to a well-defined event is referred to as the *tolerance distribution*. In a traditional fixed indirect quantal bioassay, a number of subjects are randomly assigned to receive one of several preselected dose levels of the stimulus under investigation. The occurrence of the event of interest is then documented for each subject according to a prespecified time schedule. Therefore, a quantal bioassay is an indirect bioassay since it only records whether the tolerance of a subject is higher or lower than the given dose levels. The proportions of subjects who respond at each dose level are then used to describe the tolerance distribution, which provides an estimation of the dose–response relationship of the stimulus. The most commonly employed measure to characterize the tolerance distribution is the median effective dose (MED). The MED is the **median** of the tolerance distribution, which is the dose of a stimulus that generates, on average, a predefined response in 50% of subjects. Hence, the MED is also referred to as the ED_{50} [22]. The concept of an MED was first introduced by Trevan [69] as the median lethal dose (MLD) to describe the potency of a test stimulus. In general, let p be a real number between 0 and 1, ED_{100p} (or LD_{100p}) is then the dose of a stimulus that produces an average effect in $100p\%$ of subjects. Other related measures are $\mathrm{ED}_{100p(t)}$ and $\mathrm{ET}_{100p(d)}$, where $\mathrm{ED}_{100p(t)}$ is the MED at which on average $100p\%$ of subjects will respond by time t, and $\mathrm{ET}_{100p(d)}$ is the median effect time at dose level d by which the occurrence of an event is observed in $100p\%$ of subjects [51]. Finney [22, 23] provided a comprehensive review of the design and estimation of MED and related topics. More detailed developments can be found in [33] and [48]. Wu [77] and Ashford [4] indicated that the concept of quantal responses and ED_{50} is also useful in the areas of education, economics, energy, transportation, criminology, legislation, and psychology.

Tolerance Distribution

Consider an indirect quantal bioassay in which r_i of n_i subjects respond to the ith dose level, denoted by x_i, which is often expressed on the basis of a logarithmic or other **transformed** scale of a test stimulus, where $i = 1, \ldots, k$. Let $P_i = F(x_i, \overline{\omega})$ be the probability of the response of a subject receiving the stimulus at dose levels x_i; here, $F(\cdot)$ denotes the cumulative distribution function (cdf), and $\overline{\omega}$ is a q-dimensional vector of unknown parameters to characterize the relationship between the tolerance distribution and dose levels. Given that $n_1, \ldots, n_k$ and $r_1, \ldots, r_k$ are mutually independent **binomial random variables**, that is, $r_i \sim \mathrm{B}(n_i, P_i)$, $i = 1, \ldots, K$,

the **likelihood** is given as

$$L(\overline{\omega}) = \prod_{i=1}^{k} C_i P_i^{r_i} (1 - P_i)^{n_i - r_i} \tag{1}$$

where $C_i = n_i!/[r_i!(n_i - r_i)!]$.

A commonly employed model to describe the dose–response relationship is to fit a simple **linear regression** to dose levels, with intercept α and slope β. That is,

$$\begin{aligned} P_i &= F(x_i; \overline{\omega}) \\ &= F(x_i; \alpha, \beta) \\ &= F(\alpha + \beta x_i) \end{aligned} \tag{2}$$

This formulation of the dose–response relationship, in fact, assumes a **location/scale** model for the tolerance distribution, with location parameter α and scale parameter β. One of the most commonly employed tolerance distribution in indirect quantal bioassays is the **normal distribution** for logarithmic tolerances whose probability density function (pdf) is given as

$$f(x) = \left\{ \frac{1}{\sigma(2\pi)^{1/2}} \right\} \exp\left[\frac{-(x-\mu)^2}{2\sigma^2} \right], \quad -\infty < x < \infty \tag{3}$$

Let $\Phi(\cdot)$ and $\phi(\cdot)$ denote the standard normal cdf and pdf. It follows from (2) that

$$\begin{aligned} Y_i &= \Phi^{-1}(P_i) \\ &= \alpha + \beta x_i. \end{aligned} \tag{4}$$

The inverse normal cdf applied to the probability of response is called the *probit transformation* [22]. Gaddum [24] referred to Y as the normal equivalent deviate (NED) of P_i. Since the standard normal distribution is symmetric about 0, and since ED_{50} is the dose level where the predefined response occurs in 50% of subjects, it follows from (3) that when $x = \mathrm{ED}_{50}$ $P = 0.5$, $Y = 0$ and

$$\begin{aligned} \mathrm{ED}_{50} &= \theta \\ &= -\frac{\alpha}{\beta}. \end{aligned} \tag{5}$$

A comparison between the normal pdf in (3) and θ reveals that the normal distribution in (3) has a mean,

$$\mu = -\frac{\alpha}{\beta}, \tag{6}$$

with standard deviation

$$\sigma = \frac{1}{\beta}. \tag{7}$$

In other words, one can always reparameterize the mean and standard deviation directly in terms of ED_{50} and the slope β as follows:

$$\begin{aligned} Y_i &= \Phi^{-1}(P_i) \\ &= \beta(x_i - \theta). \end{aligned} \tag{8}$$

This result is true for any distribution such that $F(-t) = F(t)$, which also includes the **logistic distribution**, with the cdf given as

$$F(\alpha + \beta x_i) = \{1 + \exp[-(\alpha + \beta x_i)]\}^{-1}. \tag{9}$$

Berkson [7] first referred to the inverse transformation of the probability from a logistic distribution as the logit, which is given as

$$Y_i = \ln\left[\frac{P_i}{1 - P_i} \right]. \tag{10}$$

In (4) and (10), both responses Y_i and stimulus are subject to measurement errors. Ashford [4] and Morgan [48] indicated that the effect of measurement errors is to decrease the slope in (4) and (10), between the inverse transformation of the cdf of the tolerance distribution and the stimulus. However, the point estimator of the MED remains unchanged. Other location/scale families include angular (*see* **Delta Method**), **uniform**, **Cauchy**, and **extreme-value** distributions. For more details about these distributions, see [22, 23, 48].

Finney [23] indicated that if a response rate is between 0.05 and 0.95, then it is difficult to distinguish between the normal, logistic, angular, and uniform distributions. In fact, one will not be able to discriminate the normal distribution from the logistic distribution for P_i, between 0.01 and 0.99. In practice, it is almost impossible to identify the correct transformation from the data. However, the impact on estimation of ED_{50} for an incorrectly selected tolerance distribution is negligible. To estimate ED_{50}, the logistic distribution is preferred owing to its nice statistical properties and the simplicity of computation. Since the difference among the normal, logistic, angular, and uniform distributions occurs only in the extreme tails of the distributions, the selection of models *(see* **Model, Choice of**) and the **goodness-of-fit** of models

are extremely important in the estimation of extreme dose levels such as ED_{05} or ED_{90}. Consequently, we may consider alternative three-parameter models such as the Aranda–Oradz model [48] or the quantity obtained from the omega distribution suggested by Copenhaver & Mielke [13] for statistical inference of ED_{05} or ED_{90}.

Estimation Procedures

We first restrict our discussion on the estimation of the MED to the simple two-parameter model. Principles and extensions to more complicated models are straightforward. Even for the simpler location/scale model, it is a nonlinear model. The **maximum likelihood** method is used to estimate unknown parameters. Let a and b denote the maximum likelihood estimates (MLE) of α and β, respectively. The MLE of ED_{50} can then be obtained either as $\hat{\theta} = [F^{-1}(0.5) - a]/b$ under model (2) or as the MLE of θ derived under model (8). If the assumed tolerance distribution, for example, the normal or logistic distributions, is symmetric about 0, then the MLE of ED_{50} is simply equal to $\hat{\theta} = -(a/b)$.

Various methods for numerical optimization can be applied to find the MLE. These methods usually involve the technique of iterative reweighted **least squares** (IRLS), which can be found in most commercial statistical computer packages such as SAS, BMDP, GLIM, IMSL, and others (*see* **Software, Biostatistical**). The Newton–Raphson method uses the Fisher **information matrix** as the weighting matrix during the iterative process, while the method of scoring employs the information matrix. Morgan [48] indicated that it is more convenient to use the method of scoring than the Newton–Raphson method, although for the logit model, both methods are identical (*see* **Optimization and Nonlinear Equations**).

Under appropriate regularity conditions [60], the vector of MLEs is asymptotically normal with mean zero and **covariance matrix** V, where V is the limit of the inverse of the information matrix, as the sample size goes to infinity and is referred to as the asymptotic covariance matrix of a and b. For the probit model, Griffiths et al. [28] compared three estimators of the covariance matrix for the MLEs of α and β. They are the inverse of the negative of the Hessian matrix, the inverse of the information matrix, and the inverse of the outer product of the first-order partial derivative of the log-likelihood function proposed by Berndt et al. [9]. These estimators of the covariance matrix V are asymptotically equivalent. However, Griffiths et al. [28] showed through a **simulation** study that in small samples, on average, both the information matrix and the Hessian matrix provide almost identical results and more accurate estimates of the asymptotic covariance matrix than the estimate proposed by Berndt et al. [9]. The **mean squared error** of the MLE is considerably larger than the asymptotic covariance matrix. As a result, the bias in finite samples could potentially be large.

After the MLEs and their corresponding estimated asymptotic covariance matrices are obtained, the following goodness-of-fit test statistic can be used to verify the underlying assumptions of the model:

$$X^2 = \sum \frac{(r_i - n_i \hat{P}_i)^2}{n_i \hat{P}_i (1 - \hat{P}_i)}, \tag{11}$$

where $n_i \hat{P}_i$ is the number of responses predicted by the fitted model.

If the model is adequate, then asymptotically, X^2 follows a central χ^2 with $K - 2$ df (*see* **Chi-square Distribution**). If X^2 indicates a significant lack-of-fit, then the possible causes should be carefully and thoroughly investigated. The possible causes of lack-of-fit include a poorly fitting model, the violation of binomial assumption due to a possible **correlation** between responses of subjects, or the existence of heterogeneity among responses of different subjects (*see* **Overdispersion**). Finney [22, 23] suggested the use of $X^2/(K - 2)$ as a heterogeneity factor for scaling up all variances. Since X^2 is used as a test statistic for goodness-of-fit, an intuitive alternative approach to the estimation of α and β is to find the estimates to minimize this quantity. The resulting method is the noniterative minimum X^2 method advocated by Berkson [8]. Taylor [68] showed that the minimum X^2 method is a regular best asymptotically normal **BAN** procedure. Therefore, one of advantages of the minimum X^2 method is that it provides noniterative explicit estimates that are asymptotically equivalent to the maximum likelihood procedure. Morgan [48] indicated that caution is required in the interpretation of the asymptotic optimality for the two methods. The optimality of the maximum likelihood method is achieved when the number of doses goes to infinity, while the minimum X^2 method reaches its optimality

when the number of subjects in each group goes to infinity [42, 61].

Confidence Intervals

Let v_{11}, v_{22}, and v_{12} be the estimated asymptotic variances and covariances of the MLEs a and b obtained from either the Hessian or the information matrices by replacing α and β with a and b. The estimated asymptotic variance of the MLE for θ is then given by

$$v(\hat{\theta}) = \frac{v_{11} + 2\hat{\theta}v_{22} + \hat{\theta}^2 v_{22}}{b^2}. \tag{12}$$

Since $(\hat{\theta} - \theta)/[v(\hat{\theta})]^{1/2}$ converges in distribution to the standard normal distribution, the $(1-\alpha)100\%$ **confidence interval** for θ can be obtained by the **delta method** as follows:

$$\hat{\theta} \pm z_{\alpha/2}[v(\hat{\theta})]^{1/2}, \tag{13}$$

where $z_{\alpha/2}$ is the $\alpha/2$ upper quantile of the standard normal distribution.

However, the $(1-\alpha)100\%$ confidence interval for θ based on **Fieller's theorem** [20, 21] is the set of θ values such that

$$\left\{\theta \left| \frac{(a+\theta b)^2}{b^2 v(\theta)} < z_{\alpha/2}^2 \right.\right\} \tag{14}$$

Let g be $z_{\alpha/2}^2$ times the inverse of the square of the statistic for testing whether the slope is different from zero. Failure to reject the null hypothesis of the zero slope implies that $g \geq 1$, and hence, the resulting $(1-\alpha)100\%$ confidence interval for the MED by Fieller's theorem will either be the entire real line or the union of two disjoint open intervals.

Consider the asymptotic **likelihood ratio test** to test the **null hypothesis**, $\theta = \theta_0$, against the **alternative hypothesis**, $\theta \neq \theta_0$. Let $l(\theta_0)$ be the value of the log-likelihood maximized with respect to β under the null hypothesis that $\theta = \theta_0$, and let $l(\theta, \beta)$ be the value of the log-likelihood maximized with respect to both β and θ under the alternative hypothesis. It follows that the $(1-\alpha)100\%$ confidence interval for ED_{50} by the likelihood ratio method is given by the following set:

$$\{\theta | 2[l(\theta, \beta) - l(\theta_0)] < z_{\alpha/2}^2\}. \tag{15}$$

Asymptotically, the $(1-\alpha)100\%$ confidence intervals for the MED derived by the delta method, Fieller's theorem, and the likelihood ratio method are all equivalent. However, the interval by the delta method always exists and is finite. On the other hand, the confidence interval produced by Fieller's theorem and the likelihood ratio test may not be of finite length. Williams [74] reported that overwhelming evidence exists that the confidence interval by Fieller's theorem is conservative.

Because Fieller's theorem is an exact method under the normality assumption, the only source of error for its corresponding confidence interval involves the normal approximation to p_i. If g is small, then both the delta and Fieller's intervals will be virtually the same. As a result, Finney [22, 23] recommended the use of Fieller's interval only if g is <0.05. However, limited simulation performed by Abdelbasit & Plackett [2] failed to support the use of Fieller's interval as advocated by Finney [22, 23]. Cox [14] found that the delta method provides a useful alternative to Fieller's theorem. Sitter & Wu [64] provided both theoretically and empirically, the most comprehensive comparison between the intervals derived by the delta method and Fieller's theorem. They showed that Fieller's interval and the delta interval differ only by an inflation factor and a shift factor, with an asymptotic order of $O_p(1/n)$. The inflation factor is 1 (<1) when the design is symmetric (asymmetric). However, the shift factor vanishes when the design is symmetric.

The simulation results of Sitter & Wu [64] provide convincing evidence to support the use of Fieller's interval rather than the delta interval for ED_{50}. Fieller's theorem will generate a confidence interval for ED_{50} with an infinite length when the slope is not statistically different from 0 (i.e. $g \geq 1$). In this situation, the relationship between the response probability and the dose levels cannot be adequately and satisfactorily established through the assumed model. Consequently, any inference, including the construction of the confidence interval for ED_{50} by Fieller's theorem based on the assumed model, is meaningless.

For responses with more than one outcome (*see* **Polytomous Data**), one possible model for the estimation of ED_{50} is the **proportional-odds model**. Let P_{ij} be the probability of observing the jth outcome of a total of J possible outcome categories at the ith dose level. Then, a **multinomial** model can be used

to describe the data using the cumulative logits

$$\begin{aligned}&\log\text{it}(P_{i1}+\cdots+P_{ij})\\&=\ln\left\{\frac{P_{i1}+\cdots+P_{ij}}{1-(P_{i1}+\cdots+P_{ij})}\right\}\\&=\alpha_j+\beta x_i,\quad j=1,\ldots,J-1;\ i=1,\ldots,k,\end{aligned}\tag{16}$$

where $\alpha_1<\cdots<\alpha_J$. The ED_{50} can be estimated in the usual way for the cumulative collapsed categories. However, the assumption of parallelism, of the lines for different values of j, must be verified before the estimates of α_j and β can be used for inferences about the ED_{50}.

Mixture Models

Similar to the "**placebo** effect" in clinical trials, the natural response in bioassay or toxicology should be also taken into account. The natural response is the response separated from that attributed to the administered stimulus. An approach to incorporating the natural response into the estimation of ED_{50} is to employ the model suggested by Abbott [1] for the following response probability:

$$F(x_i)=\lambda+(1-\lambda)F^*(x_i),\tag{17}$$

where $0\le\lambda\le1$ is the probability of natural response and $F^*(x_i)$ is the probability for dose level x_i whose occurrence of the defined event is not due to natural causes. As discussed earlier, a significant heterogeneity factor X^2 may indicate that (i) the population under investigation may not be homogeneous or (ii) the observed tolerance distribution is not unimodal. In this case, the underlying population may consist of a mixture of homogeneous subpopulations. The response probability of each subpopulation is still related to the dose by some individual tolerance distribution.

Suppose that there are a total of h subpopulations, each with a tolerance distribution F_j. For the ith dose level, n_{ij} of n_i subjects come from the jth population with probability δ_j and m_{ij} subjects respond, where $j=1,\ldots,h; I=1,\ldots,k$. Therefore, for a fixed n_i, $(n_{i1},\ldots,n_{ih})$ are jointly distributed as a multinomial distribution with parameter $(n_i,\delta_1,\ldots,\delta_h)$. In addition, the sum of m_{ij} is r_i. For fixed $(n_{i1},\ldots,n_{ih})$, m_{ij} are independently distributed as binomial random variables with parameters $[n_{ij}, F_j(d_i)]$. If a control group is also included in the study to account for natural mortality, then the likelihood may be formulated as [41].

$$\begin{aligned}L(\overline{\omega})&=C_0\lambda^{r_0}(1-\lambda)^{(n_0-r_0)}\\&\quad\times\prod_{i=1}^{k}C_iP_i^{r_i}(1-P_i)^{(n_i-r_i)},\end{aligned}\tag{18}$$

where $C_i=n_i!/[r_i!(n_i-r_i)!]$, $i=0,\ldots,k$; $P_i=\sum\delta_jF_j(d_i)$.

For the location/scale family, the parameters in $\overline{\omega}$ consist of $\lambda,\delta_1,\ldots,\delta_{h-1};\ \alpha_1,\ldots,\alpha_h;\beta_1,\ldots,\beta_h$; and if $x_i=\ln d_i$, then

$$\begin{aligned}F_j(x_i)&=\lambda+(1-\lambda)F^*(\alpha_j+\beta_jx_i),\\&\quad j=1,\ldots,h;\ i=1,\ldots,k.\end{aligned}\tag{19}$$

Lwin & Martin [41] proved that the MLEs exist under model (18). They suggested that the MLEs may be obtained either by the usual Newton–Raphson or scoring methods or the Nelder–Mead simplex algorithm [50]. In addition, they also pointed out that the **EM algorithm** [16] can be used to solve the likelihood functions for MLEs.

Overdispersion

Statistical inference about the ED_{50} as described above, assumes independence of individual subjects. In toxicology or **teratology** experiments, subjects are sampling units nested within the experimental units, such as litters. Therefore, responses observed from the subjects within the same litter are not independent. Hence, the actual variability exhibited by the data is larger than that expected under the independent binomial assumption. This phenomenon is referred to as **overdispersion** or extra-binomial variation caused by the litter effect. Other examples of overdispersion can be found in [15, 48, 75, 76].

Consider an experiment in which m_i litters receive the ith dose level of the stimulus. Let r_{ij} be the number of responses in n_{ij} subjects in the jth litter of the ith dose group, $j=1,\ldots m_i$, $i=1,\ldots,k$. Denote the corresponding response probability by P_{ij}. Then, given n_{ij} and P_{ij}, the **conditional** distribution of r_{ij} follows the binomial distribution given in (1). If we further assume that P_{ij} follows a **beta distribution** with parameters η_{1i} and η_{2i}, the marginal distribution

of r_{ij} follows a **beta-binomial distribution** with the following log-likelihood function as shown by Segreti & Munson [59].

$$L = \text{constant} + \sum_{i=1}^{k}\sum_{j=1}^{m_i}\left\{\sum_{r=0}^{r_{ij}-1}\log(\gamma_{1i}+r\gamma_{2i}) + \sum_{r=0}^{n_{ij}-r_{ij}-1}\log(1-\gamma_{1i}+r\gamma_{2i}) - \sum_{r=0}^{n_{ij}-1}\log(1+r\gamma_{2i})\right\}, \quad (20)$$

where $\gamma_{1i} = \eta_{1i}/(\eta_{1i}+\eta_{2i})$ and $\gamma_{2i} = (\eta_{1i}+\eta_{2i})^{-1}$.

Under the assumption of a common logistic distribution for the tolerance distributions for all subpopulations, the model to incorporate the natural response in (19) may describe the relationship between the response probability and dose levels of the stimulus as

$$\gamma_{1i} = \lambda + (1-\lambda)[1+\exp(\alpha+\beta x_i)]^{-1} \quad i = 1, \ldots, k. \quad (21)$$

The point and interval estimation for ED_{50} are straightforward from (21), after the MLEs of γ_{1i} and γ_{2i} are obtained by either the Newton–Raphson method or the Nelder–Mead algorithm method (*see* **Optimization and Nonlinear Equations**). The beta-binomial model assumes that the response probability from different litters follows a beta distribution. However, one can relax this strong assumption by specifying only the mean as γ_{1i} and variance as $\gamma_{1i}(1-\gamma_{1i})\rho$, where $\rho = \gamma_{2i}/(1+\gamma_{2i})$, $i = 1, \ldots, k$. It turns out to be the robust procedure of **quasi-likelihood** [43], which can be readily carried out to estimate ED_{50} by commercial statistical software packages such as GLIM (*see* **Software, Biostatistical**).

Other approaches to the extra-binomial variation for inference of the MED include the Poisson-gamma model employed by O'Neill & O'Neill [52], and the correlated-binomial model, the logistic-normalbinomial, and the probit-normal binomial models suggested by Morgan [48].

Quantal Response over Time

In a bioassay, it is not uncommon to observe responses at some prescheduled discrete time points. These time points may be selected as design points in addition to the dose of the stimulus. Time, therefore, is another classification factor [10]. If these time points are not design points but some prescheduled observing time points, then the ED_{50} is a function of time. Suppose that an experiment consists of the administration of each of k dose levels to a group of n_i subjects whose responses are observed at J time points, $0 = t_0 < t_1 < \cdots < t_J < t_{J+1} = \infty$. Let r_{ij} be the number of subjects responding in the time interval (t_{j-1}, t_j) and let $F(t_j|d_i)$ be the probability of observing a response by time t_j at the ith dose level, $j = 1, \ldots, J+1$, $i = 1, \ldots, k$. Pack & Morgan [53] showed that the likelihood can then be written as

$$L = \prod_{i=1}^{k}\left\{\left\{\prod_{j=1}^{J}[F(t_j|d_i) - F(t_{j-1}|d_i)]^{r_{ij}}\right\} \times [1-F(t_J|d_i)]^{n_i-r_i}\right\}, \quad (22)$$

where, at the ith dose level, $F(t_j|d_i) - F(t_{j-1}|d_i)$ represents the probability of observing a response during the time interval (t_{j-1}, t_j), and $1 - F(t_J|d_i)$ is the probability of no response at the end of the experiment.

Since there is a possibility that the subjects may not be affected by the stimulus, one may choose a mixed distribution with the logistic function as the mixing proportion:

$$A(x_i) = \{1+\exp[-(\alpha+\beta x_i)]\}^{-1}. \quad (23)$$

Let F_1 denote the response-time distribution for subjects who respond to the stimulus, and F_2 be that for those unaffected by the stimulus. The response-time distribution for all subjects at the ith dose level can be expressed as

$$F(t_j|d_i) = A(x_i)F_1(t_j|d_i) + [1-A(x_i)]F_2(t_j). \quad (24)$$

Note that $F_2(t_j)$ is independent of dose. Although various forms can be chosen for F_1, Pack & Morgan [53] suggested using

$$F_1(t|d_i) = \begin{cases} 1-\{1+\lambda\exp[\psi\ln(t)-\eta_i]\}^{-1/\lambda}, & \lambda \neq 0 \\ 1-\exp\{-\exp[\psi\ln(t)-\eta_i]\}, & \lambda = 0 \end{cases} \quad (25)$$

If the model ignores the part of response-time distribution for those who are not affected by the stimulus, then the inference for ED_{50} at the end of the study is the same as that for $-(\alpha/\beta)$.

The problem of overdispersion also occurs for quantal response experiments over time; see, for example, [48, 51, 54]. Petkau & Sitter [54] suggested the use of the Dirichlet-multinomial model as an alternative approach to handling the extra variation. Suppose that there are a total of L replications of the experiment. Let R_{ijl} be the cumulative number of responses observed up to time t_j for n_{ijl} subjects in the lth replicate, receiving the ith dose level. Then, given n_{ijl}, $(r_{i1l,\ldots,}r_{iJl})$ follows a multinomial distribution with probabilities $(p_{i1l,\ldots,}p_{iJl})$, where r_{ijl} and p_{ijl} are similarly defined for the lth replicates. Furthermore, if the vector of probabilities $(p_{i1l,\ldots,}p_{iJl})$ is randomly distributed as the Dirichlet distribution, then the marginal distribution of $(r_{i1l,\ldots,}r_{iJl})$ follows the Dirichlet-multinomial. As a result, Petkau & Sitter [54] suggested that the inference for ED_{50} may be obtained from the following **Weibull** response-time distribution in the absence of a replication effect.

$$F(t_j, d_i) = 1 - \exp[-\exp(\alpha + \beta x_i)t_j\gamma] \qquad (26)$$

or

$$\theta = \frac{\ln[-\ln(0.5)] - \alpha - \gamma \ln t_j}{\beta}. \qquad (27)$$

Hence, the estimated ED_{50} is a function of time.

O'Hara Hines & Lawless [51] considered a number of models for overdispersion, which can be incorporated into the **generalized linear model** framework for multinomial data. The idea is to incorporate various random components into the link function and use the quasi-likelihood or generalized least squares estimating equation to estimate the unknown parameters. O'Hara Hines & Lawless [51] found that, on average, the robust covariance matrix estimator based on the **generalized estimating equations** (GEEs) proposed by Liang & Zeger [40] performed well. As a result, it is recommended that the multinomial estimating equations with the robust variance estimate in the presence of extra-multinomial variation be used for quantal response over time. Alho & Valtonen [3] extended the results of the likelihood confidence interval for ED_{50} by Williams [74] to a generalized linear model with a known scale parameter, which permits **explanatory variables** other than those related to stimulus. Laurence & Morgan [39] and Morgan [48] provided a complete review regarding the advantages and drawbacks of the stochastic model for analysis of quantal response over time proposed by Puri & Senturia [55], which was subsequently extended by Diggle & Gratton [17].

Bayesian Approaches

Racine et al. [56] also proposed a number of **Bayesian** approaches for the estimation of ED_{50}. They suggested that either a **bivariate normal distribution** or independent beta distributions be considered as the possible choices for the **prior distribution** of the underlying parameters. For the probit model, both prior distributions yield a bivariate normal posterior distribution. However, **numerical integration** is usually required for the evaluation of the integral for the posterior distribution of ED_{50}. In addition, under the uniform and normal prior distribution, Grieve [26] derived the posterior probabilities of a substance belonging to a predetermined toxicity classes.

Grieve [27] further examined the relationship between Fieller's theorem, likelihood methods, and Bayesian methods for interval estimation of the LD_{50}. In particular, the quadratic equation of θ has its minimum at the MLE, $-(a/b)$, its maximum at $(av_{12} - bv_{11})/(bv_{12} - av_{22})$, and has an asymptote with a value, b^2/v_{22}. Therefore, if $z^2_{\alpha/2}$ is between the asymptote and its maximum, the $(1-\alpha)100\%$ confidence interval for θ is in the form of two disjoints intervals. On the other hand, if $z^2_{\alpha/2}$ is greater than the maximum, the $(1-\alpha)100\%$ confidence interval for θ is the whole real line. For the likelihood ratio interval estimate of LD_{50}, Grieve [27] showed that the likelihood function for θ always has both a minimum and a minimum. Consequently, the log-likelihood function of θ has exactly the same characteristic form as does Fieller's quadratic function shown above. Hence, there will always be a chance of α that the $(1-\alpha)100\%$ confidence interval for θ by the likelihood method will comprise the whole real line. To overcome this common problem shared by both Fieller's theorem and the likelihood ratio method, under the assumption that θ and β are **orthogonal** Grieve proposed to use the conditional **profile likelihood** (CPL) approach to interval estimation of LD_{50}. In other words, a likelihood ratio statistic is constructed from the conditional distribution of the data, given the MLE of β. The resulting CPL has the form

of the original likelihood, modified by the observed information for β, given θ. It follows that the CPL method takes into account the uncertainty regarding β, which is ignored in the likelihood approach. In addition, if the prior distribution for θ and β has the form

$$p(\theta, \beta) = \beta, -\infty < \theta < \infty, 0 < \beta, \tag{28}$$

the posterior distribution of θ derived from the Bayesian method developed in [26] is approximately the same as the conditional profile likelihood if θ and β are *a priori* independent as demonstrated by Grieve [27]. Grieve claimed that from two distinct perspectives, attempts to overcome the difficulties associated with interval estimation of LD_{50} lead to Bayesian solutions. More literature on Bayesian inference of ED_{50} can be found in [25, 45, 66, 67].

Nonparametric and Robust Methods

In the **pharmaceutical industry**, quantal response bioassays are routinely performed to examine the efficacy and safety of new drugs in animals during the early stage of drug development. It is then necessary to obtain an initial estimate of ED_{50} and its standard error with reasonable accuracy and precision. For this purpose, **nonparametric methods** are often employed for pilot bioassays to provide **robust** estimates to plan subsequent designs in the establishment of the final estimate of ED_{50}.

Under the independent binomial model (1), the unrestricted MLE for P_i is the observed proportion of the number of subjects at the ith dose level, $p_i = r_i/n_i$. To obtain nonparametric and robust estimates for ED_{50}, we may start with the MLEs of P_i under the order restriction, $P_1 \le P_2 \le \cdots \le P_k$ (*see* **Isotonic Regression**). Barlow et al. [5] gave the distribution-free MLEs of P_i under the order restriction as follows:

$$\tilde{P}_i = \max_{1<u<i} \min_{i<v<k} \left(\frac{\sum_{j=u}^{v} r_j}{\sum_{j=u}^{v} n_j} \right). \tag{29}$$

Spearman–Kärber Estimator

In 1908, Spearman [66] first proposed a simple and yet easily understood method for the estimation of ED_{50}, which was reintroduced by Kärber [38] in 1931. Let Δ_i denote the increment of the dose from dose level x_i to dose level x_{i+1}, then the Spearman–Kärber (S–K) estimator for ED_{50} is given as

$$\hat{\theta} = \left(p_1 - \frac{\Delta_i}{2}\right) + \sum_{i=1}^{k-1} (p_{i+1} - p_i) \left(x_i + \frac{\Delta_i}{2}\right) + (1 - p_k)\left(x_k + \frac{\Delta_{k-1}}{2}\right), \tag{30}$$

where $\Delta_i = x_{i+1} - x_i$. If $p_1 = 0$ and $p_k = 1$, then the Spearman–Kärber estimator in (30) reduced to its usual form, that is,

$$\hat{\theta} = \sum_{i=1}^{k-1} (p_{i+1} - p_i) \left[\left(\frac{x_{i+1} + x_i}{2}\right)\right]. \tag{31}$$

The S–K estimator for ED_{50} is in fact the area under the response probability-time curve calculated by the usual trapezoidal rule. Since the unrestricted MLEs, p_i, may not be monotonically increasing, we need to smooth p_i by using the MLEs given in (29), obtained under the order restriction before calculation of the S–K estimate of ED_{50}. The variance of the S–K estimator is

$$V(\hat{\theta}) = \sum_{i=2}^{k-1} \frac{P_i(1 - P_i)(x_{i+1} - x_i)^2}{4n_i}, \tag{32}$$

with an **unbiased** estimator,

$$v(\hat{\theta}) = \sum_{i=2}^{k-1} \frac{p_i(1 - p_i)(x_{i+1} - x_i)^2}{4(n_i - 1)}. \tag{33}$$

Morgan [48] indicated that although the S–K estimator is simple with an explicit expression, and is a function of the **sufficient statistics** $(r_1, \ldots, r_k)$, it is not unbiased for ED_{50}.

The robustness of the S–K estimator can be further improved by the use of **trimming** suggested by Hamilton in [29] and [31]. Sanathanan et al. [58] introduced the use of trimming in the logit and probit models. They suggested that the trimming χ^2 criterion be the heterogeneity factor, X^2/df, where $X^2$is the test statistic for the goodness-of-fit defined in (11). They also recommended minimizing the heterogeneity factor iteratively over the range of dose levels such that the fitted proportion is within the range of 0.0001 and 0.999 for the calculation of the information matrix. However, Morgan [48] indicated that for

quantal response data with few occurrences of 0% or 100% response, the trimmed logit procedure suggested by Sanathanan et al. [58] has very little effect. For other evaluations of S–K estimators and trimming procedures, see [29–32, 35, 48, 58].

For reference to other simple estimators of the ED_{50}; *see* **Biological Assay, Overview**.

L-, M-, and R-Estimators

For the discussion in this section, following James et al. [35], we consider a bioassay experiment in which n subjects are randomly selected to receive each of the $2k+1$ equally spaced dose levels, $x_{-k}, \ldots, x_{-1}, x_0, x_1, \ldots, x_k$. Let P_i and p_i be defined as in the previous subsection, and let Δ denote the common dose increment. Under the convention that $p_{-k-1} = 0$ and $p_{k+1} = 1$, the empirical tolerance distribution is the following piecewise linear function:

$$F(x) = \begin{cases} p_i, & \text{if } x = x_i, -k \le i \le k, \\ 0, & \text{if } x \le x_{-k-1} = x_0 - (k+1)\Delta, \\ 1, & \text{if } x \ge x_{k+1} = x_0 + (k+1)\Delta, \end{cases} \tag{34}$$

and $F(x)$is linear and continuous in $[x_i, x_{i+1}]$, for all i.

Let $J(u)$ be a nonnegative function defined on the interval [0, 1], which is symmetric about 0 and let $\int J(u)du = 1$. The L-estimator of ED_{50}, a linear combination of **order statistics**, is given as

$$\hat{\theta} = x_0 + \Delta \sum_{i=-k}^{k+1} i\, J(p_i)(p_i - p_{i-1}) \tag{35}$$

The S–K estimator is a special example of the L-estimator because (i) when $J(.) = 1$, the L-estimator is the untrimmed S–K estimator and (ii) when $J(u) = 1/(1-2a)$, where $a \le u \le (1-a)$, the L-estimator is the $100a\%$ trimmed S–K estimator.

The M-estimator of ED_{50} is the root of the following equation [45].

$$\sum_{i=-k}^{k+1} \psi\left[\frac{d_i - \theta}{s}\right][p_i - p_{i-1}] = 0, \tag{36}$$

where $\psi(.)$ is a suitable function and s is a scaling factor.

If $\psi(x) = x(1-x^2)^2$, 0 for $|x| \le 1$ or $|x| > 1$, respectively, then we have Tukey's biweight M-estimator of ED_{50}.

Let $G(u)$ be a nondecreasing integrable score function for $0 < u < 1$ and $G(1-u) = -G(u)$. The R-estimator for ED_{50} [35] is the solution to the following equation:

$$h(F,\theta) = \int G\left\{\frac{[F(x) + 1 - F(2\theta - 1)]}{2}\right\} \mathrm{d}F(x) = 0 \tag{37}$$

if a unique solution exists. If not, define

$$\hat{\theta} = \frac{\{\sup[\theta : h(F,\theta) > 0] + \inf[\theta : h(F,\theta) < 0]\}}{2}. \tag{38}$$

The **sign test** score function ($G(u) = -1$, for $u < 0.5$ and $G(u) = +1$ for $u > 0.5$), the Wilcoxon test score function ($G(u) = (u - 1/2)$ (*see* **Wilcoxon Signed-rank Test**), and the Van der Waerden score function ($G(u) = \Phi^{-1}(u)$) will give, respectively, the sample median, the Hodges–Lehmann estimator, and the normal score estimator. If $G(u) = \ln[u/(1-u)]$, then, according to James et al. [35], the resulting R-estimator is called the *logistic score estimator*. However, the R-estimator is not a **consistent estimator** for ED_{50}, and hence it is asymptotically biased.

James & James [34] defined the influence curve for the estimators of the MED in quantal bioassay under the assumption of a symmetric tolerance distribution. They also obtained the influence curve for L-, M-, and R-estimators as well as the logistic score estimator. In general, the logistic score estimator and the MLE under the logit model are not robust, while the Tukey biweight M-estimator and the Hodges–Lehmann R-estimator are robust. James et al. [35] gave a complete review of **asymptotic relative efficiency**, for different estimators of ED_{50}, under various tolerance distributions. From their paper, and from [29, 37, 48,], a moderately trimmed S–K estimator, say by 5%, may be the recommended estimator (*see* **Robustness**).

Study Design

The basic issues for designing a nonsequential bioassay to estimate the MED involve (i) selection of the dose levels, (ii) determination of the number of dose levels, (iii) estimation of the number of the subjects, and (iv) distribution of the number of subjects to a

fixed number of dose levels. Most of research concentrates on (i), (ii), and (iv), summarized below. For details on design issues about quantal response, see [2, 12, 22, 23, 36, 44, 46, 48, 49, 63, 65, 71, 77].

With respect to the estimation of ED_{50} for a symmetric tolerance distribution, various criteria can be obtained under the requirements for D-, A-, E-, G-,and F-optimality [19, 62] (*see* **Optimal Design**). All these criteria depend on the asymptotic variance of the MLEs, a and b, and hence on the information matrix of *a and b*. For example, for the D-optimality, the design is, in fact, chosen at the dose level to maximize the determinant of the inverse of information matrix, that is, to select x to maximize

$$w_D(x) = \left\{ \frac{xf^2(x)}{F(x)[1 - F(x)]} \right\}^2. \qquad (39)$$

For a logistic tolerance distribution and a two-point design, w has its maxima at $x = \pm 1.5434$. These values correspond to the response probability of 0.176 and 0.824. Consequently, the D-optimal design for a logistic distribution allocates half the subjects separately to the dose levels $ED_{17.6}$, and the other half to $ED_{82.4}$. Similarly, for the probit model, the D-optimal doses are $ED_{12.8}$ and $ED_{87.2}$.

The A-optimal design requires minimizing the trace of the asymptotic covariance matrix of a and b. The F-optimality minimizes the squared half-length of the $100(l - \alpha)\%$ confidence interval for ED_{50} on the basis of Fieller's theorem [2, 22, 23, 65]. Sitter & Wu [65] provided some numerical results for design points of dose levels for two-point and three-point designs on the basis of these criteria.

Kalish [36] considered D-optimality with the use of a second-order approximation of the order of $1/n^2$ for estimating the variances of MLEs of the MED and the slope under the formulation of the tolerance distribution in (8). She referred to these two designs as LD_{50}-optimal and slope-optimal designs. Kalish [36] recommended the equally weighted three-point design, with design points at LD_{20}, LD_{50}, and LD_{80}. From theoretical and simulation results, this design is very efficient for estimating LD_{50} and for global estimation of the dose–response curve. Sun & Tsutakawa [67] proposed Bayesian designs that avoid experiment results with little information at the expense of a small sacrifice in the Bayes risk. On the other hand, Minkin & Kundhal [47] considered the length of likelihood-based confidence interval as a criterion for the dose allocation.

From a practical viewpoint, a useful optimal design should provide the minimal number of doses and the minimal number of subjects required at each level. However, the design points derived under various optimal criteria are functions of unknown parameters. Consequently, in practice, it is extremely difficult to implement these optimal designs, not only because the number of dose levels might be unknown, but also because reliable and good initial estimates for the unknown parameters are usually unavailable during the planning stage of experiments. In this situation, Müller & Schmitt [49] recommended, for a symmetric distribution, to choose as many dose levels as possible with the allocation of one subject per dose level.

Sitter [63] used the **minimax** principle to find robust designs by minimizing the maximum of some criteria over a bounded rectangular region of possible parameters, which have the form

$$P = \{(\theta, \beta) : |\theta - \theta_0| \le \theta_\Delta, \beta_L < \beta < \beta_U\} \qquad (40)$$

where θ_Δ and (β_L, β_U) define the possible ranges, respectively, for ED_{50} and slope. Suppose that the dose levels are symmetric about the location of the tolerance distribution, θ_0, then the designs are completely specified by the number of dose levels k and the common increment between adjacent dose levels, d. Let

$$\begin{aligned} d_i &= d\beta_L \left[\frac{i - (k+1)}{2} \right], \\ x_i &= \frac{d_i}{\beta_L + \theta_o}, \\ a &= \beta_L(\theta - \theta_0), \\ b &= \frac{\beta}{\beta_L}, \\ d' &= \beta_L d. \end{aligned} \qquad (41)$$

Sitter [63] suggests a design such that

$$W(\delta) = \min_{k=2,3,\ldots} \min_{-\infty < d' < \infty} \max_S R(k, d', a, b), \qquad (42)$$

where $R(.)$ can be the criterion based on either D-optimality or F-optimality, and

$$S = \left[\frac{(a, b) : 0 \le a \le \theta_\Delta; 1 \le b \le \beta_U}{\beta_L} \right].$$

Sitter [63] provides tables for the number of dose levels and dose increments, for a number of various

combinations of θ_Δ and β_U/β_L under a logit model, and for robust designs using D-optimality and F-optimality. These proposed designs are robust to poor initial estimates of the unknown parameters and only require prior information about the possible ranges for the location and scale parameters. The minimax procedure provides the number of doses as well as the dose increment for an easy and practicable implementation of the design.

Sequential Procedures

The results of the classical fixed bioassays might either be that all subjects respond or that none responds, if the investigators misjudge the location and/or the scale of the tolerance distribution. Consequently, little information about ED_{50} can be gained and all resources are wasted. Therefore, sequential procedures provide attractive alternatives to the classical designs. The use of sequential procedures in estimating the ED_{50} goes back to Bartlett [6]. However, Dixon & Mood [18] first proposed the **up-and-down method** for the estimation of ED_{50}.

For an up-and-down experiment, after a series of equally spaced dose levels have been selected, the first subject is tested at the best guessed dose level for ED_{50}. Each subsequent test is performed at the next lower or the next higher dose level according to which the predefined response is or is not observed in the previous subject. Let x_i, where $i = 0, 1, \ldots, n$, be the dose level used in the ith trial of an up-and-down experiment, with x_0 being the initial dose level and d being the common fixed spacing between adjacent dose levels. Dixon & Mood [18] gave the following estimator:

$$\hat{\theta}_M = \sum_{i=0}^{k} \frac{x_i}{k+1}, \tag{43}$$

which was modified by Brownlee et al. [11] as

$$\hat{\theta}_B = \sum_{i=1}^{k+1} \frac{x_i}{k+1}. \tag{44}$$

Choi [12] further provided a different estimator for ED_{50} on the basis of the up-and-down experiment as

$$\hat{\theta}_C = \sum_{S} \frac{w_i}{t-1}, \tag{45}$$

where S denotes the t dose levels where a change in response at x_i occurs and

$$w_i = \begin{cases} \dfrac{x_i + \mathrm{d}}{2}, & x_i \text{ is a trough} \\ \dfrac{x_i - \mathrm{d}}{2}, & x_i \text{ is a peak} \end{cases}$$

Choi [12] also used **Markov-chain** theory for estimation of the dispersion matrix for confidence intervals of ED_{50} based on the up-and-down experiment.

In general, the $n+1$ dose level for the up- and-down experiment can be expressed as

$$x_{n+1} = x_n - 2d(I_n - 0.5), \tag{46}$$

where I_n is 1 if the response is observed at the nth dose level and is 0 otherwise. This leads to the sequential Robbins–Monro [57] method for estimating the ED_{50}, which is given as

$$\hat{\theta}_{RM} = \frac{x_n - c}{n(I_n - 0.5)} \tag{47}$$

(*see* **Stochastic Approximation**). In (47), the optimal value of c is chosen to be $[f(\theta)]^{-1}$ to minimize the asymptotic variance of $[n(I_i - \theta)]^{1/2}$. Let b_n be the estimated slope resulting from fitting a linear regression of I_i on x_i with the available results based on the current n subjects. Then, the adaptive Robbins–Monro estimator after the nth trial is given as

$$\hat{\theta}_{ARM} = x_n - \left(\frac{1}{nb_n}\right)(I_n - 0.5). \tag{48}$$

Wu [77] proposed a logit-MLE method to use all available information to date for determination of the $n+1$ dose level. Suppose that the study has completed an initial design, either fixed or sequential, with n subjects at n dose levels. The next dose level is then given as

$$x_{n+1} = x_n - \left(\frac{k_n^*}{n}\right)(I_n - 0.5), \tag{49}$$

where $k_n^* = \max[c_1, \min(k_n, c_2)]$, and c_1 and c_2 are some truncation constants. Wu [77] suggested the choice of $c_1 = 0$ to avoid possible large changes in dose levels. He reported that the relative performance of these methods heavily depends on the choice of the initial design. If n is rather large, then MLE or $\hat{\theta}_{ARM}$ should be used to take advantage of the asymptotic optimality. A large value of the constant c should be selected if the initial guess of ED_{50} is poor. If

only scant information about θ and $f(\theta)$ is available at the planning stage of the experiment for the initial design, then one needs to use a wide range of dose levels that should be evenly placed.

McLeish & Tosh [44] extended Wu's logit-MLE method in a manner such that, after k dose levels in n subjects have been tested, the next dose level is chosen so as to minimize the asymptotic variance of MLE for the θ obtained from the updated information matrix by the delta method. This method not only allows flexibility of the incorporation of cost but is also more robust against misspecification of the parameters than Wu's logit-MLE procedure. In addition, McLeish and Tosh's method for allocating dose levels seems to achieve full asymptotic efficacy of estimation.

JEN-PEI LIU & SHEIN-CHUNG CHOW

Median Survival Time

A useful summary of a survival curve is the median survival time. Approximately 50% of the population under study could be expected to survive beyond the **median**. More formally, the median survival time is defined as $M = F^{-1}(1/2) = \inf(t : F(t) \geq 0.5)$, where $F(t)$, the cumulative distribution function, is the probability of surviving less than or equal to time t. The median survival is used considerably more frequently than the mean as a summary statistic because of the difficulties in estimating means from heavily right-censored data without strong parametric assumptions.

The median is nonparametrically estimated from right-censored survival data by first calculating the Kaplan–Meier [8] survival curve $\hat{S}(t) = 1 - \hat{F}(t)$ (*see* **Kaplan–Meier Estimator**), which is an estimate of the probability of surviving beyond t. The estimated median survival time is $\hat{M} = \hat{F}^{-1}(1/2)$ which is the smallest observed event (uncensored) time where the Kaplan–Meier estimate is not greater than 1/2. There can be a great deal of variability in the estimated median if the survival curve is relatively flat near 0.5.

Several approaches have been proposed to obtain confidence intervals for the median survival. Brookmeyer & Crowley [3] suggested inverting a generalized sign test for right-censored data for testing the null hypothesis H_0: median survival time $= t$, versus H_1: median survival time $\neq t$. The generalized sign test statistic, $\hat{S}(t)$, is the Kaplan–Meier estimate evaluated at t. One does not reject the null hypothesis at level α if

$$[\hat{S}(t) - 1/2]^2 \leq \chi^2_\alpha \widehat{\text{var}}[\hat{S}(t)],$$

where χ^2_α is the α critical value of a χ^2 with one degree of freedom and where $\widehat{\text{var}}(\hat{S}(t))$ is Greenwood's estimate of the variance of $\hat{S}(t)$,

$$\widehat{\text{var}}[\hat{S}(t)] = [\hat{S}(t)]^2 \sum_{\{x_i \leq t\}} \frac{d_i}{n_i(n_i - d_i)},$$

where d_i and n_i are the number of uncensored events and number at risk, respectively, at distinct event times x_i. The $(1 - \alpha)$ 100% confidence interval is defined as the interval $I_\alpha = [t_l, t_u)$, where t_l is the smallest event (uncensored) time with $\hat{S}(t) \geq 0.5$ that is not rejected by the generalized sign test at level α and t_u is the smallest observed event (uncensored) time with $\hat{S}(t) < 0.5$ that is rejected at level α. Occasionally it happens that an upper confidence limit cannot be obtained because the last observed event time is in I_α, then I_α becomes a one-sided confidence interval of the form $[t_l, \infty]$. We also obtain a one-sided confidence interval if the Kaplan–Meier survival curve does not reach the median because of extensive censoring.

This confidence interval method can also be illustrated by the following approach [1]. First, calculate pointwise $(1 - \alpha)$ 100% confidence intervals for the entire survival curve using the Kaplan–Meier estimate and Greenwood's formula, $\hat{S}(t) \pm Z_{\alpha/2}[\widehat{\text{var}}\hat{S}(t)]^{1/2}$. Then the confidence interval for the median is defined by the times where these upper and lower confidence limits equal 1/2. This is shown graphically in Figure 1 for survival data from a colorectal cancer clinical trial consisting of 53 patients of whom 16 were censored [3]. The figure shows the Kaplan–Meier estimate along with the upper and lower 95% confidence intervals for $S(t)$. The median survival time was $\hat{M} = 61$ weeks and the 95% confidence interval was [38, 73].

Several other related confidence interval approaches have also been proposed (see, for example, [6, 12, 13], and [7]). Several researchers have suggested replacing Greenwood's estimate $\widehat{\text{var}}\hat{S}(t)$ by various estimators of the null variance of $\hat{S}(t)$ under the null hypothesis that t is the true median [3, 7, 13]. Extensive simulation studies to investigate the performance of these confidence interval procedures indicate that, in small samples ($N \leq 20$), use of

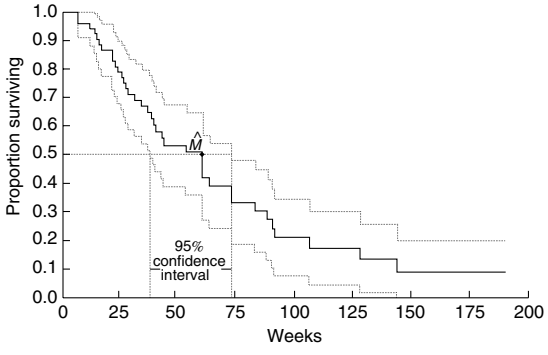

Figure 1 Illustration of confidence interval procedure for the median survival time using survival data from a colorectal cancer clinical trial [3]

the null variance may perform better than use of Greenwood's estimate with respect to coverage probabilities [7]. Pointwise confidence intervals for the survival curve based on $\log[-\log \hat{S}(t)]$ or $\arcsin\{[\hat{S}(t)]^{1/2}\}$ **transformations** have been found to perform well [2, 14]. This suggests that transformation of $\hat{S}$ may also improve the small-sample performance of confidence intervals for the median. Bootstrapped confidence interval procedures have also been described [5, 11] and give similar results. Confidence interval procedures for the difference between two medians from right-censored survival data have been described in [15]. Repeated confidence intervals for the median survival time with accumulating data have been proposed by Jennison & Turnbull [7].

To test the equality of k medians from uncensored data, the classical median test can be used [9, 16]. The median test for uncensored data consists of pooling the observations from k samples, determining the median of the pooled sample, then counting the number A_i in the ith sample that exceed the pooled median. The test statistic is

$$4\sum_{i=1}^{k}\frac{(A_i - n_i/2)^2}{n_i},$$

where n_i is the number of observations in the ith sample, and asymptotically has a χ^2 distribution with $k-1$ degrees of freedom. One generalization to right-censored data [4], involves defining the "pooled sample median" $\hat{M}$ as the median of a weighted average of the individual Kaplan–Meier estimates from each sample that is weighted by the relative sample sizes. The statistic is based on the deviation from 1/2 of each individual Kaplan–Meier estimate evaluated at the pooled median $\hat{M}$. We define $\mathbf{z} = \{\sqrt{N}[\hat{F}_i(\hat{M}) - 1/2]\}$, where $N = \Sigma n_i$, then the median test statistic for censored data is of the form $\mathbf{z}' = \hat{\mathbf{\Sigma}}^{-1}\mathbf{z}$, where $\hat{\mathbf{\Sigma}}^{-1}$ is a generalized inverse [4]. Under H_0, the test statistic is $\chi^2(k-1)$. An alternative generalization, proposed by Prentice [10], was based on a general family of linear rank tests for censored data and is particularly powerful for detecting location shifts in the double exponential distributions. Either version of the median test for censored survival data is especially sensitive for detecting differences in medians in location shifts. Other test statistics, such as the **logrank test**, will be more powerful against other alternatives such as the proportional hazards family.

Median

The sample median of a set of ordered data is the middle observation if the sample size is odd and the average of the two middle observations if the sample size is even. In the case of even sample size, any value in the interval between the middle two data points will serve as a median, but the midpoint of the interval is generally chosen by convention.

The median of a probability distribution is a point that divides the probability distribution into two equal parts. Let $F(x)$ represent a cumulative distribution function (cdf) (*see* **Random Variable**). If F is strictly increasing at m and $F(m) = 1/2$, so $m = F^{-1}(1/2)$, then m is the unique median. If a cdf is not strictly increasing at the prospective median, then more care is required for an analytical definition. Define the inverse of a cdf as $F^{-1}(t) = \inf[x : F(x) \geq t]$. Then $m = F^{-1}(1/2)$ is the unique median or is the left endpoint of the interval of medians. When F is the empirical cdf (*see* **Goodness of Fit**), m is the middle data value or is the first of the two middle data values.

The sample median is a **robust** estimate of the population median. It is robust in the sense that it is not affected by **outliers** (bounded influence function), and it takes roughly 50% contamination of the data to ruin it (50% breakdown point). The median is approximately normally distributed in large samples and the asymptotic variance (standard error) is $1/[4f^2(\mu)n]$, where f is the probability density function (pdf) of the population, μ is the population median, and n is the sample size. Sheather [3] reviews methods of estimation of the finite sample variance and the asymptotic variance of the sample median. It is interesting that the standard error of the median can be estimated using the **bootstrap** but not the **jackknife**. In fact, the bootstrap distribution of the median can be found in closed form and does not have to be **simulated** (see Efron & Tibshirani [1]).

The sample median solves the L_1 minimization problem; that is, it minimizes $\Sigma|x_i - t|$ as a function of t (*see* **Mean Deviation**). It is the **maximum likelihood estimator** for the center of a Laplace or double exponential distribution. Hence, for the Laplace distribution, the median is asymptotically optimal. On the other hand, when the underlying distribution is normal, the **asymptotic relative efficiency** of the median relative to the mean is only 0.637. The median shares efficiency properties with the simple **sign test**.

In biostatistics it may be of interest to estimate the median of a survival distribution in a **censored data** setting (*see* **Median Survival Time**). In this situation the empirical cdf is replaced by the product limit estimate (PLE) $\hat{F}$ due to **Kaplan & Meier** [2]. Then the estimate is based on $\hat{F}^{-1}(1/2)$; see Reid [5] for a nice discussion.

The median can be defined for multivariate distributions, and then estimates can be developed from the multivariate data. Small [4] surveys the various ways that the idea of median has been extended into high dimensions under various types of equivariance requirement.

Medical Devices

Introduction

A medical device is any item that treats or diagnoses a health condition but whose action is not primarily chemical or biological. Simply defined, it is any product used in medicine that is not a drug or a biological agent. The array of products that fall within the medical device category is extremely broad; they range from tongue depressors, syringes, and wheelchairs to coronary stents, DNA microarrays, and CT scanners. The diversity of the industry makes medical devices an exciting arena in which advances in a host of basic science and engineering disciplines can be brought to bear on the improvement of human health. It is also the source of many interesting research areas in the statistical sciences.

This article will focus initially on the design and analysis of therapeutic devices and implants (nondiagnostic devices), with some discussion of sham devices and **blinding**, noninferiority (*see* **Equivalence Trials**) and active control studies, **survival analysis** and repeated measures (*see* **Multiplicity in Clinical Trials**), and the use of historical controls (*see* **Bias from Historical Controls**). Attention will then turn to diagnostic devices, with emphasis on **microarrays**, and Bayesian approaches to medical device studies (*see* **Bayesian Methods in Clinical Trials**). It will conclude with some discussion of surveillance of medical devices (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**).

The Nature of Nondiagnostic Medical Device Studies

In many cases, the mechanism of action of a medical device is well understood and is local as opposed to systemic. Compared to other medical products, such as pharmaceutical drugs, medical devices tend to have a much shorter commercial life cycle. Typically, it may take only two years for a medical device to become obsolete after its first use as it is often supplanted by a newer model. In contrast, drug product lines can last 10 to 20 years or more. Devices usually evolve by a series of small changes, and the pace of invention can be very fast. Often, there is almost constant tinkering with the design and manufacturing of a medical device. Consequently, in some cases, there are a large number of models for the same, or only slightly different, indications. The fast evolution of medical devices, coupled with a built-in expectation by the public that newer is better, presents unique challenges in designing and evaluating medical device studies [92]. For some devices, a randomized **clinical trial** may not be feasible because of the difficulty in recruiting patients. Statistical challenges include coping with changes to the protocol (*see* **Clinical Trials Protocols**) and perhaps even to the new device during the course of a clinical trial to evaluate the effectiveness and safety of the device.

Placebo Effect and Sham Controls

In studies of medical devices, there are many instances in which evidence for a **placebo** effect exists, that is to say, people react differently if they are in a clinical trial, regardless of whether they know (or even strongly suspect) which treatment they are receiving. This is especially worrisome when the primary outcome measured is something like pain or function as subjectively assessed by the patient and sometimes by the physician or health care worker. The statistical issue here is, of course, bias (*see* **Bias, Overview**). One way to remove bias due to the placebo effect is to have some sort of sham (or placebo) control as a second arm in a randomized clinical trial. Therefore, the sham as a control plays an important role in the evaluation of the safety and effectiveness of medical devices, especially those devices for the treatment of pain or function [46, 61, 65, 90]. In the interpretation of study results, in addition to placebo effects, many factors could account for the apparent effect of the sham device: natural course of disease, fluctuation of symptoms, **regression to the mean**, patient bias, and physician bias.

However, compared to drug evaluations, the well-designed placebo-controlled clinical trial design is used less frequently in medical device applications because of ethical or practical reasons (*see* **Ethics of Randomized Trials**). Randomizing patients into the sham control arm may raise serious ethical concerns, especially when considerable risk is involved, such as in the case of sham surgery. As an alternative, an active control is widely used, and even a historical control (*see* **Bias from Historical Controls**) is employed when indeed appropriate. Of

course, in an active-controlled device trial, two active treatments might have different amounts of placebo effects so that an observed treatment difference might result from differences in their placebo effects rather than differences in the treatments themselves, which makes study design and interpretation more challenging.

Blinding or Masking

In a medical device study, masking (or blinding) the subjects to which treatment they are receiving is essential to control for the bias associated with knowing what treatment is being administered. Piantadosi [74] observes that **blinding or masking** helps to control the Type I error (*see* **Hypothesis Testing**). Unfortunately, in some instances involving medical devices, it may be impossible to mask the patient or the investigator/surgeon as to who receives which treatment or implant. A third party evaluator who is masked to the treatment assignment is often employed in such cases.

An interesting situation occurs when the trial is blinded, but the patients at the end of the trial are asked to guess the treatment assignment that they have received. In essence, this is a possible way to check whether the blind has been maintained. While it is possible to correctly guess the treatment in pharmaceutical trials, it is more likely in many device trials. Sometimes the symptoms one experiences are dead giveaways as to which treatment has been received. Informed consent (*see* **Ethics of Randomized Trials**) often guarantees that patients have this information. An interesting statistical problem is to figure out how to use data on patient perception of treatment assignment to assess the possible bias and, more interestingly, how to correct for it.

Comparisons of Statistical Issues for Device and Drug Trials

Medical device studies share many of the same issues that drug trials do [15]. These range from **missing data**, adjusting for interim looks, and **Data and Safety Monitoring Boards** (DSMBs) (also called Data Monitoring Committees (DMCs)) to **intention-to-treat**, **multiplicity** (of tests and endpoints), and **time-dependent covariates**. Since often there are difficulties in carrying out long-term device studies, there tend to be more missing data than one might expect for most pharmaceutical trials. In the context of medical devices, there are publications that address **surrogates** [20] and subgroup analysis (*see* **Treatment-covariate Interaction**) [86]. One topic that is of more interest perhaps in medical device clinical trials is that of the **interaction** between treatment effect (control versus new device) and center. In medical device studies, such interactions are of interest since they may be an indication that there are significant differences in how the devices are used from center to center, requiring a protocol revision or better training concerning the use of the device. Another challenging area concerns changes to the protocol or to the device during the course of the study.

Implants

Implanted medical devices pose unique challenges to the evaluation of their performance. As with most surgical procedures, there is often a learning curve; namely, the ability to implant or to use the device improves with familiarity. Implants are usually designed to be in the body for a long period of time. Therefore, there is increased importance for the statistical tools of **survival analysis** and repeated-measures analysis (*see* **Multiplicity in Clinical Trials**). Whereas the administration of drugs can be discontinued because of serious adverse events, a problematic implant may need to be explanted.

Survival Analysis

Survival analysis is frequently applied to time-to-event data in clinical studies of medical devices. For devices requiring long-term follow-up, such as implanted devices, outcomes are often expressed as probabilities or rates. For example, one might assess the 24-month fusion success/failure probabilities for spinal fusion devices and for hip and knee implants or the 6-month major adverse cardiac event rate for coronary stents. Statistical issues frequently encountered in medical device survival analysis include small sample adjustments for estimating 95% **confidence intervals** of cumulative survival probability, comparison of crude event probabilities, linearized event rates or **incidence densities**, **life-table** probability, survival experience extrapolation

and prediction beyond the last observed follow-up [50], **matched**-pair and **multivariate survival analyses**, recurrent events (*see* **Repeated Events**), and **random-effect** survival analysis with **frailty** parameters.

Since the sample sizes encountered in medical device follow-up studies are often smaller than those in drug trials, there may be fewer observed events at later, but clinically important, follow-up times. In those situations, the routinely used Greenwood formula (*see* **Median Survival Time**) available in standard statistical software underestimates the **standard error**. In [50], several statistical approaches are proposed to improve estimation of standard error and hence the 95% confidence interval.

Investigators sometimes wish to **extrapolate** or predict future survival experiences beyond the last available observation in the follow-up. For example, a two-year implanted-device survival is sometimes predicted from observed one-year data. The frequentist approach generally requires the following statistical validation procedures: parametric **model** building based on a sufficiently large number of events, parameter **estimation**, **diagnostic** checking, **prediction** or **forecasting**, and periodic model validation (*see* **Model Checking**). Clinically important **covariates** should also be investigated during parametric model building [50].

In medical device trials using the **matched-pair** design, experimental and control treatments are randomly assigned to different locations or sites within a patient, such as bilateral knees, hips, or eyes, or multiple teeth or skin locations. Owing to the correlation between two or more locations within the same patient, nonstandard survival analysis methods are required to analyze such matched-pair time-to-event data. If no censoring occurs (*see* **Censored Data**), then one may transform the time-to-event into an occurrence of an event prior to a prespecified follow-up time and analyze these data as correlated binary data; such data have been called current status data. For matched-pair survival data with censoring, which is often seen in device trials, some methods can be found in [36, 37, 56, 68].

In medical device trials, **survival analysis** is commonly applied to time-to-first-event data. However, in some cases, repeated events of the same type or different types are frequently seen. Examples are catheter restenosis for kidney dialysis patients, restenosis for cardiac patients with balloon catheterization or stent implant after catheterization, repeated air leaks for pulmonary patch, repeated device migration or infection for hip and knee implants, and repeated infections for cochlear implants. Survival analysis applied to repeated events, in addition to the first event, provides useful clinical insight into device performance over long-term follow-up. Statistical models for such data include **marginal models** [88].

Other issues, such as **time-dependent covariates**, **multivariate survival analysis**, and random-effect **frailty** models, are also relevant in medical device trials.

Repeated Measures

The repeated-measures design is common in medical device clinical studies, particularly with implanted devices for which study patients are observed at various follow-up times after initial implant, diagnosis, or randomization (*see* **Multiplicity in Clinical Trials**). Such design could occur in either a two-arm, parallel, randomized, prospective **multicenter trial** or a single-arm, prospective study. Most scheduled follow-up times are unequally spaced, such as, at baseline, 1, 3, 6, 12, and 24 months posttreatment. Types of clinical data include continuous, ordinal (such as pain score by visual analog scale), binary (such as implant success or failure), or **Poisson** count data (such as number of epileptic seizures or headaches after neurological device treatment). A repeated-measures design can also be employed in conjunction with paired data, such as those seen in ophthalmic, dental, ear, and orthopedic devices. Various statistical methods used in a repeated-measures design include repeated-measures **analysis of variance** (RMANOVA), **multivariate analysis of variance** (MANOVA), time-by-time comparisons by analysis of variance (ANOVA), general mean response or **mixed model**, **generalized estimating equations** (GEE), and profile analysis (*see* **Summary Measures Analysis of Longitudinal Data**). **Analysis of covariance** (ANCOVA) is often used to adjust treatment effects for baseline differences. Sometimes analyses are based on derived variables such as change from baseline, percentage change from baseline, binary outcome based on a clinically acceptable cutoff point such as 50% change from baseline, summary statistics such as slopes, and others. In these cases, the correlation between the individual patient baseline value

and the derived response variables should be carefully evaluated in order to choose derived response variables appropriately. The advantages and disadvantages of each of these statistical methods in the context of medical device applications are discussed in [51].

Subjects with **missing data** are a frequent occurrence in medical device repeated-measures follow-up studies. Various statistical assumptions have been made in handling missing data, including missing at random (MAR) and missing completely at random (MCAR). Those assumptions are relied upon to various degrees in mixed models, GEE, last value carried forward (LVCF) (*see* **Clinical Trials of Antibacterial Agents**), **multiple imputation methods**, and others. Both **intent-to-treat** and per-protocol (*see* **Clinical Trials of Antibacterial Agents**) approaches are often evaluated for medical device trials.

Observational Studies and Causal Inference in Medical Device Evaluation

Just as in any other area of medicine, for medical devices, the randomized clinical trial (RCT) is the most rigorous empirical tool for the investigation of treatment effects. Nevertheless, sometimes studies that do not involve explicit randomization in their design, that is, **observational studies**, are proposed as a supplement, or even a substitute, for a randomized clinical trial. A typical example in the context of medical device evaluation is using for comparison the treatment (or control) arms from previous clinical trials. Those comparison groups are usually called historical controls (*see* **Bias from Historical Controls**). It is often the case that observational studies compare favorably with RCT in terms of cost, making them an attractive alternative. Of course, any cost advantage of an observational study always comes with a major shortcoming, namely, vulnerability to potential bias. The problem of **bias in observational studies** is a challenging subject in statistics, for which systematic methodologies have been developed only relatively recently. The medical devices arena is one of the areas in which those methodologies are already beginning to have an important and fast-growing impact.

The concerns over bias in an observational study arise most naturally when the treatment group differs systematically from the historical control in the distributions of observed **covariates**, characteristics that are currently believed to be possibly related to the outcome; this situation is referred to as overt bias [76]. One way of dealing with the problem of overt bias is by dividing subjects into subclasses within which the distributions of observed covariates are similar among the treatment groups. Treatment comparison within each subclass would then have less bias due to observed covariates. Such subclasses are referred to as either strata or matched sets and their construction as **stratification** or matching. At first sight, one would expect that such a scheme of covariate balance would suffer from the usual curse of dimensionality, that is, it would be infeasible when more than a few covariates are to be balanced. The statistical theory of **propensity scores** [77] reassures us that this need not always be the case. In fact, for comparing two treatment groups, the task of covariate balance is essentially a one-dimensional problem involving a function of covariates called the propensity score, defined as the **conditional probability** of being in one of the treatment groups given the value of the covariate vector. Covariate balance using estimated propensity scores can be very effective in practice, as shown in the classic example in [78], involving 74 covariates and 2 treatment groups of sizes 590 and 925, respectively. The practical utility of the propensity-score approach has become more and more widely recognized, and there is now an emerging literature on its application in studies involving medical devices (e.g. [32, 67]).

While overt bias can be addressed by covariate balance, hidden bias is more difficult to deal with directly. To see the distinction between these two kinds of bias, we first need to define them more precisely. Within modern statistics, the notion of bias is inextricably linked to that of causal inference (*see* **Causation**), which is formulated on the basis of the two key concepts of potential outcomes and assignment mechanism [81]. According to the currently widely accepted statistical theory of causality [79], the causal effect of treatment A on a unit relative to treatment B (e.g. control) for an outcome variable is the difference between the two potential values of the outcome variable of the unit under the two treatments. A causal estimand is a parameter that compares the distribution over a set of units of the potential outcome under treatment A to that over the same set of units under treatment B (e.g. [27]). By definition, the potential outcomes of a unit under treatments

A and B can never both be observed. The task of statistical causal inference is to obtain valid estimates for causal estimands under the above constraint. This can be achieved by design, as in RCT, by assigning treatments to units according to an explicit and known probability model. In observational studies, causal inference can be conducted through the postulation of plausible assignment mechanisms. If the postulated plausible assignment mechanism is ignorable [80], that is, if it follows a probability model in which the probability of a unit being assigned to a treatment is independent of the unobserved potential outcomes, given observed covariates, then there is only overt bias, which can be addressed directly using covariate balance (*see* **Covariate Imbalance, Adjustment for**).

If the assignment mechanism is nonignorable, there will be hidden bias. Hidden bias can be modeled via a hypothetical unobserved covariate that is related to both treatment assignment and outcome. Such models may be used to perform what is called **sensitivity analysis** to address the issue of hidden bias indirectly, by asking how the causal inference would be altered under various assumptions about the behavior of a hypothetical unobserved covariate. For example, we may specify a class of probability models for the dependence of treatment assignment on the unobserved covariate and calculate extreme distributions of some test statistic under the class of models and the null hypothesis. This would give us a range for quantities determined by the null distribution, such as ***P* values** and estimates of an additive effect. If under the relatively severe dependence of treatment assignment on the unobserved covariate, the range of P values remain significant and the range of estimates point to effects in the same direction, then the conclusion of the study is said to be insensitive to hidden bias. Extensive discussions on this subject can be found in [76].

Observational studies are important to medical device evaluation and not just because they can be attractive alternatives to randomized clinical trials. It is not uncommon for studies designed as RCTs to eventually acquire features of observational studies because of complications such as noncompliance (*see* **Compliance Assessment in Clinical Trials**). Indeed, a continuum is thought to exist between an ideal RCT and a typical observational study. We often find ourselves to be at neither of the extremes and would thus benefit from statistical causal models that deal with situations across the whole continuum [3, 38]. Such statistical causal models also tend to provide a framework within which conventional statistical thinking can be improved upon. For example, the unifying theory on causal modeling [27] has proved to be helpful in giving a clearer, scientifically more meaningful definition for the concept of surrogacy (*see* **Surrogate Endpoints**). Of course, the availability of statistical techniques that address deviations from an ideal RCT does not in any way free us from the responsibility of trying our best to follow the protocol of an RCT as closely as possible.

The medical devices arena provides a fertile ground for the application of causal models. It has a large demand for empirical investigations of causal effects, and, moreover, the nature of the investigation often imposes special structural features and constraints that may present interesting and challenging cases for study design and causal modeling. The practice of double blinding, which is standard in many areas of medicine, is sometimes quite difficult to implement for medical devices. Treatments involving medical devices also tend to be more complex in structure, often consisting of multifaceted components. Devices of the same model may differ in engineering perfection, and medical professionals who are responsible for deploying them may vary in skill levels. Therefore, in conceiving a treatment with a medical device as homogeneous, some idealization is inevitable. Causal modeling can also play an important role in the evaluation of combination products, those involving both drugs and devices.

Noninferiority and Active Control Trials

A noninferiority active control clinical trial design is an increasingly popular approach for evaluating medical devices (*see* **Equivalence Trials**). The primary objective of such a trial is to demonstrate that a new (experimental) device performs as well as an existing one (active control). The design is useful when the new device is preferable for reasons such as a longer lifetime or a superior safety profile. The fundamental principles of these trials and the statistical methodologies applied in the area of therapeutic devices are the same as those in the area of drug development [10, 26, 87]. However, some statistical issues and design concerns have been encountered in medical device studies more frequently than in other

studies [96]. Some typical design and data analysis issues include the formulation of study hypotheses, the selection of active controls, the requirement of prespecified noninferiority margins δ (>0), the possibility of multiple testing procedures for different claims, and the need for appropriate data analysis for different study designs.

Blackwelder-type hypothesis testing is usually employed in medical device studies; the **alternative hypothesis** would be that the new treatment is not worse than active control by more than δ, with respect to some parameter of interest, such as proportion or mean. Unfortunately, some investigators attempt to use a conventional superiority alternative hypothesis to investigate noninferiority in some device studies. It is pointed out [10] that in determining whether a new device is as effective as an active control, the test of the conventional null hypothesis of equal effects is inappropriate and leads to logical difficulties. In particular, failure to reject the alternative hypothesis in the conventional superiority testing does not establish noninferiority [2].

An active control could be another effective device or standard of care. However, there is the danger that a series of active control trials might push the general treatment in the wrong direction by testing devices that are progressively inferior to previously active controls, which is called device creep. Also, it would be inappropriate to select as an active control a device that is out of date due to rapidly developed new technology.

A noninferiority active control study should have the ability to distinguish the new device from ineffective products; in pharmaceutical circles, this is referred to as assay sensitivity. The effectiveness of an active control can be demonstrated through its effect size, which is the treatment difference between the active control and the sham control. (A comparison to the no-treatment control instead of the sham could lead to bias and consequently a misestimated effect size.) However, the active control effect size cannot be measured in the current study since there is no sham arm; consequently, this effect size has to be deduced on the basis of historical experience showing the superiority of the active control over the sham. Some choices for estimated effect size include a point estimate of effect size from one large historical sham-controlled study or from multiple such studies. But the use of a point estimate is of concern since it disregards the uncertainty associated with the point estimate. To account for this uncertainty, a **Bayesian** approach could be employed [87].

Another crucial consideration concerns the choice of the reasonable noninferiority margin δ. This quantity should be sufficiently smaller than the effect size of active control so that from a clinical point of view a new device can be considered effective when a noninferiority claim is confirmed. In particular, the choice of δ should not lead to a situation where the new device is essentially equivalent or worse than the sham or no treatment, yet the null hypothesis of inferiority by more than δ is rejected.

In recent medical device active control studies, there is an increasing interest in hypothesis-testing procedures that simultaneously test for superiority and equivalence [64]. A test of conventional superiority (new device is better than active control) after claiming noninferiority or a test of noninferiority after failure to claim superiority reduces to simultaneous testing for noninferiority and superiority using a one-sided $(1-\alpha)100\%$ confidence interval. It is known that, given a prespecified noninferiority margin δ prior to analysis of trial data, the procedures need no adjustment for **multiplicity** by the closed testing procedure. However, it is crucial that the noninferiority margin δ be predetermined and described in a protocol; otherwise, a data analysis can always find the minimum value of δ, leading to a claim of noninferiority of the new device.

An interesting question is, given that one is willing to accept some decrease in the effectiveness up to δ for the new device and still consider it noninferior to the active control, should the device, by symmetry, be not just better by any amount but superior by a specified amount δ than the active control to qualify for superiority. That is, if the roles of the new treatment and active control are allowed to reverse, can one conclude that the active control is noninferior to the new device as long as the active control is not worse than the new device by δ? It implies that the new device is not superior to the active control if the magnitude of superiority of the new device over the active control is between 0 and δ, which conflicts with conventional superiority testing. In statistical terms, it is in fact a question of which superiority hypothesis should be tested following the noninferiority conclusion, the conventional superiority testing for any treatment difference or the one that confirms a difference of a prespecified magnitude δ [17].

Diagnostic Devices

Diagnostic devices are fundamentally different from therapeutic devices in that they are intended for detecting a condition rather than treating it. They can be broadly classified into two categories: *in vitro* and *in vivo*. Genetic tests and tests for blood glucose, cholesterol, hepatitis, and HIV are all laboratory tests based on tissue or blood specimens sampled from patients and therefore belong to the first category. Implanted glucose meters, devices using autofluorescence to detect disease, apnea monitors, and all sorts of diagnostic imaging (e.g. magnetic resonance imaging, ultrasound, mammography) are in the second category because all these involve test procedures performed directly on the patient. (*See also* **Diagnostic Tests, Evaluation of**.)

Diagnostic devices may generate quantitative or qualitative results. Blood glucose levels and cholesterol levels are examples of quantitative measures; in contrast, the results of influenza and pregnancy tests often take only two values, labeled positive and negative, and are qualitative measures. Quantitative measures can be transformed into dichotomous (qualitative) results via a threshold or cutoff value. For example, we may encode a quantitative prostate screening antigen (PSA) test result as positive or negative depending on whether the value is larger than or smaller than the threshold of, say, 4 ng/mL. Multiple cutoff points may be applied to a quantitative test to generate ordinal categories, for example, urinalysis of glucose with test results of negative, trace, 1+, 2+, and 3+ (*see* **Ordered Categorical Data**). Ordinal categories can also arise directly as in the case of the breast imaging recording and data system (BI-RADS®) scale of 0 to 5 for mammography.

If multiple tests can be applied to the same subject or specimen, it is frequently argued that the most efficient design is to have each person serve as his or her own control. However, without randomization, one must be on constant guard to control bias [4]. For large **screening trials**, randomization to one of two independent arms is often employed to compare different screening strategies. In the case of mammography, digital versus analog, the additional radiation exposure of two mammograms is a consideration for a single-arm diagnostic trial.

The performance of a test producing a dichotomous measure (positive and negative) is measured by its **sensitivity** and **specificity** when there is a truth standard (a **gold standard test**). The performance may also be evaluated on the basis of (positive and negative) **predictive values**; however, these latter values depend explicitly on **prevalence** as well as sensitivity and specificity. The comparison of two dichotomous tests is often problematic unless one test is simultaneously statistically superior to the other in sensitivity and specificity; more often than not, one test has better sensitivity and the other has better specificity. (For tests that are inherently continuous, it is usually preferable to perform the comparison before dichotomization, as discussed below.) Several references for the statistical methodologies for diagnostic tests are [71, 97]. A recent recommendation on the reporting of diagnostic accuracy studies is given in [12].

The absence of a truth standard presents challenges to the evaluation of qualitative test performance. One possibility is to evaluate a test on the basis of its agreement with another test. But two tests can agree and both can be incorrect. While it is often helpful to report the entire **2 by 2 table**, measures of agreement called positive and negative percent agreement are sometimes quite helpful. For example, positive agreement of a new test to its comparator is the percent that the new test is positive, given that the comparator is positive. Agreement can also be extended to ordered categories using the weighted **kappa** statistic. However, the comparison of two tests in the absence of truth can at most only establish equivalence but never the superiority of one test over the other.

Sometimes, the gold standard is available but cannot be applied to all study subjects for practical reasons. For example, in a study to evaluate the performance of the prostate screening antigen (PSA) test and the Digital Rectal Examination (DRE), the gold standard (biopsy) is usually not applied to the subjects with negative DRE results and negative PSA results. If the gold standard is applied when either test is positive, one could compare the performance of the two tests using the ratio of sensitivities and (1-specificities) [72]. However, sometimes this is not possible since for a new unproven test it may be very difficult to argue for the invasive biopsy. A more valid comparison in this case is to ask whether PSA adds any diagnostic capability to DRE since the PSA test is viewed as adjunctive and not "stand alone". When the gold standard is more likely to be applied to subjects who appear to be at high risk

for the disease, there can be bias in the estimation of the diagnostic accuracy of the test (verification bias). Here "intention-to-diagnose", a term coined by statisticians at the Food and Drug Administration's Center for Biologic Evaluation and Research, and not **intention-to-treat** (ITT), is the principle at work. As in ITT, it is very risky to ignore such missingness. One approach is to use imputation (*see* **Multiple Imputation Methods**) to develop unbiased estimates of sensitivities and specificities and then to inflate the nominal variances of these estimates to account for the imputed values, or alternatively, to use a **bootstrap** approach.

Sometimes, a random sample of subjects who test negative is assessed with a gold standard test. For example, in a study to evaluate the performance of the Human Papilloma Virus (HPV) test and the Pap test for the detection of cervical cancer, all women with either HPV positive results or abnormal Pap results were referred to the gold standard of colposcopy, and 10% of all women with negative HPV results and normal Pap results were also referred to colposcopy. The results of colposcopy of other subjects with negative HPV results and normal Pap tests can be considered a **missing-data** problem. With such data, it is possible to estimate sensitivity and specificity with confidence intervals [35].

A problematic but still common method of evaluating two tests is called discrepant (or discrepancy) resolution. The idea is to subject the off-diagonal entries (entries where the two diagnostic tests disagree) to further testing. The use of these results to modify the original table to produce estimates directly leads to bias in the estimation of performance [33, 63].

The diagnostic accuracy of a quantitative test can be evaluated by **Receiver Operating Characteristic** (ROC) analysis. The ROC plot is a graph of the observed sensitivity versus the 1-observed specificity of the diagnostic test, evaluated at all possible thresholds that one could use to dichotomize the diagnostic test [98]; the ROC plot is the empirical version of the ROC curve. One global measure of the diagnostic capability of the test is the area under the (empirical) ROC plot. Typically, in a study comparing a new device to an established one (the predicate device), each study specimen is tested with both the tests. The bootstrap method is quite helpful in reflecting the variability of the ROC plot and in comparative analysis [14]. In addition, if one wished to identify the threshold associated with say 90% observed sensitivity, one could reflect the variability associated with the particular derived threshold by a confidence interval based on bootstrapping.

Three measures of analytical performance of the tests are systematic bias, precision, and limit of detection. Systematic bias, the difference between the mean of the results of measurements and a true value, is one important characteristic. For the *in vitro* laboratory test, this true value could be that of an analyte, and for *in vivo* tests, an example would be temperature from an ear thermometer. Usually, systematic bias of a new test can be evaluated by a **regression** analysis of the new test on the reference method. If it can be assumed that the reference test measures the true value with no error, the performance can be determined using ordinary **least squares** regression, comparing the deviation of the slope from 1 and the intercept from 0. The amount of **random error** manifests itself through agreement between results of independent measurements under stipulated conditions. Variability is usually expressed numerically by **standard deviation** and its inverse, precision, or by the coefficient of variation (*see* **Standard Deviation**). For an analyte, as the concentration being measured gets smaller and smaller, its presence is harder to ascertain. The limit of detection is the lowest concentration that can be reliably distinguished from zero, with α and β for the two types of error. For a sample containing no analyte (blank sample), the $(1-\alpha)$-quantile of the distribution of blank values indicates a limit that for the blank sample is only exceeded by a probability of α. The samples that provide values exceeding this limit may be declared to contain nonzero analyte (type I error α). At the same time, some of the measurements of the sample with a low amount of analyte fall below this limit and hence are declared to be zero analytes (type II error β). One statistical approach to this problem that assumes Gaussian error distributions (*see* **Normal Distribution**) is given in [19].

The absence of a gold standard in the case of continuous data creates a challenge. For two tests, it may be sufficient to investigate how similar they are; this is often called method comparison. In the case in which there are **errors in variables** (or measurement error in both tests), one can employ measurement error models [28]. In the medical device literature, this approach may be remedied

by orthogonal regression (*see* **Orthogonality**), Deming regression, or Passing–Bablock regression [70]. The Bland–Altman plot is especially helpful [11] for investigating not just relative bias but also heteroscedasticity (*see* **Scedasticity**). Hawkins extends this to a more formal regression approach with regression diagnostics to examine model assumptions [34]. The notion of equivalence, especially individual equivalence, can depend not just on the slope and intercept but also on the variability about the line [75] (*See also* **Diagnostic Test Evaluation Without a Gold Standard**).

Some diagnostic devices are used for special purposes. There are qualitative tests used for triage to avoid more difficult, expensive, or invasive procedures. For example, in some age groups, a test for HPV is used to decide whether to send patients with an abnormal Pap smear to colposcopy. Monitoring devices track certain medical conditions over time to detect changes from baseline or normal or to detect changes in dose response to medications. Blood glucose meters, prothrombin time tests, and pulse oximeters are examples of such devices. For these devices, it is usually more appropriate to use equivalence based on the individual rather than on the population because the absolute difference between the measure and the true value may cause danger to patients.

Repeated measures or **longitudinal data analysis** are frequently applied to diagnostic medical devices, such as in an equivalence study via matched-pair comparison between the gold standard and the test kit for glucose measurements, taken at various follow-up times. The repeated measures can be equally spaced or unequally spaced, balanced or unbalanced (each patient may have different numbers of repeated observations), with or without missing data. Statistical methods used to evaluate equivalence of two-test methods in matched-pair repeated-measure or longitudinal data analysis include simple ordinary least squares, generalized least squares, GEE, overall mean paired difference with 95% confidence interval, random-effect regression model, repeatability and reproducibility studies, and concordance correlation [53].

Diagnostic Imaging

A particular application of *in vivo* tests is diagnostic imaging (*see* **Image Analysis and Tomography**). The data can be quantitative or qualitative and for the latter tend to be ordinal. An example of an ordinal scale is the BI-RADS scale that is employed in mammography. There are advantages to having finer ordinal scales where possible; for breast cancer, some advocate a 100-point scale corresponding to the estimated probability of malignancy rather than the coarse BI-RADS scale. ROC methodology can be used to determine whether an imaging technology has any diagnostic capability or whether a new diagnostic test has any adjunctive capability relative to other known test(s). Examples include mammography and chest X rays.

In many diagnostic-imaging situations, there is considerable variability in the readers of the images. This can be an impediment to investigating whether a new imaging system is superior to others as well as in investigating whether it is noninferior to an existing system. An example of the latter is digital mammography in comparison to analog mammography. One might expect the two to be very similar, but the reader-to-reader variability makes this difficult to assess. Beiden, Wagner, and Campbell [5] have employed **bootstrapping** to study the **components of variance** in such comparisons and to model explicitly the reader variability and the case variability in order to compare two modalities. In the case of digital mammography, this approach has been used in a study design to figure out how to trade off cases and readers.

For a recent discussion of the evaluation of medical imaging and **computer-aided diagnosis** (CAD) systems, see [91]. Diagnostic-imaging tests present unique study design problems. In the case of readers, it is often a question of what information is available and when. A reasonable design is to gradually provide more information and observe the ratings and how they change. For example, the diagnostic image may first be read with no other information and the rating recorded and then read with clinical information to see whether the rating changes. A further design difficulty in some studies that rely on the same readers for different modalities is that some readers claim to remember the films and the ratings from a first reading, even if one month or more time has elapsed. In the case of CAD, the presence of the technology may affect the performance of the reader either by increasing his or her vigilance before the application of CAD or, retarding it, by anticipating that the CAD system will pick up any oversights. There are also issues

associated with satisfaction of search after obtaining the CAD results.

Microarrays

While most diagnostic *in vitro* medical devices have been designed to test for a single analyte that is associated with disease, **microarrays** are a revolutionary medical device technology that can be used to study thousands of analytes simultaneously and, by doing so, have the potential to advance dramatically the diagnosis, treatment, and prevention of disease. Microarrays can be used to diagnose disease, screen for the mutations or single nucleotide **polymorphisms** (SNPs) associated with increased risk of disease, develop new classification systems for stages or subclasses of disease, identify drug or gene therapy targets (e.g. genes or proteins) in the treatment of disease, and predict drug response and drug toxicity in individual patients. Microarray data can also be used to study interactions on phenotypes among genes and between genes and environmental exposures. In short, microarrays enable the genomewide study of biomarkers, genes, and proteins, which promises to produce dramatic advances in our understanding of molecular variations among normal and diseased populations. A very good introduction to the relevant biology, chemistry, and technologies is given in [85]. Overviews of statistical methods for microarrays are given in [83, 85].

A DNA microarray is a glass or other surface onto which many thousands of individual **DNA sequences** are printed. The DNA sequences are called probes and are typically either cDNA, single-stranded clones of entire DNA sequences of genes, obtained by reverse transcription of mRNA, or oligonucleotides (oligos), synthetic DNA representing short specific segments of DNA sequences. In microarray experiments, mRNA from cells of a sample are extracted, labeled with fluorescent dye, and then allowed to combine with or *hybridize* to probes on the array. An mRNA molecule will, in principle, only hybridize to the complementary probe on the array. The relative expression of the gene (mRNA abundance) can be quantified by measuring the fluorescence intensity at the spot of the probe.

The large amount of information generated by gene expression microarray experiments is unfortunately accompanied by complex questions relating to quality control [49, 73]. Fluorescence measurements of gene expression are obtained by a sequence of image analysis steps that include locating the spots within grids (addressing), distinguishing spots from the background (segmentation), measuring fluorescence intensity via laser scanning, and correcting spot intensities for background intensity (cf. [94]). The intensity at the spot may have to be adjusted for the shape of the spot and the amount of probe that has been laid down. Reproducibility of intensity measurements is key to validating microarray data. Recently, guidelines on the minimum information about a microarray experiment (MIAME) have been published [13].

A major statistical issue in the design of microarray experiments is that they typically involve the study of a very large number of variables (e.g. thousands of genotypes or gene expressions) on a relatively very small number of experimental units (e.g. tumor samples). The obvious problem is that outcomes such as disease status are overfit by statistical models using as many variables as samples.

The designs of cDNA and oligo arrays are different [84]. cDNA microarrays are in an **incomplete block design** in that they involve a competitive hybridization of mRNA from two samples to the cDNA probes. The mRNA from the two samples are labeled with different color dyes (e.g. green and red fluorescent dyes Cy3 and Cy5) and mixed before hybridization. The intensities in both the red and green channels can be measured separately with the laser scanner, and a comparison is usually based on their log ratio. Early experiments compared each sample with a reference, with the same dye always being used for the reference (e.g. Cy3); statistically, this design is not desirable because it does not control for dye effects (differential dye efficiencies) and gives too much information on the reference, which is not of interest. The *dye swap design* adjusts for dye effects by comparing the sample with the reference on two arrays, with the dyes being swapped for the second array. The dye swap design is a **Latin square design**, where array and dye are **blocking** factors with two levels each. The *loop design* forms a cycle of comparisons of reference to sample 1, sample 1 to sample 2, and so on up to sample n to reference, with the first in the pair always labeled with, say, green dye [48]. This design could be considered an incomplete Latin square in that each sample appears once each in a pair of the n+1 arrays

and once for each dye. The loop design eliminates dye effects and is efficient at obtaining information on samples, but if one array is unusable, then the optimal properties of the design are destroyed. Designs that are more **robust** to unusable arrays are being considered.

In oligo arrays, each gene is represented by 16 to 20 probe pairs of oligos. Each pair consists of a perfect match (PM) probe and a mismatch (MM) probe, in which the central nucleotide base is inverted. The probes are scattered across the array. One sample labeled with fluorescent dye is allowed to hybridize to probes on the array. The intensity of the sample is measured by a summary of the PM intensities corrected for a summary of the MM intensities, which serves as a control. Because only one sample is hybridized per array, comparisons of samples are completely **confounded** by array effects unless the arrays are replicated for the sample.

Normalization refers to adjustment of the intensities for systematic biases, such as dye effects in cDNA arrays, array effects, and spatial effects within arrays. Regression models of the intensities can be used to adjust for confounding effects [16, 47, 89, 93]. Such models typically include main effects for genes, main effects for varieties of samples (e.g. tumorous versus non-tumorous), and gene by variety **interactions**; here the interactions represent the effects of interest, that is, the differential gene expressions among the varieties. Confounding effect that can be included in the model are array effects, spatial effects within arrays (e.g. spot effects), and dye effects (for cDNA arrays). Array effects are random, but nonetheless, they are sometimes considered to be fixed because this assumption simplifies the analysis considerably. The number of confounding effects can be considerable, which suggests that **propensity-score** methods [77, 78] that are used to adjust observational studies for numerous confounding effects might be useful in microarray experiments. For cDNA arrays, dye effects depend on the mean intensity level. These effects are commonly examined with a so-called M−A scatterplot, where M is the log ratio of intensities for two samples and A is the log of the geometric mean of the intensities. The intensity-specific effects are commonly adjusted out by fitting a lowess curve [18] to the scatterplot. Assuming only a fraction of the genes are differentially expressed between the two samples, the lowess curve can be considered to represent the average log ratio at a given intensity level when there is no differential expression at that level [24].

One goal of microarray experiments is to find all the genes that are differentially expressed between two varieties of samples (e.g. tumorous versus non-tumorous). These genes can then be used to create a specialized microarray for diagnostic testing, for example. When there are thousands of genes, this is a huge **simultaneous-testing** problem in need of a multiplicity adjustment. For example, if 5000 genes are studied and none are differentially expressed, then a nominal 5% level testing is expected to falsely detect differential expression in 250 genes. The adjustment need not be as severe as the **Bonferroni** correction when correlation between the tests is considered. The tests are correlated because the same samples are used to test each gene, and groups of genes with similar function can be upregulated or downregulated in tandem across samples. Permutation of the varieties of the samples can be used to approximate the joint null distribution of the P values, which can then be used to obtain an adjusted P value for a gene, that is, the familywise level of the tests at which the particular test for the gene would reject the null hypothesis of no differential expression [24]. Alternatively, a **Bayesian approach** to multiplicity considers gene effects (and/or gene by variety interactions) as random, which induces a multiplicity adjustment that is inversely related to the ratio of the variance between genes to the variance within genes [66]. A noninformative, nonparametric Bayesian approach estimates the mixture distribution of differentially expressed and nondifferentially expressed genes with the empirical distribution, estimates the null distribution for nondifferentially expressed genes via permutation, estimates the mixing proportion by exploiting bounds for it on the basis of the two distributions, and applies **Bayes' theorem** to these estimated quantities to obtain the posterior probabilities of differential expression for genes [25]. In the same paper, a connection is made between the posterior probability and the false discovery rate, the expected proportion of Type I errors, which is increasingly being controlled in large multiplicity problems, as opposed to the more traditional and more conservative familywise Type I error rate.

Microarray experiments can also be used to classify samples into defined groups, such as tumorous or nontumorous tissue, or stages of disease such as metastatic versus *in situ* cancer. Discrimination

methods have been compared, including Fisher's linear discrimination (*see* **Discriminant Analysis, Linear**), **maximum likelihood** (quadratic) discrimination, nearest neighbor, classification and regression trees (CART) (*see* **Tree-structured Statistical Methods**), bootstrap aggregating (bagging) procedures, and boosting procedures, with the simple procedures of linear discrimination and nearest neighbors appearing to work relatively well [23].

These experiments have also been employed to discover new subclasses of disease. For example, Alizadeh et al. [1] discovered two subclasses of diffuse large B-cell lymphoma, one of which did not respond well to standard treatment. Because the classification variable is completely unknown, methods for discovering new classes are termed unsupervised or clustering methods. These methods include hierarchical clustering, k-means clustering, self-organizing maps, mixture model approaches [95], factor analysis, and plaid models [55]. The latter is distinguished in that it simultaneously clusters genes as well as samples. All clustering methods are based on a summary measure of the similarity of expression profiles. The Pearson correlation is usually used as the measure of similarity modulo some transformations of the raw intensities.

Genomewide scans for SNPs can be used to rapidly identify an SNP associated with disease. Interestingly, genomewide linkage disequilibrium studies of SNPs do not have to be adjusted for multiplicity when the disease of interest is monogenic; a confidence-based approach can be used to bound the location of the disease gene to within neighborhoods of single nucleotide polymorphisms [57]. Alternatively, each SNP can be tested directly for association with disease; in contrast with linkage disequilibrium studies, association studies need to be adjusted for multiplicity [62].

Bayesian Statistics and Medical Devices

The fundamental idea of the Bayesian approach to statistics lies in representing one's uncertainty about an unknown quantity of interest as a probability distribution. In medical device clinical studies, examples of unknown quantities of interest are safety and effectiveness endpoints, a patient's outcome to be observed in the future, or even missing observations. Before medical device trials are conducted, the probability distributions assigned to the quantities of interest are called **prior distributions**. After data are gathered and new information becomes available, the prior distribution is mathematically updated according to **Bayes' theorem**, becoming a posterior distribution. This approach provides a mathematically valid way of combining previous information (the prior distribution) with current data, adjusting to changing levels of evidence, and working as Science works: today's posterior distribution becomes tomorrow's prior distribution. This approach also allows for the derivation of predictive probability, a special type of posterior probability, namely, the probability of a future observation given outcomes that have already been observed.

The incremental steps in which improvements are made in device development make the Bayesian approach particularly suitable. Good prior information is often available from, for example, trials in other countries, earlier trials on previous device versions, or possibly bench tests or animal studies. Lack of prior information is represented by a noninformative prior distribution and does not thwart the use of **Bayesian methods**.

The use of Bayesian statistics in planning and analyzing clinical trials [44, 59], especially for medical devices [9], has increased dramatically in recent years (*see* **Bayesian Methods in Clinical Trials**). The Bayesian paradigm, which serves as a basis for formal decision theory, offers an ideal framework for investigational or regulatory settings in which decisions for developing, approving, not approving, or improving medical devices are made on a daily basis. A Bayesian initiative was begun in the Division of Biostatistics at the Food and Drug Administration's Center for Devices and Radiological Health [41]. The medical device community has begun to pioneer using Bayesian methods in planning and analyzing confirmatory clinical trials in recent years.

A Bayesian clinical trial for a medical device may include prior information for the new device, for the control device, or for both the new and control devices. Previous device studies used as sources of prior information should be similar to current studies in terms of devices used, objectives, endpoints studied, protocol, patient population, investigational sites, physician training, patient management, and proximity in time. Covariates such as demographics and prognostic variables can be used to calibrate previous studies to the current study. The use of prior

information often leads to more precise estimates enabling decision-makers to reach a decision on a device with smaller and shorter trials.

Bayesian methods can play a particularly useful role in diagnostic devices studies. Recent research suggests that it may provide an analytical framework capable of estimating and comparing sensitivities and specificities of diagnostic tests in the absence of a perfect test (truth standard) [21, 30].

Although the most direct way of encoding prior information is via a probability distribution assigned to quantities of interest, in many cases, an attractive approach to incorporating information from previous device studies into the current study is by using Bayesian hierarchical modeling [29]. The **hierarchical model** assumes that study-specific parameters are realizations or values of random variables from a common distribution. This usually (but not always) results in more precise estimates of the current study parameters [60]. Thus, we often say that a hierarchical model enables the current study to borrow strength from previous studies. Hierarchical models are self-correcting in that the current study borrows less strength from the previous studies as variation between studies increases, protecting against overreliance on inadequate prior information. One way of using a Bayesian hierarchical model in a clinical trial is to supplement the concurrent control with historical controls; this can allow fewer patients in the concurrent control arm, a larger proportion of patients being allocated to the experimental device, and overall, a smaller trial. Hierarchical models can also be used to adjust subgroup analyses (*see* **Treatment-covariate Interaction**) for effects by allowing a subgroup to borrow strength from related subgroups [22]. For an application of Bayesian hierarchical modeling to coronary artery stents, see [69].

Exchangeability is a key idea in Bayesian inference. Two patients are exchangeable if their roles can be switched without affecting the inference. For technical definitions of exchangeability, see [8]. In medical device clinical trials, exchangeability may be thought of at different levels; there can be exchangeability of studies, of centers, and of patients. In the case of a single **multicenter trial**, centers are considered exchangeable if their roles can be switched without affecting the inference, such as when they are considered as elements of the same superpopulation of centers. But the exchangeability of centers does not imply the exchangeability of patients among centers. If patients treated in different centers are considered exchangeable, then they are said to be "poolable" for making inference. However, as long as the centers are exchangeable, the patients in the centers can be combined by the use of a Bayesian hierarchical model. Between-center variability, which can be large in device trials, is accounted for by assuming that center-specific device effects are random (*see* **Random Effects**). Besides device effects, there are center effects; consequently, the patients in different centers will not be completely pooled together but may be pooled to a certain degree. The degree of pooling will depend on the variability among the centers as compared to the variability among the patients within each center.

The Bayesian approach does not require the sample size to be determined in advance because inferences are based on the parameter space rather than on the sample space, as in the frequentist approach. The sample size required for a Bayesian medical device trial depends on the amount of information necessary to reach a decision, on the amount of prior information available, and on the variability of the data. It can be revised at any point in the study by considering the current posterior distribution instead of the prior distribution. The underlying idea is to gather just enough information to make a decision about the device and therefore not expose patients to unnecessary risk.

In practice, however, particularly in the medical device arena, a minimum sample may be needed to evaluate fairly rare outcomes such as complications or device malfunctions or failures, to verify model assumptions, or to ensure that the prior information does not overwhelm the clinical data of the current study. A maximum sample size may also be useful for economical or ethical reasons or to plan the logistics of the trial. Bayesian approaches to sample size determination include those based on power to make decisions [82], interval length and coverage probability [42, 43], and decision theory [58].

The Bayesian decision-making process is based on posterior probabilities that most of the time do not depend on the experimental design (the **Likelihood Principle** [7]). In contrast, in the frequentist approach, decisions are often based on P values, which strongly depend on the experimental design. As a result, the Bayesian approach can provide more flexibility in both design and analysis [6, 40]. Experiments can be altered in midcourse, arms may be dropped, the sample size may be reduced or

augmented, and interim analyses may require no adjustments. None of these modifications interfere with posterior or predictive probabilities and, therefore, are easily accommodated in the Bayesian framework. When interim looks or other modifications are performed, one may assess probabilities of type I and type II errors through simulations.

In some medical device clinical trials, it is more ethical to change the randomization rate during the course of the trial, thus increasing the chance of a patient being randomized to the "winning" arm. Here, too, the Bayesian approach is amenable to changes in the randomization rates during the course of the trial [45].

Predictive distributions are widely used in medical device clinical trials. For example, by using Bayesian predictive probabilities, one may stop a trial early on the basis of results obtained at an interim point. If the predictive probability of the trial success is sufficiently high (or low), one may stop the trial and declare success (or failure) early. Predictions can be made only if the patients yet to be observed are exchangeable with the patients already observed. In device trials, unobserved patients enrolled later in the study may not be exchangeable with patients enrolled earlier if there is a learning curve associated with the device. In addition, one can also calculate the predictive probability of the outcome of a future patient given the observed outcomes of the patients in a clinical trial, provided that the patient is exchangeable with the patients in the trial. Predictive distributions can also be used when important data are missing. In this case, missing data can be predicted given the observed data, and trial results can be adjusted accordingly. However, the adjustment strongly depends on assumptions about patterns of "missingness". A particular case occurs when patients have two measurements, the first at an earlier follow-up visit and the second, sometimes missing, at a later follow-up visit. Then predictions for the later follow-up visit may be made (even before the follow-up time has elapsed) on the basis of measures at the early follow-up visit, provided there are some patients that have results from both follow-up visits and there is a strong correlation between the early and the later measurement.

The Bayesian approach can be used for hypothesis testing and interval estimation. Bayesian hypothesis testing in medical device studies uses the posterior distribution to calculate the probability that a particular hypothesis, either null or alternative, is true, given the observed data. An alternative Bayesian approach is based not only on the posterior probabilities of the hypotheses but also on the costs of making decision errors. Bayesian interval estimates are based on the posterior distribution. If the posterior probability that an endpoint lies in an interval is 0.95, then this interval is called a 95% credible interval. For constructing credible intervals, see [39].

Bayesian calculations require integration. For example, the posterior probability of a hypothesis is expressed as an integral involving the posterior distribution. When, as is often the case, the dimensionality of these integrals is high, Bayesian calculations are made with **Markov Chain Monte Carlo** (MCMC) sampling methods, such as Gibbs sampling. The Gibbs sampling method creates a **Markov Chain** by sampling sequentially from the posterior distribution for each parameter, conditional on the last sampled values of the other parameters and the data. These distributions are called full conditional distributions. In contrast with the (joint) posterior distribution of the parameters, the full conditional distributions can often be written in closed form, making sampling from them straightforward. Under mild regularity conditions, the sampling distribution converges to the posterior distribution. Subsequent samples can then be used to compute the desired Bayesian integrals. Because the samples taken are not independent (they form a Markov Chain), a Bayesian integral is correctly computed only if enough samples are taken such that the support of the posterior distribution has been completely explored. A Bayesian statistics program that uses Gibbs sampling is Bayesian inference Using Gibbs Sampling, or BUGS [31].

In summary, the Bayesian approach is playing an increasing role in medical device clinical trials because it is compatible with the process of research and development of such products. Bayesian methods require special technical expertise and are often computer intensive. However, the savings of flexible, smaller, and, often, shorter trials usually offset the higher technical and statistical complexity.

Surveillance of Devices

The surveillance of medical devices after marketing permission, which is of concern to regulatory bodies throughout the world, generates interesting statistical problems. Postmarket surveillance is as important

in medical devices as it is in pharmaceutical products (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**). Usually, the reporting systems suffer from severe underreporting as well as the inability oftentimes to definitely link the adverse event to the use of the device. Device-specific statistical efforts to identify a signal in a database of medical device adverse event reports include [52, 54].

Medical Ethics and Statistics

Although the first topic most people consider when ethics and statistics are mentioned is **clinical trials** (*see* **Ethics of Randomized Trials**), there are several other areas where uncertainty raises ethical difficulties. Professional codes of conduct, and the foundations of medical ethics, discuss avoiding harm and providing benefit. The existence of sound knowledge of what is beneficial or harmful is largely assumed, but there is often only limited information on the effects of a medical intervention. Issues of uncertainty cannot be avoided by professionals' claiming to treat individuals, as knowledge based on some group of people must be used in deciding what will be of benefit to the person currently seeking treatment. Doctors cannot behave ethically entirely individually, nor can they treat patients as isolated individuals, except in a limited sense. Medicine and health care are too complex to be within the understanding and control of one doctor or one profession.

If health care professionals are to be able to behave ethically, they must discover what effects their interventions have on a variety of people. Uncertainty, and summarizing the characteristics of populations, are the territory of statistics. Statistics provides the optimal methods for designing studies to gain knowledge, and for making **inferences** from limited empirical data [30]. So doctors and others need to work with statisticians, and professional societies need to ensure that some of their members have a fairly good understanding of statistics.

Various questions are raised by basing health care ethics on the seemingly uncontroversial statement that "the professional must do what is best for the patient". The criteria for judging what is "best" in routine medical practice, normality, screening for disease, epidemiological research, and the communication of uncertainty are discussed. Ethics of medical research in developing countries, popular versions of uninformed consent, and cluster randomized trials, are also addressed. Areas of philosophy other than ethics are also referred to, as the moral status of many decisions and actions in health care will be related to political philosophy, logic, and the theory of knowledge. The article concludes by relating these concerns to the guidelines or codes of the **Royal Statistical Society (RSS)**, the **American Statistical Association**, and the **International Statistical Institute** [4, 36, 48].

Criteria of Excellence

Attempts to measure and define **quality of life** highlight the complexity contained in the simple moral command "do what is best". Statisticians are familiar with having to choose from several possible criteria: for example, an estimator might be **unbiased**, but less precise than a biased estimator. Health care requires consideration of what one means by doing the "best" for a patient, as one will have to choose between methods that are most satisfying for the clinician to use, economical enough to appeal to a manager, or provide the patient with the best quality of life available to them. Mediating between different interest groups means that it will often not be trivial to decide what is best, and what data a statistician should collect or analyze.

The attempt to avoid this complexity, by considering only how to treat the person now in the room with me, fails, because few doctors would insist on continuing to remove a splinter from a toe when a person outside is choking to death. Further, most people are not isolated individuals with respect to health care, because the cost of care is shared either with a political unit such as a country, or by a group defined by membership of a particular insurance scheme. Often there will be environmental influences on health, such as malnutrition, or exposure to infection or pollution. Expenditure of effort, time, or money on one person will almost always limit expenditure on another; skills acquired in treating one patient might benefit another. Finding out what is best for patients will always involve observing relevant populations. The definitions of "relevant" and "population" are often not made explicit in medical practice, nor consciously related to the particular economy.

Another potential source of confusion and conflict is that the measurement of variables such as length and quality of life might rely on different theories of measurement [26] (*see* **Measurement Scale**), and be affected by beliefs about some populations being "less worthy" than others – consider the idea of restricting health care for smokers. Most statisticians might agree that it is wise to keep measures of quality of life simple, so that the comparison of values is

explicit, rather than averaging across incommensurate and contradictory variables [18].

Normal: The Exaltation of Mediocrity

It is not clear whether statistics should be credited, or blamed, for the development of the concept of "normal", and its use as a moral and evaluative category. Social scientists began to use the **normal** (Gaussian) distribution in the twentieth century, initially as a model for the behavior of measurement errors, but then to summarize measurements on living creatures [24]. Most biostatisticians will have had requests for help with establishing a "normal range" (*see* **Normal Values of Biological Characteristics**). The various problems with reference ranges, a more appropriate name, such as the choice of subjects used to choose the range, are discussed in the textbook by Altman [3]. If sufficient caution is not exercised in establishing reference ranges, considerable numbers of people might be inappropriately treated, or alarmed. Further, the naive use of such ranges might lead to people almost always being found to "need" treatment: if a reasonably large number of tests are done, there will be a high probability that at least one result will fall outside a reference range.

Very often, the major flaw in the use of reference ranges is that the wrong question is being addressed. Reference ranges are used to justify some action, such as prescribing cholesterol lowering diets or drugs. However, the salient issue is at what level of a variable there is good reason to intervene on the basis of adequate evidence that the intervention will achieve a worthwhile aim. The relevant goal must be reduction in mortality or morbidity. To define high cholesterol as such as an indicator of morbidity is to use a circular definition, which might create work and wealth for doctors and industries, but will not necessarily improve health. In the case of cholesterol, it is not clear that attempting to make a person's blood levels "normal" benefits them [23]. Attempting to achieve "normality" might amount to maltreatment.

In mental health, the issue of appropriate reference populations is particularly important. Many psychological tests are "standardized" using "normal" people who are undergraduates, patients, or nurses. One "evaluation" of a diagnostic questionnaire for depression claims that it is normal for women to be more depressed than men [37]. Who would claim that it is "normal" for more men than women to get lung cancer? Within a science, which is attempting to measure, say, the gravitational constant, it is reasonable to wish to have one's measurements clustering about the **mean**. There is no obvious reason why the general population should conform to some average, particularly not to the tastes and habits of students or nurses. To require this is at best a recipe for mediocrity, and at worst, a totalitarian definition of what ought to be.

Ethical and political philosophy include debate about what criteria should be used to judge the morality of actions. The consequences of careless thinking, and use of some, perhaps vague, idea of "normal" as "what ought to be" is nicely illustrated by a satirical proposal to classify happiness as a psychiatric illness [10]. Some of this careless thinking might be helped by an unnoticed shift in the theory of measurement from a representational theory in physics to an operational theory in psychology [26].

Another aspect of treating a patient as a "normal" member of a particular population which has disturbing consequences arises from differences in compliance (*see* **Compliance Assessment in Clinical Trials**). As there is evidence that about 10% of patients are excellent compliers, dose levels based on the **"intention to treat" analysis** of trials will be levels such that most patients will actually take a therapeutic dose. Excellent compliers will take a higher dose, and therefore be at greater risk of side effects. Although a doctor might recognize a need to warn patients of side effects, it is difficult to predict which people will be good compliers, and, simplistically, it is not normal to take medication as prescribed. The dose level set is thus, to some extent, set to benefit the majority at the expense of the "best" patients. Any claim to be treating a patient as an individual will have limited accuracy. As a doctor will never know everything, and is unlikely to know about a patient's compliance, she must decide on a course of action likely to benefit patients belonging to some type or subgroup.

Observational and Epidemiological Research

The author wishes it were unnecessary to state that a study must be scientifically sound in order to be ethical. Altman claims that the ethical implications

of unscientific studies include the misuse of patients and resources, and the consequences of publishing misleading results [2]. Although the suggestion that the misuse of statistics is unethical has not been challenged, substandard design and incorrect analysis can be seen in almost any issue of any medical journal. If Leaning's claim, that editors are forced by the Nuremberg code (the explicit statement occurs in the Helsinki code) not to publish information that has been unethically obtained, were true [38] and rigidly enforced, the size and number of biomedical journals would be greatly reduced.

Informed consent is usually required to do the main ethical work in clinical trials. The Nuremberg code states that for research involving human *experimentation* to be ethical, "the voluntary consent of the human subject is absolutely essential" [52]. The declaration of Helsinki also concentrates on experimental research [61]. As **observational** and epidemiological research are not experimental, in that the subjects' environment or treatments are not manipulated by the researchers, the Nuremberg code and its derivatives might be deemed irrelevant. However, the RSS Code of Conduct asks that informed consent be obtained, if possible, for all enquiries involving human subjects.

Informed consent for epidemiological research, including the use of routine data, has been introduced in the European Community. Many UK biostatisticians and health care professionals are opposed to this, as being inappropriate given the risk and benefits of such research. To require individual consent for each study would introduce sufficient bias due to **nonresponse** to render the studies almost useless. The main argument for informed consent regards individual privacy as the supreme right (*see* **Confidentiality**). However, the community, including the individual, is likely to benefit considerably from epidemiological studies of the origin and course of diseases [44].

Observational studies of the nonrandom introduction of innovative treatments, which some **Bayesian** philosophers advocate, [57], evade, rather than avoid, informed consent. The use of routinely collected data (*see* **Administrative Databases**) relies on people's consent to be governed. For example, in the United Kingdom, people who have cancer could not refuse to have data on their illness sent to Cancer Registries (*see* **Disease Registers**). Consent is now required for much health data, but participation in the **census** is still mandatory. In many instances, some of the subjects on whom data are collected are dead. One cannot get informed consent, and does not need it, as there is no person whose privacy is invaded. Is there even an ethical worry at all? Privacy is safeguarded through anonymity.

Screening

The moral issues raised by population **screening** are also inherently statistical. In order to assess whether the **incidence** of a disorder is being reduced by a screening programme, adequate statistical records of the population must be kept. This raises questions about what moral framework one claims in order to justify **surveillance** of a population, and thus takes the debate into political philosophy. There is also uncertainty for the individual because of the possibility of **false positives** and **false negatives**.

The justification for screening depends on the political framework one chooses to use, such as liberal, paternalist, or statist. Doctors usually use a paternalistic definition. A liberal definition, based on a right to the knowledge needed for self-determination, is sometimes used by patients. As one is considering people who are well, the justification must rely on people's consent to be governed; it cannot rely on their becoming patients by asking for assistance. Perhaps we think that people have a duty to be enquiring both medically and socially. It is therefore legitimate to require people to think of themselves as "patients-in-waiting", who must find out their state of health, and make decisions on the basis of that information. As mentioned above, the cost of health care is usually shared by a group. The person who chooses not to have screening, and later requires lengthy and expensive medical treatment for a disease for which screening was offered, arguably has caused their group (society) to incur unnecessary costs. An insurance-based system could demand submission to screening, but a liberal democratic state should only ask it. Financial inducements to doctors to increase screening rates leads to coercion of people. For this argument to have real force, one would need to have good estimates of the **sensitivity** and **specificity**, and of all the costs, so that the scope and frequency of the programme could be decided (*see* **Diagnostic Tests, Evaluation of**).

Instead of taking a statist view, one might take a liberal or modernist stance, and argue that screening

does not give people more decisions than they can make, but enhances their autonomy and makes them better (happier rather than morally better) adults by giving them more choices to make. However, people who are very concerned about their health are often labeled as "hypochondriacs", that is, ill. Of course, if one uses "normal" as one's criterion, then by requiring most people to be anxious about their health, one could almost eliminate the disease of hypochondria! Most liberal philosophies consider society to consist of rational people, and so would require a different justification for screening children, or those whose reason is incapacitated.

A person accepting screening will have to make decisions based on uncertain results. A Health Education Authority leaflet on breast screening states "... mammography is not 100% reliable". In prenatal screening, false positives sometimes vanish magically. The standard leaflet given out by general practitioners in the United Kingdom mentions false negatives, and quotes rates for Down's syndrome and neural tube defect (NTD). False positives are mentioned for the first screening test, but not for the second. A recent reference book [39] has a careful discussion of the need to consider **prognosis** as well as diagnosis. However, in the section on NTD (pp. 10–16), the data sets mentioned are rather small, and the prognosis is not uniformly poor. After stating that ultrasound scanning is preferable, because the sensitivity is "between 60 and 90%" and "specificity is much higher", a figure illustrating a screening programme is given, which has no false positives. Even with a sensitivity of 90%, given the **prevalence** used, 0.2%, to get a ratio of one unaffected to one affected fetus among those testing positive, one requires a specificity of 99.8%. People who debate the rights or wrongs of abortion for particular conditions rarely frame the question "at what level of probability is one justified in terminating a fetus?" Given the inherent uncertainty of prenatal diagnosis, those who wish to endorse abortion in these circumstances should be willing to make statements such as "if there is a 1 in 5 chance that the infant has NTD, then it is acceptable to terminate her".

For screening programmes to be even minimally ethical, under almost any political philosophy, the statistics of screening must be available. In all cases, sensitivity and specificity rates have to be *estimated*. The popular assumption that the results of tests, and hence diagnoses, are certain has to be challenged. Careful research can reduce, but never eliminate uncertainty. The well-rehearsed recommendations about careful design as well as correct analyses apply also to screening.

Conveying Uncertainty in Diagnosis and Prognosis

As uncertainty is unavoidable and decisions about care have to be made, health care should be a fertile field for **decision analysis** [28]. Uncertainty, in diagnosis or prognosis, is often dealt with by failing or refusing to provide any information. Until quite recently, parents whose child was diagnosed as having cerebral palsy would not have been given accurate information about the child's likely survival, as no such information existed [22]. Anecdotal evidence suggests that parents with severely handicapped children would have been told not to expect the child to live much beyond the age of 10, although the **median survival** is about 20 [35].

To a patient with lung cancer or colonic cancer, the information about the median survival ("half of people with the type of cancer you have live more than x months") is potentially very important in his decisions. A study of gastroenterologists showed that there is considerable variation across Europe in honesty and respect of confidentiality with regard to cancer [53]. The authors describe deciding whether to be dishonest as a "typical ethical dilemma", but deciding whether to be dishonest requires a decision about a temptation, not a decision about a principle, rather seeing lying as a temptation. Of course, the medical profession can be characterized as the only profession that debates whether to tell the truth. To deny information, which a consultant should either know, or be able to access, is irresponsible. The UK General Medical Council's guidance requires doctors to "give patients the information they ask for or need about their condition, its treatment and prognosis". It is not clear how such a consultant could justify a claim that the patient did not want the information, which they had requested. Attempted justifications include a concern to protect the image of the profession, and a belief that patients cannot cope with truth, or uncertainty: "professed uncertainty is in itself generally undesirable" [27]. In contrast, Bursztajn et al. [12] give an enthusiastic account of the benefits of realizing that we live in an uncertain world, and

of accepting that medical choices should explicitly acknowledge this. Uncertainty is often regarded as a justification for randomized controlled trials (RCT).

In communicating risk, "nondirective" counseling is commonly held to be desirable, perhaps ethically preferable to "directive" counseling or to the doctor stating her own beliefs. A moral doctor should convey uncertainty as clearly and impartially as possible. Observations of obstetricians who are responsible for counseling parents who require information about amniocentesis [41] revealed that the same **risk** was described as high or low, depending on the topic: miscarriage or Down's syndrome. If the same risk is described in contradictory ways in a session, which is claimed to be nondirective, then there is clear dishonesty. The Chief Medical Officer has also recommended establishing a scale of uncertainty to which the general public can relate. This was, in part, because a report of increased risk of blood clots for women taking particular contraceptive pills received wide coverage in the media; the risks associated with pregnancy were not given the same prominence. In his presidential address to the RSS, Smith suggested establishing a scale of risks [50] (*see* **Risk Assessment**).

In the debate about the moral superiority of Bayes inference in assessing whether new treatments are effective, philosophers on both sides show a reluctance to acknowledge the reality of uncertainty. In an article extolling **randomization**, Papineau [46] makes a breathtaking leap from probability to certainty: "... if it turns out that T makes no probabilistic difference to R either among young people, or among old people – then we can conclude that T *doesn't* cause R, ...". The emphasis is the author's, who appears to be unaware of the concept of **power**. In arguing that randomization is unnecessary because Bayes inference can adjust for all possible **confounding** factors, Urbach [56] indicates his belief in the lack of uncertainty in medicine, which no one who is aware of, for example, the inaccuracy of **death certificates**, or the limited accuracy of prediction for survival, could espouse [16].

Medical Research Ethics in Developing Countries

The guidelines published by the **World Health Organisation** (WHO) and the Council for International Organisations of Medical Sciences (WHO/CIOMS), [17], were framed with particular concern for developing countries [29], not to duplicate the principles already established, but to suggest how these principles might be applied. Much of this is useful, but some principles verge on racism.

> *"Subjects in developing countries*
>
> 14. Rural communities in developing countries may not be conversant with the concepts and techniques of experimental medicine. It is in these communities that diseases not endemic in developed countries exact a heavy toll of illness, incapacity and death. Research on the prophylaxis and treatment of such diseases is urgently required and can be finally carried out only within the community of risk.
> 15. Where individual members of a community do not have the necessary awareness of the implications of participation in an experiment to give adequately informed consent directly to the investigators, it is desirable that the decision whether or not to participate should be elicited through the intermediary of a trusted community leader. The intermediary should make it clear that participation is entirely voluntary, and that any participant is entirely free to abstain or withdraw at any time from the experiment."

This singling out of rural communities is offensive, as the assumption that rural people in developing countries are less able to give informed consent is not justified [19]. A review of the ethics of clinical trials, and the sociocultural contexts, found no evidence of cultural objections or obstacles to voluntary consent [7].

Remarks CIOMS.18 and 19 on review procedures mention the role of statisticians, but recognize practical and political realities. As statisticians, we can welcome the recognition of our potential contribution, but even "highly developed" countries do not have an adequate supply of statisticians to support ethics committees [59]. The requirements CIOMS.27 and 28 for ethical review in both host and "external" countries are noteworthy. As recognized under review procedures, different countries have different resources for ethics committees, which require considerable expenditure, at least of time [60]. Concern was expressed about the independence of ethics committees in some countries at the international school from which the proceedings arise. A longer term view of the impact of research interventions is required by CIOMS.29, and the wider social context is stressed by CIOMS.32.

A heated debate about research in developing countries started by trials of interventions to reduce transmission of HIV from mothers to their infants, before and after birth (*see* **AIDS and HIV**). Lurie and Wolf [40] noted that an intervention, the AIDS Clinical Trials Group study 076 (ACTG076) regimen of an antiretroviral drug, AZT, had been shown to be effective in 1994, but, despite this, in many later trials of vertical HIV transmission, some or all patients were not provided with antiretroviral drugs. Of 18 studies identified, 15 used **placebo** controls. The two USA trials provided antiretroviral drugs for all patients.

Bayer makes the important point that the real ethical problem is not whether to use placebos, but the immorality of the world economic order [8]. The "maldistribution of wealth and resources" makes the vertical HIV transmission trials a focus of (emotional) outrage. The goal of reducing HIV transmission in Africa requires information on affordable, implementable interventions, which will be the basis of health care policy. Matchada cites the failure of to eradicate tuberculosis, despite "free drugs", because of infrastructure barriers [42]. He compares expenditure by African nations on war and debt servicing with that of health care. The effect of exploiting medical care for commercial gain, on a worldwide scale, is investigated by Benatar [9]. Theological equality of persons exists, but not socioeconomic equality.

Wider issues are raised by Annas and Grodin [5], who place the debate in the context of the UN Declaration of Human Rights (DH). The goal of slowing the HIV epidemic might not be most sensibly achieved by addressing vertical transmission. A fuller review of the background and arguments, and discussion of the role of statisticians is given in [32]. A useful critical overview of the philosophical debate is given by Schüklenk and Ashcroft [49]. They point out that it is doubtful that an identifiable local standard of care exists, because the standard of care in, say, Ivory Coast, depends on prices set by Western manufacturers of drugs and equipment. In order to argue that particular principles are inappropriate, one has to present a case showing, for example, that protection of profits by patent and monopoly is more important than limiting the course of an epidemic.

Although health professionals might prefer to own "their" codes, the revisions of DH were not proposed for medical reasons, and the debate is between ethics, including distributive justice, and economic prudence [5, 49]. Schüklenk and Ashcroft suggest that ownership of DH might be passed to the United Nations [49]. Even if the revision of DH were simply a matter of ethics, the application and interpretations of human rights requires law, policy, and hence politics. Adjudication among groups with different interests is a political responsibility, and ways of including the public in the debate are required [49].

The 2000 revision of DH illustrated the need for collaboration. The sentence "This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic or therapeutic method exists" [27, 61] was promptly criticized by those who carry out trials. It is precisely when proven therapies exist that placebo controls are used. In 2002, a footnote was added to DH.

Informed and Uninformed Consent

It is valuable to realize that there are various aspects and interpretations of informed consent [1]. Guidelines or codes of conduct usually focus on consent as involving delivery of information in a manner that respects the rights of the person. At one extreme, this is viewed as a polite ceremony that is not essential, as doctors always have their patient's best interests to the fore. Consent is convenient because it transfers responsibility from the doctor or researcher to the patient or subject. The other extreme views consent as necessary protection against useless, dangerous, or unwelcome interventions imposed by a powerful profession. Some people argue that requesting consent changes patients from research objects to research subjects [60], but others, both patients and doctors, feel that the process can be detrimental to the patient [27, 55].

Two systematic reviews of reasoning [6] and empirical data [20] on patients' understanding of informed consent noted that there are difficulties. However, the authors recommend that informed consent remains essential [6] or that "... the spirit of informed consent" be retained and seriously attempted, with ethics committees for further protection [20]. It is possible that the protection of patients that informed consent is intended to provide [25, 52], might be achieved by alternative forms of consent. Alternative proposals that might give such critics of informed consent and randomized trials what they say they want have been examined [34].

It is important to consider carefully what information should be provided in order to allow a patient to make an informed choice. It is arguably unethical to impose one's own standards of understanding on a patient. If a patient refuses to participate in a particular trial, we do not require this refusal to be informed, as this could be regarded as coercive. There is a dramatic contrast between the standards of ordinary medical practice and randomized trials [15].

The invitation, at a time when the patient is already under stress, to participate in a clinical trial can be upsetting [54]. It is worth considering patients' informed response to trials in general. Those who realize that trials might well be beneficial, irrespective of treatment received, are likely to want to be offered enrollment in any trial for which they are eligible [15, 20]. The idea of general prior refusal is natural enough, if a person believes that randomized trials are wrong. If the alternative to randomized trials is uncontrolled, unreliable experimentation, rather than no experimentation [14], then it is difficult to make general prior refusal entirely coherent. One can sketch the justification for having "trial-free" doctors under various constructions of professionalism [34].

Pre-exclusion of patients by doctors on grounds of guesswork about patient preferences already exists [51]. If a doctor thinks that "professed uncertainty is of itself undesirable" [27], they might not offer patients the opportunity to participate in a trial. Alternatively, if a doctor takes views the trial as the treatment, they might (logically, though not legally) use the same standard of lack of consent used in routine treatment, and enroll the patient without drawing attention to randomization, as probabilistic choices are common in medical practice.

The irony of the requests for alternatives to informed consent is that to grant them requires restrictions on patients' knowledge, personal responsibility, and freedom of choice. This implies inadequate patient protection, free-riding, unreasonable avoidance of decision-making, increased decision-making by doctors, and (self-)exclusion from optimal treatment.

Two moral concerns are addressed in informed consent: individual self-determination, or autonomy, and justice, particularly justice for groups of people such as Jewish or black people. Randomized trials do not sacrifice present patients for future patients [31]. In contrast, to insist that obtaining informed consent is more important than providing the therapeutic package most likely to lead to a better outcome for this patient, is to sacrifice this patient for the protection of other citizens. We insist on subjecting patients to the experience of being asked for informed consent, because we know that it is very dangerous to allow doctors to decide whether an experiment on people is justified [25]. If we dispense with informed consent, some group of people will suffer abuse. Even with official recognition of the need for informed consent, groups of patients sometimes suffer [58].

Cluster Randomized Trials

Cluster randomized designs (CRDs) are increasingly used in research into health care and health services (*see* **Group-randomization Designs**). Ethics of individual patient randomized trials have been elucidated in a number of different codes, but less attention has been given to the ethical issues raised by cluster randomized trials. The challenges raised by cluster randomized controlled trials are evaluated by considering the essential elements of ethical medical research, particularly experiments on people, and the distinguishing features of cluster randomized controlled trials from ordinary RCTs [33].

Cluster-randomization designs are experiments in which intact social units are randomly allocated to one of two or more intervention or treatment strategies. There are scientific and practical reasons that can be given to justify the use of CRDs. The scientific reasons are that intervention might act at cluster level, (e.g. a vaccine) or be carried out at cluster level (e.g. guidelines for medical doctors), that there might be treatment contamination if participants can exchange information, or that subject compliance can be enhanced by discussions. Logistical and political constraints include administrative convenience, political necessity for permission to be obtained and requirements of access to routine data.

The fact that the unit of randomization includes several patients or participants has implications for both consent and the science of CRDs.

Protocols must make adequate provision for professional statistical input in order to be scientifically sound, and hence ethical in the light of the Nuremberg principles 2, 3, 6 & 8. The need for appropriate methods of analysis is relevant both to the design, in assessing previous knowledge, and the analysis of the results. An important issue in ensuring that a

study will be able to yield useful information (Nuremberg 2) is the sample size, and the effective size of a CRD is smaller than the total number of individuals studied. Few CRDs allow for between-cluster variation when estimating the power of trials, and not all reports of CRDs allow for the clustering in the analysis. Thus, any summary of previous knowledge might be affected by previous errors. The funding of a new CRD obviously must include provision for specialist skills to ensure correct analyses of past and current data and a thorough analysis of the risks and benefits (Nuremberg 6). Resource use requires social and political categories of thought.

Decisions about early stopping are dependent on planned and unplanned interim analyses, in CRDs as in RCTs (Nuremberg 10). The decisions might well be more complicated in CRDs, as there might be a need to accrue sufficient numbers in each cluster, and the point at which there is convincing evidence of benefit or harm might be very difficult to discern (*see* **Data and Safety Monitoring**). Disadvantages associated with early stopping of a RCT, such as lack of credibility and realism, imprecision, and bias [47] will be accentuated for CRDs.

The important structural features of CRDs for consideration of informed consent are the units of randomization or allocation, units of intervention, and units of observation. The various units are not necessarily the same people, as patients might receive treatment, but the conduct of nurses be the focus of observation and a general practice the unit of randomization. There might be gate-keepers; alternative interventions might not be easily available and in some instances, a participant cannot easily withdraw, for example, if an insecticide is sprayed throughout a village. In the case in which a professional is the primary experimental subject, if she chooses to leave a trial early, she will effectively remove all her patients also (cf Nuremberg 9).

The different levels of randomization and intervention mean that there are potentially various types of consent and levels at which it can be sought. Consent might be sought, or not sought, at some of the various levels, for use of routinely held data, for collection of additional data, with or without the use of invasive procedures, or for the offer, or administration, of an intervention. We usually think of consent as operating at the level of the individual person: with CRDs, there are further levels to consider. The definition of a community, and how its representatives are chosen, takes the debate on ethics into political philosophy. A Nigerian study indicates that the leaders' views, which are cheaper and easier to obtain, cannot be relied on as proxies for the opinions of heads of households [45]. There is no firm evidence that in any cultures heads of household might give or withhold consent for adults in their household [6].

Guidelines of WHO/CIOMS accept the possibility that individual consent is not feasible. The decision to undertake the research is then given to a "public health authority", with attention given to providing the community with information on the research [29]. This authority must therefore take responsibility for the consequences of the research, although the people who are such authorities might not themselves be directly exposed to the interventions. However, it is not obvious that there will be only one authority which can, or should, take such decisions and responsibility. Here again the political dimension of research ethics is clear. The Nuremberg code was drawn up as a result of the failure of political authorities to protect all groups of citizens [58]. Mere feasibility is not a strong reason to fail to request individual consent. The fact that subjects might not be able to avoid the treatment, although they do not consent to it, or might not otherwise have access to treatment, is a reason not to impose the treatment, not a reason to evade individual voluntary informed consent.

Consent should be obtained before any intervention, but it is not ethically essential that it is obtained before decision as to what intervention would be offered if the person were to agree to enter the trial. One seeks consent to be in an experiment, not simply consent to a particular treatment. The primary reason for obtaining consent before randomization is a scientific one: it reduces the possible bias arising from different patterns of consent in the various treatment arms. Scientific and logistical constraints associated with CRDs imply that consent cannot necessarily be requested before an intervention is assigned to a person. This is not a problem, as trial entry and treatment assignment are not equivalent. For example, a person could refuse the vaccination, after their community had been assigned this intervention, which operates at both community and individual level.

Guidelines on the scientific and ethical conduct of CRDs are provided by the UK Medical Research Council [43].

Statistical Ethics

The *International Statistical Institute Declaration on Professional Ethics* [36] recognizes the variety of settings in which statisticians work, and the many branches of the discipline. The Declaration is therefore an informative framework of principles, not a set of regulations. Each principle is followed by a commentary and bibliography. The intention is that statisticians who consider departing from the principles do so as a result of deliberation, not ignorance. The principles are grouped into four categories, with no category having priority: Obligations to society, funders and employers, colleague, and subjects are considered.

Social obligations comprise considering conflicting interests, including guarding against misuse and misinterpretation of statistics; extending the scope of statistics to benefit as large a community as possible; and pursuing objectivity with openness about limitations. Obligations to paymasters require clarity about roles and responsibilities; impartial assessment of alternative statistical methods; no pre-emption of outcomes, and safeguarding privileged information, while revealing the statistical methods and techniques used. In return for respect for exclusive technical and professional knowledge, statisticians must be honest about the limits of their expertise.

The three obligations to colleagues described are maintaining confidence in statistics, transparency of methods, and knowing one's own ethical principles as well as those of one's collaborators. These principles arise from the value of professional citizenship, which confers privileges of access to data, and the dependence of the reputation of statistics on the conduct of individual statisticians. A difficult responsibility is neither ". . . overstating or understating the validity or generalizability of data . . ." (ISI.3.3).

Animals as subjects are acknowledged, but the subjects to whom obligations are described are individual people, households, and corporate entities. Statisticians should avoid intrusion. There is an excellent discussion of the implications of the obligation to obtain informed consent, in terms of adequacy of information and of consent. Statisticians are expected to ". . . adhere to the principle of obtaining informed consent directly from subjects" even if they first have to negotiate with a "gate-keeper" who is blocking access. Careful consideration of modifications to informed consent addresses observation studies, dealing with proxies, secondary use of records and misleading potential subjects. With respect to the last, withholding information is deceitful, and instances when legitimate censure can be avoided because of special research requirements are rare, and difficult to justify. In such cases, posthoc consent should be considered.

The interests of subjects must be protected, not merely within the study, but also with regard to subjects' relationships with their environment. Social position can hold risks: "The interests of subjects may also be harmed by virtue of their membership of a group or section of society (see Clause 1.1). So statisticians can rarely claim that a prospective inquiry is devoid of possible harm to subjects. They may be able to claim that, as individuals, subjects will be protected by the device of anonymity. But, as members of a group or indeed as members of society itself, no subject can be exempted from the possible effects of decisions based on statistical findings." Confidentiality of records is essential, as is inhibiting disclosure of identity by providing configurations of attributes, which are distinctive.

The *RSS Code of Conduct* [48] primarily describes the professional duties of a statistician, with a view to upholding the reputation of the profession. Nevertheless, some of the rules do address ethical matters. Part of the context for the rules is the recognition that the general public have no easy way of judging the quality of statistical work.

The "Public Interest" is the focus of the first two rules. Fellows of the RSS are required to have knowledge of, and comply with, the legislation, regulations, and standards "relevant to their chosen field". Hence any statistician involved in refereeing articles or grants that have a component of medical research should be familiar with the Nuremberg code [52] and the Declaration of Helsinki [61]. The second rule has wide implications, as it expects Fellows to avoid any actions that damage basic human rights:

> Fellows shall in their professional practice have regard to basic human rights and shall avoid any actions that adversely affect such rights. Enquiries involving human subjects should, as far as practicable, be based on the freely given informed consent of subjects.

Although the adjectives qualifying "informed consent" shows more imagination than some codes, the subordinate clause recognizes that there can be

studies for which it is not practical to obtain informed consent. Confidentiality should always be respected.

With respect to statisticians' duties to employers or clients, the RSS Code acknowledges that the professional judgment of statisticians may be overruled. Most medical statisticians will have experienced this, in collaboration, consultancy, refereeing, or as a member of an ethics committee or regulatory body. In such circumstances, the RSS code (RSS.3) requires the Fellow to indicate the likely consequences of ignoring their judgments. It is possible to understand why point 4 of the RSS code asks fellows to try to avoid becoming party to activities that conflict with the basic public interest. It is not clear why fellows should avoid becoming "privy to information" concerning activities that would conflict with their public responsibilities. If a statistician can discern that a study ignores basic human rights because it is poorly planned, and is using people and resources in an endeavor that cannot result in any useful information, rather than trying to avoid such information, finding it and advising appropriate authorities of it so that the misuse of resources can be terminated would be acting in the public interest [13, 21]. Statisticians are prohibited (RSS.6) from allowing their name be associated with "any misleading summary of data", with particular attention to "the way the data were selected". Two other common concerns are: accurate description of reasons and assumptions behind the method of analysis, and giving opinions not supported directly by the data reported.

The American Statistical Association's *Ethical Guidelines for Statistical Practice* [4] emphasize the duty of statisticians to maintain professional integrity. In particular, they should provide honest and objective interpretation, based on evidence, with disclosure of any special interests. Statisticians have a responsibility to respondents who provide data, especially with respect to privacy and confidentiality. This includes establishing informed consent, and detailed concerns about offering and ensuring confidentiality. Statistical work must be open to assessment, with the limits and source of data made clear, and the role of statistical analysis, including choice of procedures visible. Data should be available for analysis by appropriate others. As users of statistics may be dependent on expert advice, good conduct and good communication are essential. The guideline on collecting "only the data needed for the purpose of their inquiry" is worth bearing in mind, as accuracy can be discouraged by excessive requests. The tendency in medical research to request information "while we are there" can add unnecessarily to the cost in time and effort of clinical research.

Conclusions

Although most of us use "Nazi medicine" as the epitome of unethical research, it is not trivial to explain exactly what was wrong [11], why the atrocities occurred in the one country that had a legal doctrine of informed consent and medical ethics [58] and why no use should be made of data that are improperly collected [38]. Doctors cannot easily deny the willing involvement of their profession in **eugenics**. Eugenics was widely supported in the 1920s and 1930s; new eugenics are popular now in antenatal screening. Statisticians cannot thank God that they are not like other men: **Galton** coined the term "eugenics".

The most interesting ethical problems arise from the use to which the statistics will be put. Any reasonable code of conduct will require statisticians to exercise competence and diligence, to be willing to consider their fallibility, and to be vigilant in the communication of the results of analyses and their interpretation, regardless of the area of application.

Medical Expenditure Panel Survey (MEPS)

The Medical Expenditure Panel Survey (MEPS) provides nationally representative data on **health care utilization**, expenditures, insurance coverage, sources of payment, and access-to-care measures at the individual and family level. The survey was designed to facilitate analyses of how individual characteristics, behavioral factors, and financial arrangements affect health care utilization and expenditures (*see* **Surveys, Health and Morbidity**). MEPS is sponsored by the Agency for Health care Research and Quality (AHRQ) and cosponsored by the **National Center for Health Statistics**, **Centers for Disease Control** and Prevention (NCHS/CDC).

Since its inception in 1996, MEPS has been a continuous ongoing survey of the US civilian noninstitutionalized population. Predecessors were once-a-decade surveys: the 1977 National Medical Care Expenditure Survey and 1987 National Medical Expenditure Survey.

Survey Design and Content

The MEPS is a family of three-interrelated surveys of the US civilian noninstitutionalized population: the Household Component, the Medical Provider Component, and the Insurance Component. The MEPS Household Component contains data on health care use, medical expenditures, sources of payment and insurance coverage, **health status**, demographics, employment, and access to health care. Households are selected for the annual Household Component from those participating in the previous year's National Health Interview Survey (NHIS), an ongoing annual household survey of approximately 42 000 households (109 000 individuals) conducted by NCHS/CDC to obtain national estimates of health care utilization, health conditions, health status, insurance coverage, and access. Combined use of NHIS and MEPS data adds capacity for longitudinal analyses. MEPS has a multistage, clustered sample design (*see* **Multistage Sampling**) with 195 primary sampling units (PSUs) [3]. Sampling weights are used to produce population estimates for individuals, families and population subgroups, such as the elderly and children.

The survey employs an overlapping **panel study** design in which any given sample panel is interviewed in person 5 times over 30 months to yield annual use and expenditure data for two calendar years. **Computer-assisted** personal interview (CAPI) is used in an interview with a family respondent who reports for him/herself and for other family members [5]. In the initial year of the survey (1996), the household sample consisted of 8655 families and 21 571 individuals with calendar year data. In 1997, the MEPS sampled 13 087 families and 32 626 individuals, with oversampling of: Hispanics, blacks, adults with functional impairments, children with limitations in activities, individuals predicted to incur high-levels of medical expenditures, and low-income households. Since 1997, data from two panels are combined to produce estimates for each calendar year. Since 2002, the MEPS sample seeks 15 000 families and 40 000 individuals yearly.

The MEPS Medical Provider Component collects detailed data on expenditures and sources of payment from the medical providers, facilities, and pharmacies that serve individuals surveyed for the Household Component. These data are the primary source for imputing medical expenditure data to correct for item **nonresponse** by the MEPS household sample participants [8].

Medical providers (MD/DO) for households where expenditure data was expected to be particularly insufficient were sampled at higher rates, for example, households with any Medicaid enrollees or with HMO enrollees. All hospitals providing inpatient and/or outpatient services to household members are contacted. The data from medical providers include: the dates, medical content, and charges and payment sources associated with each encounter. Data from pharmacies describe each prescription: fill date; drug name, dose and NDC code; charges and payments by source. Hospitals self-administer their data collection; physician offices are contacted by telephone; pharmacies receive a mail survey with telephone follow-up. Since 2002, each annual Medical Provider Survey involves interviews with more than 4000 hospitals and related outpatient facilities, 22 000 office-based providers, 11 000 hospital-identified physicians, 800 home health providers and 9000 pharmacies.

The MEPS Insurance Component was designed to produce national, regional, and state estimates of the amount, types, and costs of job-related health insurance. Mail interviews are conducted annually with

30 000 establishments to support estimates of health insurance availability at the workplace, to describe the types of employer-sponsored coverage and their associated costs. Establishment survey data include: size, the type of workforce employed, aggregate data on payroll and available fringe benefits, industrial classification, corporate status, and the number and characteristics of health plans offered [9]. Data are collected for each plan: its scope and breadth of benefits; copayments; number of current workers and retirees enrolled; and whether it is fully or self-insured. Since 2000, the Bureau of Economic Analysis has used MEPS health insurance premium cost data to estimate the health component of the Gross Domestic Product. States also use the data to assess time trends in employer-provided health benefits, and to compare their employers' health insurance cost experience to national, regional, and other states' profiles.

National Estimates of Health Care Expenditures and Coverage

Health care expenditures representing over one-seventh of the US Gross Domestic Product are growing faster than other sectors of the economy and consume much of the Federal and states' budgets. Researchers have used the MEPS data to determine the direction of the association between the use of newer drugs and all other types of nondrug medical spending [7], and to identify inappropriate medication use, a major patient safety concern with significant cost consequences [10].

Health care spending is highly concentrated. The 1996 MEPS found the top one percent of the population accounting for 27% of the total health care expenditures incurred by the civilian noninstitutionalized population, and the top five percent of people, accounting for 55% [2]. Consequently, the MEPS uses oversampling and **poststratification** (to conform to more accurate population estimates of decedents) to improve the quality of survey estimates for this policy-relevant population subgroup.

Access to health insurance coverage is a critical public policy issue. The MEPS data support estimates of the size and composition of the insured and uninsured populations, and reveal how demographic characteristics, economic factors, and health status affect health plan eligibility and decisions to enroll in health insurance plans. In addition to providing cross-sectional estimates of health insurance coverage each year, the MEPS data can identify individuals with gaps in coverage over a calendar year as well as the duration of gaps for up to 24 months. From 1996 to 1999, between 59 million and 62 million Americans were uninsured at some point each year [6]. The MEPS data support estimates of out-of-pocket health care burdens and the extent of underinsurance in the United States.

Recent Design Enhancements

Beginning in 2000, a self-administered questionnaire was added to enhance the value of MEPS for exploring a range of issues relating to access to care, health care quality, health status, and patient satisfaction. Questions include a subset of those developed for the Consumer Assessments of Health Plans Study (CAHPS®), all questions from the SF-12 (Medical Outcomes Study, Short Form) [1], and, to facilitate international comparisons on health status and quality measurement, the questions that comprise the EuroQol 5D (EQ-5D) [4]. The MEPS is further supplemented by "provider accountability" measures for individuals with high prevalence, serious medical conditions, such as diabetes, asthma, and hypertension. For example, a self-administered questionnaire for diabetics obtains yearly information on the frequency of health professional examinations for hemoglobin A-1-C, foot sores or irritations, and eye examinations with pupils dilated.

Data Products

MEPS releases person level, medical event level, condition level, and job level data. Each year, MEPS releases eight specific event files: dental, emergency room, home health, hospital stays, medical visits, outpatient stays, and other medical and prescribed medicines. Each record in a condition file represents a health condition reported by a person in a survey household. Each record in a job file describes a job held by a surveyed person, including wages, benefits, and industry type (e.g. service or manufacturing).

MEPS public use data files on health care utilization, medical expenditures, insurance coverage, and sources of payment are produced annually. Each file includes information from several rounds of data

collection that together comprise a complete calendar year's worth of information. MEPS also releases annual point-in-time ("snapshot") files, for example, the health insurance file that describes coverage for the first part of each calendar year. At this time, annual public use files are typically released within 12 months. For example, most 2001 files were available by the beginning of 2003.

Many MEPS databases contain detailed personal information. To maintain respondent confidentiality while enabling valuable research that could not be accomplished without such data, AHRQ maintains a closely monitored Data Center where researchers can access the protected information needed for approved projects.

Summary

The MEPS has become more comprehensive over time through design and content enhancements, including its greater flexibility to permit sample size enhancements for new initiatives and to facilitate oversampling of policy relevant population subgroups. The survey continues to serve as a national resource for examining the dynamics of recent patterns in health care utilization, expenditures, coverage, and access to care at the national level. The public sector (e.g. Office of Management and Budget (OMB), Congressional Budget Office (CBO), Medicare Payment Advisory Commission (MedPAC), and Treasury Department) uses the MEPS to evaluate health reform policies, the effect of tax code changes on health expenditures and tax revenue, and proposed changes in government health programs, such as Medicare. Since 2000, data on premium costs from the MEPS Insurance Component have been used by the Bureau of Economic Analysis to produce estimates of the GDP for the nation. The MEPS Insurance Component establishment surveys have been coordinated with the National Compensation Survey conducted by the Bureau of Labor Statistics through participation in the Interdepartmental Work Group on Surveys to minimize overlap in content. Private businesses, foundations, academic institutions, and the health services researchers also use these data for a wide range of purposes.

The MEPS website (`www.meps.ahrq.gov`) provides more detailed information on data availability and research summaries that illustrate the analytical breadth and utility of the MEPS to measure health care trends and inform health policy and practice.

The views expressed in this chapter are those of the author and no official endorsement by the Department of Health and Human Services or the Agency for Health care Research and Quality is intended or should be inferred. The author wishes to thank Dr. Arlene Ash, Dr. Paula Diehr, Ms. Trena Ezzati-Rice and Ms. Elizabeth Conklin for their careful review of the article and for their helpful suggestions.

STEVEN B. COHEN

Medical Journals, Statistical Articles in

There are thousands of publications dealing with aspects of statistics throughout the medical literature. Many of these are "Letters to the Editor", that are critical of some statistical aspect of an already published article; they appear frequently with a response, usually defensive, from the author(s) of the original article. This simple exchange of views is rarely extended in print, and the "response" from authors automatically gives the final word. The adversarial format of these exchanges forestalls scientific resolution of contentious issues and consequently does not provide a satisfactory solution. Less often, but with higher profile, statistical criticism sometimes appears in focused editorials that are invited by editors (sometimes from anonymous authors), and that are published in the same issue of journals as the study (or paper) they comment on. Such editorials can influence the scientific credibility of important studies, because they are published at the same time as the study they focus on and are given some prominence. However, they are usually not peer-reviewed and the statistical criticisms they make may be inaccurate.

Many articles discussing statistical issues appear, as would be expected, in journals devoted to methodologic aspects of epidemiology (notably ***Journal of Clinical Epidemiology***, *American Journal of Epidemiology* and the online BioMed Central (BMC) *medical Research Methodology*), **clinical trials** (***Controlled Clinical Trials*** and, *Clinical Trials*), and diagnosis (*Medical Decision Making*); they have also been published for many years in journals devoted to psychology, especially *Psychological Bulletin, Applied Psychological Measurement*, and *Educational and Psychological Measurement*; indeed, psychologists and psychiatrists have their own sophisticated journals of methodology, *The British Journal of Mathematical and Statistical Psychology*, *Psychometrika*, *Multivariate Behavioural Research* and the *International Journal or methods in psychiatric Research*. The papers in these journals are not discussed further; the remainder of this article will concentrate upon the general medical and medical specialty journals.

Apart from letters, editorials, and papers in the journals mentioned above, there are still many articles each year that deal with statistical issues in an elaborate way; they may be categorized broadly under the following headings:

1. isolated papers on a particular statistical issue
2. series of thematic papers dedicated to a narrow statistical area
3. series of papers covering broad areas of medical statistics
4. guidelines
5. surveys of published papers reporting the frequency of usage of statistical techniques
6. reviews of published papers examining critically aspects of design, analysis, conduct, presentation, and summary
7. systematic reviews (meta-analysis) incorporating assessment of methodologic quality.

Each of these types is described and discussed briefly with some examples. Those chosen are illustrative, if not fully representative, of each category, and have not necessarily been selected as the best or the most comprehensive. Some papers bridge two categories. Some articles on statistics are accompanied by editorials, particularly when they have been commissioned by a journal; some attract criticism in published letters. It is also notable that some of the papers focusing on statistical issues, particularly those in the fifth and sixth categories, do not appear to include a statistician either among the authors or among the acknowledgments.

Isolated Papers on a Particular Statistical Issue

Isolated papers that discuss one particular statistical issue occur sporadically throughout the worldwide medical literature. Some are written to provide examples of the correct application of a statistical technique stimulated by obvious misapplications within a particular specialty of medicine or more widely; some are written to explain the basis of more complicated statistical methods; others are more provocative and written to stimulate debate about controversial issues. The standard of presentation varies widely: some are regarded as "classics", while others, written by authors who do not fully appreciate the complexities of the subject they are writing about, are inaccurate.

Much has been written about all aspects of clinical trials within many specialties of medicine; such papers covering design, conduct, analysis, and

reporting inevitably range across many statistical features. In particular, the small size of many trials inevitably led to the appearance of papers, explaining the need for "proper" **power** calculation during design (*see* **Sample Size Determination**). More controversial issues, particularly analysis under the paradigm of "**intention to treat**", produced, and indeed continues to generate, discussion papers within specialties. Wider application of **Bayesian** analysis and interpretation, realized through massive increases in computer processing power and storage, has resulted in papers explaining why it is needed and how it works [51, 52]. Some papers meet a specific need, for example setting out the classical analysis for both continuous and discrete variables in **crossover trials** [48]; others explain and reexplain concepts such as **regression to the mean** that continue to confuse medical researchers [59, 60, 88].

The need for better understanding of elementary techniques is illustrated: first by Godfrey [38], who sets out the basics of **linear regression** analysis with examples from 36 papers published in *New England Journal of Medicine (NEJM)* over two years; secondly by Hoffman [49], who points out the problems of applying the standard **chi-square test** to paired data; thirdly by Brown [15], who seeks to dispel confusion between **standard deviation** and **standard error**; and finally by Elashoff, commenting on multiple *t*-tests (*see* **Multiple Comparisons**) [26].

Of course, it is not just the application of elementary techniques that requires care. The introduction of more complicated methodology usually found in the pages of statistical journals demands more ready explanation and illustration in the medical journals, where it will need to be interpreted. For example, modeling techniques such as **logistic regression** [33] and the **Cox regression model** [27, 78] were described in the medical literature long before simple exposition in textbooks of medical statistics. Recently techniques for handling "missing" data have been developed in the statistical literature, and are now extending rapidly into specialised medical areas, for example, psychiatry [81], and obesity [35]. Some papers develop links between apparently disparate areas to develop clearer interpretation – for example, Hanley & McNeil [43] – drawing on the association between the area under the **receiver operating characteristic (ROC) curve** and the **Wilcoxon–Mann–Whitney** statistic.

A more controversial issue was the introduction of the randomized consent design [89], a new method for planning clinical trials, published in *NEJM* as a "Special Article" and accompanied by three editorials discussing its merits and demerits (*see* **Ethics of Randomized Trials**). This design, which requires the **randomization** of patients without their prior knowledge and consent, raises difficult ethical and legal issues. A further commentary on this design, summarizing experience of its use, appeared in the same journal five years later [28].

Fourteen papers that appeared originally in *NEJM* were updated and published collectively as a book [9]; an additional six articles were written specifically for the book itself. A second edition with substantive changes followed six years later in 1992 (some chapters were removed, some added, and some updated); they covered fundamental statistical concepts, use of statistical analysis, design, **controls**, series of consecutive patients, classification of research reports, decision analysis, linear **regression**, comparing multiple means, ordered categories (*see* **Ordered Categorical Data**), reporting methods in clinical trials, power and sample size, and **meta-analysis**; another article on statistical reporting in medical journals was drawn from *Annals of Internal Medicine*. Compendia of this type constitute a valuable resource; to our knowledge no others have been published.

Series of Thematic Papers Dedicated to a Narrow Statistical Area

There are many series of published papers that consist of up to three or four articles, occasionally more, focused either on the application of a particular statistical technique in medicine or on one particular area. One example of the former is the series of eight papers in *British Medical Journal (BMJ)* on systematic reviews (overviews or meta-analysis) produced in 1994 as a consequence of the huge increase in the number of such studies and the need to explain their rationale and methodology in greater detail; the series was later published in a book with an extensive bibliography [17] that expanded with the second edition published six years [25]. Another example was the ambitious trio of papers published by the *Lancet* introducing and explaining the ideas and concepts of **neural network** techniques (first paper [21]). Occasionally whole issues of journals have been devoted

to statistical issues, for example meta-analysis [65] and design and analysis of studies of gingivitis and periodontitis [77].

Several examples are needed to illustrate the diversity of applications to a particular area. First, the move away from ***P* values** and **hypothesis testing** towards **estimation** in the mid-1980s would only be realized if data analysts could readily calculate **confidence intervals** for a range of summary statistics. Since the literature on this was widely scattered and remote from the medical literature, *BMJ* responded by publishing a series of four papers in 1988 that both explained the reasons for interval estimation (*see* **Estimation, Interval**) and provided the methodology. The series was later collected in a book [36], that included both an earlier motivating paper and statistical guidelines [5, 37]; a second edition with further additions appeared eleven years later [6]. A second series of three papers set out the basic principles of good form design (*see* **Questionnaire Design**). Although not necessarily regarded as a subcomponent of "statistics", this is an area that is frequently discussed with statisticians to control both the extent and quality of data to be collected [85]. As a third example there are the two seminal papers by Peto et al. [62] that had a great influence, not just in cancer but far beyond, on the analysis and reporting of pragmatic clinical trials that followed patients to a specified event such as death. These two papers discussed in great detail not just the methods of analysis but also how to handle many of the problems encountered in such trials. The final examples illustrate medical journals responding to topical issues with a need for better understanding of contemporary techniques in assessing **quality of life** (three papers) [32], in estimating and interpreting costs (*see* **Health Economics**) (six papers) (first paper [69]); in better management (15 papers including **decision theory**) (first paper [74]), and in "qualitative" research (seven papers) (first paper [64]); or discussing perennial favorites like placebos (*see* **Blinding or Masking**) (seven papers) (first paper [40]), and epidemiology and clinical trials (eleven papers) (first paper [41]).

Of course, series of papers on a specific statistical theme are not restricted to general medical or cancer journals. In particular, in **psychiatry** the importance of statistics has been debated and acknowledged for many years. For example, May et al. [56], discuss the assessment of psychiatric outcome in both **cross-sectional** and follow-up studies, while Streiner spans a wide range of research methods in a series of 23 articles that started in 1990, and continues today (first paper [75]).

Series of Papers Covering Broad Areas of Medical Statistics

There have been several series of papers covering broad areas of medical statistics. The earliest and best known is, of course, the one by **Bradford Hill** that was published weekly in the *Lancet* from 2 January to 24 April 1937. The first article was prefaced by an editorial entitled "Mathematics and Medicine", that opened with the words

> Statistics are curious things. They afford one of the few examples in which the use, or abuse, of mathematical methods tends to induce a strong emotional reaction in non-mathematical minds. This is because statisticians apply, to problems in which we are interested, a technique which we do not understand. It is exasperating, when we have studied a problem by methods that we have spent laborious years in mastering, to find our conclusions questioned, and perhaps refuted, by someone who could not have made the observations himself. It requires more equanimity than most of us possess to acknowledge that the fault is in ourselves.

This series of 17 3–4-page articles which covered the aims of statistics, selection, presentation, variation, averages, proportions, differences, **chi-squared**, **correlation**, **life tables**, and **survival**, common fallacies and difficulties, proportional rates, crude rates, and the calculation of standard deviation and correlation coefficient, was quickly published collectively as the celebrated book, *The Principles of Medical Statistics* [46] in the same year, and in 11 subsequent revised and expanded editions spanning 54 years [47].

One of the longest series was the extensive collection written by Feinstein under the heading *Clinical Biostatistics* and published in *Clinical Pharmacology and Therapeutics* from 1970 onwards. (He also wrote three other much shorter series for *Archives of Internal Medicine, Annals of Internal Medicine*, and *Yale Journal of Biology and Medicine*.) Twenty-nine articles selected from the first 40 were published collectively as a book with the same title [31]. This extensive series of over 50 articles built on and was

inspired by an earlier series in the same journal by **Mainland** and an unpublished collection of 145 "Notes from a laboratory of medical statistics", also by Mainland. These long articles discussed in detail not just the features of design, analysis, presentation, and interpretation, but also included quantitative surveys of the medical and statistical literature, critiques of individual studies, and discussion of the **teaching of statistics** and the ethics of research.

By contrast to the series above, that taught much about concept and methodology, a later series of short appealing articles published in *BMJ* in 1976 by Swinscow reflected the need of both the medical profession and journals at the time by presenting a very practical approach to the application of statistics through simple calculation of summary statistics (**means**, standard deviations, standard errors, proportions, correlation, and regression) and immediate application of significance tests (t-test (*see* **Student's *t* Statistics**), chi-square, **Fisher's exact**, rank sum). This series was also published as a book [76], the immense popularity of which can be gauged from the ten editions, and many reprintings, published over 26 years. This success was repeated several years later with a series on the basics of epidemiology [70].

As a follow-up to the papers by Swinscow and to remind researchers and doctors that there is more to medical statistics than the calculation of summary measures and hypothesis tests, *BMJ* commissioned two further series that were published contiguously in 1982. The specific aims were to remind researchers and authors that "they need statistical advice before starting a project and not at its end", to make medical statisticians "appreciate that most doctors are still bewildered by statistical jargon and too often react by ignoring the more important aspects of logic and correctness of argument", and finally to educate editors of journals (and their advisers) "to be on the lookout for pitfalls and use expert statistical advisers more frequently than they do". The two series were *Statistics and Ethics in Medical Research*, that covered misuse, design, sample size, data collection, analysis, presentation, interpretation, and how to improve the quality of statistics in medical journals, and *Statistics in Question*, which in two parts covered many aspects of clinical trials (13 articles), and the principles of data display, presentation, summary, and interpretation (10 articles). Following the precedent established with the earlier series, these two series were also published as a book [39].

Starting in 1994, and perhaps harking back to the seminal *Notes* of Mainland, *BMJ* has introduced a longer series of very brief occasional *Statistics Notes*, not just to remind readers (yet again!) about basics, but also, and importantly, "to keep them up to date with more complex techniques that are finding their way into medical studies" [13]. Each note occupies at most one page, dwells on a single topic, and is self-contained. By 2003, the series extended to 47 *Notes* and included some topics that are needed frequently in practice but are not easy to locate – for example, regression to the mean, quantiles (*see* **Quantiles**), multiple significance tests, correlation with repeat observations on the same subject (*see* **Longitudinal Data Analysis, Overview**), data summary after **transformation, measurement error**, and **Cronbach's alpha**.

Another long series (17 papers under the heading *Statistics from the Inside*) by Healy (first paper [44]) appeared in *Archives of Diseases in Childhood* over the period from 1991 to 1995; as well as the usual basic statistical concepts, it also covered diagnostic and **screening** tests as well as reference values. Somewhat shorter series are more common. An example is a series of four basic articles on general statistical principles under the heading *Basic Statistics for Clinicians* in *Canadian Medical Association Journal* [42].

Guidelines

Guidelines are intended to present a succinct summary (sometimes highly detailed) of procedures or standards that should be followed in performing set tasks; several have been written for performing or assessing research. A few examples are guidelines for performing clinical trials in particular specialties of medicine [10, 66], for evaluating the quality of clinical trials generally [18], for reporting epidemiologic studies [14, 31] and studies of screening tests [79], for structuring reports [54], and for evaluating them [67, 87]. The Evidenced Based Medicine Working Group in Canada has produced several guides for assessing and interpreting reviews [61]. There are many others. There are also more general statistical guidelines [5] that some journals draw attention to in their advice to authors. Other guidelines concern licensing applications to Regulatory Authorities [20]. Abbreviated guidelines in the form of checklists have also been produced,

for example for designing clinical trials [19] and for statistical review [37]. Among more recent guidelines is the CONSORT statement [11], that was intended to improve and standardize the presentation of results from randomized clinical trials. Unusually, the authors of these guidelines included some journal editors, which may explain why the CONSORT statement was adopted by many leading journals; with a consequent improvement in publication standards [23]. Further improvement is expected following publication of the revised CONSORT statement [58], accompanied by a detailed explanation of its use [7], and the recent extension to cluster randomised trials [16]. Similar initiatives have been instigated to improve reporting in other areas of medical research.

Surveys Reporting the Frequency of Usage of Statistical Techniques

There have been several surveys of the use of statistical techniques in the biomedical literature. Although these "content analyses" are sometimes combined with the assessment of correct usage, as discussed in the next category, their aim is generally to review the knowledge required to understand published papers rather than whether or not the reported techniques are used correctly. For example, Hokanson et al. [50], adopting categories established by previous investigators [29], estimated the frequencies with which various statistical techniques were reported in almost 5000 papers published in five major American **oncology** journals in 1983 and 1984; they concluded that readers familiar with about a dozen techniques could expect to understand approximately 90% of quantitative concepts in those journals; not surprisingly the techniques were mostly those covered in many elementary texts about medical statistics. These results were supported by those of Marsh & Hawkins [55], who used similar techniques to survey 44 publications from multicenter randomized clinical trials sponsored by the National Eye Institute or the National Heart, Lung, and Blood Institute. They found that knowledge of 12 techniques would be sufficient to understand 90% of the published analyses. However, they also showed that no publication from the set of 44 was fully accessible with knowledge of just the six most frequently used statistical techniques (descriptive statistics, **contingency tables**, *t*-test, power, life tables, and regression for survival).

However, there have been major changes in more recent years. Later surveys of *NEJM* [2, 30] found great increases in the use of more complex methods (notably logistic regression and survival analysis) and also an increase in the average number of techniques used in each paper. They provide a rare example of longitudinal content analysis within one journal. The contrast between two time periods is also discussed in [4].

Critical Reviews of Published Papers

Since 1920 there have been several hundred reviews of the published medical literature that have examined in some detail various aspects of design, data collection, analysis, presentation, and summary. Their objective is to report the frequency of statistical misuse or bad practice. Many have focused on clinical trials and/or epidemiologic studies within specific subspecialties of medicine, and others on specific statistical techniques; some were restricted to specific journals, while others were very broadly based. The earliest we know of was published in 1929 [24], and consists of a survey of the extent to which "statistical logic" is used in a sample of 200 medical–physiologic papers from then current American periodicals. This is a long paper and, at over 120 pages, is longer than many of the series covered in the third category above; the second page reports the results of the survey and the remainder essentially form a textbook of medical statistics for physiologists. Although Bradford Hill reviewed papers published in the *Lancet* when preparing his famous series in 1937, the next review we know of appeared in 1951 [71], and looked at the use of **controls** in papers that appeared in five leading American periodicals during the first half of 1950. From then the increase has been seemingly exponential. Indeed, reviews of this type have become an industry of their own, with over 120 journals having had their content subjected to statistical scrutiny. The surveys range from the simple bald summary that "we conducted a review of the literature" and found that "not more than a dozen adequately designed long-term follow-up studies are available" to far more elaborate studies examining in excess of a thousand publications and reporting the findings in detail.

One of the first large studies, and certainly one of the most influential, was the two-part review by

Schor & Karten [72]. They chose ten from among the 67 most frequently read medical journals, randomly selected three issues of each from the first three months of 1964, and then reviewed each article to investigate whether or not the conclusions that were drawn "were valid in terms of the design of the experiment, the type of analysis performed, and the applicability of the statistical tests used or not used". Their conclusions suggested that "none of the ten journals had more than 40% of its analytical studies considered acceptable; two of the ten had no acceptable reports". The second part of this review went a stage further when, later in 1964, one of the ten journals instituted statistical review of submitted papers that were judged medically acceptable for publication. In the next 18 months 514 manuscripts were submitted to statistical evaluation, of which 133 (26%) were considered acceptable and 34 (7%) were so poor as to be considered unsalvageable. Amongst other recommendations, the authors suggested that a statistician "either be part of the research team or be consulted before a study is attempted", a cry that has been repeated many times over the subsequent 30 years (*see* **Statistical Review for Medical Journals, Guidelines for Authors**; **Statistical Review for Medical Journals, Journal's Perspective**).

One of the best known reviews is that of Freiman et al. [34], who looked at the results from 71 randomized clinical trials that were "negative" in the sense that the comparison of control and experimental therapies was not statistically significant at the 5% level ($P > 0.05$); the trials were reported in 20 different journals over the period from 1960 to 1977. The authors observed that 67 (94%) of the trials had a greater than 10% risk of missing a true 25% therapeutic improvement and that 50 (70%) had a similar risk of missing a 50% improvement. Many other surveys have looked at statistical power, with similar findings, a recent one actually appearing in a new journal publishing negative results [45].

A much broader review is that of McGuigan [57], who looked for statistical errors in all papers (164 in total) reporting numerical results published in the *British Journal of Psychiatry* during 1993. Using the methods established in an earlier survey of the same journal by White [82] (covering the period 1977–1978), McGuigan reported an overall error rate of 40% (compared with White's 45%); individual types of error (rate) were characterized as: description of randomization or control selection (43%); measures of location (27%); measures of dispersion (27%); Student's t-test (80%); chi-square test (15%); **null hypothesis** description (5%); description of methods (16%); description of statistic (1%); statement of results (17%); interpretation of P values (2%); and incorrect or inadequate analysis (27%). McGuigan also plotted the rates from 14 surveys of statistical errors in the medical literature and published between 1960 and 1993; the median was in excess of 50% (although the definition of statistical error was not the same in each study (cf. [1]). Such surveys now extend more widely, for example, to Chinese [80] and Czech [63] biomedical journals.

Three further examples will suffice to demonstrate the character and range of these surveys. Badgley [8] surveyed all articles published in two Canadian journals in the first half of 1960, looking for those (103) that used "group data" (i.e. epidemiologic surveys and clinical trials and excluding case reports (*see* **Case Series, Case Reports**), reviews, descriptive papers, and articles providing a survey of the literature on a given topic); he reviewed five aspects of each article: the definition of terms; the selection of a population or sample; the use of controls; types of statistical analysis; and the derivation of conclusions. His summary reported that the "assessment revealed the need for greater precision in the design of many studies using group data and for caution in the interpretation of results". Ried & Hall (in a letter [68]) reported a survey of 569 papers published between 1980 and 1983 in the *American Journal of Clinical Nutrition*, looking for multiple significance testing within a single dataset. They found a median of 21 tests per paper (quartiles: 6 and 48) and commented "13% of the papers failed to state the type of statistical test that was used, only four papers made an allowance for the multiple use of statistical tests and 427 of the papers (84%) failed to specify predetermined levels of statistical significance". Linnet [53] reviewed assessments of diagnostic tests published in *Clinical Chemistry* during the period 1979–1983, looking at sample sizes and the statistical confidence of **sensitivity** estimates. He found 84 relevant papers and concluded from his review that "the precision of sensitivity estimates of tests was seldom considered by the investigators, and the significance of differences of sensitivity estimates was, with a single exception, not tested". Others were summarized by Altman [1, 2].

Interpretation of the results from the reviews themselves is not without difficulties. Williamson et al. [84] reported in 1986 an analysis of 33 surveys of the quality of the medical literature. Three experienced medical statisticians independently evaluated the quality of these review articles using a checklist of 40 items indicating the extent to which the assessment methods reported in an article substantiated the authors' results. While none was entirely unsubstantiated or contradicted, 15% were only weakly substantiated.

Systematic Reviews (Meta-analysis)

The last 15 years have seen a huge increase in the use of systematic reviews (meta-analysis) in medicine, especially of therapeutic trials [25]. This has led to much greater scrutiny of the statistical techniques employed in the design, analysis, and reporting of clinical trials, and to empirical studies of the relation between study features and the results of trials [73]. Meta-analyses quite often report the credibility of individual trials using assessment schedules that focus on key features. Such information can be used to determine which studies are included in a meta-analysis, or may be used as part of a **sensitivity analysis**. It is also possible to generate a quality score [18] that can be used to weight the results of individual trials before combination in the overview [22], although this is not a generally accepted approach. Systematic reviews are now more common in various nonexperimental situations, for example, epidemiologic studies and diagnostic tests, and concerns about the quality of primary studies has already resulted in quality assessment of the Catter [83].

Discussion

It is unfortunate that to date no annotated bibliography or catalog of all the articles in the first six categories listed above has been constructed. This would be an extremely valuable scientific resource both for research and for teaching and, further, would prevent unnecessary duplication among journals. There are no useful combinations of keywords that can be used in a search of electronic databases to identify the great majority of articles within the categories above, except perhaps for guidelines and meta-analyses. Some papers have titles that give no clue to the inclusion of a review of methodology [38, 53]. As we have noted, there is a considerable body of statistical articles within the medical literature; papers on statistics can appear in any medical journal. In particular, all the leading general medical journals have published important papers on aspects of statistics reflecting their appreciation of the importance of the sound application of the statistical components of any research article. The BMJ has been foremost in the drive to achieve higher standards, first by publishing far more such papers than any other journal, second by commissioning both individual papers and thematic series that can be readily understood and applied by physicians, and third, by republishing some articles collectively in compact, low-priced books.

Didactic articles have a long history and seem to be especially valued by journals and readers. Such articles may describe standard methodology or may introduce new methods in a doctor-friendly manner. Expository statistical papers (e.g. [12, 62] – category 1 above) can reach 500 citations within 4–5 years [4].

Perhaps second in impact are those studies of the quality of the statistical aspects of published research. Over a period of more than 70 years such reviews have consistently shown that many published papers are flawed. In some cases such reviews have led directly to changes in editorial policy, especially regarding increased statistical review of manuscripts. The main impact of such studies is probably slowly cumulative over time, and permeates gradually across the literature from the general journals to the specialist journals.

Statistical errors can occur at every stage of a research project, although reviews of the literature have been mainly concerned with methods of analysis. The underlying reason for the plethora of statistical errors is that the majority of statistical analyses are performed by people with an inadequate understanding of statistical methods [86]. They are then peer-reviewed by people who are generally no more knowledgeable [3]. There are other contributory reasons, such as the fact that several introductory textbooks in statistics are themselves full of errors [3]. Another problem is the copying of incorrect methodology from one study to another – for example, use of the correlation coefficient for comparing two methods of measurement [12].

Altman & Goodman [4] studied citations of 18 important statistical publications and also some content analyses to evaluate the speed with which new statistical methods infiltrate medical journals. They suggested several possible reasons for the apparent increased speed of diffusion: the increasing number of statisticians working in medicine, the wide accessibility of powerful desktop computers, and the more rapid development and dissemination of software to implement new statistical methods (*see* **Software, Biostatistical**). It is likely that general understanding of basic statistical methods (*t* and chi-square tests, for example) has improved, but there is ample evidence that many errors still occur in the use of these simple methods [57]. The increased use of more complex methods [2, 30], aided by easy access to powerful computers, has led to new problems, many of which cannot be detected in published papers. Several more complex statistical methods introduced in the 1980s are beginning to be seen more frequently – examples include neural networks, **multilevel models**, and Gibbs sampling (*see* **Markov Chain Monte Carlo**) [4]. Journals should expect to see growing numbers of papers using them, and doubtless a cluster of new didactic articles describing them. Nevertheless, the speed with which new methods are introduced may pose problems for statistical referees, for the physicians who read the published work, and for the journals themselves.

Medical Research Council (MRC)

The Medical Research Committee was set up in the UK in 1913 by the Government. The name Medical Research Council (MRC) was established by Royal Charter in 1920. At the outset, tuberculosis was a particular research target, but the scope of the MRC soon broadened to most areas of medical research.

The central institute of the Medical Research Committee was set up in Hampstead (London) in 1914, becoming the National Institute for Medical Research (NIMR) in 1920. The founding departments were bacteriology, applied physiology, biochemistry and pharmacology, and medical statistics. The inclusion of a department of medical statistics demonstrates the MRC's early recognition of the importance of statistics in medical research.

In fact, the Medical Research Committee had a Department of Medical Statistics since 1914, under the leadership of **John Brownlee**. This Department carried out original statistical research, but also undertook much routine work such as the sorting and classification of medical records. This latter activity was especially heavy during the war years, at which time more than 100 clerical staff were employed. In 1920 **Major Greenwood**, who was Statistical Medical Officer on the staff of the Ministry of Health, moved to NIMR. Greenwood became chair of the Industrial Health Statistics Committee and also a new Nutrition Committee. The latter, rather than Brownlee's department, became an advisory committee on statistical matters for the whole of the Council's work, and in 1925 its name was changed to the Statistical Committee.

During the 1920s it became clear that the MRC needed to reconsider the organization of its statistical work. In 1927 Greenwood was appointed to direct the Department of Epidemiology and Vital Statistics at the London School of Hygiene and Tropical Medicine (LSHTM). Brownlee's sudden death allowed the MRC to transfer all its statistical activity to the LSHTM. From 1928 the staff of the NIMR Department, Greenwood's Ministry of Health Department, and the Statistical Committee were merged into a single unit at the LSHTM.

In 1931 the MRC set up a Therapeutic Trials Committee (TTC) to oversee **clinical trials** in many areas, especially of potential new remedies. Surprisingly there were no statisticians on this committee, although Greenwood and **Bradford Hill** could be called upon to give statistical input where necessary. Although these early trials were controlled, it was not until 1946 that **randomization** was used. The concept of randomization had been introduced in agricultural research by **R.A. Fisher**. Despite his involvement with other MRC committees, such as the Human Genetics Committee, it seems that Fisher did not have any involvement with the TTC, but he did direct an MRC program of research into the genetic study of **blood groups**.

Greenwood retired in 1945 and was succeeded by Bradford Hill, under whose leadership the MRC group became the Statistical Research Unit. Under Hill the Unit developed an increasing reputation, notably becoming heavily involved in the MRC's clinical trials program. The introduction of randomized controlled trials was clearly a major event; the most famous of these was the **Medical Research Council Streptomycin Trial**, which was the first randomized trial to be published. Hill also made crucial contributions to epidemiologic research. In particular, in 1947 he embarked with Richard Doll on a series of famous studies of smoking (*see* **Smoking and Health**). This work led not only to clear evidence of a causal link with lung cancer, but it also stimulated Hill's development of the underlying principles of **observational studies** and the criteria for establishing causality from such studies (*see* **Hill's Criteria for Causality**).

In 1960 Bradford Hill was succeeded by Richard Doll, who directed the Unit until 1969. Doll was appointed deputy director of the MRC's new Clinical Research Centre (CRC) at Northwick Park (Harrow) but shortly afterwards moved to Oxford as Regius Professor of Medicine. The double move led to the disbandment of the Statistical Research Unit and many of the staff left the MRC and joined Doll in Oxford. The MRC set up a new small group, the Statistical Research and Services Unit headed by Ian Sutherland. In 1980 the Unit relocated to Cambridge, at which time it became the MRC Biostatistics Unit. As Sutherland's retirement approached, there was some uncertainty about the future of the Unit owing to the MRC's financial crisis, but in 1986 Nicholas Day was appointed Director. In recent years the Unit has increased in size to the point where it is one of

the largest biostatistics groups in the UK. Day retired in 1999 and was succeeded by Simon Thompson.

As the MRC's activities have diversified, and the need for statistical input was recognized increasingly, other statistical groups have been set up within the MRC. Following precedent, a medical statistics group was one of the first to be set up in CRC in 1970, initially under the leadership of Michael Healy. That group ceased to exist in 1993 as a consequence of the closure of the CRC.

Another Unit with considerable statistical expertise is the Clinical Trials Unit. This was founded in 1998 and consists of three Divisions. The Cancer Division was formerly the Cancer Trials Office (CTO), founded in Cambridge in 1977, and coordinates clinical trials in cancer. A meta-analysis group, originally set up by the CTO, continues to coordinate international collaborations on **meta-analysis** of cancer trials and has extended its remit to other disease areas. The HIV Division, formerly the HIV Clinical Trials Centre, conducts and coordinates trials in HIV (*see* **AIDS and HIV**), many of which are international studies. The Division Without Portfolio initiates trials in other areas where there are important questions but either insufficient infrastructure or few clinical trials at present.

While the MRC supports medical research by giving grants to individual scientists, it also provides long-term one of its main means of providing long-term support for research is through its establishments where it employs its own staff, currently three institutes and approximately 50 units. Statisticians are employed in many of these units. Two of the most prominent over the years have been the MRC Pneumoconiosis Unit near Cardiff, once headed by **Archie Cochrane**, and the Environmental Epidemiology Unit in Southampton, both now closed. An Epidemiology Unit in Cambridge has recently been established.

The MRC receives an annual grant to support research from Parliament via the Department of Trade and Industry. It also receives funding for some projects from other government sources including the Health Departments, the Overseas Development Administration, and the Ministry of Defence. Other sources of funding include industry and international agencies such as the **World Health Organization** and the European Commission. The MRC supports some research jointly with medical charities. The MRC is independent in its choice of what research to support.

The focus of this discussion has been on statistics within the MRC. In this regard the MRC has consistently been a major player within the UK, recognizing at a very early stage the essential importance of statistics to sound research, especially in clinical areas. The wider history of the MRC is considered at length in [1–3].

Medical Research Council Streptomycin Trial

The first **Medical Research Council** (MRC) trial of streptomycin in the treatment of pulmonary tuberculosis [10] occupies a special place in the history of medical statistics. This is not primarily for the findings, although these had important implications for subsequent tuberculosis research, but because the trial provided an explicit model for that research and served as a catalyst for the scientific investigation in man of other treatments and interventions throughout clinical and preventive medicine.

At the time, just after World War II, tuberculosis was the principal medical cause of death among young adults in Europe and the US, and streptomycin was the first drug to offer real promise of effective treatment. The antituberculosis activity of streptomycin was discovered in the US in 1944. Although suggestions for adequately controlled studies were put forward [8, quoted in 12], no controlled assessment of the efficacy of streptomycin in man had been undertaken by 1946. Limited supplies of the drug were made available to the MRC for such an assessment in the UK. The MRC set up a research team, their Tuberculosis Research Unit, with Dr Philip D'Arcy Hart, already deeply involved in tuberculosis research, as its director and Dr Marc Daniels as the clinical coordinator for the study. General responsibility for the planning, direction, and reporting of the study lay, from September 1946, with a special MRC committee with Dr Geoffrey Marshall, a leading tuberculosis physician, as chairman, D'Arcy Hart as secretary, and a membership which included **Professor Austin Bradford Hill**. The principal credit for the study that ensued belongs jointly to D'Arcy Hart, Daniels, and Bradford Hill [7]. All three were well prepared, indeed poised, to undertake the "rigorously planned investigation with concurrent controls" that was needed [10]. Bradford Hill had set down the principles of clinical experimentation in man in 1937 [4], including "random allotment" achieved by strict alternation or (in later editions of [5]), by using random sampling numbers (*see* **Randomization**). D'Arcy Hart [9] and Bradford Hill [13] had separately been involved in planning and executing rigorously controlled MRC trials – the one using alternation and the other random sequences. Daniels had been a principal investigator in the Royal College of Physicians' epidemiologic survey of tuberculosis in young adults [2].

The main aim was to assess the effect of the drug in pulmonary tuberculosis, carefully defined as "acute progressive bilateral pulmonary tuberculosis of presumably recent origin, bacteriologically proved, unsuitable for collapse therapy, age-group 15 to 30". At the time the only treatment for such patients was bed rest, and this fully justified treating the parallel **control** group in the trial with bed rest alone, especially as the available supply of streptomycin was insufficient to treat all such patients. Between January and September 1947, 109 patients, assessed as suitable by a central panel, were admitted to the trial from seven centers in England, Wales, and Scotland. Two patients died within a week, leaving 55 allocated to streptomycin and bed rest (S) and 52 to bed rest alone (C).

The allocation "was made by reference to a statistical series based on random sampling numbers drawn up for each sex at each center by Professor Bradford Hill" [10, reprinted in 6] and contained in a numbered set of sealed envelopes held by the coordinator, the appropriate envelope being opened as each patient was admitted. The details of the control scheme remained unknown to the coordinator and all of the investigators throughout. C patients were not informed they were part of a special study and "usually they were not in the same wards as S patients, but the same régime was maintained". All patients were treated with bed rest for 6 months, and their condition was assessed on admission and monthly thereafter. S patients received in addition 2 g streptomycin daily in four injections for 4 months.

Randomization was shown to have "equalized the groups; if anything, there are more severe cases in the S group". Changes in the radiologic picture were regarded as the most important single measure of response, and were assessed by three specialists reading the films independently, not knowing whether they were of C or S cases. There was fair agreement, any differences being readily resolved at a joint session. The changes during the 6 months are shown in Table 1. The difference in the percentages showing considerable improvement is significant (chance probability less than one in a million; *see* ***P* Value**).

There were correspondingly large differences between the S and C series in other measures and

Table 1 Assessment of radiologic appearance at 6 months as compared with appearance on admission

	Streptomycin group		Control group	
Radiologic assessment	Number	Percentage	Number	Percentage
Considerable improvement	28	51	4	8
Moderate or slight improvement	10	18	13	25
No material change	2	4	3	6
Moderate or slight deterioration	5	9	12	23
Considerable deterioration	6	11	6	11
Deaths	4	7	14	27
Total	55	100	52	100

assessments of response at 6 months. The greatest benefits from streptomycin were among the most acutely ill patients. Most of the improvement in the S cases occurred during the first 2–3 months, and thereafter many patients began to deteriorate. The short-lived benefit from streptomycin was shown to be related to the rapid emergence of strains of tubercle bacilli resistant to high concentrations of the drug. In addition, vestibular toxicity occurred frequently in the S series. The report [10] contained many illustrative case histories with radiographs; an addendum showed a significant difference in mortality between the two series at the end of one year.

The trial was designed to answer a specific group of questions concerning the effects of streptomycin on the progress of tuberculosis in man. The restriction of the intake to pulmonary tuberculosis hitherto treatable only by rest in bed, the random selection of those to receive streptomycin, and the precautions to avoid **bias** in management and assessment of the patients enabled the effects of the added streptomycin to be separated from those of the natural course of the disease. The answers for that type of tuberculosis, in a particularly lucid and detailed report, were unequivocal, on efficacy and its duration, on bacterial resistance, and on drug toxicity. The limited amount of streptomycin available to the MRC greatly facilitated the introduction of the random allocation scheme that was crucial to the reliability of the trial findings. Many years later, Bradford Hill [7] expressed doubts whether the random allocation would have been achieved if supplies had been greater.

The clear demonstration in the report of the advantages and disadvantages of the first effective drug treatment for a widespread and lethal infectious disease made a considerable impact on clinicians and statisticians. In the field of tuberculosis, the trial initiated a 40-year series of mostly multicenter controlled chemotherapy trials [3] (*see* **Multicenter Trials**) under MRC auspices in Britain, East Africa, India, and Hong Kong: in different types of tuberculosis; assessing new drugs in combinations to combat bacterial resistance; comparing different durations of treatment for the prevention of subsequent relapse; comparing treatment at home with treatment in a sanatorium [1, 11]; investigating alternative dosages and rhythms of administration to reduce toxicity; and comparing supervised with unsupervised regimens to improve compliance.

The use of random allocation, and the attention paid throughout all aspects of the trial design to obtaining an **unbiased** comparison, also provided a major stimulus to the postwar development of the **clinical trial** in other diseases. Although there is still a place for systematic allocation schemes that are effectively random, e.g. [9], the introduction of allocation schemes based on random sequences is undoubtedly the most important single advance in the evolution of the clinical trial [12] during the twentieth century (*see* **Randomized Treatment Assignment**).

Medicare Data

A portion of this work was supported by the ResDAC contract from CMS.

Medicare is a federal health insurance program for nearly all Americans aged 65 and over, for younger persons entitled to Social Security disability payments for at least 2 years, and for people with end-stage renal disease (ESRD). It is administered by the Center for Medicare and Medicaid Services (CMS, formerly the Health Care Financing Administration, HCFA) in the US Department of Health and Human Services. In 2003, persons with entitlement due to these mandates numbered approximately 34.7 million, 5.8 million and 300 000 respectively. By 2020, total enrollment is expected to exceed 60 million. Medicare data are a notable research resource because of the program's huge size and national scope, the range and quality of information captured, the fact that each beneficiary's eligibility is known in each month, and because most beneficiaries remain continuously enrolled until their death. Medicare is the largest single purchaser of health care services in the United States, spending over $260 billion dollars in 2003, including three-quarters of costs for patients with ESRD, nearly half of all hospital revenues and over 70% of hospice spending.

Medicare files contain information on all beneficiaries enrolled and the nature of their benefit, medical problems, (diagnoses) and utilization (claims and costs) for the approximately 87% of Medicare beneficiaries enrolled in the "traditional" fee-for-service (FFS) plan, as well as financial and other descriptive data on licensed providers (e.g. hospitals and physicians).

Eligibility data, including extensive demographics and enrollment information, are available in the annual Denominator files, with one record per beneficiary eligible to receive Medicare benefits during any part of that year. Medicare enrollment is by calendar month, with 12 monthly indicators of when each person is enrolled for Part A (Hospital Insurance, HI) and Part B (Supplemental Medical Insurance, SMI, covering physician and ambulatory care) benefits, and whether they are receiving the FFS or managed care (Medicare Advantage, formerly Medicare + Choice) option.

The valuable annual Medicare Provider and Review (MedPAR) research file, containing one record per hospital or skilled nursing facility discharge, has been available since 1984. Information includes: a hospital identifier, admission and discharge dates, up to 10 diagnoses and 10 procedures, and the **diagnosis related group (DRG)**, a classification that largely determines Medicare's payment. The first listed, or "principal", diagnosis conveys the medical condition determined (at the time of discharge) to have been the principal cause for hospitalization. Charges across several categories of services (e.g. bed charges and intensive care unit utilization), allowed charges, and payments (reimbursements) by CMS and others are also noted.

Research opportunities expanded considerably in 1992 when "final action" (fully adjudicated billing) data from skilled nursing facilities, home health care, hospice, hospital outpatient and physicians, other suppliers and health professionals became available in standard analytical files (SAFs). All SAFs contain provider identifiers, service date(s), diagnoses, services provided, and CMS payments.

Methodological studies validating the Medicare claims information, the demonstrated value of claims data in predicting health care outcomes, such as cost, hospitalization and death, and the recorded experience of nearly all Americans over the age of 65, make Medicare data an important source of information on health care delivery and its consequences in the United States. The data, of course, only relate to covered benefits. Thus, at present they contain information on drugs only when administered in facilities (such as chemotherapy), and most nursing home utilization (because it is covered by Medicaid, rather than Medicare) is missing. Also, the data indicate when a test was done, but not the result; the absence of follow-up treatment could equally well indicate a negative finding or a lapse in patient management. While dates of death are accurate and complete, the data contain neither cause nor place of death. (This information can be merged on from the National Death Index, maintained by the **Centers for Disease Control and Prevention (CDC)**.) Comprehensive profiles of a person's medical problems can be extracted from diagnoses coded on claims using the **World Health Organization's international classification of diseases** (ICD) coding system [2, 6]. A "clinically modified" ICD version, ICD-9-CM, maintained by the National Center for Health Statistics

(NCHS), has been in use in the United States since 1980. However, detailed physiologic information, such as blood pressure or hematocrit readings, cancer stage or cardiac ejection fraction, is not available.

Data Completeness

The Medicare program is complex. Knowing what can be found in the claims files (and where) requires understanding the program's benefits and how they are paid. For example, the managed care option (called Medicare Advantage, formerly Medicare + Choice) allows beneficiaries to choose a commercial managed care plan to coordinate their care (*see* **Health Services Organization in the US**). For the beneficiary, this can provide reduced or waived copayments and deductibles or pharmacy benefits. However, these arrangements create data gaps, since CMS does not currently require Medicare Advantage plans to submit encounter records (dummy claims). Between 2000 and 2003, CMS used diagnoses from Medicare Advantage hospitalization records to calculate payments to plans based on enrollees' expected future health care use [4]. The hospitalization records used in these calculations, however, are not systematically available in research files, although some Medicare Advantage hospitalizations appear in MedPAR. Medicare Advantage enrollment of the beneficiary and readmission within two weeks of a previous discharge are the main reasons for zero-reimbursement MedPAR hospitalizations. Beginning in 2004, CMS will calculate payments to plans based on "expected future need" as calculated from submitted lists of their enrollees' medical problems. It will no longer require encounter records (either hospital based or ambulatory) from Medicare Advantage plans [7].

The claims data can also be incomplete for the 3 to 4% of beneficiaries who do not take part in both parts of the Medicare benefit. Medicare Part A (hospital, skilled nursing facility and hospice) coverage is automatically received by almost all Medicare recipients, while Part B (principally physician and ambulatory care services) coverage is available for a monthly fee ($58.70 in 2003). Persons with both Parts A and B coverage use more Part A services than those with Part A coverage only. Why? Part B coverage provides such good value, that people who do not purchase it often have generous alternative insurance that pays for their hospitalizations as well. Because billing data provide an incomplete record of care for both M + C enrollees and those missing either Part A or Part B entitlement, studies of service gaps (such as failure to receive appropriate surgical follow-up) typically exclude such enrollees.

Other data gaps are less easy to remedy. For example, although the veterans health affairs system maintains merged Medicare/VHA files and has documented the substantial size and nature of overlapping health care use for over 1 million Medicare beneficiaries who use the VHA [8], Medicare data cannot identify VHA users, and thus, (unknowingly) views their Medicare utilization as complete.

Another form of data incompleteness occurs for surgical care when multiple provider/patient encounters are "bundled" into a single global payment. Suppose, for example, that a surgeon receives a single payment for all the care surrounding a mastectomy: preoperative evaluation, the surgery itself, and routine postoperative care, including routine follow-up. No individual bills are submitted for bundled surgical care (and if they were, they would be rejected), so the claims data provide no evidence as to the nature or timing of the follow-up services actually delivered.

Demographic Data

Medicare enrollment files contain dates of birth and death, gender, and race. Since 1994, every beneficiary is assigned to one of seven race codes: white, black, Asian, Hispanic, North American Native, other, and unknown. These codes are the basis for numerous studies examining whether patterns of care and care outcomes vary across racial groups. A study comparing self-reported race with Medicare's race variable, found good accuracy for blacks, but other racial groups were often misidentified as white [1] probably because an earlier form of the variable offered only four choices: white, black, others, and unknown. Undercounts are most problematic for Native Americans and Hispanics. The undercount of Native Americans, a not-very-populous group that may be receiving particularly poor **quality care**, makes studying their care particularly difficult. Even the "new" Medicare race categories pose problems, since most federal race coding schemes (including the National Death Index and the Census) distinguish between race (white, black, Asian, North American Native) and ethnicity (Hispanic heritage or not). Thus, people can be white Hispanic, white non-Hispanic, and

so on. In Medicare, a person of Hispanic heritage is so classified, regardless of race. Despite these problems, Medicare data are crucial for studying racial disparities in health care because most commercial insurance databases do not record race.

Although Medicare knows each beneficiary's residential address, standard research files indicate, at most, state, country, and zip code of residence. Socioeconomic status (SES) indicators, such as income and education, are not directly available, but can be proxied from census data (such as median income or percent with less than a high school diploma) merged in at the zip code or census-tract level.

Nearly one-fifth of Medicare FFS beneficiaries are also dually entitled to Medicare and some form of Medicaid benefit. Medicaid benefits, such as pharmaceuticals and nursing home care, frequently supplement, rather than substitute for, Medicare utilization, and most, but not all, Medicaid beneficiaries can be identified in Medicare through the denominator file variable "state buy-in", an indicator of participation in one of eight [9] programs. These programs provide a variety of benefits ranging from help in paying Medicare premiums through full Medicaid coverage. The Medicaid eligibility variable ("state-buy-in") is often treated as an indicator of poverty. Researchers write, for example, that "the effect of factor X disappears 'after controlling for' Medicaid enrollment (or poverty)" However, "state-buy-in" does not identify all Medicaid enrollees, nor does it coincide with a coherent definition of poverty. While all states' Medicaid programs require income less than twice the federal poverty level, program income thresholds differ. Further, even for those entitled to Medicaid, enrollment requires a request. Thus, this variable identifies some, but not all, low-income elderly, and some, but not all, Medicare beneficiaries who also receive Medicaid benefits.

The group health plan master file contains data on beneficiaries who have ever been enrolled in a Medicare Advantage (managed care) organization, including dates of enrollment and changes in enrollment, as well as the specific plan(s).

Utilization Data

One of the most challenging aspects of studying Medicare utilization is figuring out how health care is divided across files. For example, emergency room (ER) care is stored in inpatient files (such as the MedPAR) if the ER use results in a hospitalization, but is stored in the "outpatient" file if it is not followed by a hospitalization. Likewise, the meaning of "outpatient" is not the opposite of "inpatient". Medicare files are divided by type of care and billing form. Claims from providers that bill using the UB-92 will be in different files than claims from providers that bill on CMS-1500 forms. Some patients are treated on an ambulatory basis by facilities that bill using the UB-92. Those bills will be found in the Outpatient file, whose name refers to hospital outpatient departments. Other providers that treat ambulatory patients use the CMS-1500 form for billing. The Carrier file, formerly called the *physician/supplier Part B file* (also, the *national claims history* file, or *NCH*) contains bills from physicians for care provided in any setting, facility bills for care received in freestanding ambulatory surgical centers, and bills from other providers, such as nurse practitioners, ambulances, and freestanding laboratories. Thus, the same type of procedure (such as a cataract excision) resides in the Outpatient file if done in a hospital outpatient department, or in the Carrier file if done in a freestanding ambulatory surgical center.

Finding all procedures or health care system encounters, requires examining both "facility" and "physician/provider" bills. And, payments for a single procedure often generate more than one bill. For example, there will be a facility or technical charge for an x-ray (for using the x-ray machine, for the machine technician, the film, etc.) and a professional charge for the radiologist who reads the x-ray. We are most familiar with this pattern in the context of inpatient hospital stays. The MedPAR contains facility bills for an inpatient hospital stay (the technical charges) and the Carrier file will contain bills from physicians who care for the patient during the stay – emergency room physicians, radiologists, surgeons, anesthesiologists, cardiologists, and so on. These physician bills are the professional components. If users of **administrative data** are not careful, they can overcount services by counting technical and professional bills separately rather than combining them into a single service.

Coding protocols for procedures are entirely different depending on whether they appear in facility bills (ICD-9) or are coded from doctors' offices (current procedural terminology, CPT-4). While the

ICD system is public and can be obtained from NCHS [10], CPT is copyrighted by the American Medical Association and its use in any product or publication requires a license [11]. The CMS-1500 bill, used both for some facility and all physician bills, codes services (procedures) in three components: the code, the modifier, and the units. Sometimes both physician and facility bills for the same service are submitted on the same CMS-1500 form. The code modifier provides further details on the service provided, or by whom. Modifiers answer questions such as: was the surgery on the left or right eye? Is the bill for a facility, a physician, or both? Is it for a solo surgeon or an assisting surgeon? Information in the units field on the CMS-1500 varies by provider type, such as: ambulances are paid by the mile, anesthesiologists by the minute, and radiation oncology by number of treatments. For people in special circumstances, additional information is often available in separate files. All Medicare-certified nursing homes must collect extensive data on the health status on admission, at least quarterly, and with a significant change in status, for all patients. These data are available to researchers in the minimum data set (MDS) [12]. Another interesting Medicare data source is the outcome and assessment information set (OASIS) data for home health care. OASIS records the problems being addressed, and **comorbidities** and functional impairments used to determine a Home Health Resource Group (HHRG) global payment for all home health services during a 60-day "episode" [5].

Some information used to justify submitted bills (such as proof of an inconclusive CT scan prior to PET scan) is not available in Medicare research files.

Provider Files

Medicare also maintains substantial information about the providers with which it contracts, such as physicians, hospitals, skilled nursing facilities, providers of durable medical equipment. The provider of services file (POS) contains information about institutional providers including freestanding ambulatory surgical centers. Cost report files contain detailed information about the costs to institutions of providing care for Medicare beneficiaries and how that care relates to payments received. The Unique Physician Identification Number (UPIN) master file contains information about physicians such as their specialty and practice location. These files can be ordered directly from CMS [13].

Special Linked Data Files

The Medicare Current Beneficiary Survey (MCBS) is a rolling **panel survey** of a nationally representative sample of about 18 000 beneficiaries, living independently or in long-term care facilities. This CMS survey provides longitudinal information on health service utilization, insurance, and expenses (by all payers, not just Medicare); health and functional status; income, assets, living and care arrangements, and **quality of life**. These data are linked to Medicare's usual files and provide a unique source of data relating to the total health and health spending profile of Medicare beneficiaries [14].

The Surveillance, Epidemiology, and End Results Program (SEER), run by the National Cancer Institute (NCI), collates data from participating cancer registries across the United States (*see* **Cancer Registries**). These registries have been linked with Medicare data in a data system called "SEER-Medicare", maintained by the NCI [3] or [15]. The linked SEER-Medicare files contain all incident cancer cases identified in SEER registries and all Medicare claims for these cases from 1986 forward (regardless of when they were diagnosed with cancer). A comparison file is also available, containing Medicare claims for a similar period of time for a 5% **random sample** of Medicare beneficiaries living in cancer registry areas.

The United States Renal Data System (USRDS), begun in 1988 and jointly funded by the National Institute of Diabetes and Digestive and Kidney Diseases and CMS, collects, analyzes, and makes available for extramural research, substantial information in addition to Medicare's usual data. USRDS data describe entry into the program (date, initial treatment modality, cause of renal failure, and other health factors) and follow-up information (such as wait-list status for transplant, changes in treatment modality, and the date and cause of death) [16].

Data Artifacts

Observed changes in patient care data over time can be artifacts. Across the history of the Medicare program, there have been numerous changes in coding,

payment, and recording of services. It is important to distinguish true secular changes from mere data changes. For example, since 1991, the number of preventive services covered by the Medicare program has steadily increased. Colorectal cancer **screening** became a covered benefit in 1998 and prostate cancer screening in 2000. Previously, when only diagnostic testing (but not screening) was covered, some people received screening coded as a diagnostic work-up, some paid for screening themselves (and the bills did not show up in Medicare), and many simply were not screened. Thus, it is hard to disentangle changes in screening and diagnostic testing from changes in how these tests appear in Medicare's bills. Secular trends can be subtle. Both absolute and relative payment rates have changed during the 1990s, particularly for physicians. The prospective payment system, applied to hospitals since the 1980s, has now been expanded to include hospital outpatient services, home health, and skilled nursing facility care. Over this same period, Medicare managed care expanded considerably and then retracted slightly. Racial coding shifted from four levels to seven. Diagnostic codes, presently using the ICD-9-CM coding system, and becoming richer every year, will eventually convert to the ICD-10 formats already in use in other countries. The lack of a simple map between ICD-9 and 10 will complicate **longitudinal analyses**, just as other changes in the population and their data always have.

Although beneficiaries receive their care under a unique health insurance claim (HIC) identifier, a small percentage (no more that 2% per year) change HICs (most commonly due to a change in marital status for people with Medicare entitlement via their spouse's work history). In longitudinal studies, researchers should request files from CMS that substitute a single identifier for each person.

With over 40 million Medicare beneficiaries, 10 million hospitalizations and more than a billion total annual claims for Medicare enrollees, researchers will inevitably find data problems, such as an occasional person whose age exceeds that of the oldest living person in the Guinness Book of World Records, or service care dates that extend beyond the date of death. Likewise, while problems are occasionally found, zip codes of residence are accurate for 99.9% of beneficiaries.

Data Availability for Research

Although CMS's primary obligation is to serve and protect beneficiaries, it also invests in making Medicare data available to researchers. Given the huge scope of data, it is often adequate (and prudent) to conduct research on Medicare's 5% research files. These files consist of all the data for a random 5% sample of Medicare enrollees.

Most academic researchers use research identifiable files (RIFs). Such data are not sold, but only loaned (on a need-to-know basis) for use in answering a specific question via an approved research protocol. Additional questions may be pursued only with explicit permission. Files have a data retention date, after which they must be returned or destroyed. The data may not be used for direct marketing, to make unauthorized patient contact or to identify individuals. CMS reserves the right to preview presentations and publications, with the key concern that no publication release information on a subgroup with 10 or fewer people. CMS funds a Research Data Assistance Center (ResDAC) to help researchers obtain and appropriately use CMS data [17]. In the past, beneficiary data were also available as encrypted files for use by researchers or research projects that could not meet the threshold set by CMS for using identifiable data. Owing to privacy rules of the Health Insurance Portability and Accountability Act of 1996 (HIPAA), CMS no longer sells the beneficiary encrypted files, substituting limited data sets (LDS).

In summary, Medicare data is a unique source of data for **health services research**, due to its richness, size, national representativeness, continuity of enrollment, presence of race and date-of-death data, well-documented history of use in research, and the help available for researchers wishing to use it for studies of potential benefit to Medicare beneficiaries.

Medicines and Healthcare Products Regulatory Agency (MHRA) (Formerly MCA)

The UK Medicines and Healthcare products Regulatory Agency (MHRA) was established in April 2003 by the merger of the previously existing Medicines Control Agency (MCA) and Medical Devices Agency (MDA). The MHRA has responsibility for the protection and promotion of public health through the regulation of the safety, quality, and efficacy of human medicines (*see* **Drug Approval and Regulation**) and for monitoring medical devices. The Agency has a Medicines and a Devices Sector – most of the statistical involvement in terms of professional statisticians within the Agency comes from within the medicines sector and this article focuses on those activities. Before the merger, the Devices Agency used outside statisticians for some assessments of applications for new products.

The MHRA safeguards public health by ensuring that all medicines on the UK market meet the appropriate standards of safety, quality, and efficacy. It does so using duties and powers in the Medicines Act 1968, as well as with more recent UK and European legislation.

The principal functions of MHRA are the assessment of applications from pharmaceutical companies for marketing authorizations, surveillance of medicines after they are on the market (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**), inspection of manufacturing sites, enforcement of the Medicines Act, and the setting of public health standards for pharmaceutical products.

The regulatory framework within which the MHRA operates includes:

1. The *Licensing Authority* is stipulated in the Medicines Act as the Ministers responsible for Health in England, Scotland, Wales, and Northern Ireland, together with the Agriculture Ministers for veterinary medicines. This is invariably unified through decisions and actions taken by the Secretary of State for Health in England, acting through the MHRA for the entire United Kingdom. The MHRA is the executive body that carries out the decisions of the Licensing Authority. In coming to decisions as to the granting of a marketing authorization or action on changes to current authorizations, Ministers may take expert advice from the *Committee on Safety of Medicines* (CSM) and from the *Medicines Commission* (MC).
2. The *Medicines Commission*, an independent body with academic, consumer, and industry representation, also advises the Secretary of State on a wide range of policy matters related to the regulation of medicines, including veterinary medicines. It also hears representation from applicant companies appealing against advice from the CSM.

Each year around 20 to 30 new biotechnologic and other products receive a centralized European authorization, valid in all European Union (EU) Member States. Assessment is coordinated by the European Medicines Agency (EMEA), but professional staff of the EU Member States carry out the scientific evaluation. The MHRA is one of the leading evaluators in this European system. For these products, the European Community is the Licensing Authority. Their licensing decisions are based on recommendations from the Committee for Human Medicinal Products (CHMP), which is the expert advisory group to the EMEA and comprises experts from each Member State. However, the MHRA acts on behalf of the UK licensing authority to undertake postmarketing surveillance for products marketed in the United Kingdom, as this is a national responsibility.

In summary, the key activities of the MHRA (Medicines Sector) are to implement and enforce domestic European legislation, by

1. issuing and maintaining marketing authorizations, which allow drugs to be marketed in the United Kingdom, thus protecting the health of UK citizens; this involves issuing national licenses, and participating in the centralized and mutual recognition of European licensing systems;
2. monitoring medicines on the UK market for adverse reactions and taking any necessary action in domestic and international contexts to protect UK public health;
3. controlling the sale and supply of medicines;

4. inspecting and licensing manufacturers and wholesalers to ensure the quality of medicines on the UK market;
5. enforcing Medicines Law;
6. advising Ministers on medicines regulation in both the domestic and European as well as wider international context;
7. publishing, through the *British Pharmacopoeia,* standards relating to the quality of medicines.

The Agency has approximately 750 staff, which as of 2004 includes four professional medical statisticians working on licensing issues and one working on pharmacovigilance. There are additional professional academic statisticians who sit on advisory boards such as the Committee on Safety of Medicines and the Medicines Commission. In 2003, the Agency issued 24 licenses for new drugs, 1500 abridged licenses, and 21 000 variations to licenses, as well as receiving and analyzing nearly 17 000 adverse drug reaction reports from the United Kingdom and 44 000 from outside the United Kingdom. All of this work is in the context of increasing complexity in the scientific assessment work that needs to be undertaken and in the legal and administrative environment.

Licensing work also includes control of **clinical trials**, parallel imports, and registration of homeopathic medicines.

Postmarketing surveillance is a particularly important area for protecting public health and is an essential part of the regulatory process. New medicines inevitably come to market with limited experience. After licensing, safety issues not identified from clinical trials are recognized and acted upon. Statistical work has been done to improve the processes of analyzing these adverse reaction reports so that the UK system for surveillance tends to be more developed than those of most other Member States, and hence, it tends to be at the forefront of action required to protect public health. The Licensing Authority has powers to revoke or suspend licenses compulsorily. These issues tend to be controversial and complex in nature, and attract considerable media attention.

Further information about MHRA is available from their web site at `www.mhra.gov.uk`.

Medico–Legal Cases and Statistics

Medico–legal statistics concerns the use of biostatistical and epidemiologic data and methods in the context of law and government regulatory policy. Statistical reasoning has an important role in legal cases concerning product liability, compliance with environmental or **occupational health** and safety laws, the safety and efficacy of drugs and medical devices, medical malpractice, and the determination of safe levels of exposure to potentially toxic chemicals (*see* **Risk Assessment for Environmental Chemicals**). Recently, several Lanham Act cases concerned with commercial issues such as fair advertising, validity of patents, and intellectual property have involved biostatistical evidence. An introduction to the area is given here with citations to relevant cases and references.

Malpractice

An illustrative example is the *Brochner* malpractice case, 724 P2d 1293 S.Ct CO (1986). In 1964 a hospital granted Dr Brochner staff privileges and over the next few months he performed numerous craniotomies. The hospital noticed that tissue samples from many of his patients appeared normal and in 1966 required that he obtain outside consultation. In March of 1968 the hospital learned that 14 of 28 tissue samples of his neurosurgery patients were normal. In November 1968 Dr Brochner performed a craniotomy on Ms Cortez, who was injured. She filed suit against both the doctor and the hospital. At the trial her expert testified that an acceptable rate of normal tissues amongst patients who were operated on was one in 100 and that two of 28 should require investigation. Essentially, the expert used the **Poisson** approximation to the **binomial** to conclude that the probability of observing two or more normal tissues in a sample of 28 when each sample has probability 0.01 of being normal is about 0.001. Similarly, the probability of observing 14 or more normal tissues assuming Dr Brochner was selecting patients according to the standard medical criteria was less than one in a billion. Thus, the statistical evidence strongly supported the plaintiff's claim that Dr Brochner was subjecting healthy patients to the risk of surgery, and the time when the information was known showed that the hospital was aware of it but did not revoke his right to operate. Both parties settled with the plaintiff and the lawsuit concerned whether the doctor was liable to the hospital's insurer. As both parties were at fault, he did not need to indemnify the company. McClellan [28] discusses recent developments that have eased plaintiffs' burden of proving that they were harmed by a doctor's or hospital's negligence. Early cases often required that an expert state that had the negligent act not occurred to a "reasonable medical certainty" the patient would not have been harmed. In *Hamil vs. Bashline*, 392 A.2d 1280, S.Ct PA (1978) the court awarded damages when an expert testified that the patient would have had a 75% chance of survival had the negligent act not occurred. Thus, probabilistic estimates of the survival probabilities assuming the appropriate medical treatment should play a role in determining liability and in the award of damages.

Food and Drug Law

In the United States new drugs have to be approved for safety and efficacy by the **Food and Drug Administration (FDA)**. To demonstrate efficacy the FDA requires companies to submit two well-controlled studies establishing that the drug will have the effect it purports to have (*see* **Drug Approval and Regulation**). The formal regulations, approved of by the Supreme Court in *Weinberger*, 412 US 609 (1982), state that the study plan should describe the selection of subjects, and use **randomized treatment assignment** to assure the groups are balanced with respect to relevant **covariates** such as age, prior health, etc. Usually, the efficacy requirement is satisfied by a placebo-control double-blind (*see* **Blinding or Masking**) study (*see* **Clinical Trials, Overview**) [38]. Both the US and UK have set up a multiphase process (21 CFR Sec. 314.126; [32]), first to determine the pharmacodynamic properties and safe dose level of a new drug and finally to assess its efficacy. In response to the rapid increase in **AIDS** cases, the FDA modified some of its previous procedures to bring new therapies to patients and clinicians [34], and may place greater weight on the preferences of the diseased population in weighing the factors of safety and efficacy in its future risk–benefit decisions. The standards

of the countries in Europe are being unified by the European Community. At least one clinical trial demonstrating efficacy is required, and recent developments are reviewed by Kingham et al. [21] and Lewis et al. [26]. The standards for approving medical devices are described by Horton [20] and Munsey [31].

Statistical issues often arise in assessing clinical trials. There has been a substantial literature concerning whether one-sided or two-sided tests should be used [9, 11, 22, 33] (*see* **Alternative Hypothesis**). The FDA typically requires two-sided tests when the **controls** receive a standard regimen and the new drug is given to the experimental group. Even with placebo controls, two-sided tests are used to ensure that any observed effect in the treatment arm exceeds the "placebo effect". One-sided procedures have been developed for **bioequivalence** studies (*see* **Equivalence Trials**) where the **null hypothesis** is nonequivalence and the alternative is equivalence [8]. Often proponents of a new drug or procedure assert that studies that do not show an effect should not detract from studies showing a statistically significant effect or that the drug is effective in several subgroups of patients and should be approved for them. The appropriate approach is to account for the number of tests made using **multiple comparison** methods [18, 30] and to use combination methods, such as Fisher's summary chi-square, to pool the results of several studies (*see* **Meta-analysis of Clinical Trials**).

Generic drugs are regulated under different laws from those for new drugs [12]. Typically, a manufacturer needs to show that its product is bioequivalent to one which was approved as a new drug previously. This means that the drugs deliver the same total dosage over a reasonable time period, e.g. 24 h, and reach similar maximum dose levels at about the same time. Both the FDA and the producer of the original older drug may challenge the data used to support the claim of bioequivalence. The FDA requires a generic equivalent to carry out full testing if its excipients differ from the already approved drug. In *Premo vs. US*, 475 F.Supp. 52 (SD NY, 1979) the district court accepted the Premo's equivalence data (reproduced in the opinion and in Gastwirth [14, p. 775]); however, the appellate court reversed this decision and held that the lower court wrongly substituted its opinion on safety and efficacy for that of the FDAs. The data showed that the established drug reached a higher dose level than the generic one and reached that level faster.

In addition to approving drugs, in the US the FDA also monitors adverse effects by requiring manufacturers to report them. As the ascertainment of cases and the follow-up information on the patient's status are often incomplete, standard methods for estimating **relative risks** are inappropriate. Brookmeyer & Yasui [4] discuss the use of passive surveillance (*see* **Follow-up, Active Versus Passive**) **disease registry** data and show that it is a useful supplement to **cohort** data.

Unfair or False Advertising Cases

The Lanham Act is designed to ensure that consumers receive reasonably accurate information about products and to assure manufacturers who produce reliable products that others will not unfairly infringe on the good reputation of those products. A number of major cases have dealt with the fairness or accuracy of advertisements, especially comparative advertisements where one firm asserts that its product is superior to that of a named competitor. There are two types of cases. In the first case firm A claims that its product is superior to firm B's but does *not* assert that this claim is supported by scientific studies. The second type deals with cases in which firm A has stated or implied that the claim of superiority is supported by scientific studies. As the law recognizes that the public takes a skeptical view of unsupported claims, the burden on the complaining party, firm B, differs in the two types of cases.

In the first type, to challenge successfully an unsupported claim that A's product is better, firm B needs to show that the claim is false. This is usually accomplished by firm B carrying out an appropriate study demonstrating that the two products are equivalent, i.e. it is not necessary for firm B to show that its product is better – only that A's product is not superior. In the second class of cases, firm B needs only prove that the studies firm A relied upon to support its claim were not sufficiently reliable to permit one to conclude, with reasonable certainty, that the claim of superiority was established. Sometimes a suit is brought by a competitor, but the Federal Trade Commission (FTC) and FDA also regulate health claims [36]. In the case of *Stirling Drug Inc. vs. FTC*,

741 F.2d 1146 (9th Cir., 1984), the firm's advertisement claimed that Bayer aspirin was pharmaceutically superior to its competitors with regard to purity, freshness, and speed of disintegration, and indicated that these claims had been established by scientific means. Stirling Drug had based its claim on one in-house study, and the FTC's analysis indicated that the claims of superiority regarding the named attributes were not supported. The opinion noted that the FTC requires a well-controlled clinical trial where real patients having actual symptoms are studied. There should be a written protocol (*see* **Clinical Trials Protocols**), double-blinding, and a placebo control, and the data should be analyzed by established statistical techniques and indicate both statistical and clinical significance (*see* **Clinical Significance Versus Statistical Significance**). In *Proctor & Gamble* vs. *Chesebrough Pond Inc.*, 747 F.2d 114 (2d. Cir., 1984) the first firm claimed its hand lotion was superior to the product made by its competitor, while the second firm only advertised that no other lotion was better. After describing the studies [14, pp. 777–780], the court decided that neither company's evidence was sufficiently strong to justify a preliminary injunction, which would have stopped the advertisements of the party with the much weaker case until the full trial was held. Related cases involving the soundness of the clinical studies supporting advertising claims are *Thompson Medical Co. vs. Ciba Geigy*, 672 F. Supp. 679 (SD NY, 1985), *ALPO Pet Food Inc. vs. Ralston Purina*, 913 F.2d 958 (DC, 1990), *McNeill-P.C.C. vs. Bristol Myers Squibb Co*. 938 F.2d 1544 (2d Cir., 1991), and *Mylan Labs. vs. Metkari* 7 F.3d 1130 (4th Cir., 1993). The *Rhone-Poulenc Rorer Pharm. Inc. vs. Marion Merrell Dow* Inc. (8th Cir., 1996) case discussed the **bioavailability** studies of their drugs for treating hypertension and angina. RPR launched its drug, Dilacor, by advertising that it was the same but cheaper than MMD's older drug, Cardizem. MMD's counteradvertising campaign first said that Dilacor had only 50% the bioavailability of Cardizem, but later advertisements based on a better study claimed that Dilacor delivered only 74%–81% of the relative doses of Cardizem. RPR claimed that its own studies refuted the study of MMD; however, the court found that even RPR's study showed a reduced bioavailability of its drug. The court found that RPR's original advertisement falsely represented that the two drugs were interchangeable. It also noted that the early MMD advertisement violated the Lanham Act as it exaggerated the shortfall in bioavailability; however, it found that the advertisements based on the later study were not false and declined to award RPR monetary damages because it had not demonstrated injury. In addition to the biostatistical evidence, MMD noted that surveys showed that consumers viewed the products as similar. When one product infringes on another, it is typical for the opposing party to introduce **survey** evidence demonstrating that consumers are confused by an alleged similarity [7; 14, Chapter 9; 16]. Such evidence is also helpful in estimating monetary damage, as the fraction of consumers who are misled may be regarded as the potential market share the infringer unfairly gained.

Environmental and Occupational Health

To protect public health, governments regulate the amount of potentially toxic chemicals that workers can be exposed to [37], that can remain in foods treated by pesticides [6] or that can escape into the atmosphere or water supply. Reporting and self-monitoring requirements are used to ensure the safety of the public [35, 41]. The responsible government agencies prescribe the sampling procedures that need to be carried out by the producers in great detail. The decision in *US v. Marine Shale Processors*, 81 F.3d 1329 (5th Cir., 1996) shows that courts are not sympathetic to a firm that does not carry out sampling according to the specified procedures and later claims that it was unable to carry out the appropriate statistical tests. In that case the firm's own daily data indicated that it had violated a regulation on 27 occasions.

Many cases concern the scientific underpinning of a mandated exposure limit [13]. In the US, when human data as well as animal experiments indicate an increased **risk** of a serious illness, e.g. cancer, courts typically uphold a regulation [as in *Society of Plastics Industry Inc. vs. OSHA*, 509 F.2d 1301 (2nd Cir., 1975)]. Much more controversy arises when there are little data on humans demonstrating that reducing exposure to the proposed level will actually lower the expected number of cases. In particular, whether or not one assumes a threshold below which no harm is expected to occur can lead to very different estimates of toxicity and corresponding safe dose levels [40] (*see* **Dose–Response Models in Risk Analysis**; **Extrapolation, Low Dose**). The basic literature is reviewed by Armitage [2], Krewski & Brown [23],

and Leape [25]. Recent developments are summarized in Lin et al. [27], who reiterate the fact that many models approximately fit the data and that current bioassay experiments (*see* **Biological Assay, Overview**) do not enable one to estimate reliably the interspecies concordance – the percentage of chemicals classified the same way in tests on both species. The problem of unchecked or unverifiable assumptions arises in other applications of risk assessment in environmental safety [15].

In addition to regulation, members of the public who are exposed to toxic chemicals due to the negligence of a producer or user of the agent can file a tort law claim. In these cases plaintiffs may rely on epidemiologic studies demonstrating that the chemical in question increases the risk of a serious disease. Data from several such cases are reported in Gastwirth [14, Chapter 14]. Harr [17] describes the litigation arising from contamination of well water in Woburn, MA, and Finkelstein & Levin [10, p. 298] discuss the data from the original **case–control study** [24]. The current status of the law is comprehensively treated by Boston [3].

Related Developments

The use of statistical evidence in legal cases has affected the patients or respondents in surveys and case–control studies. The protection of the **confidentiality** that investigators can provide participants has been questioned as litigants have sought to subpoena the raw data underlying a publication. In *Lampshire vs. Proctor & Gamble*, 94 FRD 58 (ND GA, 1982), the district court did not allow access to the patients who served as cases and controls in a study of Toxic Shock Syndrome. The **Centers for Disease Control (CDC)** argued that allowing the defendant firm to reinterview would diminish the likelihood of participation in future studies. Indeed, the CDC submitted a survey of the respondents; a high percentage did not wish to be interviewed by the defendant. The court noted also that there was no reason for respondents to give biased answers, as the cases desired the best treatment, and even the controls would only benefit from good science. For further examples and discussion see Cecil & Boruch [5] and McHale [29], where cases arising from the lack of informed consent in clinical trials are cited.

Outside of violations of informed consent rules, there have been few cases involving liability for injury or death of patients in clinical trials of new drugs. The death of five patients in the clinical trial of the experimental drug fialuridine, however, led to the case *In re* Fialuridine Products Liability Litigation, 163 FRD 386 (DC, 1995), which was settled. Traynor [39] summarizes the principles of products liability law and notes that drug manufacturers of prescription drugs have the benefit of the "learned intermediary rule" that assumes that once the appropriate health care provider has been notified of the potential risks as well as benefits of the drug, the patient also has been properly warned. The rationale is that the physician will take into account the situation of the specific patient. The rule was developed for prescription drugs but may not be relevant for clinical trials as double-blinding means that the treating physician does not know whether the patient is receiving the drug or the placebo. Hence, they can no longer be considered a "learned intermediary" who is in a position to explain the precise risks of the treatment to the patient. Disentangling the effect of the drug from that of the illness may prove difficult, so patients may have a problem in showing that the experimental drug was the legal cause of their injury [39]. Ethically, patients should be compensated for injuries they sustain in clinical trials, but, pragmatically, payment for the costs of medical treatment by the sponsor of the investigational drug may deter claims.

Several cases have been filed alleging that enrollees were not informed of the nature of the risks involved, the financial interests of the sponsors and investigators, or of adverse effects suffered by other patients in the clinical trial. One such case, *Wright versus Fred Hutchinson Cancer Research Center*, described in Jedrey and Feltz [19], is still pending. Subsequent to the filing of the case in 2001 the Center, however, announced changes in some of its policies. Now researchers are prohibited from stock ownership or royalties on patents that are directly and significantly related to their research. Moreover, they are required to disclose to participants and in publications any financial interests have in for-profit companies sponsoring clinical trials. Another pending case, *Grimes versus Kennedy Krieger Institute*, 782 A. 2d 807 (Md. 2001), an affiliate of Johns Hopkins, deals with the legal duty or responsibility researchers owe to participants. The investigators were examining techniques for removing lead paint from residential buildings and planned to measure the amount of lead in the blood of children to assess the effectiveness of

partial lead-paint removal. Allegedly, the researchers encouraged participating landlords to rent to families with small children even though they were aware that they knew of the hazards of lead dust exposure to children. The informed consent document, which simply stated that "lead poisoning in children is a problem" and that exposure to lead in paint, dust, and soil is a major source of exposure in children allegedly failed to mention the known harmful effects of lead. The trial court dismissed the complaint but the appeals court reinstated the negligence suits. It held that the consent agreement imposed special duties on the researcher to ensure that participants are given appropriate warnings of the risks involved.

Recent Developments

The requirement in the U.S. that companies inform employees of medical and scientific literature showing a link between disease and exposure to a toxic chemical was adopted in a recent French case, *Garafalo versus IBM France*, Tribunal de Grande Instance de Nanterre, 11/25/03). The court appointed a medical expert to assess claims that several of the plaintiff's ailments were due to his exposure to unacceptably high levels of ethylene glycol and other toxic solvents in "clean rooms" designed for dust-free manufacture of semiconductors.

While most *false advertising* cases are brought by producers of competing products, governmental agencies can also sue manufacturers who make false safety claims. The case, *Spitzer versus Dow AgroSciences LLC*, N.Y. Sup. Ct. No. 403920/03 was settled after the firm agreed to pay $2 million for violating an earlier consent decree prohibiting it from claiming that its insecticide containing chlorypyrifos was safe. In 2000, the U.S. Environmental Agency had arranged for a phasing out of the use of the chemical in homes and gardens. Scientific studies that showed the chemical was toxic to the brain and nervous system, especially to the development of infants, played a role in establishing that the chemical was harmful.

The importance of proper statistical analysis of data will play a role in a case [1] currently being litigated in which a generic drug company, Ivax Corp. is challenging the validity of a clinical study used by Eli Lilly & Co. when it obtained its patent on Zyprexa, a drug used to treat schizophrenia. In the clinical study of 40 beagles of both sexes were randomly assigned to be given Zyprexa, the current drug (called molecule 222) or a placebo. Lilly used the study to show that its drug was significantly different from 222. The study was originally designed to assess whether the new drug had lower toxicities for blood disorders as the company thought that 222 would cause them. It turned out that neither drug nor placebo caused them; however, a Lilly scientist noted that some of the female dogs given high doses of 222 had higher cholesterol levels. Allegedly, Lilly reanalyzed the data comparing these eight females obtaining a statistically significant difference in cholesterol levels between them and the other females. This result was used to demonstrate that its drug differed from 222. The generic companies claim that Lilly did not inform the FDA that the effect was not seen in male dogs, indicating that the effect might not translate to humans. Lilly argues that it gave all the information to the FDA and that its drug was a major improvement in treatment. From a statistical view, the propriety of examining the data to find a hypothesis to test and testing it on that very data may be an issue. The number of other effects tested, the **multiple comparisons** problem, may deserve consideration by the court. From a legal viewpoint, it will be interesting to compare the court's ultimate decision with the decision in *Warner-Lambert versus Hechler*, 787 F.2d 147 (3rd Cir. 1986). In that case, the court rejected the claim that a drug was effective based on statistically significant results of tests on six subgroups as the firm had conducted 240 comparisons.

JOSEPH L. GASTWIRTH

Mendel's Laws

The beginning of the science of genetics is usually credited to the experiments of Gregor Mendel, first announced in 1865 [2, 3]. However, while Mendel understood the importance of his own discoveries [1], the rest of the scientific community at the time did not, even though Mendel's experiments were beautifully designed, and his interpretation was clear and insightful. Mendel's work was virtually ignored until 1900 when it was finally rediscovered. The reasons for this initial neglect were twofold. First, Mendel was the first to focus on the numerical relationships among traits appearing in the offspring of carefully controlled matings. This quantitative approach, with its emphasis on probability and ratios, was unfamiliar in biology, which was at the time thought to be too complicated to be understood with such simple models. Secondly, Mendel used discrete instead of continuous characters for his experiments, and introduced the important concept that the hereditary material was particulate. Because the emphasis in discussions of heredity at the time was focused on interspecific differences, and because the prevailing view of heredity was that of continuous variation which blended from one generation to the next, it was difficult for scientists of the time to understand the relevance and importance of the results of Mendel's experiments on a series of simple, discrete traits.

Mendel performed his experiments with seven discrete traits in the garden pea, each trait consisting of a pair of alternative, visible, and highly contrasting characteristics. For example, the seed color could be green or yellow, or the flowers white or violet, with each plant producing just one type of seed or flower color. By focusing on single, dichotomous traits and controlled matings, Mendel was able to use these experiments to determine the underlying, discrete basis of the hereditary system in the pea, and by extension, ultimately the fundamental hereditary system of most organisms. He postulated two laws to explain his results.

Mendel's first law, or the *law of segregation*, describes the inheritance of a single trait, such as seed color. On the basis of the results of his experiments, Mendel postulated the existence of discrete factors that are transmitted from parent to offspring through the gametes (the egg or ovum, sperm, or pollen), with different factors determining the characteristics of different traits. These inherited factors are now called **genes**. Mendel also hypothesized that these factors occur in pairs in individuals, and that when a gamete is formed, only one of the two factors is included in the gamete. Furthermore, on the basis of his numerical results, he postulated that each of these two factors has an equal chance of being passed to an offspring, that is, the factors *segregate* during the production of gametes (meiosis), and that gametes thus have only one of each pair of factors. In addition, he proposed that these particulate factors persist in an unchanged state through successive generations of hereditary transmission. Conversely, when the gametes from the male and female parents fuse to form a zygote, the doubling of factors is restored.

Mendel's second law, or the *law of independence*, describes the joint behavior of loci controlling two different traits. The principle is simple: it states that the alleles at one locus segregate independently of the alleles of other loci. This proposition is now known to be strictly true only for loci that are on different chromosomes. Because the seven traits that Mendel used were, in fact, on different chromosomes, the traits Mendel used behaved in this fashion. Genes that are on the same chromosome tend to be inherited together (*see* **Linkage Analysis, Model-based**), in which case this principle will not necessarily hold.

One of the major differences between Mendel's two laws and many other quantitative models in the biological sciences is our understanding of the underlying processes leading to the observed data, and our resulting confidence in our ability to predict numerical outcomes. While Mendel did not yet know about chromosomes and the mechanism by which chromosomes are packaged into gametes (gametogenesis), this mechanism is now known to provide the basis behind the equal probability of transmission to a child of either member of a pair of genes. Gametogenesis involves the segregation of the two different members of a pair of chromosomes (carrying the two different genes for a particular trait) into two daughter cells, each with only one chromosome. Gametes are formed after one more round of duplication of these daughter cells, but the resulting ratio of gametes carrying each of the two original genes remains at one-to-one, resulting in the 50% probability in Mendel's first law that a particular gamete contains either of the two original genes. In addition, different pairs of chromosomes segregate independently in gametogenesis,

leading to the independence of inheritance of genes on different chromosomes.

To this day, Mendel's first law still forms the fundamental basis behind much of genetics. Although the law is elegant and simple, its consequences are not simple and can lead to complicated distributions of traits in populations and pedigrees. Mendel's second law is slightly less general since it is not applicable to genes that are on the same chromosome, or are at least not far apart on the same chromosome. However, because of the large size of the genome in most organisms, the second law usually adequately describes the behavior of the inheritance of multiple genes, although there are exceptions for linked genes (*see* **Linkage Analysis, Model-free**). This second law forms the basis of important assumptions made in the methodology behind many areas of genetic analysis (*see* **Polygenic Inheritance**; **Segregation Analysis, Classical**; **Twin Analysis**).

ELLEN M. WIJSMAN

Merrell, Margaret

Born: December 3, 1900, in LaGrange, Illinois.
Died: December 21, 1995, in Shelburne, New Hampshire.

Margaret Merrell is considered to be among the most admired of the early teachers of biostatistics. After graduating from Wellesley College in 1922, she taught mathematics at the Bryn Mawr School in Baltimore until 1925. She then entered the Johns Hopkins University School of Hygiene and Public Health as one of the first graduate students in biostatistics, at the same time beginning a career as member of the faculty in the department that would continue until she retired in 1959. She completed the requirements for a doctorate in biostatistics in 1930.

Merrell made significant contributions both as a developer of new methodology and as a consulting biostatistician for the conduct of infectious disease **clinical trials**. Her great legacy, however, was the standard she set for the **teaching of biostatistics** to health professionals. The Johns Hopkins University awarded her an honorary doctorate in 1981. She was a Fellow of the **American Statistical Association**, the American Association for the Advancement of Science, and Sigma Chi.

DENNIS O. DIXON

Meta-analysis in Epidemiology

Because of the pressure for timely and informed decisions in public health and clinical practice and because of the explosion of information in the scientific literature, research results must be synthesized to answer urgent questions [2, 25, 73]. Principles of evidence-based methods to assess the effectiveness of health care interventions and to set policy are cited increasingly [17]. Approaches to summarizing evidence include narrative reviews, systematic reviews and meta-analysis.

In general, randomized (controlled) clinical trials (RCTs) provide more useful evidence than do cohort studies, and cohort studies often provide better evidence than do case–control studies [137]. Cross-sectional studies and case series provide a weaker basis for etiologic reasoning. Because there are usually too few RCTs available to test clinical hypotheses, and because RCTs are rarely available to test etiologic hypotheses, particularly for chronic conditions, combining data from observational (cohort and case–control) studies is often necessary [10, 35, 131, 152, 165] (*see* **Case–Control Study**; **Cohort Study**).

Scientific Synthesis

In a traditional narrative review of the epidemiologic or medical literature, subject-matter experts review studies, decide which are relevant to the particular topic, and highlight their findings in terms of results and, to a lesser degree, methodology. The limitations of this or any approach to a literature review include: (a) biases in the original studies, reporting and publication policies; (b) absence in reported studies of specific data needed for the review; (c) investigator bias caused by subjective inclusion of studies; (d) uneven quality of the primary data; and (e) biased interpretation of outcome [156]. Such limitations have caused some authors to disregard the results of such reviews as having been prepared "with disregard for scientific principles" and therefore resulting in misleading decisions with serious consequences, often affecting health and quality of life [25, 111].

Systematic review methods have been adopted to address these problems. Systematic rules for conducting a synthesis include an explicit description of methodology so that results can be interpreted in light of biases and limitations [41]. Use of such systematic rules enables the investigator to refine large amounts of information, provide estimates of variables needed for economic and decision analysts, provide an efficient scientific technique, establish generalizability of scientific findings, assess consistency of relationships, explain data inconsistencies, increase statistical power and increase the precision of estimates [14, 25]. The techniques of meta-analysis use all of the steps of a systematic review, but in addition include a statistical combination of the results of previous studies to arrive at conclusions about a body of research (e.g. [150, 156]). Although systematic reviews in general, and meta-analyses specifically, are not immune to the potential pitfalls of a narrative review, the technique reduces the possibility of such errors and explicitly describes potential limitations (e.g. bias) of the results and interpretation [3, 112].

The statistical roots of systematic reviews can be found as early as the beginning of the twentieth century [127]. The term *meta-analysis* was first used in 1976 in the educational literature [69]: "the statistical analysis of a large collection of results from individual literature, for the purpose of integrating the findings". Since the method usually uses as "data" summary statistics derived from published reports of original studies, it is an *analysis of a statistical analysis* (thus, *meta*-analysis). Meta-analysis is most useful when individual study results are inconsistent and primary study sizes are small [97, 102, 128], since combining studies increases power. Meta-analysis is often recommended before undertaking a new study, to learn from earlier studies and to determine whether a new study will add substantially to what is already known about the topic [76, 95, 96].

While systematic reviews of evidence are usually desirable, meta-analysis (the statistical synthesis of results) should not be used indiscriminately [39, 42, 43, 62, 77]. In fact, legal suits have been brought by industry against researchers, charging "negligent misleading" when disparate findings are summarized by a single "class effect" [82]. The method is inappropriate if the number of studies is small or if there are large differences among the studies in study populations, interventions or effect measures [57, 92].

Approaches to summarizing data other than meta-analysis include vote counting and pooling [121,

122]. Vote counting relies only on the statistical significance of results [105], and may tend to indicate the wrong decision more often as the amount of evidence (number of studies) increases and does not incorporate characteristics of the original studies [80]; thus, we do not discuss that method here. The use of pooling, or combining original data, may be limited by the availability of data from primary authors [146]. When feasible, however, pooling original data offers definite advantages. Measures of exposure and outcome can be standardized, and adjustment for confounders can be done in a consistent manner across studies if the original data are available. Thus, with pooling, preliminary analyses yielding summary estimates of exposure effect for each study may be rendered more homogeneous than would be the case in more conventional meta-analyses. Once these study-specific estimates are obtained, standard meta-analytic techniques may be used to combine them. Lubin et al. [110] used pooling to combine data from cohort studies of underground miners to estimate the effect of radon exposure on risk of developing lung cancer.

Uses of Meta-analysis in Epidemiology

Meta-analyses were first used in clinical studies to combine results from RCTs [19, 27, 119, 133]. For example, a meta-analysis of 33 trials that compared treatment using intravenous streptokinase with a placebo in patients hospitalized for acute myocardial infarction showed a favorable effect of treatment, whereas only six of the 33 primary trials showed a statistically significant effect [100]. Continuously updated reviews, such as those provided by the Cochrane Database of Systematic Reviews [26, 32] facilitate proper conduct of meta-analyses of RCTs. Guidelines for publication of RCTs have been developed to encourage the inclusion of sufficient information in the published report to properly analyze the data using a meta-analysis [37, 115] and guidelines for the reporting of meta-analysis of RCTs have been developed [114].

Meta-analysis is being used increasingly to combine results from observational studies when randomized controlled designs are not available or not feasible [153]. Here, we define an observational study as an etiologic or effectiveness study using an analysis from an existing database, a cross-sectional study, a case series, a case–control design, a design with historical controls or a cohort design [71, 126]. Observational designs lack the experimental element of a random allocation to an intervention and rely on studies of association between changes or differences in one characteristic (e.g. an exposure or intervention), and changes or differences in an outcome of interest. These designs have long been recommended and used in the evaluation of educational programs [40] and of exposures that might cause disease [92]. For example, studies of risk factors generally cannot be randomized, because they relate to inherent human characteristics or practices, or because such a randomization might be unethical [106, 126]. At times, clinical data on treatments may be summarized in order to design a randomized treatment comparison [89, 161]. Observational data may also be needed to assess how well an intervention works in a community as opposed to the special setting of a controlled trial [111].

Meta-analyses of observational studies present particular challenges because of inherent biases and differences in study designs [65, 93]. Nonrandomized comparisons are subject to both selection bias and other types of confounding, and combining several studies all subject to the same bias will only reinforce that bias [144] (*see* **Bias in Case–Control Studies**; **Bias in Cohort Studies**). In addition, observational studies may lack some of the elements of a well-designed clinical trial, such as careful definition of endpoints, interventions and study population [119]. Also, observational studies may have different exposed populations and control groups, may suffer from measurement error of exposures, and may explore only varying outcome measures. Because such factors may influence various studies differently, a single summary measure for exposure effect may be misleading. A more important use of meta-analysis of observational studies may well be as a tool for understanding and quantifying sources of heterogeneity in results across studies [113, 120].

Although meta-analysis of observational studies may not always be appropriate (e.g. [74, 139]) – particularly if the goal is to produce a single summary estimate of an association [101] – the number of published meta-analyses concerning health issues has increased substantially during the past four decades: from 678 before 1992; to 525 from 1992 through 1995; to approximately 400 in 1996 alone. Furthermore, a 1997 study of published

meta-analyses documented that 86% of authors were the first or second author of only a single meta-analysis before the one used in the study [140], indicating the broadening use of this method.

Steps in a Meta-analysis

The basic steps in a meta-analysis include: (a) a clear statement of the problem and hypothesis to be tested; (b) a clearly defined statement of inclusion and exclusion criteria for admission of studies; (c) a methodology for locating research studies; (d) the classification and coding of study characteristics to be combined in the meta-analysis and a quantitative measurement of study characteristics and of the effect of the exposure on outcome; (e) an assessment of the quality of the methods used in the studies; (f) a statistical analysis that includes methods for combining study results when appropriate and determining the sources of heterogeneity of the data; and (g) interpretation of results, including an assessment of bias of individual studies, a discussion of heterogeneity, and identification of areas for further research [128, 156].

Statement of the Problem and Hypothesis to be Tested

Problem formulation is critical and includes the explicit definition of both outcomes and potential confounding variables. This step enables the investigator to abstract accurate and consistent data from reports of studies and to choose appropriate statistical models for the analysis. This step is especially critical for meta-analyses of observational studies. For example, suppose the major task is the exploration of evidence for a theory: Does a high level of homocysteine contribute to increased risk for cardiovascular disease [20]? Such a statement of the problem allows exclusion of studies using patients with competing conditions, which may preclude a clear evaluation of outcome.

As for any study, the protocol is the blueprint for the conduct of the meta-analysis. The protocol should contain a clear statement of the problem, objectives, hypotheses to be tested, background and specifications for information retrieval, data collection and analysis.

Establishing Inclusion and Exclusion Criteria

As in any statistical study, sample design is an important determinant of the utility and scientific validity of results. In a meta-analysis, the sampling units are the results of published or unpublished studies. The study inclusion/exclusion criteria provide the "case definition" for results to be used in the synthesis. Objective exclusion criteria should be determined a priori to meet scientific criteria and not as a matter of convenience. For example, a decision to exclude studies published before a specific date should be based on evidence that a technology or therapy changed at that time (and therefore historical results may not be comparable with more recent results), and not on the fact that earlier studies may not be cataloged electronically. "Fugitive literature" refers to studies that may be published in documents that are difficult to locate, because they are not published, are published but not abstracted, or have limited circulation (e.g. dissertations, conference abstracts and proceedings or government reports). If studies in the "fugitive literature" are to be excluded, a rationale should be given. Similarly, a decision to exclude foreign language studies should follow a determination that studies published in a language other than English are different in some substantive way, and not be made merely on the basis of a lack of translation capability [60, 75, 116]. Although some control over heterogeneity of design may be accomplished through the use of exclusion rules, a more informative approach could be to use broad inclusion criteria for studies, and then to perform analyses to determine whether measured design features influence measurements of exposure effect on outcome [11].
