The goal of the search process is to (a) identify all relevant primary studies (published and unpublished) for potential inclusion in the meta-analysis; and (b) to determine which studies are to be included. Accurate and thorough specifications of the search strategy will allow for the replication of the meta-analysis and permit others to evaluate the external validity of the findings. Examining the search strategy in depth can help to explain different conclusions from different meta-analyses on the same topic [157]. The term "search" implies the entire process, which is usually composed of several different methods of searching. A 1996 review of 103 meta-analyses in education documented that search procedures were described inadequately, fewer than half of the meta-analyses

reported details of classifying and coding the primary study data and only 22% assessed quality of the primary studies [140].

The literature search should be systematic and comprehensive. The researcher uses several sources of information to locate data for retrieval, including written indices; computerized searches; bibliographies of published papers; and unreferenced and sometimes unpublished data from academic, private and governmental researchers [23, 38]. Complete searches should go beyond computerized indices, which have been shown to have a sensitivity as low at 50% in some examples [52]. Researchers estimate that 25%–50% of all initiated randomized controlled trials are never published, and excluding data from unpublished studies may result in bias or loss of precision in estimation of effect size [51].

Several computerized databases exist, many operated by the National Library of Medicine and included in the Medical Library Information Retrieval System (MEDLARS). These include AIDSLINE (for AIDS-related citations, 1980 to the present), CANCERLIT (containing cancer literature from journals, government reports and conferences, 1963 to the present), TOXLINE (containing citations on the effects of drugs and other chemicals), and Dissertation Abstracts (containing abstracts of American and Canadian doctoral dissertations, 1861 to the present). Registries of randomized trials [32, 55] provide information prior to publication of RCTs for topics of interest to the collaborators. For other study designs, or for situations in which registries do not exist, contact with experts in the field may yield more complete ascertainment. It is important to identify and remove redundant reports for the same study [90]. When computerized indices are used, the search strategy should be specified completely to allow replication. The description should include keywords used, fields searched (e.g. whether the search was by text word, title or subject), software used for searching (e.g. OVID), and any software-specific functions (e.g. "explosion" of terms).

Classification, Coding and Measurement of Study Characteristics and Measurement of Exposure Effect on Outcome

The classification and coding of study characteristics follows directly from problem formulation [156]. This step can consume the majority of time invested in a meta-analysis – approximately 90% [86, p. 85]. In addition to increasing the time required for a synthesis, adding characteristics of the studies included increases the probability of finding at least one chance association as significant. Thus, many meta-analysts recommend coding a study characteristic only when theoretical justification exists [149]. This recommendation is controversial, however, since additional information about study characteristics can provide documentation for findings, can assist analysis of sources of heterogeneity and can provide areas for additional research. Furthermore, the requirement for formal theoretical justification can restrict creative hypothesis generation.

Blinding (masking) readers to identifying information about papers (e.g. author's affiliation) has been advocated. In a study of blinding, five meta-analyses of RCTs were conducted in parallel by two groups randomly assigned to read papers that either had or had not been masked as to the identity of the authors and institutions producing the original papers, and as to which treatment group was which. Although the unmasked readers assigned higher quality scores on average than the masked readers, masking made little difference in the summary odds ratios [7, 16]. We are unaware of any published studies of the effects of blinding on meta-analyses of observational data.

Assessment of Quality of Included Studies

The use of quality scoring in meta-analysis is controversial [57, 61]. One potential use of quality scores is to assign greater weight to some studies than others when combining results. A second use is for grouping studies according to quality to determine whether estimates of exposure effect depend on study quality [67, 77]. Quality scores constructed in an *ad hoc* fashion, however, may lack demonstrated validity. Furthermore, examples indicate that estimates of exposure effect are not always associated with quality [74]. Nevertheless, some *particular* aspects of study quality, such as adherence to the randomization scheme in RCTs, have been shown to be associated with effect size [13, 118, 138].

Statistical Methods for Combining Study Results and Analyzing Heterogeneity

Statistical issues related to combining data from multiple sources in meta-analysis are the subject of ongoing research [61, 104]. The most important statistical

issues concern which studies should be combined. When feasible, meta-analysis should be restricted to RCTs, the study design that provides most useful evidence. When too few RCTs are available, combining data from observational (cohort and case–control) studies is necessary.

Beyond the determination of studies to be combined, a central question is whether variations in research studies (methodologic or contextual) are related to variations in effect size. This question can be approached by the use of *fixed-* or *random-effects models*. The simplest fixed-effects models assume that the exposure effect is constant across studies and that variation from one study to the next is due solely to within-study random variation. More elaborate fixed-effects models may allow the outcome to depend on several fixed effects, corresponding to several variables that characterize the studies [79]. Random-effects models allow the intrinsic exposure effect to vary from study to study so that variation in the estimated exposure effects reflects both sampling error within studies and effect variation across studies [81]. Random-effects models assume that the studies included are selected randomly from a population of studies with varying exposure effects and are used to accommodate unexplained heterogeneity of exposure effects [87]. Random-effects models increase the estimated variance around estimates of associations and produce different point estimates than fixed-effects models. It should be emphasized, however, that using random-effects models to account for unexplained heterogeneity should not substitute for a thorough exploratory (fixed-effects) analysis of how study design and population characteristics affect estimates of exposure effects. If random-effects models are used, then the rationale for model selection should be given, and estimates of among-study variation should be reported [53].

Epidemiologic studies undertaken to establish causal explanations of disease–exposure association frequently estimate risks at different levels of exposure [84]. Such dose–response studies yield study-specific slopes that may be combined using meta-analytic techniques [141, 160]. One meta-analytic method for estimating a combined dose–response effect from case–control and cohort studies incorporates the same dose–response model in each component of the likelihood, which is the product of the study-specific likelihoods [15]. Brumback [22] used the estimation–minimization (EM) algorithm (termed the "method of weights") to maximize this likelihood; the calculations use standard weighted regression software.

Regardless of the statistical measure used to combine data, a meta-analysis to combine results across studies should include: (a) presenting the study-specific exposure estimates with estimates of study-specific random error; (b) presenting summary estimates of exposure effect across studies, with estimates of variability; (c) testing for heterogeneity of exposure effects across studies, and, if present, investigating possible causes of heterogeneity; and (d) providing quantitative support for interpreting the results.

Interpretation of Results

The interpretation should focus on a discussion of the strengths and weaknesses of the evidence, including possible biases, and on the justification for combining estimates in the presence of potential heterogeneity of study results. Bias has been defined as any systematic error that leads to the distortion of accurate results (e.g. [128]). In the original studies, bias can result from flaws in the study design that tend to distort the magnitude or direction of associations in the data. In meta-analyses, additional bias can result from the way in which studies are selected for inclusion and from the way in which data are gathered and analyzed (*see also* **Bias, Overview**).

Assessment of Bias in Individual Studies. One approach to assessing the research quality of observational studies is based on "threats to validity" [40]. Thirty-three independent threats to validity are categorized into four groups – internal, external, statistical conclusion and construct validity. Internal validity is "the truthfulness with which statements can be made about whether there is a causal relationship from one variable to another in the form in which the variables were manipulated or measured" [40, p. 38]. External validity reflects the extent to which the relation can be generalized across other populations. Statistical conclusion validity refers to the quality of the statistical analysis and inference. Construct validity concerns threats that may confound cause and effect measurement.

In general, quality assessment indicates that not all studies retrieved should be included in the meta-analysis. Construct and external validity can be used

to determine whether a study addresses the hypothesis of interest, participants, time period and location; i.e. the relevance of the study to the meta-analysis [135]. Construct validity can also be used in meta-analyses assessing theories [109]. Studies with fewest threats to internal validity should be considered highest quality [167]. Improper statistical techniques may also render a study unacceptable for inclusion (e.g. inappropriate statistical tests, incorrect grouping of values, inappropriate conclusions or the absence of information needed to calculate effect estimates or variability). Other scientific methods may also yield problems for quantitative synthesis. Toward this end, guidelines have been developed for assessing the methods in data on gene-disease associations [108].

Publication Bias. One reason this occurs is that authors are less likely to submit manuscripts reporting negative results to journals. There is no evidence that publication bias occurs once manuscripts have been submitted to a medical journal [124]. Publication bias, i.e. the selective publication of studies on the basis of the magnitude and direction of their findings, represents a particular threat to the validity of any meta-analysis [51, 56, 132]. Statistical methods assist in the assessment of publication bias and in correcting for this problem [5, 6, 46]. Methods for detecting publication bias include correlating the observed exposure effect size with design features of the studies that might be "risk factors" for publication bias (such as sample size, presence or absence of randomization and prospective vs. retrospective design) [12, 50, 70, 78]. For example, for a meta-analysis using a mixture of randomized and nonrandomized studies, if randomization status appears to be associated with size of risk estimates, then one might eliminate (or analyze separately) the nonrandomized studies [134].

The effect of sample size on publication bias can be assessed graphically by a "funnel plot" of sample size vs. effect size [104]. In the absence of publication bias caused by sample size, the plot should appear as an inverted funnel; that is, large variability will be shown with small studies and decreasing spread as the sample size increases, with constant mean effect size regardless of sample size. If this shape is not apparent, then publication bias should be suspected. For example, if large studies are clustered around the null value with smaller studies skewed around a positive effect, then one suspects that some small negative studies were not included, revealing publication bias [93].

The use of the funnel plot should not be substituted from a careful examination of the literature search [142]. Formal statistical significance tests can be used to determine whether estimates of intervention effects are correlated with sample size [8]. A rank correlation based on Kendall's tau [1] requires no underlying assumptions, but may lack power. Alternatively, a test based on Spearman's rho is more tractable computationally [36]. A formal sensitivity analysis may be a more robust approach to assessing publication bias [44].

Statistical methods for correcting for publication bias include sampling methods and analytic methods. Sampling methods are based on the following logic: if publication bias is caused by preferential publication based on study results, then this problem can be prevented by restricting the search to a sampling frame that cannot be influenced by study results, such as registries of prospective trials [55]. There are few registries of observational studies [30]. Attempting to locate all relevant observational studies through contact with experts and use of sources of unpublished reports to supplement standard computerized searches remains an option [45].

Analytic methods for addressing publication bias include the "file drawer" method [132], which addresses the question: If a combined estimate indicates a statistically significant exposure effect, then how many studies with null results must exist somewhere (the file drawer) to overturn the results? Hedges & Olkin [81] answer a similar question for methods that combine evidence from the individual studies' significance levels, rather than methods that obtain a combined estimate of exposure effect. Some methods to correct for publication bias are based on the assumption that a study is included in the meta-analysis with probability proportional to the estimated effect size [29, 125].

Heterogeneity. Heterogeneity of populations (e.g. study subjects), study designs (e.g. case–control vs. cohort studies), methods for measuring exposure and outcomes, analytical approaches to confounding and other issues must be recognized, reported, and, when possible, addressed in the analysis of the data by exploring associations between variation in study design and analysis and variation in estimated exposure effects [11]. In cases where heterogeneity of

exposure effects is large, a single summary measure of exposure effect may be inappropriate. Analyses that stratify by study feature or regression analysis with design features as predictors can be useful in assessing whether these features influence estimates of exposure effect [158]. Studies should never be discarded solely on the basis of having results that disagree with those of the majority of other studies [34], but rather should be examined for underlying characteristics of design or analysis that may have led to the discrepant results.

Statistical tests for heterogeneity include DerSimonian & Laird's Q-test [31, 47], an approach based on weighted least squares [107], an application of the likelihood ratio test [151], and measures developed by Higgins and Thompson, from mathematical criteria, that are independent of the number of studies and the treatment effect metric [83] and methods based on a bootstrap approach [155]. The power of these tests to detect heterogeneity is often small, however, because the number of studies (the effective sample size) is typically less than 30 [76]. Empirical evaluation shows that the DerSimonian and Laird Q-statistic is preferable from the point of view of validity, power and computational ease [155]. Graphical displays, stratification and regression analysis are useful methods to address criticisms of summarization in the presence of heterogeneity [74]. In the absence of absence of an a priori hypothesis about the source of heterogeneity, classic methods such as regression may prove difficult. In such cases, a graphical method to identify sources of heterogeneity may be preferable [4]. For the specific case of combining comparative trials with uncontrolled historical studies, Begg & Pilote have proposed a method using a random effects approach [9]. Investigating heterogeneity was a key feature of a meta-analysis of asbestos exposure and risk of gastrointestinal cancer [68]. This example shows that sources of bias and heterogeneity can be hypothesized before analysis and subsequently confirmed by the analysis.

Finally, sensitivity analysis can permit exploration of sources of heterogeneity and can suggest future research directions. Sensitivity analysis can be used in each step of a meta-analysis. During the search and citation retrieval step, use of more than one investigator is helpful when the research question spans disciplines and requires different subject-matter expertise. Exploratory data analysis [72] can be used to investigate features of articles retrieved in the search and reveal factors that may have impact on the choice of more formal statistical procedures. Combining P-values and regression analysis [81, Chapter 12] aids in sensitivity analysis.

Schlesselman [136] used the possible association between endometrial cancer and oral contraceptives to comment on issues related to potential bias in the studies of this association. His meta-analysis combined both cohort and case–control studies and used a sensitivity analysis to illustrate the effect of omitting specific studies. He addressed possible bias caused by restriction to English language articles by performing analyses limited to such studies.

In summary, interpretation should include assessing the internal validity of component studies; namely, whether they were well-designed, executed and analyzed. Discussion of whether the studies included are appropriate for answering the meta-analytic question should include efforts taken to avoid publication bias. For example, do funnel plots support the contention that publication bias has been minimized? If not, how much bias can be anticipated? To what extent should heterogeneity of effect estimates be related either to systematic features of various studies (such as sample size, type of study or study quality) or to nonidentifiable random variation? In view of any heterogeneity of results, is it reasonable to summarize the results in a single measure of exposure effect (with an estimated confidence interval), or rather to state that a single summary is not appropriate and that further research is needed to define the sources of variation and extent of the association?

A Case Study

A 1991 study of the effects of duration of estrogen use on breast cancer risk [148] illustrates many of the decisions made in performing a meta-analysis in epidemiology. Published reports agreed on the risk associated with ever-use of estrogen replacement therapy, but little evidence was shown for increases in risk due to short-term use (less than five years), and there was less agreement on the effect of long-term use. The authors located case–control and cohort studies; among the case–control studies, designs were heterogeneous in choice of controls (e.g. hospital or community). Heterogeneity testing

was used to determine criteria for subgroup analysis. Estimated dose–response slopes from primary studies were used for the meta-analysis to account for inter-study variability. Fixed- and random-effects models were computed, and assumptions such as equal baseline risk were evaluated by sensitivity testing. Because tests of homogeneity were significant, the authors analyzed data from studies that used community controls separately from those that used hospital controls [147].

Increased risk of breast cancer with duration of estrogen use was found among studies with community controls (risk of breast cancer after 10 years of estrogen use increased by at least 15%); studies with hospital controls showed a similar increase when a single outlier study conducted in Europe was excluded. Differences in results of fixed- and random-effects models may have been due to this source of variation. Other sources of heterogeneity explored included study design, location of study population (US vs. Europe) indicating differences in estrogen preparation; the two European studies using hospital controls showed an increased risk, while studies in the US showed a small decrease in risk with duration of estrogen use.

This example indicates the role of heterogeneity of study design in the interpretation of results of a meta-analysis. In this case, many health conditions are associated with estrogen use and a woman's decision to use estrogen. Thus, the choice of controls may have been a critical determinant of heterogeneity. For example, greater use of estrogen among women who receive acute care in hospitals might explain the apparent decrease in breast cancer risk shown by studies that used hospital controls.

Discussion

Taking stock of what is known in epidemiology involves reviewing the existing literature, summarizing it in appropriate ways, exploring the implications of heterogeneity of study designs, and determining how heterogeneity of design might relate to heterogeneity of study results. Meta-analysis provides a systematic way of performing this research synthesis, while indicating when more research is necessary and is a widely used and increasingly popular technique. Nevertheless, some criticisms and caveats are important for using the results of meta-analyses of observational studies [54, 64, 66, 143].

Criticisms of Meta-analysis in Epidemiology

The use of meta-analysis in epidemiology is not universally accepted due to several limitations [162]. First, bias can occur in the original studies (resulting from flaws in the study design that tend to distort the magnitude or direction of associations in the data), or from the way in which studies are selected for inclusion [18, 63]. Methods have been developed to aid in the detection of publication bias, a particular threat to the validity of meta-analysis of observational studies [56, 132]. In addition, funding source can be an important source of bias affecting results [94].

Secondly, when combining observational studies, heterogeneity of populations (e.g. US vs. international), design (e.g. case–control vs. cohort studies), and outcome (e.g. different studies yielding different relative risks that cannot be accounted for by sampling variation) is expected [11, 159]. In cases where heterogeneity of outcomes is particularly problematic, a single summary measure may be inappropriate. Analyses that stratify by study feature or regression analysis with design features as predictors can be useful in assessing whether study outcomes indeed vary systematically with these features [34, 154].

Thirdly, the use of quality scoring in meta-analysis is controversial [61] because scores constructed in an *ad hoc* fashion may lack demonstrated validity, and results may not be associated with quality [21].

Fourthly, a statistical summary of evidence may be misused to obscure important variations in exposure effects [57]. Meta-analyses have been criticized because of discrepancies between their results and those from large randomized trials [24, 28, 48, 91, 103, 130].

Extensions and Related Areas

Cumulative Meta-Analysis. The concept of the cumulative meta-analysis was introduced in 1993 [27]. In a cumulative meta-analysis, studies are combined and data synthesized on an ongoing basis. As soon as a study relevant to the particular topic is published, its results are entered into the meta-analysis and estimates of effect or relative risk are then updated. Adaptation of methods from interim analyses of clinical trials has been used in this situation [58, 129, 164]. This updating enables the most current estimation of the effect of a particular intervention or particular risk factor. Retrospective analysis of clinical trials for myocardial infarction indicates

that a cumulative meta-analysis of the effects of thrombolytic therapy and lidocaine on cardiovascular mortality could have changed clinical practice as much as 10–15 years earlier had such analyses been conducted, published and disseminated adequately [100]. Alternatively, one may perform the cumulative analysis by adding sequentially studies with increasing quality score or increasing study size to investigate the effects of these factors. Attention should be paid to the results of repeated testing by adjusting significance levels.

Cochrane Collaboration, investigators of a particular subject-matter area, aggregate data on an ongoing basis, conduct cumulative meta-analyses and make the results available to clinical researchers and others interested in clinical and public health policy [18, 33, 166].

Statistical Software. Egger et al. [59] attribute part of the growth in the number of meta-analyses to the recent appearance of software packages that implement the methods. Available packages vary in their provision of tutorials, graphical features and flexibility of modeling. Almost all packages include the capability for fixed- and random-effects modeling, tests of homogeneity and ability to handle multiple types of response. Some, such as RevMan© produced by the Cochrane Collaboration, are available via the Internet. For many applications (e.g. dose–response analyses, or meta-regressions), one must still use preliminary programs to estimate inputs, such as slopes, for use in meta-analytic programs.

Conclusions: The Role of Meta-analysis in Epidemiology

Regardless of the problems and technical solutions, an analytic synthesis of evidence is critical for policy in epidemiology and public health [163]. When policy-makers attempted to study the effect of passive smoking in public places (inhalation of others' smoke), tobacco-industry lobbyists presented competent studies showing little evidence of harm, and antismoking activists presented studies that showed passive smoking to be a cause of lung cancer [85].

The systematic evaluation of any health topic is essential to excellent clinical or public health practice [98]. The Guide to Community Preventive Services tries to determine what works in community health using systematic reviews on a variety of health topics important to communities, public health agencies, and health care systems. Systematic reviews evaluate the evidence of effectiveness, which is then translated into a recommendation or a finding of insufficient evidence. For those interventions where there is insufficient evidence of effectiveness, this process provides guidance for further prevention research [168]. The results of such evaluations also help define priorities in research. The conduct of meta-analyses, therefore, warrants rigorous implementation. The introduction of systematic reviews and meta-analyses has fostered controversy [49], but it has also initiated a critical examination of the process of research synthesis. This process must continue with careful consideration given to both epidemiologic and statistical issues and appropriate examination of the impact on health and quality of life. In addition to the specific methodologic issues mentioned above, more effort must continue in the design and implementation of primary studies and the reporting of such studies, including methods as well as results [7, 42, 99, 117, 123, 145]. Efforts such as the Cochrane Collaboration have demonstrated the value of careful collection and storage of information in readily accessible computer data banks. The development of computer software both for data manipulation and transport, as well as statistical analysis, will continue to reap rewards for researchers and practitioners. Improved accessibility of the results of meta-analyses is another potential benefit of the computerization of data. At the same time, researchers and practitioners must be trained to understand the benefits and limitations of alternative methods of data synthesis, as should those who make public policy decisions and influence medical care and public health practice. Statisticians have a critical role in developing methods for special problems and assisting in the design, execution and analysis of these studies.

Meta-analysis in Human Genetics

Replication or confirmation of scientific findings is a hallmark of good science. Laboratory experiments may be relatively easy to replicate, but field studies or observational studies can be quite challenging. Especially difficult are studies involving human populations. Indeed, most studies reporting new genetic linkage findings have had little success in being replicated [3, 24, 39]. In some cases, however, the effects of trait loci (*see* **Gene**) are so strong that replication is easily observed. Mendelian traits (*see* **Mendel's Laws**) fall into this category and include diseases such as cystic fibrosis and hypercholesterolemia. **Complex diseases** (e.g. heart disease, diabetes, schizophrenia, asthma) and quantitative traits (e.g. height, low density lipoprotein cholesterol), which are believed to be influenced by any number of genetic loci (*see* **Genotype**), require relatively much larger sample sizes or special sampling designs to attain sufficient statistical power to detect and locate the underlying **genes**. Replication of genetic findings for these non-Mendelian traits appears to be very difficult. The reasons are many, including **genetic heterogeneity**, sampling designs and **ascertainment** rules, environmental factors, and **covariates** such as age and sex. It may be possible to statistically adjust for some of these factors, for example by **regression** methods or stratification. Even after statistical adjustment, however, differences may remain among the primary studies. These differences may be real or due to chance. Combining results across studies may aid in assessing the overall genetic findings, the results of which can have important ramifications. For example, since it is now possible to develop molecular-based pharmaceutical treatments, it is vital to have an understanding of the genetic mechanisms underlying a given human trait. The synthesis of findings from similar studies forms the basis of much scientific understanding and meta-analysis is one approach to this end.

Basic Ideas and Methods of Meta-Analysis

The standard scientific review of a collection of studies addressing the same question often takes the form of a subjective qualitative assessment. Meta-analysis is a term used to describe *quantitative* methods to integrate or pool the numerical results from a collection of similar studies. Hedges & Olkin [23] narrow the definition by noting that "because meta-analysis usually relies on 'data' in the form of summary statistics derived from the primary analyses of studies, it is truly an analysis of the results of statistical analyses". It is in the spirit of this definition that meta-analysis is used in genetic studies.

Pooling information across replicate or similar studies is a common problem. If the studies are sufficiently similar, then combining the raw data from the different studies and analyzing this combined data set is the best one can do. More often, however, only published results (summary statistics, ***P* values**) are available for analysis. A formal approach for analyzing P values was proposed by Fisher [12] and Pitman [33], both of whom wrote about summarizing statistical findings across a collection of analogous studies. Assume that each of k independent studies tests a common **null hypothesis** and that each yields a one-tailed P value in the same direction. Under the omnibus null hypothesis that each of the k null hypotheses holds true, the test statistic

$$X^2 = -2\sum_{i=1}^{k} \log(P_i)$$

follows a χ^2 distribution with $2k$ degrees of freedom. Therefore, it is possible to jointly evaluate the evidence in favor of the alternative hypothesis by using a single test and all that is required are the published P values from the individual studies. Variations on this approach include analysis of the P value order statistics and a weighted linear combination of the P values to account for varying sample sizes across the studies [23]. This method is still widely used (e.g. in epidemiologic studies and clinical trials) as an approach to meta-analysis despite known limitations. It is well known, for example, that the X^2 statistic can be highly influenced by a single highly significant P value, which in turn may be due to a large sample size. Another concern is the simple fact that a single P value is used to summarize each (possibly complex) study as a basis for meta-analysis.

A more informative approach to meta-analysis is based on combining parameter estimates that reflect the treatment effect. For example, in clinical trials one may be interested in knowing the difference in the proportion of treatment and control subjects

$(p_T - p_C)$ that experience relief. A P value analysis will indicate whether there is consensus across the studies, but it may be more important to know the overall strength of the deviation from no treatment effect. This may not always be possible in practice since different studies addressing the same null hypothesis may use different statistics. When it seems reasonable to provide an overall estimate of a common parameter, it is important to make a careful judgment about the similarity of the studies. If one concludes that the studies are sufficiently homogeneous in design and sampling scheme that they are measuring or estimating the same quantity (δ), then it is appropriate to "pool information across studies" using a **fixed effect** model,

$$d_i = \delta + e_i,$$

where d_i is the observed value for the fixed effect δ from the ith study, and e_i is viewed as a random error term, independent and identically distributed across studies. The pooled estimator of δ is a weighted (least squares) average of the individual d_i:

$$\hat{\delta}_w = \frac{\sum_{i=1}^{k} w_i d_i}{\sum_{i=1}^{k} w_i},$$

where the weights are inversely proportional to the (estimated) **variances** of e_i, $w_i = \text{var}^{-1}(e_i)$. Genetic studies, even when "replication" is intended, in general tend not to be sufficiently homogeneous that it is believed the same quantity is being estimated from study to study. Indeed, population **admixture**, ascertainment, and **marker** maps, to name a few factors, vary enough so that the fixed effect model does not adequately reflect the study heterogeneity. A standard test for homogeneity makes use of a χ^2 statistic:

$$Q_w = \sum_{i=1}^{k} w_i (d_i - \hat{\delta}_w)^2,$$

which is approximately distributed as a χ^2 variable with $k - 1$ degrees of freedom.

If one judges that the differences in the d_i are due to both within-study variation (e_i) and among-study variation, then the model for d_i may be generalized to a **random effect** model to account for the two sources of variation. In this case it is useful to view the actual conducted studies as being a sample from a larger population of similar studies, each with an underlying (but unknown) δ that reflects the individual characteristics of its study. Thus, there is a corresponding population $\{\delta_j\}$, with mean δ and variance σ_δ^2. A two-stage or **hierarchical model** describes this situation:

$$d_i = \delta_i + e_i;$$

$$\delta_i = \delta + \varepsilon_i,$$

where $\text{var}(\varepsilon_i) = \sigma_\delta^2$, e_i is as above, and all the error terms are independent. In other words,

$$d_i = \delta + \varepsilon_i + e_i, \quad i = 1, \ldots, k.$$

From the hierarchical modeling perspective it can be seen that there is information about δ_i in all the studies, since they all vary about a common mean (δ). In this case, one can "borrow strength across studies" to estimate δ_i. Note that if there is no study-to-study variation [$\text{var}(\varepsilon_i) = \sigma_\delta^2 = 0$], then the random effect model coincides with the fixed effect model. If some of the study-to-study variation can be explained, then further modeling of δ_i may be incorporated in a mixed effect model. As with the fixed effect model, an estimate for the common δ is a weighted average:

$$\hat{\delta}_w = \frac{\sum_{i=1}^{k} w_i d_i}{\sum_{i=1}^{k} w_i},$$

where now the weights reflect both within-study variation and among-study variation, $w_i = [\text{var}(e_i) + \text{var}(\varepsilon_i)]^{-1}$. In practice, the variances (and, hence, the weights) are almost always estimated [8]. It is important that the hypothesis of homogeneity be investigated since the standard errors based on the two modeling approaches may differ substantially. The fixed effect standard error tends to be optimistically too small when sources of among-study variation are ignored.

Meta-Analysis Applied to Statistical Genetics

Application of the above methods in **human genetics** involves the common null hypothesis of no

association or linkage at a given marker locus or along some chromosomal region. Lack of consensus across studies may be due to having some studies supporting linkage and others supporting no linkage, or having most studies support only marginal significance, but none or very few showing strong evidence of linkage. The former may likely be due to substantial study heterogeneity, while the latter may arise because of low statistical power at the level of the individual studies. The main objective of a meta-analysis is to combine the results from the different studies to obtain an overall assessment of association or linkage in a given chromosomal region. The idea for meta-analysis in genetic studies is not exactly new. When the recombination fraction (θ) is the appropriate genetic parameter of interest [38], the lod function, $Z(\theta) = \log_{10}[L(\theta)/L(\theta = 0.5)]$, for each study is maximized to obtain independent estimates of θ [32]. An overall estimate can be determined from the sum of the individual lod functions and a test of homogeneity can subsequently be carried out.

As an illustration of meta-analysis involving modern genetic linkage studies, Allison & Heo [2] use Fisher's P value method in a meta-analysis of six independent samples, each concerning linkage of body mass index to the region of the human genome containing the OB gene. In the primary meta-analysis, Allison & Heo show three samples with evidence of linkage at the 0.05 significance level, while three samples do not show significant linkage. The X^2 meta-analysis statistic yields a P value of 1.5×10^{-5}, providing strong overall evidence of linkage. One of the main problems with such standard meta-analytic methods is the level of study-to-study heterogeneity, especially **genetic heterogeneity**, as well as sample size, ascertainment of families, marker maps (marker distribution, average intermarker distance, marker heterozygosity), disease definition, and statistical analysis [34]. As such, it is not always a simple matter to extract a single P value from each of the primary studies, as demonstrated by Allison & Heo. Even if this can be accomplished, it should be noted that this approach to meta-analysis is unequivocally valid only if the P value is taken at the same marker locus from each study. In practice, however, the individual study P values are associated with the most significant marker within a given chromosomal region, which may contain more than a handful of markers. In practice, then, we may expect an increased false-positive rate. Additionally, it has been observed [35] that there is a **bias** in Fisher's X^2 test when it is applied to model-free linkage methods that constrain lod scores to nonnegative values. The bias is especially acute in the context of genome scans, but an adjustment is available. Guerra et al. [20] discuss Fisher's P value method in the context of genome scans.

In those situations where a common parameter estimate of linkage or association is available, a goal of the meta-analysis is to obtain a combined estimate to indicate the overall strength of the **correlation** across studies. Thus far, two common situations arise in practice. The first deals with population-based studies of associations between marker **polymorphism** and disease status. The standard study design is a **case–control study** where the cases and controls are affected and unaffected subjects, respectively, and the "treatment factor" is a specified marker **genotype**. Thus, if there is interest in the association between the AA genotype at a given locus and disease status, then the data for each individual study are typically shown as a table of counts (Table 1), and relevant differences in proportions, **relative risks**, or **odds ratios** [1] are analyzed. In genetic studies [27, 41] it is common to work with the observed odds ratio ($OR = ad/bc$). In this case, a test of homogeneity for a common OR is performed and, if not rejected, a common OR is estimated and used as an overall estimate of the genotype–phenotype association. The overall estimate can be calculated as a crude OR based on pooled counts (which are typically available in the primary publications), Mantel–Haenzsel estimator, or Woolf estimator. The latter appears to be a popular choice among genetic studies, perhaps due to its early appearance in the genetics literature, where it was introduced in the context of correlating **blood groups** with disease. Instead of using the ORs themselves, Woolf [46] proposed using the logarithms of the ORs since on this scale they are approximately normally distributed. For k studies he proposed using a weighted average

Table 1

	Affected	Unaffected
AA genotype	a	b
Not AA genotype	c	d

of these logarithms,

$$\log(OR_{\mathrm{W}}) = \frac{\sum_{i=1}^{k} w_i \log(OR_i)}{\sum_{i=1}^{k} w_i},$$

where the weights are given by the inverse of the variance of the log *OR*:

$$w_i = \mathrm{var}^{-1}[\log(OR_i)] = \left(\frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \frac{1}{d}\right)^{-1}.$$

Woolf's test for homogeneity is based on a χ^2 statistic,

$$X^2 = \sum_{i=1}^{k} w_i \left[\log(OR_i) - \log(OR_{\mathrm{W}})\right]^2,$$

which, under the null hypothesis of a common *OR*, approximately follows a χ^2 distribution with $k-1$ degrees of freedom. Case–control studies in genetics have been used to evaluate the total evidence for population associations between marker genotypes and a variety of genetic traits, including schizophrenia [9], hypertension [26], and cleft lip [31]. To investigate various genotype effects (e.g. homozygosity, additivity), as well as to account for **covariates**, the meta-analysis can also be carried out by **logistic regression** with case–control status as the dependent variable [40, 41].

Analogous to the case–control analysis for disease data one can analyze an overall mean difference of a quantitative trait between two groups defined by genotypes. For example, Juo et al. [25] conducted a meta-analysis of the mean difference in apolipoprotein A-I levels between two genotype groups defined by an A/G **polymorphism** in the promoter of the apolipoprotein A-I gene. The overall mean difference is a weighted average of the primary study mean differences. A test of homogeneity and a confidence interval for the overall difference form the basis of the analysis [16]. Juo et al. [25] include a good discussion of **confounding** factors and stratification as they pertain to meta-analysis.

Genetic linkage studies allow for other measures of genetic effect size that can be defined and pooled across a collection of genetic studies. For model-free methods that do not depend on a parametric genetic model for analysis, allele-sharing data may be used [18, 19] to define a genetic effect size. Affected sib pairs, for example, are expected to share a higher proportion (π) of alleles than that expected ($\pi = 0.5$) under no linkage. The mean proportion of identity-by-descent (ibd) (*see* **Identity Coefficients**) allele-sharing at a specified locus can therefore be taken as an interpretable parameter to be combined across studies. Let $\overline{\pi}_i, i = 1, 2, \ldots, k$, denote the average proportion of ibd allele-sharing among n_i affected sib pairs in study i. A combined estimate of mean allele-sharing across homogeneous studies can be constructed by a weighted least squares estimate based on a fixed effect model as discussed above:

$$\overline{\pi}_w = \frac{\sum_{i=1}^{k} w_i \overline{\pi}_i}{\sum_{i=1}^{k} w_i},$$

where $w_i = 1/\hat{\sigma}_i^2$, the reciprocal of the estimated variance of $\overline{\pi}_i$. A standard error for the combined estimate can be easily calculated according to the result $\mathrm{var}(\overline{\pi}_w) = 1/\sum w_i$. The homogeneity hypothesis can be tested with the following statistic:

$$Q_w = \sum_{i=1}^{k} \frac{(\overline{\pi}_i - \overline{\pi}_w)^2}{\hat{\sigma}_i^2},$$

which asymptotically follows a χ^2 distribution with $(k-1)$ degrees of freedom under the null hypothesis. Under the more realistic scenario of study heterogeneity, Gu et al. [19] have proposed a random effect modeling approach where the observed proportion ($\overline{\pi}_i$) of ibd sharing in study i reflects a random effect due to study-to-study variation and a random effect due to within-study variation. Following their notation, the model for $\overline{\pi}_i$ is

$$\overline{\pi}_i = \tau + \delta_i + \varepsilon_i,$$

where the within-study variation is $\mathrm{var}(\varepsilon_i)$ and the among-study variation is $\mathrm{var}(\delta_i)$. Estimating the two variance components and the overall measure of allele-sharing (τ) follows the general approach discussed above and is detailed in Gu et al. [19], while Goldstein et al. [15] investigate both fixed effect and random effect models for $\overline{\pi}_i$ in the context of genome scans. The random effect model can be extended to include study-specific covariates [17].

There are other types of studies that make use of allele-sharing data, but which may not explicitly provide observed values of $\overline{\pi}_i$. Nevertheless, it is still possible to extract this information from a variety of studies [18]. Once such information is obtained, the above models may be used with the derived or estimated proportions of allele-sharing. Similarly, random effect and Bayesian hierarchical models have been proposed for combining Haseman–Elston slope estimates (see below) from independent studies investigating linkage to a common quantitative trait locus using the same marker.

The above meta-analysis methods for linkage have not been specifically designed for genome scans; they are clearly applicable for investigating linkage at a single locus or very small chromosomal region. However, as with previous statistical methods developed for genetic linkage at a single marker, one can obtain a meta-analysis test statistic score map along the genome and assess significance through a multiple testing procedure. The standard guidelines for **genome-wide significance** levels were given by Lander & Kruglyak [28], but it is unclear how they may apply to meta-analysis. It is thought that less stringent significance levels than those proposed by Kruglyak & Lander may be appropriate for meta-analyses of genome scans, but a definitive theory or strong empirical evidence does not exist at this time. Badner & Goldin [4] depart from the standard approach of generating and analyzing a meta-analysis version of the underlying test statistic. They seek to answer the natural question, "How often can we expect more than one genome scan to exceed a given threshold in a defined region if, in fact, linkage is absent in the region?" A binomial probability model is applicable and used to find theoretical answers to the question. For a single-point linkage analysis in the primary studies, the basis of their meta-analysis method [the multiple genome test (MGT)] is to calculate the chance of having observed r_k out of s studies with significant linkage in each of k chromosome regions, each defined by a range of consecutive markers (e.g. four). Meta-analysis based on **multipoint linkage** is similarly defined by considering 30 cM contiguous regions. By varying the thresholds in the binomial model, Badner & Goldin demonstrate that less stringent thresholds at the primary study level may yield highly significant results at the meta-analysis level. **Simulation** studies show good agreement between theoretical and empirical estimates of false-positive rates for a single-point analysis, but not a multipoint analysis. On balance, for the simulations investigated, the MGTs did not show a significant advantage in power over the Kruglyak & Lander guidelines. Although several limitations are discussed, their method is potentially quite useful as it directly addresses the question of consensus. For related issues, see the variety of significance thresholds used for meta-analysis in Genetic Analysis Workshop 11 [4, 15, 17, 20, 44, 47].

Relatively few meta-analytic methods specifically designed for genome scans currently exist. Each is based on obtaining a meta-analysis test statistic value in each of k_c user-defined segments per chromosome (C) and then testing for significance within each segment. Common marker maps are not assumed and each method proposes an approach to control the genome-wide type I error probability that results from multiple testing (*see* **Multiple Comparisons**) across the segments. A nonparametric rank-based method has been proposed by Wise et al. [45], who apply it to four screens for multiple sclerosis and 11 screens for autoimmune disorders; Wise & Lewis [44] investigate the type I error and the power of the method in a simulation study. Within each of m studies, each chromosome is divided into segments of equal length and the most significant result from each segment is ranked among all segments covering the entire genome; the most extreme results have the higher ranks. Under the null hypothesis of no linkage in any segment, the ranks within each primary study will be uniformly distributed throughout the genome. Within each defined segment, the primary study ranks are summed across the m genome scans, and for n segments across the genome, the chance that the ranks, $X_i, i = 1, \ldots, m$, from a fixed segment sum to R is

$$\Pr\left(\sum_{i=1}^{m} X_i = R\right) = \frac{1}{n^m}\sum_{k=0}^{d}(-1^k)\binom{R-kn-1}{m-1} \times \binom{m}{k}, \quad m \le R \le mn,$$

and 0 if $R > mn$. In the formula, d is the integer part of $(R-m)/n$. This method, like most developed thus far, treats each genome scan equally and does not incorporate strategies to allow for study differences such as may be due to marker maps and sample sizes. However, it is broadly applicable as it can be used across studies that use different analyses (e.g.

model-based and model-free), disease definitions, and even different diseases (e.g. different psychiatric disorders).

Meta-analytic approaches for multiple genome scans based on a genetic effect size *per se*, instead of significance results, are also being developed. We consider a method proposed by Etzel [10] and further developed by Etzel & Guerra [11]. To fix ideas, assume that there exists at most a single trait locus and that each of k studies have used the Haseman–Elston robust sib-pair method [22] to search for the gene in a chromosome scan of length L cM. This situation will illustrate some of the issues that arise in developing a meta-analytic procedure for genome scans. The approach is not unique to the Haseman–Elston method and is generally applicable to other genetic effect sizes or test statistics. Assume that within each of m nonoverlapping, contiguous segments of equal length covering the chromosome, each study has exactly one marker $(M_{ij}, i = 1, \ldots, k; j = 1, \ldots, m)$ at distinct locations. The Haseman–Elston method regresses the square of sib-pair phenotypic differences on the proportion of shared ibd (marker) alleles and a significant negative slope gives evidence of linkage. The expected value of the slope estimate, $\hat{\beta}$, is a function of the recombination fraction (θ) between the marker and trait loci and the variance component (σ_g^2) due to polymorphism at the trait locus:

$$\mathrm{E}(\hat{\beta}) = -2(1 - 2\theta)^2\sigma_g^2.$$

Therefore, assume that each study provides a summary statistic $(\hat{\beta}_{ij}, S_{ij}^2), i = 1, \ldots, k, j = 1, \ldots, m$, at each marker locus, where S^2 is the estimated variance of $\hat{\beta}$. The meta-analytic method is defined as follows. At each of q test points along the chromosome, an overall estimate of the Haseman–Elston slope is calculated as a weighted average of normalized $\hat{\beta}$s that correspond to the segment in which the test point is located. The weights correspond to a random effect estimator that reflects both within-study and among-study variation. The test point at which the overall estimate is most significant is taken as the most likely location of the trait locus. The normalization is required to adjust for the fact that within each chromosomal segment the study markers are at different loci and therefore the recombination fractions implicit in the slope estimates are different. That is, the method does not require studies to use the same marker maps. The weighted averages are calculated from the following normalized statistics:

$$\hat{\beta}_{ijq} = \frac{\hat{\beta}_{ij}}{(1 - 2\theta_{ijq})^2} \quad \text{and} \quad S_{ijq}^2 = \frac{S_{ij}^2}{(1 - 2\theta_{ijq})^4},$$

where θ_{ijq} is the recombination fraction between the marker M_{ij} and test point q, calculated by applying a mapping function (*see* **Linkage Analysis, Multivariate**). The overall estimate of the Haseman–Elston slope is calculated as:

$$\hat{\beta}_q = \frac{\sum_{i=1}^{k} w_i \hat{\beta}_{ijq}}{\sum_{i=1}^{k} w_i}; \quad w_i = \frac{1}{\hat{\sigma}_q^2 + S_{ijq}^2},$$

where $\hat{\sigma}_q^2$ estimates the study-to-study variation at test point q:

$$\hat{\sigma}_q^2 = \frac{1}{k-1}\sum_{i=1}^{k}(\hat{\beta}_{ijq} - \overline{\beta}_q)^2 - \frac{1}{k}\sum_{i=1}^{k} S_{ijq}^2,$$

with $\overline{\beta}_q$ the average of the $\hat{\beta}_{ijq}$. The overall slope estimate is standardized by its standard error (se) to assess its significance with reference to a standard normal distribution:

$$z_q = \frac{\hat{\beta}_q}{\mathrm{se}(\hat{\beta}_q)}; \quad \mathrm{se}(\hat{\beta}_q) = \left(\sum_{i=1}^{k} w_i\right)^{-1/2}.$$

Denoting the most significant overall slope by β_q^*, the genetic variance component can be estimated as $\hat{\sigma}_g^2 = -\beta_q^*/2$. Simulations have been carried out [10] to determine if the meta-analysis method increases power to detect linkage over the pointwise (Haseman–Elston) method at the primary study level, compare its performance under various configurations of primary study evidence, and assess its accuracy in locating the trait locus and estimating the component of genetic variance σ_g^2. Since it is unknown how to select significance thresholds for a meta-analysis of genome scans, two approaches were taken. First, z_q was referred to the normal quantile (-2.633) corresponding to a chromosome-wide significance level of 0.05, which in turn corresponds to a pointwise level of 0.004 by the method of Lander & Kruglyak [28]. Secondly, the standard 0.05 threshold at the pointwise level was used, ignoring multiple

testing. The Haseman–Elston slope estimate at the primary study level was evaluated using a Bonferroni correction ($0.05/m$) for multiple testing across a map of m markers. Simulation configurations varied over marker density, sib-pair sample size, and trait gene location. The main findings show that:

1. Both meta-analysis methods provided substantially better power than the individual studies.
2. The type I error probability of the meta-analysis method using the standard pointwise 0.05 threshold was consistently higher than that based on the Lander–Kruglyak (LK) genome-wide threshold.
3. The power of the meta-analysis using the LK threshold was slightly less than the meta-analysis based on the 0.05 pointwise threshold. However, the pointwise method showed a high false-positive rate outside a relatively small neighborhood (± 10 cM) of the trait locus. In practice, the size of the neighborhood can be expected to be a function of the marker density.
4. In all cases, the meta-analysis based on the LK threshold located the trait locus within 2.5 cM.
5. Meta-analysis with the LK threshold consistently provided unbiased estimates of the genetic variance, σ_g^2. It is unknown whether the Lander–Kruglyak threshold is appropriate for this meta-analytic approach; in particular, the Lander–Kruglyak guidelines assume a dense marker map, which is not the case in the meta-analysis simulation or in most real genome scans.

To minimize statistical parametric assumptions (e.g. normality of a test statistic) and to reflect the inherent characteristics (e.g. marker map) of different genetic studies, randomization (permutation) or Monte-Carlo methods [5, 7, 21, 42] can be use to construct nonparametric null distributions for the overall slope estimate. In this case, a permutation approach resulted in an improvement in the meta-analysis type I error probability and therefore increased the precision in locating the gene locus [10]. The power of the permutation test to locate the trait locus within 10 cM was, on average, slightly less than the power of the meta-analysis method that used the Lander–Kruglyak normal critical value. In the simulations considered, the permutation test is superior to the parametric meta-analysis method when the trait locus is located near either end of the chromosome. Inspection of the permutation thresholds also shows that the thresholds vary markedly with the position of the trait locus, confirming that the method adjusts to the specific characteristics of the study [5].

Meta-analysis methodology is just emerging as a tool for modern genetic analysis, but its usefulness and importance is quickly being recognized [28, 36] as we learn how difficult it is to replicate initial linkage or association findings. In addition to the technical methodology, there are practical issues that must be addressed, especially as more genetic studies on the same trait become available. The planning of a meta-analysis requires great care. Some studies will be useful and others will not. The following steps summarize what must be done to increase the chances of a successful and informative meta-analysis:

1. Formulate a specific purpose and explicitly define the outcome to be extracted from each study. Bear in mind that genetic effect sizes are more informative than significance results.
2. Identify relevant primary studies.
3. Establish inclusion/exclusion criteria for primary studies.
4. Detail data abstraction and acquisition.
5. Decide on data analysis method(s) and understand their limitations. Carefully investigate study-to-study heterogeneity.
6. Give a careful interpretation, especially as it applies to extrapolation of findings.

A basic reference for meta-analytic ideas, concepts, and methods is Hedges & Olkin [23], while Draper et al. [8] provide a general discussion on combining information. Mann [30] gives an overview of meta-analysis in medical research. Rao & Province [37] cover statistical genetics, including a chapter on meta-analysis; see also Cooper & Hedges [6]. The meta-analytic methods detailed in this article cover current methods that appear to be the most common in human genetics studies. Other approaches include a Bayesian method [43], Morton's β model [29], and model selection [14]. The term meta-analysis was coined by Glass [13].

Meta-analysis of Clinical Trials

Meta-analysis is the systematic and quantitative review of the results of a set of individual studies, intended to integrate their findings [11]. Informal synthesis of evidence has always been practiced, and even the idea of combining results quantitatively across research studies can be traced back to the early 1900s. The basis of the statistical methods now generally used is also long established [6]. Meta-analysis as a specific technique was developed in the **social sciences**, but soon became adopted as a fundamental tool in medical research, especially as a way of reviewing and combining the evidence from **clinical trials**.

There are a number of reasons why meta-analysis is such an important technique in clinical trials research [22, 26]. It is now recognized that narrative reviews of a set of clinical trials can be very misleading, being potentially distorted by the selection of evidence, the emphasis placed on its components, and the personal opinion of the reviewer. Secondly, the explosion of research evidence, in the form of published trials, often cannot be easily assimilated without formal review. Thirdly, in assessing the benefits of a particular medical treatment, judgments should be based on the totality of reliable evidence, for example from all relevant well-conducted randomized clinical trials. Fourthly, given that sample sizes of individual clinical trials are often too small to detect clinically important effects reliably, synthesis of evidence across trials is necessary.

Meta-analysis therefore has a number of aims: to review systematically the available clinical trial evidence; to provide quantitative summaries of the results from each study; to combine these results across studies, if appropriate; and to provide an overall interpretation. By combining results, more statistical **power** for detecting treatment effects is available and the precision of estimated treatment effects is enhanced. Meta-analysis discourages the common simplistic and misleading interpretation that the results of individual clinical trials are in conflict because some are labeled "positive" (i.e. statistically significant) and others "negative" (i.e. statistically nonsignificant). Yet it allows the investigation of possible reasons for real differences between the treatment effects in different clinical trials, i.e. sources of heterogeneity.

Meta-analysis has both qualitative and quantitative components. For example, the description of the available trials, in terms of their relevance and methodologic strengths and weaknesses, plays a crucial part in providing a meaningful interpretation, but is essentially qualitative. Summarizing the trials' results and their combination is clearly quantitative. Various synonymous terms are used to describe meta-analysis. The term "overview" has been used by some authors, and "pooling" by others. Because the first fails to indicate the quantitative aspect of the analysis, and the second gives the unfortunate (and incorrect) impression that the data from each trial are simply lumped together, these now tend to be avoided. More recently, the term "systematic review" has been coined, and some authors use this to refer to the whole process of qualitative and quantitative review, restricting the term meta-analysis to the quantitative aspects.

In this article, we start by discussing the nature of practical meta-analyses, then focus on the quantitative and statistical aspects, and conclude by considering interpretational issues.

Types of Meta-Analysis

In principle, the trials included in a meta-analysis might be clinically homogeneous. For example, they might all study a similar type of patient for a similar duration with the same treatments in the two groups of each trial. In practice, however, the trials included are usually heterogeneous. For example, the **eligibility criteria** may differ between trials, the treatments used may not be identical, the duration of treatment and length of follow-up may differ, and the use of ancillary treatments or care may not be the same. Hence, in most situations, the objective of a meta-analysis cannot be equated with that of a single large trial, even if that trial has wide eligibility criteria. While a single trial focuses on the effect of a specific treatment in specific circumstances, a meta-analysis aims to obtain a more generalizable conclusion about the effect of a generic treatment policy in a wider range of situations. For example, a meta-analysis of blood cholesterol lowering trials included trials using

drugs, dietary intervention, and even surgery; the focus was on the effect of cholesterol reduction itself, rather than on the specific regimens used to lower cholesterol [31].

There has been enormous growth in the number of meta-analyses published in recent years [11] over all fields of medicine, so that examples can currently be found in almost any year's issue of a general or specialist medical journal. Some are investigations of published trials (meta-analysis of the literature), others use summary statistics or tabulated data obtained from the individual trialists (meta-analysis of summary data), while others are based on the individual patient data (IPD) from each trial (meta-analysis of patient data). The latter usually require the formation of international collaborative groups and long-term resource commitment; for example, see [1, 12].

While the majority of meta-analyses currently rely on published data, sometimes supplemented by additional summary data for certain trials, the proportion of those based on IPD is increasing. The use of IPD allows checking of the original data (whereas published information can be wrong or misleading), permits the updating of follow-up information (which is particularly useful in **survival** studies), and has much greater potential than summary data for investigating which patients may benefit most from treatment. For these reasons, IPD meta-analyses must be regarded as the gold standard [25]. However, they cannot always be carried out, either because individual patient data are not available (whether for practical, scientific, or political reasons) or because the exercise is too costly.

The worldwide **Cochrane Collaboration** has been a recent and important development promoting the production and dissemination of systematic reviews of high quality, in an effort to achieve **evidence-based medical practice**. The aims of the Collaboration are to facilitate meta-analyses of randomized clinical trials in all areas of medicine, to disseminate their results effectively, and to update them regularly. To this end, a number of Cochrane Centres have been established in different parts of the world, as well as Review Groups with responsibility for coordinating the work in specific medical areas. The meta-analyses are performed according to certain methodologic guidelines [24] and checked by editorial teams. They are then released in a standard format on compact disc together with searching software (the Cochrane database of systematic reviews – CDSR). Many meta-analyses now being undertaken contribute to the Cochrane Collaboration and the CDSR.

Preliminaries

A meta-analysis, like other scientific research, requires a written structure or protocol which defines its objective and scope. The identification of trials for inclusion in a meta-analysis is the next, but difficult, stage. Simply identifying relevant randomized trials through computerized bibliographic searches such as Medline is usually inadequate; it is often necessary to search reference lists and citations and to communicate with specialists in the area. One also has to decide whether to include abstracts, how to include data from trials in progress, and how to identify relevant non-English publications; all are difficult issues [24]. The decision as to whether particular trials are relevant to the objective of the meta-analysis can be somewhat subjective, and so one needs to be explicit about the criteria for including trials and to give a list of excluded trials.

A qualitative review of the individual trials, for example delineating their methodologic weaknesses, is a necessary step for a later overall interpretation of results. Failure to undertake proper **randomization**, to maintain follow-up of all patients, or in some circumstances to preserve blinding of treatments (*see* **Blinding or Masking**), can lead to **bias** in individual trials and hence in the overall meta-analysis [27]. Unfortunately, these weaknesses are not always clear from publications. One may even have to decide that the trials are not combinable, either because the quality of the reported results is poor or because the treatments or patients are not similar enough. The quality of a meta-analysis is only as good as the quality of the component trials which are included in it (except with regard to sample size): if the trials are biased, so will be the meta-analysis.

The essential quantitative information needed is the estimated treatment effect, measured on the same scale in each trial, and its **variance**. One common problem in undertaking a meta-analysis of published trials is that this information is not available. For example, treatment effects may be presented in different ways in different trials, particularly in survival studies, or their **standard errors** may not be available. Sometimes these can be derived from other published information, such as the raw numbers or

***P* values**, but often the original trialists have to be contacted to supply the necessary information.

Scale of Treatment Effects

Many trials have **binary** event data, such as death, as the outcome. Treatment effects can then be expressed as **risk** differences, risk ratios (*see* **Relative Risk**), or **odds ratios**. Any of these can be used as a basis for comparing results across trials, but because **absolute risks** will be very dependent on the underlying risk of the patients included and the duration of follow-up, risk differences are often severely heterogeneous across trials. Hence meta-analyses are usually based on relative measures, odds ratios being the most commonly used in practice because of the variety of statistical methods that are available. For similar reasons, hazard ratios (*see* **Hazard Rate**) are most often used for survival studies. For ordinal data a **proportional odds** method of analysis can sometimes be applied. A logarithmic **transformation** (log odds ratio, or log hazard ratio) is generally used, since this improves the **normality** of the estimate's **sampling distribution**.

In trials where the outcome is continuous, for example blood pressure, treatment effects are usually expressed as **mean** differences. However, some trials may express their results using change from baseline, proportionate change from baseline, baseline adjusted levels, a data transformation (such as logarithm), or **medians**. Not all of these methods are compatible, but a consistent manner of expressing results is required for meta-analysis. In some fields, such as psychology, it is common to express results as effect sizes, by dividing means by the overall **standard deviation** of the measurements. This is especially so when somewhat different outcome measures have been used to assess the same underlying quantity (*see* **Normal Scores**).

Statistical Tests Used in Meta-Analysis

It is now useful to introduce some notation. We suppose there are k trials, $i = 1, \ldots, k$, each with a treatment group and a **control** group, and that

θ_i = true treatment effect in trial i,

$\hat{\theta}_i$ = estimated treatment effect in trial i,

v_i = variance of $\hat{\theta}_i$,

$w_i = 1/v_i$.

For example, $\hat{\theta}_i$ could be the observed log odds ratio in a trial with binary outcomes, or the observed mean difference in a trial with continuous outcomes, and is an estimate of the true but unknown θ_i. In practice, v_i is an estimated quantity based on the data in each trial. In what follows, the summation sign always refers to summation over all trials $i = 1, \ldots, k$.

An overall **null hypothesis** that the treatment effect is zero in every trial is $H_0 : \theta_i = 0$ for all i. Two tests of this null hypothesis are [31]:

1. $\sum w_i \hat{\theta}_i^2$ referred to a $\boldsymbol{\chi_k^2}$ **distribution**; this is a general test similar to **Hotelling's $\boldsymbol{T^2}$**, which has no particular alternative hypothesis in mind.
2. $(\sum w_i \hat{\theta}_i)^2 / \sum w_i$ referred to a χ_1^2 distribution; this is a "directional" test more powerful than the general test above against alternatives of the form $H_1 : \theta_i < 0$ for all i (or $H_1 : \theta_i > 0$ for all i).

In the context of meta-analysis, the directional alternatives are those of most medical interest (and indeed are generally the most plausible) and so it is the directional test that is used. Moreover, the directional test is particularly powerful against the alternative $H_1 : \theta_i = \theta (\neq 0)$ for all i, that the true treatment effect in each trial is the same nonzero quantity. Using χ^2 distributions assumes that the estimated treatment effects are normally distributed.

For binary outcomes, each trial's results can be summarized as a **2 × 2 table** of counts. The **Mantel–Haenszel** test is in fact a particular example of the directional test. It has been rephrased by Peto [39] in terms of comparing the observed (O_i) number of events in the treated group of trial i with that expected (E_i) under the hypothesis of no treatment effect $(\theta_i = 0)$. Using the variance V_i of O_i from the **hypergeometric distribution** for a 2×2 table, the Mantel–Haenszel test of H_0 refers $[\sum (O_i - E_i)]^2 / \sum V_i$ (if a continuity correction (*see* **Yates's Continuity Correction**) is not used) to a χ_1^2 distribution. This can be seen to be (asymptotically) equivalent to the directional test by noting that $(O_i - E_i)/V_i$ is an approximation to the log odds ratio estimate (that is $\hat{\theta}_i$) with variance $1/V_i \approx v_i$ [38].

If this overall null hypothesis is rejected, an assumption often made in meta-analysis is that the

true treatment effects in each trial are the same nonzero quantity, θ (a **fixed effect** model). A test of the hypothesis $H_0 : \theta_i = \theta$ for all i is a test of homogeneity (or test for heterogeneity), achieved by referring $Q = \sum w_i(\hat{\theta}_i - \hat{\theta})^2$, where $\hat{\theta} = \sum w_i\hat{\theta}_i / \sum w_i$, to a χ^2_{k-1} distribution. This is a test of trial by treatment interaction, and like other tests of **interaction** lacks power in many practical situations. Hence, in particular, nonsignificance of the test cannot be taken as evidence in favor of treatment effect homogeneity, and so the test has somewhat limited usefulness in the context of meta-analysis.

If the assumption of homogeneity of true treatment effects (θ_i) is not accepted, either because of the above test or for reasons of principle, variation in the θ_i between trials must be accommodated (a **random effects** model). If it is assumed that the θ_i have some distribution across trials, with mean θ^* and variance σ^2, then we have a **hierarchical model** for the observed data:

$$\hat{\theta}_i \sim \text{mean } \theta_i, \text{ variance } v_i,$$
$$\theta_i \sim \text{mean } \theta^*, \text{ variance } \sigma^2.$$

A test of whether the "average" treatment effect θ^* is zero is similar to the directional test above, except that different weights are used. Now $(\sum w_i^*\hat{\theta}_i)^2 / \sum w_i^*$ is referred to a χ^2_1 distribution, where $w_i^* = 1/(v_i + \sigma^2)$. In using the χ^2 distribution, normality of both the estimated treatment effects within trials and the true treatment effects across trials is assumed. To carry out this test, the between-trial component of variance must be estimated (see below).

Table 1 shows the data from a meta-analysis of nine controlled trials of the use of diuretics in pregnancy to prevent preeclampsia [7, 33]. The estimated odds ratios and 95% **confidence intervals** for each trial are shown in Figure 1. Using a log odds ratio scale for the preeclampsia outcome, the directional test of $H_0 : \theta_i = 0$ for all i yielded $\chi^2_1 = 21.6 (P < 0.001)$. The conclusion is not that the treatment worked in all the trials, but only that at least one of the true treatment effects is nonzero. The test for heterogeneity (of $H_0 : \theta_i = \theta$ for all i) yielded $\chi^2_8 = 27.3 (P < 0.001)$, indicating that the true treatment effects were not the same in all trials. If one was prepared to use the hierarchical random effects model above, the test of $H_0 : \theta^* = 0$ yielded $\chi^2_1 = 6.4 (P = 0.01)$. Hence, allowing for the apparent heterogeneity of true treatment effects between trials reduced the evidence for an overall treatment effect. This emphasizes that a test of an assumed common treatment effect is different, both logically and in practice, from a test of an average treatment effect.

Table 1 Incidence of preeclampsia in nine randomized trials of diuretics, and odds ratios

Trial[a]	Incidence of preeclampsia (number of patients)		OR
	Diuretic	Control	
Weseley	11% (14/131)	10% (14/136)	1 · 04
Flowers	5% (21/385)	13% (17/134)	0 · 40
Menzies	25% (14/57)	50% (24/48)	0 · 33
Fallis	16% (6/38)	45% (18/40)	0 · 23
Cuadros	1% (12/1011)	5% (35/760)	0 · 25
Landesman	10% (138/1370)	13% (175/1336)	0 · 74
Krans	3% (15/506)	4% (20/524)	0 · 77
Tervila	6% (6/108)	2% (2/103)	2 · 97
Campbell	42% (65/153)	39% (40/102)	1 · 14

Fixed Effect Methods of Estimation

It is more informative to provide overall estimates (*see* **Estimation**) of treatment effect, together with confidence intervals, than simply to test hypotheses. The vast majority of published meta-analyses use "fixed effect" estimates of treatment effect, making the assumption of homogeneity ($\theta_i = \theta$ for all i). Whether this is reasonable is discussed below, but for the moment we pursue this analysis.

In estimating an assumed common θ, the weighted average $\hat{\theta} = \sum w_i\hat{\theta}_i / \sum w_i$ is an **unbiased** estimate, and has the smallest variance, namely $1/\sum w_i$, amongst weighted averages of the $\hat{\theta}_i$ (*see* **Minimum Variance Unbiased (MVU) Estimator**). Assuming normality allows the calculation of a 95% confidence interval for θ, being $\hat{\theta} \pm 1.96(1/\sum w_i)^{1/2}$. In this "inverse-variance" weighting, the greatest weight is given to the largest and most informative trials, which have more precisely estimated treatment

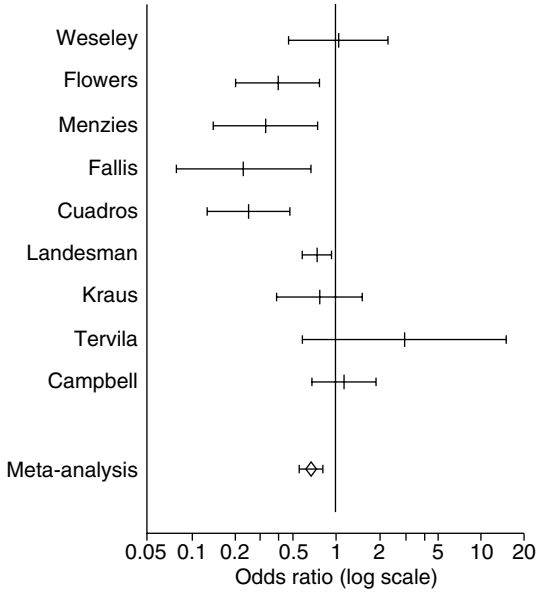

Figure 1 ORs for preeclampsia and 95% confidence intervals in nine trials of diuretics (ORs less than unity represent beneficial effects of diuretics; meta-analysis based on fixed-effect assumption). Reproduced from Thompson & Pocock, *Lancet*, vol. 338, pp. 1127–1130 [33]. © The Lancet Ltd, 1991.

effects (small v_i, so large w_i). The estimate is not derived simply from lumping together the data from each trial, but appropriately from a stratified analysis (*see* **Stratification**) by combining trial-specific estimates. For trials with binary outcomes, this method can be used directly for log odds ratios; the use of empirical logits, for example adding 0.5 to the cells of 2×2 tables which contain a zero, is then necessary. Asymptotically equivalent results can be obtained using **logistic regression** [31] or Peto's method based on $(O - E)/V$ as an approximation to the log odds ratio [7, 39], although the latter can be biased in some extreme situations [16]. Each of these methods gives an overall log odds ratio and confidence interval, which can be exponentiated to provide results on the untransformed odds ratio scale. The Mantel–Haenszel estimator weights the untransformed odds ratios approximately inversely proportional to their variances. In numerical examples all these methods produce nearly identical results [13, 31]. A general formulation of these and similar methods can be made in terms of score statistics and Fisher **information** [38].

The main practical issue is not the choice of particular method, but whether the assumption of homogeneity of true treatment effects on which these methods are all based is justified. It is also informative to calculate the proportion of weight allocated to each trial ($w_j / \sum w_i$ for trial j). Often it is just one or a few trials that dominate the overall results, in which case one may be justly concerned about the generalizability of the results [33].

Random Effects Methods of Estimation

The homogeneity assumption can be relaxed by using the hierarchical model given above, which incorporates a between-trial component of variance σ^2. This leads to estimation of the overall average treatment effect θ^* around which, it is assumed, the true treatment effects in each trial are randomly distributed. The variance of each $\hat{\theta}_i$ is now $(v_i + \sigma^2)$ and the appropriate weights w_i^* are put equal to the reciprocal of these variances. The average effect of treatment is estimated as $\hat{\theta}^* = \sum w_i^* \hat{\theta}_i / \sum w_i^*$, with variance $1/\sum w_i^*$. Assuming normality both within and between trials allows the calculation of a confidence interval for θ^*.

To carry out these calculations, σ^2 must be estimated. Usually a **moment** estimator is used since it can be derived straightforwardly from the heterogeneity statistic Q [10]. In principle, **maximum likelihood** estimation is preferable but this requires an iterative solution [10, 17]. In most practical situations, the choice between estimators is unimportant. The important aspect is that σ^2 is now allowed to be positive, permitting between-trial heterogeneity of true treatment effects; when σ^2 is zero the random effects method becomes identical to the fixed effect method. In moving from a fixed effect analysis to a random effect analysis, the weights given to each trial become more evenly distributed, so that in a random effects analysis small trials receive relatively more weight.

Related Methods

Use of $1/\sum w_i$ as the variance of $\hat{\theta}$ assumes that the individual v_i are known rather than estimated. Use of $1/\sum w_i^*$ as the variance of $\hat{\theta}^*$ assumes in addition that σ^2 is known. Allowance for the imprecision in the estimate of σ^2 can be made using a marginal

profile method [17], but allowing also for the imprecision in v_i requires exact methods for fixed effect analyses [21] or a full **likelihood** approach for random effect analyses [36]. These extensions can also be used in deriving significance tests. The construction of confidence intervals for θ and θ^* requires assumptions of normality, which can be investigated using normal plots of $w_i^{1/2}(\hat{\theta}_i - \hat{\theta})$ or $w_i^{*1/2}(\hat{\theta}_i^* - \hat{\theta}^*)$, respectively. However, such techniques are of limited usefulness when only a few trials are included in the meta-analysis.

As well as estimating an overall treatment effect, there can often be interest in estimating the true treatment effect θ_i in each trial. These are most easily obtained as **empirical Bayes** estimates, which are shrunk (*see* **Shrinkage**) from the usual (maximum likelihood) estimate towards the overall average treatment effect by a factor which depends on the ratio of within-trial to between-trial variances [30]. Confidence intervals for these estimates can also be calculated. In the case of the fixed effect model, the estimates for each trial equal the overall estimated treatment effect, so that there is complete shrinkage. As σ^2 increases, the posterior empirical Bayes estimates of the true treatment effects become more widely spread.

Fully **Bayesian** approaches for random effects meta-analysis are now also computationally feasible [30]. These can be viewed as hierarchical models, where the conditional independence between parameters is used in deriving an appropriate graphical model. **Priors** have to be set on certain parameters, such as θ^* and σ^2. These can be uninformative, but some authors argue for the use of informative priors for σ^2 derived on the basis of other related meta-analyses [18]. Fully Bayesian approaches utilizing **Markov chain Monte Carlo methods** (Gibbs sampling) can easily extend the usual normality assumptions for true treatment effects to allow for a heavier tailed distribution, such as a **Student's *t* distribution**.

Methods have been developed for more complex situations, for example to include trials with more than two treatment groups [18, 31] or to combine randomized clinical trial evidence with that from **non-randomized studies** [23]. Methods for simultaneous consideration of multiple outcomes (*see* **Multiple Endpoints, *P* Level Procedures**) have been proposed [2], as have techniques for cumulative meta-analysis [19]. The latter have been used to show how appropriate changes in medical practice could have occurred earlier if meta-analyses had been performed and their conclusions implemented. Meta-analysis techniques have also been applied to the analysis of **multicenter trials** [17], to the analysis of paired cluster randomized trials [34] (*see* **Group-randomization Designs**), and to the evaluation of **surrogate endpoints** [9].

Interpretation

The fixed effect method of estimation of a common treatment effect yields a narrower confidence interval than the random effects estimation of an average treatment effect when there is heterogeneity in results between trials. For example, in the nine diuretic trials to prevent preeclampsia in pregnancy (Table 1, Figure 1), the estimated overall odds ratios and 95% confidence intervals were 0.66 (0.57–0.79) and 0.60 (0.40–0.89), respectively, using the two methods. By incorporating the between-trial component of variability into the analysis, the inference about the magnitude of the treatment effect is appropriately less certain. The simplistic assumption of a common treatment effect in all trials used in a fixed effect analysis ignores this potential extra source of variability and can lead to overdogmatic interpretation [33]. Since the trials in a meta-analysis are almost always clinically heterogeneous, it is to be anticipated that to some extent their quantitative results will be statistically heterogeneous [32]: there will tend to be more variation between the results of the trials than is simply compatible with chance, even though a test for heterogeneity may not be formally statistically significant. Hence a random effects model appears more justified in practice than a fixed effect model in terms of making **inferences** which apply to future trials or patients.

Not all agree with this argument, however, and Peto, in particular, has argued strongly for a fixed effect approach [12]. His view appears to be based on hypothesis testing rather than estimation, with the ***P*-value** indicating the extent to which the results could have arisen simply through the play of chance with respect to the randomization process in each trial. Combined with the common-sense and empirical view that qualitative trial by treatment interactions (where the direction of true treatment effects differs across trials) are unlikely, the fixed effect

estimate of treatment effect is interpreted only as some "typical" treatment effect for the trials that have been performed, rather than more formally as a basis for inference to future trials or patients. Indeed, how the results of a meta-analysis can be used to inform decisions about treating individual patients in clinical practice is not simple, usually requiring assumptions about generalizability or **extrapolation** which are based on very little evidence.

The random effects method does not completely solve the problem of heterogeneity. It relies, for example, on the simplistic assumption that the heterogeneity between trials can be represented by a single variance. Moreover, the idea that the available trials have true treatment effects which are drawn from some distribution is unrealistic, and provides only a convenient way of allowing for unexplained variation between them. However, heterogeneity can be regarded as an asset rather than a problem. It allows clinically and scientifically more useful approaches attempting to investigate how potential sources of heterogeneity impact on the overall treatment effect [32], as discussed below.

Sources of Heterogeneity

Rather than estimate a single treatment effect, it is possible to investigate whether certain trial characteristics, such as drug dose, duration of treatment, or length of follow-up are related to the treatment effects observed. For example, in analyzing the effects of BCG vaccination on the risk of tuberculosis, the effect of the geographic latitude of each trial was investigated [3]. In the blood cholesterol lowering trials, the reduction in heart disease risk was related to the extent and duration of cholesterol reduction [32]. In **AIDS** trials, the reduction in mortality was related to the change in CD4 counts [9]. Ideally the **covariates** used in such analyses should be specified in advance to reduce the risk of post hoc conclusions prompted by inspecting the available data; as in subgroup analyses for individual clinical trials (*see* **Treatment-covariate Interaction**), there is a danger of **false positive** results. Similar analyses are also possible for patient characteristics, provided that individual patient data are available. The statistical purpose of such analyses is to see to what extent, and with what certainty, covariates can explain the between-trial component of variance. Hence a mixed effects model is obtained, where some or possibly all of the "random" between-trial variation is explained by fixed covariates. The medical outcome should be a better scientific understanding of the data and more useful clinical conclusions on which to base decisions about medical interventions [32].

It can be useful to calculate the contribution of each trial to the heterogeneity statistic Q, i.e. $w_i(\hat{\theta}_i - \hat{\theta})^2$ for trial i, which under the assumption of homogeneity should have approximate χ^2_1 distributions [31] (*see* **Agreement, Measurement of**). This can show that the results of just one or a few trials are anomalous, and suggest that either particular clinical aspects or methodologic biases may be the cause. In analyses which relate the observed treatment effects to covariates, weighted **regression** is appropriate. The weights used must, however, reflect both the within-trial variances and the residual heterogeneity, i.e. variability between trial results that is not explained by the covariates [3].

One particular potential source of heterogeneity, the underlying risk of the patients in the trial, has often been investigated recently, for a number of reasons. That the overall treatment effect, for example the odds ratio, does not depend on this underlying risk is a strong assumption [4]. Moreover, if there were a relationship with underlying risk, such an analysis would help identify the patients who were likely to benefit most from a treatment, or whether some groups of patients might even be disadvantaged. Such analyses also have **health economic** consequences for the appropriate use of the treatment. However, in most meta-analyses, the only available measure of underlying risk is the observed rate of events in the control group of each trial. In relating this to the observed treatment effect in each trial, there can be a severe **bias** stemming from **regression toward the mean** [28]. Correct analyses are more difficult and are based on certain assumptions, but take into account the sampling variation in the observed control group risk estimates [20, 35]. The future of such analysis is to use individual patient data to relate treatment benefit to measured patient covariates (or a prognostic score) rather than the unmeasured "underlying risk", so that clinically useful results can be obtained.

Presentation

There is a move towards ensuring that the quality of reported meta-analyses is as high as possible [8], especially since they underpin the practice of evidence-based medicine. Presentation is one component of this. Meta-analysis in medical journals usually contains a brief tabular description of the characteristics of the trials included, and of their principal quantitative results (such as Table 1). In addition, figures have been developed to show the main results diagrammatically. Typically these comprise the estimates and 95% confidence intervals for each trial, together with an overall estimate and confidence interval (such as Figure 1). Such diagrams are sometimes called "forest plots". Some authors use 99% confidence intervals for individual trials to offset the fact that many trials are being displayed simultaneously. Others use filled squares or circles to represent each estimate, with areas proportional to the inverse of the variance, so that the eye is drawn not to the trials with wide confidence intervals which are least informative but towards those with greatest precision (see, for example, [1]). Overall effects from survival studies, analyzed as log hazard ratios, may be transformed to approximate overall survival curves to convey the clinically important messages clearly [12].

Such diagrams are not very useful for revealing heterogeneity, and "radial plots" of the standardized treatment effect $\hat{\theta}_i / v_i^{1/2}$ against reciprocal standard error $1/v_i^{1/2}$ have been advocated instead [31]. In the presence of heterogeneity, separate results according to the relevant covariates need to be shown. In the case of a continuous covariate, this can also be represented diagrammatically (see, for example, [32]).

Biases and Sensitivity Analyses

Not all trials are free from bias, nor are all trials analyzed on an **intention to treat** basis. In the absence of properly conducted randomization, adequate blinding, or complete follow-up, the bias in individual trial results can lead to bias in the overall results of a meta-analysis. The problems are even more severe in the meta-analysis of epidemiologic studies, since **confounding** factors may be a major issue. Even with full intention to treat analysis of clinical trials, the degree of patient **compliance** may have differed across trials, leading to problems in the overall interpretation of a meta-analysis.

The possible consequences of such biases need to be addressed, albeit imperfectly in practice. For example, the effect of randomization concealment can be investigated as a potential source of heterogeneity [27]. Alternatively, the methodologic quality of the trials can be rated, and this used as a rationale for excluding the weakest trials, or as a covariate in analysis [15]. Individual patient data allow much more scope than published data or summary data for the more definitive identification of poor quality trials, or the correction of errors in the publication of trial results [25].

Publication bias has become a particular concern in meta-analysis, since the aim is to obtain a summary of the totality of evidence. Even though large **multicenter trials** will tend to be published whatever their results, small studies may be published only if they have impressive observed results. Hence the published literature is potentially biased. Empirically, a "funnel plot" of the observed treatment effects against sample size (or precision) may show some evidence that small negative studies are missing from the published literature [37]. In the presence of such evidence, a random effects model is not necessarily desirable since it puts more weight than a fixed effect model on the small studies which are available. Various methods have been proposed to calculate the number of negative unpublished studies that would be needed to overturn the qualitative conclusion of a meta-analysis [14]. More constructively for the future, registers of clinical trials which are in progress, or are funded or have been approved by ethical committees, are being kept so that the completeness of the published literature can be assessed directly, and unpublished information sought [29].

In the presence of imperfect information, **sensitivity analysis** is a useful tool, for example to investigate the extent to which conclusions change if methodologically weak trials are excluded. They can also be used to investigate the **robustness** of conclusions to the inclusion criteria for trials originally adopted. Where one or just a few trials dominate the overall results of a meta-analysis, sensitivity analyses can be conducted to see how the conclusions change when these trials are omitted. Indeed, the random effects method can be viewed as a sensitivity analysis for the failure of the assumption of

homogeneity [31]. While these analyses are useful in judging the effects of the more subjective decisions taken in conducting a meta-analysis, it can sometimes be difficult to form an overall interpretation from the results of many sensitivity analyses, especially when the number of trials included in a meta-analysis is small.

The Future of Meta-Analysis

Meta-analysis has rightly had a major impact on medical science in the past 10 years, and has formed the basis for the development of evidence-based medical practice. The statistical basis of meta-analysis is well developed. Although the fixed vs. random effects discussion will linger on, it seems likely to be superseded by greater use of mixed models in which potential sources of heterogeneity are directly investigated. Although there will continue to be development of statistical methods at the margin, the main need is now more practical. The majority of meta-analyses are currently still based on published data. Hence, for example, empirical work is required on the practical problems in meta-analyses of imperfect published data, and on delineating appropriate sensitivity analyses that will aid interpretation. Statistical support for the many meta-analyses undertaken is woefully limited, resulting in poor quality in some cases and consequent but unjustified disillusionment with the underlying idea. Alternative methods for the dissemination of meta-analytic results in order to affect clinical practice need to be assessed [5]. The use of individual patient data meta-analyses is likely to expand in the future, since it gives more scope both for including only reliable evidence and for allowing more detailed investigation of results, especially with regard to heterogeneity of treatment effects according to patient characteristics.

SIMON G. THOMPSON

Meta-analysis of Diagnostic Tests

If we wish to know the accuracy (e.g. **sensitivity** and **specificity**) of a diagnostic test, there may be several appropriate studies from which to derive estimates. First, we need to identify the pool of relevant studies. Secondly, we need to appraise the methodological quality of each of the studies and select those which reach a minimum standard, or use the quality items as predictors in a **regression** model. Thirdly, we need to derive a summary estimate from these selected studies. Such a meta-analysis will have two advantages: (i) it will provide greater precision in the estimates of accuracy (sensitivity and specificity) than from a single study, and (ii) it will allow an examination of the existence and the causes of heterogeneity between studies, for example, because of differing patient populations, test methods, or quality [9].

In this article, we deal with these three steps in performing such a systematic review.

Finding the Studies

Finding all of the relevant primary studies is not a trivial task. A standard strategy would include the search of a computerized database (including the identification of any review articles that might identify studies not picked up in the searches), hand searching of selected journals, and checking of the references of all of the relevant studies identified [4]. Electronic databases can be searched to find studies in which both the name of the tests and the disease of interest appear in the title or abstract. If this process results in a large number of articles that are not relevant, some means is needed of confining the search to those studies looking at diagnostic accuracy. This can be achieved, though at the risk of missing some relevant papers, by limiting the search to papers that contain or are indexed using methodological terms that identify diagnostic test studies. For example, in MEDLINE, the library database of the National Library of Medicine, it has been shown that most good diagnostic test articles would be detected by a search of the terms accuracy (appearing in the title or abstract) OR sensitiv* OR diagnos* appearing in the title, abstract or MEDLINE-indexed keywords [6]. The * indicates a wildcard so that it includes, for example, sensitivity and sensitivities. How to specify the wild card "*" varies with the MEDLINE interface. A set of these methodological filters is described and available for use electronically in the PUBMED version of MEDLINE (`http://www.pubmed.gov/query/static/clinical.html`).

Because studies of diagnostic tests may sometimes be done using routinely collected data, and are therefore less resource intensive than clinical trials, the likelihood of many unpublished studies, and hence of significant publication bias, is higher. (*see* **Meta-analysis of Clinical Trials**)

Quality Appraisal

The assessment of study quality can be used either to limit the meta-analysis to those studies of better quality or to explore the extent to which elements of study quality are related to the results. The assessment of methodological quality can be biased by the reviewer's preconceptions about what the results of the study should show. Therefore, the appraisal of primary studies should be based on a prespecified set of criteria that indicate objective standards of quality and be based on assessment by two independent reviewers with resolution of disagreements by consensus or the use of a third reviewer. On the basis of conceptual considerations and empirical evidence about the effect of elements of study quality on study results [13], several sets of criteria are now available [1, 25]. Common important elements in the criteria are:

1. Were the tests compared with a valid reference standard?
2. Were the test and reference standard measured independently (blind) of each other? Categories consist of:
   (i) test measured independently of reference standard and reference standard independently of test (MOST VALID);
   (ii) test measured independently of reference standard but not vice versa;
   (iii) reference standard measured independently of test but not vice versa;
   (iv) test and reference standard not measured independently of each other (LEAST VALID).

3. Was the choice of patients who were assessed by the reference standard independent of the test's results? (Avoidance of verification bias – this occurs when, for different test outcomes, the fraction subjected to the reference standard varies.)
4. If tests were compared, were they read independently on all individuals, or were different tests randomly allocated to study participants?

Issues to Consider for Applicability (Exploring Heterogeneity)

To help decide which studies to include and the extent to which heterogeneity in test accuracy should be explored, meta-analysts should also consider the potential sources of heterogeneity [7], of which the following are some of the major issues:

sequence: how the test(s) of interest are being used in the sequence of available tests;

role: whether tests are being evaluated as replacements for existing tests or additional tests;

test type: where there are several tests, ascertaining differences in accuracy may be the objective of the meta-analysis [21];

population and setting: for example, whether the test is being performed in primary care setting on people who present for the first time with a set of symptoms, or in a hospital setting after having been through a "referral filter", which would have excluded people with milder forms of disease, people who responded to first-line treatment, or people who were easier to diagnose.

Combining Studies

To combine studies, we must choose summary measures to represent each study, with sensitivity and specificity being commonly used. However, studies differ in their "threshold" for calling a test positive. For example, if the test-reader is very concerned about missing a disease case, they may choose a very low threshold point along the spectrum from negative to positive, and thus favor high sensitivity over high specificity. The **Receiver Operator Characteristic (ROC) curve** plot (see Figure 1) shows this variation in threshold by plotting sensitivity versus specificity (or more precisely, 1 – specificity). Thus, plotting the data in ROC space should be used as an initial

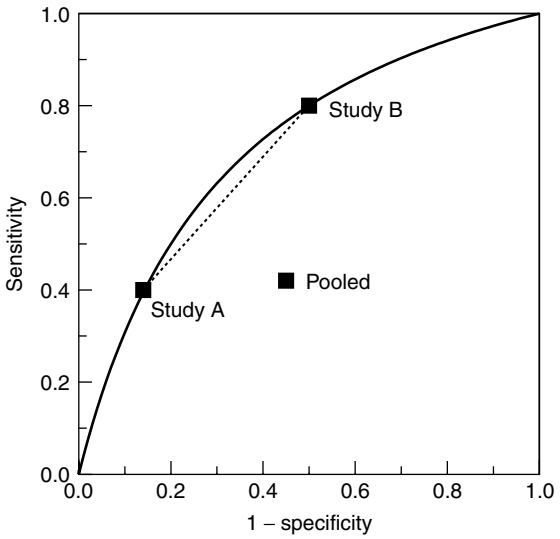

Figure 1 The receiver operating curve of two hypothetical studies, *A* and *B*

summary of all studies. We then require a method of combining studies, which accounts for both the discrimination ability of the test and this variation in threshold.

There are two widely used methods of combining the results of studies of diagnostic accuracy [8]. The first and worse of these is direct pooling. In Table 1, study A has a high specificity, but few nondiseased cases; study B has a high sensitivity but few diseased cases. Although the **odds ratio** in each individual study is 4 (indicating a reasonable discrimination ability), the overall odds ratio is 0.87 (indicating a worse-than-useless test). As illustrated in Table 1 and Figure 1, direct pooling can result in large distortions of the true accuracy of a diagnostic test. This is because of **confounding** from different thresholds being applied to studies in which there are different disease prevalences. The size and direction of this distortion is unpredictable, but it is particularly likely to be a problem if there is a wide range of prevalences of disease across the different diagnostic studies.

An alternate method that has been suggested to avoid this problem is to calculate the sensitivity and specificity within each study first, then calculate a (weighted) average of the sensitivities and, separately, calculate a (weighted) average of the specificities [2, 17]. This avoids the confounding problem associated with direct pooling, but may still lead to

Table 1 Results from two hypothetical studies (A and B), plus pooled results

Test	D	ND	Sensitivity	Specificity	Odds ratio	Youden
+	200	10				
−	300	60				
Total A	500	70	0.4	0.86	4	0.26
+	20	200				
−	5	200				
Total B	25	400	0.8	0.5	4	0.3
+	220	210				
−	305	260				
Total A + B	525	470	0.42	0.55	0.89	−0.03

Youden = Sensitivity + Specificity − 1.

an underestimation of the true accuracy if there is variation in the threshold used by different studies, that is, there is evidence of an association between sensitivity and specificity across studies. For example, Figure 1 shows the two studies from Table 1; any averaging of the sensitivity or specificity will lie along the dotted line joining A and B, with the location depending on the relative weighing used. If the same weights are used for sensitivity and specificity (e.g. equal weights or weights based on study size), then this is one point on the line. If different weights are used to combine sensitivity and specificity (e.g. based on disease numbers for sensitivity and nondiseased numbers for specificity), then these may be read from different points on the line, and hence the joint estimate is not confined to the line.

Combining Dichotomous Test Results Via SROC

There are a number of appropriate meta-analytic techniques for diagnostic tests, most of which plot the sensitivity against specificity for each of the primary studies, and then attempt to construct a summary Receiver Operator Characteristic curve (SROC) through these data points [8]. We will deal first with dichotomous tests, then outline briefly methods for tests with continuous or ordinal results.

For dichotomous tests, one convenient presentation is to use the odds ratio as a summary measure of the discrimination ability of a test. If the odds ratio is constant across different thresholds, then this will lead to a symmetric SROC curve. However, this is an assumption that can and should be tested. Before going into the details of these methods, to understand their interpretation better, we first look at the relationship between odds ratios, **likelihood ratios**, and the sensitivity and specificity.

Besides characterizing the accuracy of a test, the other use of sensitivity and specificity is in the calculation of **predictive values** via **Bayes' Theorem**. One convenient formulation of this is the odds–likelihood ratio version of Bayes' Theorem, namely,

$$\text{posttest odds} = \text{pretest odds} \times \text{likelihood ratio}, \quad (1)$$

where the likelihood ratio (LR) is $\Pr(result|disease)/\Pr(result|non\ disease)$. Thus, for a positive result, the $LR^+ = \Pr(+ve|D)/\Pr(+ve|non\ D) = sensitivity/(1 - specificity)$; similarly, for the negative result the $LR^- = \Pr(-ve|D)/\Pr(-ve|non\ D) = (1 - sensitivity)/specificity$. Hence, the odds ratio, OR, can be expressed as

$$\begin{aligned} OR &= \frac{sensitivity}{(1 - sensitivity)} \Big/ \frac{(1 - specificity)}{specificity} \\ &= \frac{LR^+}{LR^-} \end{aligned} \quad (2)$$

The log-odds ratio (using natural logarithm) can be expressed as

$$\begin{aligned} A &= \text{logit}(sensitivity) - \text{logit}(1 - specificity) \\ &= \log OR = \log LR^+ - \log LR^- \\ &= \log LR^+ + \frac{1}{\log LR^-} \end{aligned} \quad (3)$$

Since the LRs are measures of the **power** of the test to change the pretest odds, the OR can be viewed as summarizing the total discrimination ability of the test. Thus, A ($= \log OR$) is a measure of a test's discrimination ability (note that the other common measure is the area under the ROC). If the positive result and negative result change the odds equally, that is, $LR^+ = 1/LR^-$, then the threshold

is not skewed (or "biased" in ROC jargon) toward either diagnosis. The implicit test threshold may be represented by:

$$S = \text{logit}(\textit{sensitivity}) + \text{logit}(1 - \textit{specificity}) \quad (4)$$

Note that if sensitivity = specificity, then $S = 0$ and also $LR^+ = 1/LR^-$, indicating no skew in favor of either false positive or false negative rates. Thus for each study, we can obtain a measure of the discrimination ability, A (as measured by the log-odds ratio) and the threshold (as measured by S). S can be regarded as a proxy for test threshold, since it is the sum of the log odds of a positive test result in the diseased and the log odds of a positive test result in the nondiseased groups. Hence, S will increase as the criterion for a positive test becomes less stringent.

The *OR* may increase or decrease with the threshold, and hence lead to an asymmetric SROC curve. Therefore, Moses and coworkers [14, 18] suggest plotting A against S to check whether the discrimination ability varies with the threshold. Regression lines may be estimated in several ways, usually by weighted or unweighted **least squares**. The weighted analysis weights each study by the inverse variance of the log *OR* for that study ($\text{var}(\log OR) \approx 1/a + 1/b + 1/c + 1/d$, where $a - d$ are the observed counts in the four cells of the **2 x 2 table**); 0.5 is added routinely to all cell counts for all tables when computing the log *OR* and corresponding weight. A **robust regression** may also be used when assumptions are not met for the least squares analysis.

If the regression of A on S shows that the slope is not significantly different from zero, then the SROC may be considered symmetric, the constant *Bo* represents log *OR*, and hence exp *(Bo)* represents the odds ratio. If A does not depend on S, then any of the standard techniques for combining odds ratios can be used, for example, **Mantel–Haenzsel** if a fixed effect is assumed for test accuracy across studies or DerSimonian–Laird if **random effects** are assumed [8]. However, if the slope (coefficient of S) is significantly different from zero; the discrimination ability of the test varies with test threshold, and thus, the SROC is asymmetric. Model coefficients can be used to estimate the area under the SROC [24].

The Moses–Littenberg and SROC plots are illustrated in Figures 2 and 3, respectively, for ultrasound of the carotid arteries (data taken from Table 2 of Hasselblad & Hedges [5]). In Figure 2 is shown a log *OR* ranging between approximately 3 and 7.

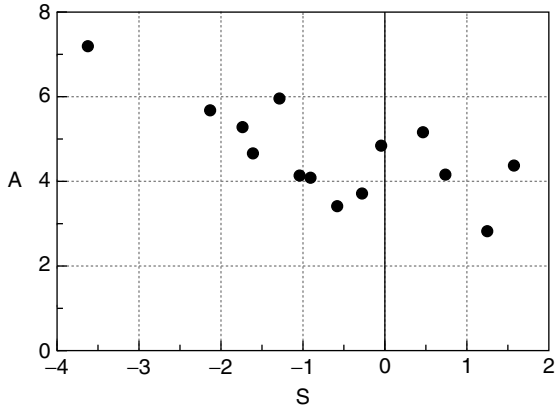

Figure 2 A plot of discrimination ability A [log (odds ratio)] versus S (a measure of threshold) for studies of ultrasound for carotid artery stenosis

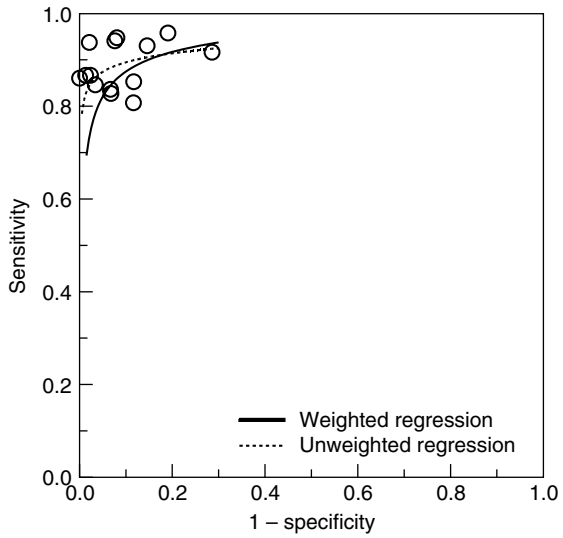

Figure 3 An SROC plot for studies of ultrasound for carotid artery stenosis

An unweighted regression gave an estimated intercept of 4.3, which indicates a good test with an intercept odds ratio of 74, but the negative slope of −0.57, indicates that the *OR* decreases with increasing S (threshold). The corresponding estimates for the weighted regression are 4.1 and −0.28 for the intercept and slope respectively. Figure 3 shows the corresponding SROC plots. The cluster of studies in the top-left corner indicates generally good discrimination ability (a perfect test would include the 100%

sensitivity, 0% 1 – specificity point, whereas a worthless test would be a straight diagonal from the 0–0% to 100–100% points).

The summary ROC curves shown in Figure 3 are obtained by computing the expected sensitivity for chosen values of 1 – specificity that lie within the range observed for the studies included in the analysis. Back transformation is used to express the expected sensitivity as a function of 1 – specificity and the parameter estimates of the model [18]. In the example, both of the resulting SROCs are moderately asymmetric (closer to the left-vertical axis than the top axis), particularly for the unweighted analysis.

Exploring Heterogeneity

If the ROC plot shows important heterogeneity in threshold, discrimination ability or both, the analyst should look to explain this. The causes may be categorized as (i) study design features, (ii) population differences, and (iii) test differences. A useful tool for exploring this is meta-regression: a regression analysis over all studies with study features used as predictors [12]. For example, in a meta-analysis of Thallium Scintigrams for coronary artery disease, Irwig et al. [9] add to their regression of A on S an indicator variable (*see* **Dummy Variables**) for whether the reading technique was computerized. This showed no difference in A for computerized versus noncomputerized reading, although computerized readings had a significantly lower threshold (more sensitive but less specific) as shown by a t test on S.

Further Methods

Alternatives for Combining Dichotomous Test Studies

The technique described above is the most commonly used in practice, but it is only one of several ways of combining studies with dichotomous test results. The first method developed [10] plotted and regressed logit(sensitivity) against logit(specificity); if the slope is 1, this implies a constant odds ratio but with shifting threshold between studies. This is conceptually equivalent to the method described above, but with a different parameterization; the authors also used the **profile likelihood** method rather than the linear and robust regression used for estimation by Moses and Littenberg. Both methods assume that the model parameters are fixed effects.

An alternative approach, based on a latent scale **logistic regression** model, provides a more flexible framework for SROC modeling. The hierarchical summary Receiver Operator Characteristic (HSROC) approach developed by Rutter and Gatsonis [19, 20] allows test threshold (cut-point), test accuracy (location), and the dependence of test accuracy on threshold (scale) to be modeled. Under this model, the probability of a positive test result π_{ij} in study i and disease group j ($1 =$ diseased, $2 =$ nondiseased) is assumed to follow a **binomial distribution**. The model takes the form $\text{logit}(\pi_{ij}) = (\theta_i + \alpha_i\, dis_{ij}) \exp(-\beta\, dis_{ij})$ where dis_{ij} represents the "true" disease status (coded as -0.5 for the nondiseased and 0.5 for the diseased). Each study has its own implicit threshold (θ_i, equivalent to $S_i/2$) and diagnostic accuracy (α_i, log-odds ratio), both specified as random effects. The scale parameter (β) provides for asymmetry in the SROC by allowing accuracy to vary with implicit threshold. This parameter is assumed to be fixed as no single study can provide an estimate of the shape of the SROC. The random effects are assumed to be independent and normally distributed with $\theta_i \sim N(\Theta, \tau_\theta^2)$ and $\alpha_i \sim N(\Lambda, \tau_\alpha^2)$. The parameter estimates can be used to estimate the summary ROC, the expected operating point (1 – specificity, sensitivity) and corresponding likelihood ratios for a diagnostic test. This model also has the advantage that it takes into account both within study variability and heterogeneity between studies. Covariates may be added to the model to assess whether test threshold, accuracy, and/or SROC shape vary with study or patient characteristics. Rutter and Gatsonis outline how the model may be fitted using a fully Bayesian analysis using MCMC estimation [20]. Empirical Bayes estimates of the model parameters can also be obtained using Proc NLMIXED in SAS [15].

Combining tests that are Continuous variables

Hasselblad & Hedges [5] suggest another alternative that provides a connection with continuously valued diagnostic tests. This is based on the finding that, if the diseased and nondiseased populations have **normally distributed** test results, then log OR is approximately constant over the range of possible threshold choices. If the distributions of test results

are logistic and have equal variances, then log *OR* constancy is exact rather than approximate. Under these circumstances, the log-odds ratio is simply a constant multiplied by the standardized difference between the two means

$$\Delta = \left(\frac{\sqrt{3}}{\pi}\right) \log OR \tag{5}$$

where Δ is the standardized difference between the two means (a commonly used alternative measure of discrimination ability), and the two constants come from the logistic density function. Hasselblad & Hedges [5] also show that this method is relatively robust to violations of the assumptions of equal variance and **logistic distributions**.

This relationship leads to a simple approach to providing summary estimates for several studies with continuous test results, or for a mixture of dichotomous and continuous results. In either case, the discrimination ability of each test can be represented by a summary estimate ($\log OR$ or Δ) and these combined as a weighted mean, with the inverse of the variance used as the weights:

$$\log \overline{OR} = \frac{\sum w_i \log OR_i}{\sum w_i} \tag{6}$$

where w_i is the inverse variance of log *OR*, and the variance of the weighted mean is the inverse of the denominator in the above equation.

Combining Tests that are Ordinally Valued

For ordinally valued test studies, ordinal regression methods have been suggested (*see* **Polytomous Data**). The simplest of these assumes a constant odds ratio and a fixed number of result categories [22]:

$$\text{logit}[\Pr(Y \leq j | x_1, \ldots, x_k)] = \theta_j + (\alpha_1 x_1 + \cdots + \alpha_k x_k), \tag{7}$$

where θ_j is a separate constant for each category and $x_1, \ldots, x_k$ are a series of **explanatory variables**. This approach is only valid if it is reasonable to assume that the SROC is symmetric.

An alternative, computer-intensive method used by Kester and Buntinx fits the Moses model to estimate an ROC for each study [11]. The **bootstrap method** is used to obtain a valid estimate of the constant and coefficient of *S* for each study that take into account correlation between multiple estimates of *A* and also *S* within the same study. Summary estimates across studies are then obtained using the random effects bivariate regression method of van Houwelingen and Zwinderman [23]. Dukic and Gatsonis describe a Bayesian **hierarchical model**, which assumes a study-specific ROC that is sampled from a population of ROC curves for such studies [3]. Studies are not constrained to have the same set or number of categories. SROC curves and corresponding credible regions can be constructed using this approach. Dukic and Gatsonis also describe a simpler, **fixed effects** model that assumes the ROC curves for all studies have the same location and scale parameters, that is, the same accuracy and shape. However, thresholds may again vary across studies.

Combining Areas under ROCs

We have focused on methods that use the odds ratio as the summary measure of discrimination, and then used this to derive the SROC. An alternative is to use the area under the ROC for each study [16, 26], and combine areas. This can be used for dichotomous, ordinal, or continuous data, but has a clear advantage for ordinal data where studies can be combined readily even if the number of categories differs between studies. The disadvantage is the loss of ability to explore threshold variation and shape of the ROC curve.

Meta-analytic methods for diagnostic tests are less well developed than for clinical trials. The development of a mixed model for fitting SROC curves to dichotomous test results and the availability of software for fitting the model provides a general approach for the meta-analysis of diagnostic studies that takes into account within and between study variability. Both the SROC and HSROC methods provide a means of exploring heterogeneity between studies. However, the HSROC model has not been widely used and is not well tested in practice. Current methods for the meta-analysis of ordinal test results are either very complex to fit, or make simplifying assumptions that may be inappropriate. The potential impact of publication bias, and other problems of meta-analysis have been little explored.

While a number of analytic methods have now been developed for different types of tests, presentation of these results for clinical use has been less well explored. An SROC alone is insufficient to allow application in a clinical setting. A minimum requirement is back transformation to the sensitivities and

specificities for particular cutpoints. However, this raises the problem of whether the scaling of measurements is comparable between studies. Further attention is needed to the clinical application of the meta-analytic results.

Method of Moments

The *method of moments* is a straightforward statistical technique for constructing point estimators of the parameters in a statistical model. In the early days of statistics it was a fundamental statistical tool; in particular, **Karl Pearson** encouraged its use as a method of fitting frequency curves that deviated from the normal. However, Fisher [4] established that it could be highly inefficient, and since that time it has been largely displaced by methods known to be more statistically efficient, primarily **maximum likelihood**. Even so, the method continues to play an important auxiliary role in estimation owing to its flexibility, because one can often derive computationally simple methods in otherwise difficult problems. The method is nearly foolproof in the sense of providing consistent estimators with easily derived standard errors. An additional motivation for the use of the method is that its validity depends only upon a small number of easily stated and easily checked assumptions about the structure of the statistical problem.

The Basic Method

Suppose we have a statistical model for a univariate variable X, with a d-dimensional parameter $\boldsymbol{\theta}$. In its most basic form, the method of moments requires setting up a system of d equations for the d unknown θs by equating the first d sample **moments** of the variable X with their expectations under the model, then solving that system for the method of moments estimator $\hat{\boldsymbol{\theta}}$. That is, if the data $X_1, X_2, \ldots, X_n$ form a random sample of univariate observations, then let the sample moments be denoted by $m_r = n^{-1}\sum_{i=1}^{n} X_i^r$, and let the theoretical moments be denoted by $\mu_r(\boldsymbol{\theta}) = \mathrm{E}_{\boldsymbol{\theta}}[X^r]$, where $\mathrm{E}_{\boldsymbol{\theta}}$ indicates the operation of **expectation** under the proposed probability model. The basic *method of moments estimator* would then be the value of $\boldsymbol{\theta}$ that solves

$$m_r = \mu_r(\boldsymbol{\theta}) \quad \text{for } r = 1, 2, \ldots, d. \tag{1}$$

Ideally, this system can be solved explicitly for the estimators, or the solution can be obtained with low computational difficulty. The question of the existence and uniqueness of the solutions is not always elementary; see [9] and [10] for a careful analysis in the case of the *mixture model*.

It should be noted that a single problem has more than one method of moments because one can transform the data, say by $y = g(x)$, and use the moment system determined by the new variable y. The transformation could be chosen either to simplify the equations or for a gain in efficiency.

Elementary Examples

If the parameter dimension is two, then the first two moments are matched, which is equivalent to matching the sample mean and variance of X to the theoretical mean and variance. Thus in the **normal** model with $X \sim \mathrm{N}(\mu, \sigma^2)$, the method of moments estimator for μ is the sample mean, and for σ^2 it is the sample variance. If the model is **gamma** with parameters (α, β), then the first two moments of the gamma distribution are $\mu_1 = \alpha\beta$ and $\mu_2 = \alpha\beta^2 + \alpha^2\beta^2$. Equating these quantities to m_1 and m_2 yields the solutions $\hat{\alpha} = m_1^2/(m_2 - m_1^2)$ and $\hat{\beta} = (m_2 - m_1^2)/m_1$. Thus, unlike the maximum likelihood equations, there is a solution that does not require an algorithmic method.

Multivariate Data

The extension of the basic method of moments to multivariate data is not elementary. The reason is that if the variable X is of dimension p, then there are p first moments, $p(p-1)/2$ second moments, $p(p-1)(p-2)/6$ third moments, and so forth. It follows that setting up a system of exactly d equations will typically be impossible without the careful selection of a subset of higher-order moments. For more on this, see Lindsay & Basak [11], who created a system of multivariate moment equations for the normal mixture model based on the criteria of having unique and simple-to-compute estimators.

Generalized Method of Moments

There are some natural extensions of the method of moments that enrich the approach, allowing the user to create equations that are either easier to solve or more theoretically efficient. For example, one could choose a set of d functions of the variable x, say $g_1(x), \ldots, g_d(x)$, and then find the solution in $\boldsymbol{\theta}$ to a set of *generalized moment equations* that equate

the sample average of these variables with their theoretical expectations:

$$\overline{g}_r = n^{-1} \sum_{i=1}^{n} g_r(X_i) = \mathrm{E}_{\theta}[g_r(X)], \quad \text{for } r = 1, \ldots, d. \tag{2}$$

Note that if $g_r(X) = x^r$, then this is the basic method of moments. If one sets $g_r(x) = \exp(t_r x)$ for a set of grid values $t_1, \ldots, t_d$, then one is matching the empirical **moment-generating function** $n^{-1} \sum \exp(tX)$ to its theoretical value $\mathrm{E}_{\theta}[\exp(tX)]$ along the grid values. One can use generalized moment equations in the case of multivariate X by using scalar-valued functions $g_r(\mathbf{x})$ in the above equations.

It should be noted that in the **exponential family of distributions**, the maximum likelihood equations are generalized moment equations for a set of appropriately chosen functions g_r. In this case, and this case only, the method of moments yields fully efficient estimators. For example, in the normal model the functions $g_1(x) = x$ and $g_2(x) = x^2$ give full efficiency, while in the gamma model the necessary functions are $g_1(x) = x$ and $g_2(x) = \ln x$. It follows that if one uses x and x^2 in the gamma, as was done above, then the estimators do not have optimal efficiency.

Least Squares Method of Moments

A further extension of the method allows one to use a set of functions $[g_r(X) : r = 1, \ldots, R]$ whose cardinality R is greater than the dimension d of the parameter vector. In parallel with **least squares** estimation, one establishes an objective function of the form

$$S(\boldsymbol{\theta}) = \sum_{r=1}^{R} \{\overline{g}_r - \mathrm{E}_{\theta}[g_r(X)]\}^2. \tag{3}$$

The *least squares method of moments estimator* is the value of $\boldsymbol{\theta}$ that minimizes $S(\boldsymbol{\theta})$. This method was used by Quandt & Ramsey [16] to determine estimators in the mixture-of-normals problem. They used the system of functions $g_r(X) = \exp(t_r X)$ for a grid of values t_r, so that the method was based on finding a close fit of the fitted moment-generating function to the empirical one.

Distributional Theory

The asymptotic distribution theory of the method of moments estimators is easily derived using the **delta method**. This leads in a ready fashion to the asymptotic normality of the estimators as well as to a formula for the asymptotic **covariance matrix**. The most natural approach to the statistical theory is through the wider subject of **estimating functions** [6, pp. 3–20]. This theory deals with estimators that are derived as the solutions to a set of equations of the form:

$$h_r(X, \boldsymbol{\theta}) = 0, \quad \text{for } r = 1, \ldots, d, \tag{4}$$

where the functions $h_r(X, \boldsymbol{\theta})$, $r = 1, \ldots, d$, have mean zero under the probability model: $\mathrm{E}_{\theta}[h_r(X; \boldsymbol{\theta})] = 0$. The method of moments simply corresponds to the use of functions h_r of the special form $\overline{g}_r - \mathrm{E}_{\theta}[g_r(X)]$.

If one wishes to use a set of $R > d$ moment equations, as in the least squares method of moments, there is an optimal way to combine the moment equations linearly to construct a set of d equations. Hansen [7] and Lindsay [8] showed that the highest efficiency for the resulting estimators arises from solving

$$\{\nabla \mathrm{E}_{\theta}[\mathbf{g}(X)]\}^{\mathrm{T}} V(\boldsymbol{\theta}) \{\overline{\boldsymbol{g}} - \mathrm{E}_{\theta}[\mathbf{g}(X)]\} = 0, \tag{5}$$

where $V(\boldsymbol{\theta})$ is the inverse of the theoretical covariance matrix of $\{\mathbf{g} - \mathrm{E}_{\theta}[\mathbf{g}(X)]\}$. Under some regularity assumptions, the resulting estimators are asymptotically equivalent to those arising from minimizing

$$S^*(\boldsymbol{\theta}) = \{\overline{\boldsymbol{g}} - \mathrm{E}_{\theta}[\mathbf{g}(X)]\}' V(\boldsymbol{\theta}) \{\overline{\boldsymbol{g}} - \mathrm{E}_{\theta}[\mathbf{g}(X)]\}, \tag{6}$$

a generalized least squares criterion. If the covariance matrix is a constant multiple of the identity, then minimizing $S^*(\boldsymbol{\theta})$ is equivalent to minimizing $S(\boldsymbol{\theta})$, but otherwise efficiency is improved.

A review of the modern literature shows a wide range of continuing applications of the method of moments. Some of the more important ones include the following:

1. *Regression modeling*. Hansen [7] introduced a generalized method of moments estimator for the **regression** problem as follows. Suppose $\mathbf{u}_r$, $r = 1, \ldots, R$, is a system of n-dimensional vectors, each of which is uncorrelated with the residual

vector $\mathbf{Y} - Z\boldsymbol{\beta}$, so that $\mathrm{E}_\beta[\mathbf{u}'_r(\mathbf{Y} - Z\boldsymbol{\beta})] = 0$. Then it is clear that one can use the functions $g_r(\mathbf{Y}) = \mathbf{u}'_r\mathbf{Y}$ together with the aforementioned optimal linear combination criterion to perform generalized method of moments.

2. *A binomial example*. O'Quigley [15] considered a problem in which the goal was to estimate the **binomial** parameter n based on a sequence of independent data of the form $(X_i, p_i), i = 1, \ldots, N$, where the variable X_i was bin (n, p_i). The estimation problem arose in the context of estimating the number of stem cells involved in repopulating the marrow following allogenic bone marrow transplantation. It was shown that one could generate a method of moments estimator for n based on asymptotic moments that is similar in efficiency to maximum likelihood, and an improvement upon the moment estimator that had been used previously.
3. *Mixture models*. Finding the maximum likelihood estimators in the mixture model is quite computationally onerous. There are typically multiple solutions to the **likelihood** equations. A computationally intensive approach to this problem is to try to determine all the solutions, then use the one with the highest likelihood. The problem is aggravated by the fact that the commonly used algorithms are either unreliable or slow at finding roots. This creates a situation where the method of moments provides a useful tool, even though the estimators are not highly efficient. Instead of searching for the maximum of the likelihood, one uses the solution to the likelihood equations found by searching algorithmically from a moment-based estimator. The consistency of the moment estimator ensures that the resulting solution has good theoretical properties. Furman & Lindsay [5] and Lindsay & Basak [11] show that such moment-based estimators can be very effective when used as starting values for the **EM algorithm**.
4. *Supplementary moment estimators*. Another important modern use of the method of moments idea is as a supplement to another system of estimation. For example, if one is using the **quasi-likelihood** approach described in [13, p. 325], then the regression parameters are found from a system of estimating equations, while the dispersion parameter is fit by equating a theoretical and observed moment [12, 17]. The advantage to this methodology is that one can form a simple consistent estimator with a minimum of additional assumptions, satisfying a basic goal of quasi-likelihood theory. Williams [18], Breslow [3], and Moore [14] have extended this approach in the context of regression analysis in overdispersed binomial and **Poisson regression** problems.

Beal [2] and Altman [1] provide further examples of the use of the supplementary method of moments to handle otherwise difficult problems in the estimation of variances and correlations.

BRUCE G. LINDSAY

Michaelis–Menten Equation

The *Michaelis–Menten equation* describes the theoretic relationship between the initial velocity, v, of a simple enzymatically catalyzed reaction and the substrate concentration, s. It has the following form:

$$v = \frac{Vs}{(K_m + s)}, \tag{1}$$

where the constants V and K_m are the *maximum velocity* and the *Michaelis constant*, respectively. The curve described by (1) is a rectangular hyperbola through the origin, with asymptotes $s = -K_m$ and $v = V$. Substituting $v = V/2$ in the above expression, it can be seen that the value of the Michaelis constant is, in fact, the substrate concentration at half-maximal velocity. V is not a fundamental property of an enzyme, but it depends on the enzyme concentration.

The detailed properties of enzyme systems that can be described by the Michaelis–Menten equation are given in Cornish-Bowden [1], as is the history of the development of enzyme kinetics. Michaelis & Menten published details of their equation in 1913, and are regarded as founders of modern enzymology, although their equation had been derived earlier by Henri (see [1]).

Graphical Representations

If a series of initial velocities is measured at different substrate concentrations, it is natural to examine the relationship between them through the use of simple plots. The most obvious starting point is to plot v vs. s. Much more commonly, however, the investigators take reciprocals of both sides of (1) to produce

$$\frac{1}{v} = \frac{1}{V} + \frac{K_m}{Vs}. \tag{2}$$

A plot of $1/v$ vs. $1/s$ will be a straight line with slope K_m/V and intercept $1/V$ on the $1/v$ axis. This is known as the *double-reciprocal* or *Lineweaver–Burk plot*. Multiplying both sides of (2) by s yields

$$\frac{s}{v} = \frac{K_m}{V} + \frac{s}{V}. \tag{3}$$

This indicates that a plot of s/v vs. s should be a straight line, with slope $1/V$ and intercepts K_m/V on the s/v axis and $-K_m$ on the s axis. This is known as the *Hanes plot*. Finally, the *Eadie–Hofstee plot* is a graph of v vs. v/s and should be a straight line with slope $-K_m$ and intercepts V on the v axis and V/K_m on the v/s axis. This relationship is obtained by multiplying both sides of (2) by vV and rearranging to give

$$v = V - \frac{K_m v}{s}. \tag{4}$$

All three of these straight-line relationships can be used for diagnostic purposes and for obtaining preliminary parameter estimates. They should not, however, be used with simple **linear regression** programs for any formal approach to the analysis of data of this type. If the investigator wishes to affect the activity of an enzyme system with some sort of inhibitor, then these diagnostic plots can be very useful in indicating the type of inhibition. A *competitive inhibitor* (the most common type), will affect K_m but not V; a series of plots with differing concentrations of the inhibitor would be expected to yield a set of double-reciprocal plots passing through a common intercept on the $1/v$ axis.

Curve-Fitting and Parameter Estimation

It is straightforward to fit data directly to the Michaelis–Menten equation using **least squares** (either unweighted or weighted to allow for heteroscedasticity) or **maximum likelihood** criteria. An early paper by Wilkinson [9] showed how one might adapt a simple linear regression program to fit data to the Michaelis–Menten equation; and McCullagh & Nelder [4] discuss techniques for adapting GLIM procedures (*see* **Software, Biostatistical**). Following Nelder [5, 6], examination of the double-reciprocal plot in (2) shows that the Michaelis–Menten equation is an example of a **generalized linear model**. The link function relating the response (initial velocity) to the linear predictor is the reciprocal; and the linear predictor is given by the right-hand side of the equation. Errors could be assumed to be normal with a constant variance but, more naturally, they might be regarded as **gamma** variates.

Robust and Distribution-Free Estimation

The most popular distribution-free method of estimating the parameters of the Michaelis–Menten equation is based on the method of Theil [8]. This is the method that biochemists call the *direct linear plot* [2, 3]. Distribution-free methods (*see* **Nonparametric Methods**) have been used by biochemists because of their **robustness** to departures from the statistical assumptions usually made about the measurement errors: the direct linear plot method is insensitive to the occasional laboratory blunder. Consider any two pairs of observations, (s_i, v_i) and (s_j, v_j), with s_j assumed to be greater than s_i. Using these two pairs of observations, estimates of the Michaelis–Menten parameters can be obtained from the following [2]:

$$\left(\frac{1}{V}\right)_{ij} = \frac{(s_j/v_j) - (s_i/v_i)}{s_j - s_i}$$

and

$$\left(\frac{K_m}{V}\right)_{ij} = \frac{(1/v_i) - (1/v_j)}{(1/s_i) - (1/s_j)}. \qquad (5)$$

Note that these are the estimates of the intercept and the slope of the double reciprocal plot (2). In all, there are N pairs of observations, and there are $N(N-1)/2$ different possibilities for the parameter estimates, provided that the s_i are all different. The direct linear plot estimates for $1/V$ and for K_m/V are given by the **medians** of the $N(N-1)/2$ solutions provided by (5). Estimates of V and K_m are then calculated from these two medians. Although this estimation method is easily programmed for use on a personal computer, it has traditionally been used as a graphical estimation method – hence its name [3]. An alternative estimation procedure is provided by the *repeated median estimator* [7] (*see* **Robust Regression**).

GRAHAM DUNN

Midwifery, Obstetrics, and Neonatology

Midwifery is undoubtedly the oldest of the professions concerned with caring for women and their babies before, during, and after birth. The word "midwife" comes from Middle English and means "with the woman", while the French word "sage-femme" (wise woman), reflects the way that the women who cared for other women during labor and childbirth might also be traditional healers.

The word "obstetrician" comes from "obstetrix", the Latin word for midwife, itself derived from the verb "obstare", meaning stand at, before, or against. In Europe, male doctors' involvement with childbirth as "man midwives" or obstetricians dates back to about the middle of the eighteenth century, when they began to establish themselves as the practitioners for complicated deliveries, and their knowledge and influence grew [44]. Obstetricians had relatively low esteem during the latter half of the nineteenth century when most women were delivered by midwives or general practitioners.

A feature of maternity care over the past two centuries has been interprofessional rivalry between midwives and specialist and generalist doctors. Controversy has raged not only about who should do what tasks – for example, whether midwives could do forceps deliveries – but also about who is entitled to conduct deliveries at all. The outcome has varied widely between developed countries. Thus, in the US, certified midwives conducted just 8.0 of live births in 2001 [51]. For many years, midwifery was actually illegal in most Canadian provinces.

In contrast, midwives conduct about two-thirds of deliveries in the UK. Even where midwives are the most usual birth attendants and are officially recognized as the independent practitioners responsible for supervising normal pregnancy and birth, the rise in obstetric technology led to a downgrading of their role. In reaction to this there has been a reassertion of the role of midwives in the UK and elsewhere since the early 1980s, and a growing interest in basing practice on research evidence and developing midwifery research [54]. This has coincided with a reawakening of interest in midwifery in the US and moves to legalize midwifery in some Canadian provinces.

Some international agencies concerned with developing services for women in less developed countries have been active in training existing traditional attendants in appropriate practices and in training midwives, but other agencies are dominated by North American views that every woman should be delivered by an obstetrician.

Special care for immature newborn babies dates back at least to the 1890s and developed considerably in the 1920s and 1930s [56]. Nevertheless, the most widespread developments took place from the 1960s and 1970s. Since then, there have been parallel developments of neonatology (meaning "the science of the care of the newborn") as it is now known, as a separate subspecialty within pediatrics, and of neonatal nursing as a specialism within nursing.

What are the Questions?

In this context, it is inevitable that key issues from the nineteenth century onwards have related to the relative merits of different settings for birth and of the types of practitioners working in them. Attention has also focused on geographic variations and trends over time in the outcome of pregnancy and the relative strength of **association** between the socioeconomic circumstances of the child-bearing population, genetic factors, and the quality of the services available to women giving birth. Although questions have been raised for centuries about specific practices, it is only in the past 20 or 30 years that systematic attempts have been made to evaluate them.

What Methods have been Used?

As in many other areas, there is a long history of descriptive studies based on case series (*see* **Case Series, Case Reports**) and population-based data. These were given added impetus by the introduction of civil registration in many countries during the nineteenth century. Inevitably some analyses were hospital-based and the **selection biases** inherent in this were recognized in the latter half of the nineteenth century. During the first half of the twentieth century, **correlation** and **regression** were introduced into descriptive studies and **multivariate analysis** became more widespread with the availability of

electronic computers in the second half of the century. These greatly increased the potential for **record linkage** and follow-up studies, including those which follow-up **cohorts** of babies for a year or so, into childhood, or in some cases for the rest of their lives. **Case–control** studies were first used in this field at the beginning of the twentieth century and became much more widespread towards the end of the century. **Quasi-experimental methods**, notably "natural experiments", have a long history in this field, and the first controlled trials (*see* **Clinical Trials, Overview**) were done in the 1920s.

What is Measured?

Up to the mid-twentieth century the overriding concern has been to prevent death or severe morbidity in the mother. Concern about the health of children in the nineteenth century related more to public health and the living circumstances of young children than to conditions at birth. Although there was concern about **infant mortality** at the beginning of the twentieth century, this became the major outcome only after the massive decline in **maternal mortality** in the mid-twentieth century. Towards the end of the twentieth century, the increasing survival rates of very immature babies, largely as a consequence of developments in neonatal intensive care, has led to concern about monitoring morbidity in the survivors. Costs have always affected women's choice of maternity care, but the increasing extent to which this is funded either by public funds or by major institutions, such as insurance companies, has led to increasing concentration on measuring the costs of care. Reaction to the increasing use of technology at birth and the rise of consumerism has led to work to obtain women's views of the care they receive.

Measuring any of these is far from straightforward, and some of the problems were already recognized by the mid-nineteenth century [55] (*see* **Nightingale, Florence**). An advantage when doing **population-based studies** in this field, is that the usual denominators, the numbers of women giving birth and the numbers of babies born, can usually be assessed fairly accurately. On the other hand, the fact that a pregnancy can result in one, two, or occasionally three or more babies presents problems when doing analyses in terms of outcomes for the babies.

Time Trends and Geographic Variations in Infant Mortality – "Nature", "Nurture", or "Quality of Assistance"?

With the development in the nineteenth century of birth and death registration and publication of statistics derived from them, geographic variations in infant mortality became visible (*see* **Vital Statistics, Overview**). In England and Wales, **William Farr** used the "healthy districts", with the lowest mortality, as a yardstick with which to compare the others and make the case for improving sanitation and public health. For example, he showed that the aggregated mortality rate for 1861–1870 among children aged under 5 in Liverpool was more than three times higher than in the "healthy districts" [26].

In the last quarter of the nineteenth century, a rise in infant mortality in England and Wales coincided with decreases in both general mortality and the birth rate. This came at a time when controversies about Charles Darwin's theories of evolution were leading to debate about whether infant mortality was the consequence of poor living conditions, lack of maternity care, or a beneficial culling of potentially unfit members of the population. The debate was further fuelled by the discovery that many potential recruits for the Boer War were unfit. This led to a much closer scrutiny of infant mortality rates and associated factors and to developments in statistical methods [21, 50].

In the first volume of ***Biometrika***, founded "especially for those who are interested in the application to biology of the modern methods of statistics" [28], **George Udny Yule** asked, "Would it not be worth while for an evolutionist statistician to give some attention to the mass of material accumulated in the Decennial Supplement to the reports of the Registrar General for England and Wales?" [78]. He suggested calculating correlation coefficients between childhood and adult death rates.

At the General Register Office, John Tatham compared infant mortality rates for urban and rural counties in 1873–1877 with those in 1898–1902. He found no change in the rural rate, but a rise in the urban rate [63]. The extent to which this may reflect selective migration as well as differences in conditions is unclear. A series of reports from the Local Government Board, whose responsibilities included public health, looked in detail at geographic differences in infant mortality and the mortality of children

under the age of 5 and the factors associated with it. The first report used rankings of counties and simple descriptive techniques [42]. It discussed associations between infant mortality and sex of babies, "legitimacy", family size, stillbirths, quality of help available, age of the mother, nondomestic employment, overcrowding, sanitation, "ignorance", and "fecklessness". The introduction by the Board's Chief Medical Officer, Arthur Newsholme, included a discussion of possible associations with death in later life. In an Appendix, "On the possible selective influences of mortality on the mortality in the next four years of life", G. Udny Yule calculated correlation and regression coefficients between local infant and childhood mortality rates in successive years and found little evidence of negative correlation between infant and childhood mortality beyond the second year of life.

Karl Pearson's response, "The intensity of natural selection in man", used **life tables** for the periods 1838–1854 to 1891–1900 for England and Wales as a whole and for the "healthy districts" [64]. He found negative correlations between rising infant mortality and falling childhood mortality. He interpreted this as showing the survival of the fittest [57]. In a later analysis at a time of falling infant mortality, Karl Pearson and Ethel Elderton used the method of finite differences to try to adjust for environmental influences [24]. The results still supported their view of natural selection. This work was heavily criticized, notably by **John Brownlee**, who criticized their analyses on the grounds that they did not relate deaths to their corresponding cohorts of births and took no account of the periodicity of epidemic diseases, which were a common cause of death at the time [9].

These analyses were based on aggregated data for geographic areas (*see* **Ecologic Study**). The introduction of the Hollerith counter sorter into US vital statistics offices from the 1890s and the English General Register Office from 1911 [37, 62] extended the range of analyses which were feasible and made it possible to relate births and deaths to local government districts in which people lived.

The Local Government Board's third report focused on Lancashire, and five towns in particular [43]. The comparison between three of these – Burnley, Nelson and Colne, which had infant mortality rates of 176, 130, and 87, respectively, in 1911–1913 – has much more recently given impetus to a succession of studies comparing the health of adults in the 1980s and 1990s with their circumstances at birth [5, 6, 41], although similar studies had already been done in the 1970s [27]. Such studies have used either longitudinal **birth cohort studies** or a variety of other techniques for locating people and following them up.

In the US, birth and death registration was still incomplete in some states in the early years of the twentieth century. Nevertheless, analyses of infant mortality showed wide variations and prompted local investigations and the establishment of the Children's Bureau [76]. The Bureau's investigation of infant mortality in eight cities, directed by Robert Morse Woodbury, took a cohort approach [73]. This involved ascertaining all the births in the cities from a variety of sources and following them through the first year of life. Analysis of data about 2555 infant deaths and 22 977 live births on a relatively primitive punched card system was a challenge. Lacking techniques for multivariate analysis, he used a method of standardization, the "method of expected deaths" (*see* **Standardization Methods**). Using this, he concluded that the inverse association between infant mortality and the babies' fathers' earnings was much stronger than that with other factors, including family size, mothers' age, parity, birth interval, and type of feeding.

In an extensive analysis of data from England and Wales published in 1929, Peter McKinlay suggested that factors associated with infant mortality could be grouped into "(1) the quality of obstetric assistance in childbed (2) the health of the mother (3) social and environmental conditions". He used correlation coefficients, including multiple and partial correlation, to investigate associations with stillbirths and infant mortality, which he divided into "antenatal", "neonatal", and "postnatal" deaths [52]. He found the strongest associations with **quality of care** in the antenatal and neonatal periods, although environmental factors were also important in the latter, while the health of the mother and environmental factors were prominent in the postnatal period (*see* **Environmental Epidemiology**).

In the 1940s, Barnet Woolf & John Waterhouse used **multiple regression** in two papers on infant mortality in county boroughs of England and Wales. Motivated by a desire to counter what they felt to be insidious influences of the **eugenicists** in hindering social reform, they started from the standpoint that "a large proportion of infant deaths are preventable and no other vital index approaches infant mortality

in variability or sensitivity to social conditions" [74, 75]. They found it was strongly associated with overcrowding, male unemployment, percentages of males in social classes IV and V, percentages of women employed on manufacturing processes, and latitude.

The advent of computers considerably reduced the laboriousness of such analyses. There were many similar analyses in the 1960s and 1970s using multiple regression and **principal components analysis**, which found stronger associations with social and environmental factors than with the availability of health care [3, 48, 49]. In general, these treated proportions and rates as continuous variables, while further analyses in the 1980s and 1990s have tended to use **logistic regression**.

Computers have also increased the potential for **record linkage**, although the first study to link records of deaths of babies under the age of 1 year to their birth records was done in the punched-card era. This was a study of the 44 000 deaths in the first year of life in 1949 and 1950, together with the 1.5 million live births and 33 000 stillbirths [35]. The 1600 deaths in the second year of life among babies born in 1949 were also studied. The aim was to use data collected at birth registration to identify the categories of women with the highest mortality, with the aim of giving them priority for specialist maternity care. These analyses and others which followed suggested that the association between mortality of fetuses, babies, and mothers and mothers' ages and their parity, the number of previous births, was U-shaped, with the highest mortality being amongst the youngest and oldest women and their babies. In contrast, a study which followed up successive pregnancies to women in Aberdeen, Scotland, who had their first pregnancy during the years 1949–1954 suggested that perinatal mortality rates declined during women's reproductive career [7].

In the 1970s, such record linkage became routine in England and Wales and in an increasing number of US states. By the 1990s, most Nordic countries, Scotland, England and Wales, Israel, and some states of the US and Australia had taken this further and were able to link together successive pregnancies to the same woman. Some are able to link other records, such as **census** returns, hospital admissions, abortions, and cancer registrations (*see* **Disease Registers**) [1]. This makes it possible to analyze the outcomes of successive pregnancies according to the characteristics of both women and their babies. One of the first of these, based on all births in Norway from 1967 to 1973, reached similar conclusions to those of the earlier analysis from Aberdeen [4]. This gave rise to considerable debate about how to account for effects of self-selection for further pregnancies.

Where to be Born?

In the mid-nineteenth century, it was unusual to give birth in a hospital or lying-in institution, for very good reasons. William Farr was alluding to the results of numerous descriptive analyses when he wrote, "Contrary to expectations the advantages these institutions offered were overbalanced by one dread drawback; the mortality of mothers was not diminished; nay it became in some instances excessive; in others appalling" [25]. Much of this high mortality was due to puerperal fever – a major cause of maternal mortality up to the 1930s.

The discovery of the cause and contagiousness of puerperal fever is widely and incorrectly attributed to Ignaz Semmelweiss, whose famous treatise, "The aetiology, concept and prophylaxis of childbed", was published in 1861 [58]. In fact this had already been demonstrated in a descriptive account at least 50 years earlier by an Aberdeen obstetrician, Alexander Gordon [31], and other descriptive accounts were published during the first half of the nineteenth century [44], including a review by the American physician and poet, Oliver Wendell Holmes [19].

In this work on puerperal fever, Semmelweiss was able to use data from a "natural experiment". At the time of his appointment to the Vienna Maternity Hospital in 1846, it was divided into two clinics, and women were admitted to the two clinics on alternate days. One was for the instruction of medical students and doctors, and mortality in this clinic was much higher than in the second clinic, which was used for the instruction of midwives. Semmelweiss found that medical students would attend post-mortems of women who died of puerperal fever before going over to the clinic and doing vaginal examinations, without first changing their clothes or washing their hands. After he insisted that medical students wash their hands in disinfectant, mortality in their clinic fell [44].

Such comparisons of mortality have never been straightforward, however. First there are problems of definition, as Florence Nightingale found out when she tried to compare mortality rates for different places of birth: "Midwifery statistics are in an unsatisfactory condition" and "... there appears to have been no uniform system of records of deaths or the causes of deaths, in many institutions ..." [55]. Despite the introduction of antiseptic and aseptic techniques, which lowered mortality rates in some hospitals towards the end of the century, rates were higher than at home. The question of selection bias was raised, however. In 1904, William Williams suggested that "the majority of the worst cases are brought to hospital after labor commences and that a large number undergo some of the major operations" [72]. The high mortality in workhouse infirmaries which catered for destitute women was often attributed solely to their resulting poor health. This was questioned by Sidney & Beatrice Webb, who pointed to the inadequate care and unsavory conditions in some infirmaries [69].

The issue of selection bias is one which has always dogged the debate about the relative risks and merits of different settings for birth. In England a policy of universal hospital birth was adopted in the light of the observation that perinatal mortality had fallen at a time when the percentage of births in hospital had fallen [61]. This was parodied by **Archie Cochrane**, who pointed out that the length of postnatal stay after childbirth had fallen over the same period [15], and challenged extensively by Marjorie Tew [65]. Although it is possible to do randomized trials to compare other outcomes of care in different settings, the key issue is still safety [11].

Evaluation of Specific Aspects of Care

Although singled out by Archie Cochrane for the "wooden spoon", obstetrics, together with midwifery and neonatology, have been well ahead of other clinical professions in evaluating the care provided, particularly in the use of randomized trials. The numbers of trials published rose from fewer than 20 in 1950 to over 400 in 1990 [32]. By 2003, the Cochrane Pregnancy and Childbirth Group had 9129 trial reports in its register [23] and the Cochrane Neonetal Group had about 3000 [22].

Trials were being done much earlier, however. As early as the 1920s, nearly 400 women took part in a trial of the effect of shaving women's perineal hair on admission to hospital on the incidence of puerperal fever [39]. Neither this trial nor any later research showed shaving to be beneficial, but it was still common practice in England and Wales in the early 1980s [29].

Five trials published in the 1950s with sample sizes ranging from less than 100 to over 1600 compared diethylstilbestrol (DES), a drug thought to prevent miscarriage, with concurrent controls. Three of the trials were double-blind (*see* **Blinding or Masking**). None showed a difference in rates of miscarriage, stillbirth, and neonatal death, although in the 1980s a reanalysis of one trial suggested that DES was harmful [30]. DES continued in use until a case–control study published in 1970 [36] showed that between 1.4 and 14 per 10 000 women exposed to it as fetuses were likely to develop a very rare cancer – cancer of the vagina.

The rise in the numbers of neonatal trials is partly a reflection of the growth of the specialty. Some of the key research relates to the use of supplemental oxygen for babies born preterm. Trials compared giving preterm babies air with more than 50% oxygen with much lower concentrations of oxygen. These showed higher rates of retrolental fibroplasia, now known as retinopathy of prematurity, which can lead to blindness among surviving babies who received the higher concentrations [59], and led to policies of keeping the oxygen concentrations below 40%.

Inappropriate subgroup analyses have been a problem in this field, as in others. For example, a structured review of the relevant trials showed that administering corticosteroids to women who are about to deliver preterm can help their babies' lungs mature [18]. Nevertheless, this practice was not adopted for some time after the early trials were published, as a subgroup analysis suggested that the result applied only to black female babies [16].

Some of the earlier trials in this field were dismissed as they were not large enough to detect small or moderate treatment effects. For example, two small trials involving 350 and 462 women comparing the rates of seizures among babies whose mother had electronic fetal monitoring in labor with those who had intermittent auscultation were unable to detect a difference, although in both cases the rate appeared to be lower in the monitored group. A larger trial of nearly 13 000 women was able to detect a difference in the rate of seizures in the neonatal period but no

difference in cerebral palsy rates when the children were 4 years old [46].

One response to the problem of small sample size is to pool the results of trials formally through systematic review and **meta-analysis**. The first attempt to do this consistently for a given area of health care was in the Oxford Database of Perinatal Trials, the first release of which was published in 1988 [13]. It was used for the two volumes of *Effective Care in Pregnancy and Childbirth* [14] and a third book, *Effective Care of the Newborn Infant* [60]. The database also acted as the prototype for the Cochrane Database of Systematic Reviews (*see* **Cochrane Collaboration**).

As in other fields, there are important questions which randomized trials are unable to answer. One example is the relative safety of different settings for birth. Mortality rates are now so low that it is impossible to do a large enough trial to compare mortality for women at low risk of complications without completely reorganizing the maternity services in a wide geographic area and thus interfering with the types of service being compared. Furthermore it is impossible to blind participants or caregivers to the form of care being given [11].

Other Issues Related to the Care of Individuals

There is a long history in this field of "confidential enquiries" which examines the circumstances and pathology of individual deaths of women and babies at or around the time of birth. All too often this is done without reference to any comparison group, even though a study which compared 2527 maternal deaths in Scotland in the years 1927–1932 with all women who gave birth in a 6 month period during this time was published as long ago as 1935 [20]. The Confidental Enquiry into Stillbirths and Deaths in Infancy in England, Wales, and Northern Ireland used controls in a study of deaths at 27 to 28 weeks of gestational age in [17].

Caregivers have always wanted to identify the women who are likely to experience problems. Since the beginning of the twentieth century, obstetric textbooks have listed social and physical "risk factors", associated with complications of pregnancy and poor outcomes. The development of computerized databases in the 1960s made it possible to use multivariate analysis to develop more formal scoring systems aimed at predicting a variety of complications and adverse outcomes. One of the first of these was derived by Harvey Goldstein from his analyses of the survey of deaths among babies born in Great Britain during a week in 1958 [10].

In general, these scoring systems have had poor predictive value for the individual and often do not apply outside the populations in which they were developed. A review in 1989 commented that

> When risk scoring is applied in clinical practice, there is a very real danger that a potential but highly imprecise risk of adverse outcome becomes replaced by the certain risk of dubious treatments and interventions whose benefits have not been demonstrated and whose hazards are largely unknown [2].

Since the beginning of the twentieth century, statisticians have been interested in the statistical properties of the distribution of babies' **birthweights**, particularly among the smallest babies, who have the highest mortality rates [77]. As a result, they have been of greatest concern to clinicians as methods of neonatal care developed. By the middle of the century, it was recognized that birthweight alone was inadequate as a measure of maturity as there is a difference between preterm babies who are small because they are born too early and growth-retarded babies who are born later. This led to the construction of "standard" charts giving centiles of the birthweight distribution at each of the gestational ages (*see* **Quantiles**) [45, 66]. There are two sets of statistical problems involved – those of selecting the "standard" population and the choice of methods for fitting curves to data.

As birthweight means and distributions have been shown to vary according to the baby's sex and multiplicity, the mother's age and parity, the parents' racial and socioeconomic characteristics, and the altitude at which the mother lives, the question of choosing an appropriate population is far from trivial [40, 53]. In addition, early data came from hospitals at a time when many women gave birth at home, so they may not have been representative of the surrounding population [49].

The data used to construct the first set of standards widely used in the US came from a hospital and also related to women living at a high altitude in the state of Colorado [45, 47]. The first set widely used in the UK was based on 52 004 singleton births

within marriage which took place in the city of Aberdeen, Scotland, in the years 1948–1964 [66]. As well as being restricted to births within marriage, the population was ethnically homogeneous, even though socially varied. Since the 1970s, the tendency to induce babies or deliver them by elective Caesarean section before term has foreshortened gestational age and affected its distribution. The way it is estimated has changed with the development of ultrasound scanning. Furthermore, for very preterm babies, the numbers of babies in any data set are likely to be small and the question of whether or not to restrict the tables to live births or to add in fetal deaths becomes increasingly crucial [67]. The question of how to deal with **extreme values** is an issue at all gestations.

The methods used to fit curves to the distributions have inevitably developed over time in response to the availability of computing power and statistical methods. An important factor is the extent to which the non-normality of the birthweight distribution is taken into account [12]. In some populations, it is bimodal, particularly at low gestational ages [66]. Approaches which have been used range from a simple step function [66], using bivariate elastic **spline** interpolation to fit contours to distributions of birthweight and gestational age [38], using **nonparametric methods** to smooth empirical centiles (*see* **Nonparametric Regression**) and fitting **polynomial regression** curves to birthweight at each gestational age, assuming a **normal distribution** [8].

The differences in birthweight distributions for different populations also make it difficult to compare their mortality rates. Standardization of birthweight-specific mortality rates has been shown to be **biased**, in particular against populations with heavier birthweights [70]. An alternative method aims to eliminate this bias by using the frequency distribution of birthweight and the curve of weight-specific mortality to describe the **excess mortality** in one population compared to another [71]. So far, it has not been widely used in routine practice, probably because of its relative complexity.

Future Questions – Heredity, Environment, Clinical Effectiveness, and Quality of Care

So far, the design of randomized trials in this area has been relatively basic, in comparison with those used in agriculture or psychology. A relatively recent development, from the late 1980s onwards, is the use of **split plot designs**, described as "cluster randomization" (*see* **Randomized Treatment Assignment**) in this context, especially when comparing programmes of care, such as antenatal care [32, 33, 68]. The introduction of **Bayesian methods** into trials has in this field begun [34]. In descriptive studies, **multilevel modeling** is now being used to bring together analytically the characteristics of parents and the areas in which they live in studies of geographic variation (*see* **Geographic Epidemiology**).

As described earlier, statistical techniques developed at the beginning of the twentieth century were used in the heated debate about whether differences in mortality were related to "heredity", "environment", or "quality of assistance in childbed". As we begin the twenty-first century, it is increasingly recognized that genetic factors (*see* **Genetic Epidemiology**), clinical effectiveness, **quality of care**, and socioeconomic and environmental factors may all be related to a variety of measures of the outcome of pregnancy. The challenge for statistics is to develop appropriate quantitative techniques for describing and assessing pregnancy and its outcome.

Migrant Studies

Studies on migrant populations are based on the assumption that migrants carry a risk that to some extent reflects that of their country of origin rather than the host country. Migrant studies are, therefore, a category of **ecologic studies** in which geographic differences in **risk** are replaced by risk differences among population groups (immigrants vs. host population and vs. population of origin).

Migration can be studied for three main reasons:

1. The study of migrant populations can be used for generating (as opposed to "testing") or confirming hypotheses derived from etiologic studies of environmental risk factors associated with disease occurrence.
2. The study of the health status of minorities who have emigrated from abroad has recently acquired public health significance, because of the effect of migration from the underdeveloped to the developed world on the occurrence of acute and socially relevant diseases in the host country.
3. Migrant status may be used in **case–control** and **cohort** studies as a variable representing possible **confounding** exposures.

Definition of Migrant Status

There are several ways of defining a subject as a migrant.

Place of birth Subjects born abroad are considered to be immigrants. This definition is the most widely used in epidemiologic studies. For diseased subjects, the information is either obtained from **death certificates**, which report the country of birth, or from **disease registries**, such as cancer registries. Furthermore, place of birth is usually enumerated in population **censuses**, but sometimes only for a subset of the population.

Citizenship Subjects with foreign citizenship are considered to be immigrants. The original citizenship may be retained by residents of foreign countries or obtained by the spouse of a migrant. The foreign offices of some countries provide periodic information on these persons.

Ethnic origin Subjects may be considered as migrants if both parents were born abroad or if they answer positively to the question: "Are you a migrant?" (*see* **Ethnic Groups**).

Each of the above-mentioned definitions identifies a population group of different size. For example, Table 1 shows the number of Italian migrants in the US in the decade 1970–1980 according to each definition [8].

Sources of Information for Migrant Studies

Information on Diseased Subjects

First-Generation Migrants. In the majority of migrant studies, information on diseased subjects is derived from routine **surveillance** systems. These are mortality statistics, when the content of the death certificates allows it, or cancer registries statistics, when the interest is focused on cancer risk. Other pathology reporting systems have begun to include information on migrant status in order to evaluate the effect of migration on the epidemiology of some diseases of emerging interest, such as tuberculosis and **AIDS**.

If information on the date of migration is recorded individually, the duration of stay and the age at migration to the host country can also be computed [4, 36]. This information is, however, seldom routinely available. In the US, the Social Security Number (SSN), which is assigned sequentially to all residents, has been used as a proxy of age at migration. If the SSN is assigned to a migrant after the usual age of entry to work, it is considered most likely that he/she migrated as an adult (late migrant). In contrast, those whose

Table 1 Number of Italian migrants in the US in the decade 1970–1980

Italian-born	831 000
Italian citizens	230 000
First- and second-generation immigrants	5 000 000
Italian origin	8 800 000
Italian origin identified as one of the subject's roots	12 180 000

Source: [4]. Reproduced with permission of IARC.

SSN was assigned at the usual age of initial employment are considered to have migrated in childhood (early migrant). Unfortunately, such information can be used only for cases and not for the general population, thus limiting the choice of study design [24].

Second-Generation Migrants. Parents' birthplace is routinely recorded on death certificates in some countries and by some cancer registries, allowing for the identification of second-generation migrants [9, 35]. Alternatively, studies on second-generation migrants may be based on information on both ethnicity and birthplace. Members of ethnic groups born locally are considered to be second-generation migrants, while those born abroad are first-generation migrants [39].

If second-generation migrants can be identified, the modification of risk between first-generation migrants and their descendants can be estimated. Moreover, disease risk can be studied in individuals of mixed parentage, in whom the genetic susceptibly may be intermediate between those of the two populations; furthermore, environmental exposures, such as lifestyle habits, may be influenced to different extents by the origin of the father and the mother [9, 35].

Information on the Population

First-Generation Migrants. To estimate incidence or mortality rates by migrant status, information is required on the population at risk of developing the disease under study. This may be provided by censuses, as long as the definition of migrant status in the denominator is the same as that in the numerator.

The use of censuses as a source of information for the denominator tends to limit the number of variables that can be considered in the study, as time since migration, age at migration, and other variables for diseased or deceased subjects, are seldom available for the population at risk.

Second-Generation Migrants. Only some population censuses include the country of birth of the parents of the enumerated subjects [35]. When available, this allows estimation of disease and death rates for second-generations migrants.

Use of Census Information for Longitudinal Migrant Studies

The identification of a cohort of migrants (first- or second-generation) through censuses may allow follow-up and cross-linking with routine information on diseases and deaths [15] (*see* **Record Linkage**). The number of persons "lost to follow-up" in these cohorts, however, tends to be high, because of the tendency of people who migrate once to move again, often back to the country of origin.

Information on Other Variables: Socioeconomic Level and Lifestyle

In some countries, routine sources of numerators and denominators provide some information on socioeconomic level, usually approximated by occupation, educational level, or a combination of the two [6] (*see* **Social Classifications**).

Surveys of the frequency of exposure to disease determinants (tobacco, alcohol, dietary habits) at a population level seldom include information on migrant status [22, 25]. When this is not available, exposure **prevalence** derived from population-based surveys in the country of origin, and in the host country, may be used to interpret differences in the disease risk of migrants [28].

Information on the prevalence of lifestyle habits of migrants may be derived from **control** groups in case–control studies in which migrant status is considered [38].

Exposure to lifestyle, environmental, and other risk factors in migrants, and in control groups, has been determined directly in only a few studies. It can be done through the use of questionnaires in cohort or case–control studies and makes it possible to disentangle the roles of different exposures in determining the risk pattern related to migrant status. The exposures of interest tend to vary widely among first- and second-generation migrants and in relation to duration of stay, providing greater **power** to detect associations and therefore smaller study size in comparison with populations in which the level of exposure is more homogeneous. Furthermore, direct measurement of exposure makes it possible to study the relationship between time variables, such as age and time at migration, and lifestyle changes. Most studies [40] have addressed the role of diet in determining the risk for cancers at various sites. In some

cases, blood samples were obtained so that internal doses of nutrients and micronutrients could be measured in a prospective **cohort** design [30].

Sources of Bias in Migrant Studies

If a different definition of migrant status is used for the denominator than for the numerator in computing mortality or morbidity rates, erroneous estimates of the rates in an unpredictable direction may result (*see* **Denominator Difficulties**).

Because of the infrequency of censuses (commonly at 10-year intervals), censuses must often be interpolated to estimate appropriate denominators for migrants. This may introduce an additional source of **bias**, due to an underestimate of the denominator, when active migration is still occurring during the period of interpolation.

The accuracy of diagnostic information and of the coding of diseases changes geographically. This may lead to artifactual differences when the rates in one country (local-born and migrants) are compared with those in another (country of origin), due to information bias on disease status. If diagnostic procedures and coding practices are not selective by migrant status, this source of bias does not affect comparisons between migrants and locally born people within the host country. It can be hypothesized, however, that the access to certain diagnostic procedures may be different for migrants within the same country, especially for those of low socioeconomic status, owing to communication problems or legal status. This will introduce bias in disease status, partially hampering comparisons of rates with those of locally born persons.

Furthermore, a possible selection of subjects who migrate, in contrast to the population of the country of origin, must be considered.

First, migration may be selective by subarea within the country of origin [8]. If there are different patterns of risk in the population of origin by subarea, any comparison between migrants and the population of country of origin as a whole will be incorrect. If information on the subarea of origin is available, however, a specific comparison with the subarea may be accomplished.

Secondly, subjects who decide to migrate may have a different disease occurrence pattern from that of the population as a whole, as health status is related to the opportunity to migrate. This **selection bias** usually leads in the direction of a lower disease risk among migrants (healthy migrant effect) [26]; however, it may be associated with a higher disease risk if diseased subjects tend to join a family that has previously migrated, or tend to migrate to another country for retirement or care (unhealthy migrant effect). To evaluate the relevance of this selection bias, the disease experience in the first period after migration is sometimes considered separately, when information on the date of migration is available [36] (*see* **Bias, Overview**).

Finally, if migrants are reluctant to use unfamiliar medical services or unable to afford to do so, they may "go back home" when severely ill, thus disappearing from the numerator while still contributing to the denominator [29]. This will lead to an underestimate of mortality and incidence rates.

Statistical Methods

All classical **descriptive epidemiological** methods can be used in migrant studies.

Variables Under Study

Migrant status is the exposure variable for which disease risk is estimated: the reference category is represented by nonmigrants in the host country or by subjects resident in the country or origin. Time variables, when available, can be investigated.

Age. The first time variable to be considered is age, because changes in risk result from aging and because of the peculiar age structure of migrant populations, which tend to an overrepresentation of young adults, especially in recently migrated groups. Age is, therefore, associated with both disease and migrant status (*see* **Confounding**).

Calendar Time. Disease rates are likely to change over calendar time. If this happens differentially in the country of origin, in the host country, and in the migrant population, any comparison should take into account the effect of such changes.

Duration of Stay and Age at Migration. Duration of stay is an index of duration of exposure to determinants of the disease under study during the stay in

the host country, and therefore represents a proxy of cumulative exposure levels. If differences in disease risk between migrants and locally born people, and between migrants and the population of origin, are related to differential exposure levels, these should be found to be associated with the duration of stay. Furthermore the speed with which the disease pattern in migrants changes by duration of stay can be interpreted in terms of duration of exposure (or non-exposure) to etiologic agents in the host country.

Age at migration is strictly related to duration of stay, as subjects migrating at younger ages tend to stay longer. In terms of the natural history of the disease, this variable is potentially informative for latency, estimated as the interval between the beginning of exposure and disease occurrence (*see* **Latent Period**). For example, the finding that subjects migrating from a high-risk to a low-risk country at a young age retain a life-long higher risk than that in the host country, and than that of people who migrated during adulthood, indicates that exposure during childhood is relevant for the disease. In cancer studies, and in general for diseases with a multistep etiologic process, it suggests that the determinants involved in migration act as initiators of the disease.

Ideally, one would examine simultaneously the effect of age on arrival and duration of stay in the host country, controlling for the other relevant temporal variables (age and period of occurrence of the disease). This is not feasible, however, as age, duration of stay, and age on arrival are not independent: the definition of two of them implies knowledge of the third. The situation is similar to that of the **age–period–cohort** problem framework. To overcome this difficulty, separate analyses sequentially ignoring one of the two variables (duration of stay or age on arrival) are performed in migrant studies [4].

Other Variables. Information on other variables related to both disease and exposure may be considered when available. As mentioned above, this is possible in case–control and cohort studies in which individual questionnaires are used. Additional variables can be derived from routine surveys, such as on occupation and education, as a proxy for socioeconomic status, and on place of residence in the host country as a proxy for access to diagnostic procedures and care (*see* **Surveys, Health and Morbidity**).

Statistical Analysis

The statistical analysis of migrant studies depends upon the data sources available.

Denominator-Based Analysis. *Age-Standardized Rates*. Iuf the information on the denominator is reliable, incidence or mortality rates for migrants can be calculated and compared with those of residents of the host country and/or the country of origin. Direct standardization is used to adjust for age distribution [32]. Standardized rate ratios (SRRs) are generally computed, since interest is focused on the magnitude of the difference between the two rates (migrants vs. locally born and/or migrants vs. country of origin) [3]. The choice of a common standard population (e.g. locally born in the host country) allows the use of rate ratios.

Direct standardization, however, is sensitive to small numbers of events in the study population [32]. For migrants, some age-specific rates may be based on very few cases. The result is unstable rates and large **confidence intervals** around the rate ratios.

To increase the precision of the measure, indirect standardization, from which a smaller **standard error** is expected, is used for rare diseases and for small migrant groups, with the estimation of Standardized Mortality or Incidence Ratios (SMRs, SIRs). The standard set of rates are the age-specific rates of the host country as a whole or, more properly, of the local-born, from which migrants have been excluded [42]. It must be considered, however, that SMRs and SIRs are internally standardized and not mutually comparable [32] (*see* **Standardization Methods**).

Other Methods of Adjustment. When variables other than age are considered in a study, the **Mantel–Haenszel** estimator can be used to obtain a summary estimate of risk, adjusted by age and by the other variables. **Loglinear models**, however, are currently preferred for migrant studies, when several variables are available for analysis and **stratification** would fail because of insufficient numbers.

Recently, loglinear modeling based on the **Poisson distribution** has been applied to migrant studies in order to control simultaneously for a number of confounding factors [17]. This application is based on the following two assumptions:

1. The number of cases per cell is assumed to follow a Poisson distribution, with a **mean** value proportional to the number of **person-years at risk**.
2. The logarithm of the rate is assumed to be a linear function of the combination of classification variables that best describe the disease risk in the migrant population.

The **relative risks** obtained by model fitting are expected to show a greater numerical stability in comparison with those computed by traditional standardization methods.

A comparison of risk estimates with 95% confidence intervals obtained when different methods were applied to a large set of mortality data for Italian migrants to Canada is shown in Table 2 for deaths from selected cancers [19].

Numerator-Based Analysis. When the denominator is not available, or the population at risk cannot be cross-classified by the variables of interest, the analysis is based on diseased/deceased subjects only. The **proportional mortality** or incidence ratio (PMR or PIR) is the measure often used in such cases [36], and the relative proportion of diseases in the locally born population other than the one of interest is taken as the standard to adjust by age.

A proportional mortality or incidence study can be classified as a variant of a case–control study, where the cases are deaths or incident events classified by migrant status and the controls are other deaths or incident events of a different disease occurring in the same base population. This study design is based on the assumption that the migrant status among the controls has the same distribution as in the base population, i.e. that the overall rate of the disease/s in the controls is not related to migration.

Instead of PMRs or PIRs, a Mantel–Haenszel or, more frequently, a loglinear modeling approach is used in numerator-based studies when variables of interest other than age are considered. The assumptions described for PMR and PIR studies are used. When **logistic regression** models are applied, the cases in the cells are assumed to follow a **binomial distribution**, and the logit **transformation** of the disease probability is considered to be a linear function of the classification variables. If the assumption that the disease or death risk in controls is not related to migration is true, the estimates from the logistic model approximate those derived from the Poisson regression. The choice of appropriate controls is therefore crucial in this study design.

A comparison of the results obtained from the same set of cancer deaths among Italian migrants to Australia using Poisson and logistic regression (the latter using three sets of controls) is shown in Table 3 [19]. The risk estimates obtained using non-cancer or all other deaths as controls are consistently greater than those obtained using cancer controls or Poisson regression. This result is due to a lower risk of death from all causes and from causes other than cancer in migrants than among locally born persons. The results, therefore, do not confirm the assumption that the disease in controls are unrelated to migration when these two sets of controls are considered.

Evaluation of Goodness of Fit of Regression Models – the "Overdispersion" Phenomenon. When the analysis is based on modeling, **Goodness of**

Table 2 Comparison of age-adjusted estimates of risks and their 95% confidence intervals obtained by different methods, for male Italian migrants relative to locally born, Canada, 1964–1985

Cancer site	SRR[a]	SMR[b]	RR[c]	RR[d]
Esophagus	0.72(0.60–0.87)	0.69(0.56–0.82)	0.69(0.58–0.83)	0.69(0.57–0.83)
Stomach	1.28(1.18–1.39)	1.30(1.20–1.40)	1.30(1.20–1.40)	1.30(1.20–1.40)
Lung	0.76(0.72–0.80)	0.74(0.70–0.78)	0.74(0.70–0.78)	0.74(0.70–0.78)
Melanoma	0.96(0.71–1.29)	0.86(0.63–1.09)	0.86(0.65–1.14)	0.86(0.65–1.14)
Leukemia	1.18(1.05–1.33)	1.18(1.05–1.31)	1.18(1.05–1.32)	1.18(1.05–1.32)

fit can be assessed with the log **likelihood ratio** statistic [17]. Provided that the Poisson or binomial assumptions hold, and the regression model is correctly specified, this statistic is of the same magnitude as the **degrees of freedom**, or smaller for small cell sample size. However, especially when a large data set is used and the **contingency table** is not classified by factors that are relevant to the response, the phenomenon of **overdispersion** may occur, reflected in a log-likelihood ratio greater than predicted.

This case occurs frequently in migrant studies, especially when the comparison is between those born in the host country and the general population in the country of origin, thus involving very large data sets with few **explanatory variables** available for the analysis. The problem of overdispersion can be addressed in the analysis by using a conservative approach in estimating the confidence intervals of the effect parameters [1].

Contribution of Migrant Studies to Insight into Disease Etiology

Most studies of migrant populations address cancer incidence or mortality (for some relevant references on this issue, see Geddes et al. [10], Steinitz et al. [36], Haenszel [13], Haenszel et al. [14], and Thomas & Karagas [40]). The published studies refer to migration from high- to low-risk countries for some cancer sites (e.g. stomach cancer in migrants from Japan and Italy to the US and Australia) or from low- to high-risk countries (e.g. breast cancer in migrants from Japan and China to the US). The analysis of temporal variables, such as duration of stay in the host country, and age at migration, and the study of second-generation migrants have provided valuable information on the size and timing of changes in cancer risk in response to changes in the external environment and/or lifestyle [9, 20, 35].

Another result of migrant studies is information on cancer rates in the migrant's country of origin, when these are not currently recorded or reasonably valid. This is of particular value for migrants from the underdeveloped world who have recently migrated to developed countries. Such estimates should, however, be considered with caution because of the possible **selection bias** of migrants (see above).

The relation of risk to the frequency of exposure to dietary factors, as derived from **cross-sectional studies** of migrants, their offspring, host countries, and countries of origin, has been highlighted in some studies [22, 23, 28].

The results of studies in which dietary and other variables were considered have been used to infer possible environmental factors in the geographic differences in cancer rates. Although such studies are not common, they represent a potential field of development in migrant studies.

Other migrant studies, mainly based on mortality data, address cardiovascular disease and stroke [15, 16, 37]. In these studies, temporal variables and measurement of risk are treated by methods similar to those used in cancer studies.

Another developing field of interest is of diseases and accidents that are suspected of being determined by migration itself, or which are prominent in the migrant population, thus affecting the rates in the host country. This is the case of studies on suicide [21],

homicide [34], work-related fatalities [7], tuberculosis [5, 27], birth outcomes [2, 12, 33], psychiatric disorders [31], hepatitis [18, 41] and HIV/**AIDS** [11].

Most of these studies, however, do not involve use of the methods described above, and risk estimates are not provided for the migrant population in comparison with the locally born population or with the country of origin. This may be due to the lack of population-based registries for the diseases under study and to the relatively small groups of subjects involved.

Migration Processes

In a migration process, both immigration and emigration take place. Immigration causes a population size to increase, while emigration causes a population size to decrease, just as in a birth–death process (*see* **Stochastic Processes**). However, there is a fundamental difference between the two processes. In a migration process the immigration rate (immigration intensity) is independent of the population size, whereas in a birth–death process the birth rate (birth intensity) is a function of the population size at the time of birth. This difference affects the complexity of the two processes. While the formulas in a birth–death process usually are complicated, especially when the birth intensity and the death intensity are functions of time, the formulas in a migration process are relatively simple. Generally, in a single colony migration process, the population size distribution is a combination of a **binomial** distribution and a **Poisson distribution**. The binomial distribution is related to the initial population size, and the Poisson distribution is associated with migration. The two distributions are independent of each other. If the initial population size is zero, then the population size distribution is Poisson. If there is no immigration, then the population size distribution reduces to a binomial distribution, as shown below.

A Simple Migration Process

Suppose that a population's growth is subject to a migration process with immigration intensity η and an emigration intensity μ. Let $X(t)$ be the population size at time t, with the initial population size at $t = 0$, $X(0) = i$. Let the probability distribution of $X(t)$ be denoted by

$$P_{ik}(0,t) = \Pr[X(t) = k | x(0) = i], \quad k = 0, 1, \ldots. \tag{1}$$

We derive a system of differential equations for $P_{ik}(0,t)$:

$$\frac{\mathrm{d}}{\mathrm{d}t} P_{i0}(0,t) = -\eta P_{i0}(0,t) + \mu P_{i1}(0,t) \tag{2}$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t} P_{ik}(0,t) = -(\eta + k\mu) P_{ik}(0,t) + \eta P_{i,k-1}(0,t) + (k+1)\mu P_{i,k+1}(0,t), \tag{3}$$

with the initial conditions at $t = 0$:

$$P_{ii}(0,0) = 1 \quad \text{and} \quad P_{ik}(0,0) = 0, \quad \text{for } k \neq i. \tag{4}$$

Each of the differential equations in (3) contains three unknown probabilities – $P_{ik}(0,t)$, $P_{i,k-1}(0,t)$, and $P_{i,k+1}(0,t)$ – and cannot be solved directly. We resort to the method of probability **generating functions** [4].

Let the probability generating function of $X(t)$ be denoted by $G_x(s;t)$, so that

$$G_X(s;t) = \sum_{k=0}^{\infty} s^k P_{ik}(0,t), \tag{5}$$

with the initial condition at $t = 0$:

$$G_X(s;0) = s^i. \tag{6}$$

Taking the derivatives of (5) with respect to t, we find a partial differential equation for the probability generating function:

$$\frac{\partial}{\partial t} G_X(s;t) = \mu(1-s)\frac{\partial}{\partial s} G_X(s;t) - \eta(1-s) G_X(s;t). \tag{7}$$

Solving (7), with the initial condition (6), we find

$$G_X(s;t) = [1 - (1-s)\exp(-\mu t)]^i \times \exp\left\{-(1-s)\frac{\eta}{\mu}[1 - \exp(-\mu t)]\right\}. \tag{8}$$

When $s = 1$, $G_x(1,t) = 1$, so the distribution of $X(t)$ is proper. For each $t > 0$, we can find the probability $P_{ik}(0,t)$, for each k, the expectation $\mathrm{E}[X(t)]$, and the variance of $X(t)$, by taking appropriate derivatives of $G_x(s;t)$, although the computations are quite involved. However, these quantities can be derived directly with a different interpretation of (8).

Formula (8) is a product of two factors:

$$G_X(s;t) = g_Y(s;t) \times g_Z(s;t),$$

where

$$g_Y(s;t) = [1 - (1-s)\exp(-\mu t)]^i \tag{9}$$

and

$$g_Z(s;t) = \exp\left\{-(1-s)\frac{\eta}{\mu}[1 - \exp(-\mu t)]\right\}. \tag{10}$$

Formula (9) is the probability generating function of a binomial random variable, say $Y(t)$, with parameters i and $\exp(-\mu t)$; while formula (10) is the probability generating function of a **Poisson** random variable, say $Z(t)$, with a parameter function

$$\left(\frac{\eta}{\mu}\right)[1-\exp(-\mu t)]. \tag{11}$$

According to a theorem in probability generating functions, $X(t)$ is the sum of two independently distributed random variables,

$$X(t) = Y(t) + Z(t),$$

with formulas (9) and (10) as their respective probability generating functions. It follows that the distribution of $X(t)$ is a convolution of the distributions of $Y(t)$ and $Z(t)$, and

$$P_{ik}(0,t) = \sum_{j=0}^{\min[i,k]} \Pr[Y(t)=j] \times \Pr[Z(t)=k-j],$$

where $\min[i,k]$ stands for the smaller of i and k,

$$\Pr[Y(t)=j] = \binom{i}{j} \exp(-j\mu t)[1-\exp(-\mu t)]^{i-j}$$

and

$$\Pr[Z(t)=j] = \frac{\left(\frac{\eta}{\mu}\right)^j [1-\exp(-\mu t)]^j}{j!} \times \exp\left\{-\frac{\eta}{\mu}[1-\exp(-\mu t)]\right\}.$$

The expectation of $X(t)$ is

$$\mathrm{E}[X(t)] = \mathrm{E}[Y(t)] + \mathrm{E}[Z(t)] = i\exp(-\mu t) + \frac{\eta}{\mu}[1-\exp(-\mu t)], \tag{12}$$

and the variance of $X(t)$ is

$$\mathrm{var}[X(t)] = i\exp(-\mu t)[1-\exp(-\mu t)] + \frac{\eta}{\mu}[1-\exp(-\mu t)].$$

If the initial population size is zero, $i = 0$, then $X(t) = Z(t)$ has a Poisson distribution; if there is no immigration, $\eta = 0$, then $X(t) = Y(t)$ has a binomial distribution, as noted earlier. In general, $Y(t)$ and $Z(t)$ correspond, respectively, to individuals that were and were not present in the population at time $t = 0$.

In the above discussion we have assumed that the migration intensities were constant. When they are functions of time, $\eta(t)$ and $\mu(t)$, the binomial probability becomes

$$\exp\left[-\int_0^t \mu(\tau)\,\mathrm{d}\tau\right] \tag{13}$$

and the Poisson parameter in (11) becomes

$$\int_0^t \eta(\tau)\exp\left[-\int_\tau^t \mu(\xi)\,\mathrm{d}\xi\right]\mathrm{d}\tau. \tag{14}$$

With the substitutions of (13) and (14), we will have the same formulas as before for the generating functions, the probabilities, and the expectations.

A Survival Distribution

In this distribution we assume that there are two forces continuously acting on an individual to influence his survival and death. One force causes the mortality intensity function to increase, while the other causes the mortality intensity function to decrease. As a concrete example, consider an individual who is continuously exposed to a low level of radiation and other toxic material in the environment. During a time interval $(\tau, \tau + \mathrm{d}\tau)$, for $0 < \tau < t$, there is a probability $\eta\,\mathrm{d}\tau + o(\mathrm{d}\tau)$ that the individual will absorb a unit of toxic material, and a probability $\nu\,\mathrm{d}\tau + o(\mathrm{d}\tau)$ that the biological reaction inside the human body will cause a unit of toxic material in the body to be discharged. The units thus follow a migration process with initial population size $i = 0$, and, from (12), the expected number of units at time t is

$$\frac{\eta}{\nu}[1-\exp(-\nu t)]. \tag{15}$$

This is the expected total amount of toxic material absorbed during the interval $(0, t)$ and is present at time t. Since the toxic material is supposed to be harmful to an individual, a reasonable assumption is that the force of mortality at time t, $\mu(t)$, should be a function of the quantity in (15). The simplest

function is proportional, so that the force of mortality (*see* **Hazard Rate**) at time t is

$$\mu(t) = \frac{\beta}{\nu}[1 - \exp(-\nu t)],$$

where $\beta = b\eta$, b being the proportionality coefficient. It follows that the cumulative survival function is

$$\int_0^t \mu(\tau)\,\mathrm{d}\tau = \frac{\beta}{\nu}\left\{t - \frac{1}{\nu}[1 - \exp(-\nu t)]\right\}.$$

(*See* **Survival Distributions and Their Characteristics**).

Let T be the survival time of an individual. Then the distribution of T is given by

$$F_T(t) = 1 - \exp\left\{-\frac{\beta}{\nu}\left[t - \frac{1}{\nu}[1 - \exp(-\nu t)]\right]\right\}.$$

As $t \to \infty$, the distribution function tends to 1, and therefore the distribution of the survival time T is proper. The expectation of T is

$$\mathrm{E}[T] = \frac{1}{\nu}c^{-c}\mathrm{e}^{c}\Gamma(c, c),$$

where $\Gamma(c, c)$ is an incomplete **gamma** function

$$\Gamma(c, c) = \int_0^c y^{c-1}\mathrm{e}^{-y}\,\mathrm{d}y,$$

$$y = \frac{\beta}{\nu^2}\exp(-\nu t) \quad \text{and} \quad c = \frac{\beta}{\nu^2}.$$

This distribution was proposed in Chiang & Conforti [5] and was useful in the estimation of the time to tumor.

A Multi-colony Migration Process

Suppose now that the population consists of m colonies, labeled $1, 2, \ldots, m$. For $i = 1, 2, \ldots, m$, let η_i and μ_i denote, respectively, the immigration and emigration intensities for colony i. Thus, the probability that an individual immigrates into the population via colony i in the time interval $(t, t + \Delta t)$ is $\eta_i \Delta t + o(\Delta t)$, and the probability that an individual, who is in colony i at time t, emigrates from the population during $(t, t + \Delta t)$ is $\mu_i \Delta t + o(\Delta t)$. For $i \neq j$, let v_{ij} denote the migration intensity from colony i to colony j, so the probability that an individual, who is in colony i at time t, migrates to colony j during $(t, t + \Delta t)$ is $v_{ij}\Delta t + o(\Delta t)$. Suppose that at time $t = 0$ there are n_i individuals in colony i ($i = 1, 2, \ldots, m$). This model is fairly straightforward to analyze, since the behaviors of distinct individuals follow independent Markov processes. Here, we outline the key results. Further details may be found in [6].

For $i = 1, 2, \ldots, m$ and $t \geq 0$, let $X_i(t)$ denote the number of individuals in colony i at time t, and suppose that of those $Y_i(t)$ are *original* (i.e. in the population at time $t = 0$) and $Z_i(t)$ are *new* (i.e. have immigrated into the population during $(0, t]$.) Let $\boldsymbol{X}(t) = (X_1(t), X_2(t), \ldots, X_m(t))^{\mathrm{T}}$, where T denotes transpose, and define $\boldsymbol{Y}(t)$ and $\boldsymbol{Z}(t)$ similarly. Then,

$$\boldsymbol{X}(t) = \boldsymbol{Y}(t) + \boldsymbol{Z}(t) \quad (t \geq 0), \tag{16}$$

and the independence of individuals implies that $\boldsymbol{Y}(t)$ and $\boldsymbol{Z}(t)$ are also independent.

The distributions of $\boldsymbol{Y}(t)$ and $\boldsymbol{Z}(t)$ can be described as follows. For $t \geq 0$, let $P(t) = [p_{ij}(t)]$, where $p_{ij}(t)$ is the probability that an individual is in colony j at time t given that it was in colony i at time 0 ($i, j = 1, 2, \ldots, m$). The movement of an individual among the colonies follows a continuous time Markov chain, that may be transient due to emigration. Standard theory for such processes implies that

$$P(t) = \exp(Vt), \tag{17}$$

where V is the $m \times m$ matrix with elements v_{ij}, if $i \neq j$, and $v_{ii} = -\left(\mu_i + \sum_{k \neq i} v_{ik}\right)$, and $\exp(Vt) = \sum_{k=0}^{\infty} t^k V^k / k!$ is the usual matrix exponential (see e.g. Bellman [1], page 169). For the formulae of the individual $p_{ij}(t)$, reference may be made to Chiang [3, 4].

For $i = 1, 2, \ldots, m$, let $\boldsymbol{Y}_i^*(t) = (Y_{i1}^*(t), Y_{i2}^*(t), \ldots, Y_{im}^*(t))^{\mathrm{T}}$, where $Y_{ij}^*(t)$ is the number of original colony-i individuals that are in colony j at time t. The independence of individuals implies that $\boldsymbol{Y}_i^*(t)$ follows the defective (owing to emigration) multinomial distribution given by

$$\Pr[Y_{i1}^*(t) = r_1, Y_{i2}^*(t) = r_2, \ldots, Y_{im}^*(t) = r_m] = n_i! \prod_{j=0}^{m} \frac{\{p_{ij}(t)\}^{r_j}}{r_j!} \left(r_j \geq 0\ (j = 1, 2, \ldots, m), \sum_{j=1}^{m} r_j \leq n_i\right), \tag{18}$$

where $r_0 = n_i - \sum_{j=1}^{m} r_j$ and $p_{io}(t) = 1 - \sum_{j=1}^{m} p_{ij}(t)$. Moreover, $\boldsymbol{Y}_1^*(t), \boldsymbol{Y}_2^*(t), \ldots, \boldsymbol{Y}_m^*(t)$ are independent. Now

$$Y_i(t) = \sum_{j=1}^{m} Y_{ji}^*(t) \quad (i = 1, 2, \ldots, m), \tag{19}$$

so the joint distribution of $\boldsymbol{Y}(t)$ is completely described.

Turning to the distribution of the numbers of new individuals $\boldsymbol{Z}(t)$, since individuals immigrate into the m colonies at the points of independent Poisson processes and they behave independently, $Z_1(t), Z_2(t), \ldots, Z_m(t)$ follow independent Poisson distributions, with means given by

$$E[Z_i(t)] = \sum_{j=1}^{m} \eta_j \int_0^t p_{ji}(t-u)\,\mathrm{d}u \qquad (t \geq 0; \quad i = 1, 2, \ldots, m). \tag{20}$$

Further, provided the immigration, emigration, and migration rates are such that any individual ultimately leaves the population with probability one, the integral in (20) can be obtained using

$$\int_0^t P(t-u)\,\mathrm{d}u = V^{-1}(\exp(Vt) - I). \tag{21}$$

Equations (16) to (21) specify completely the distribution of the population at any time $t > 0$. The matrix exponential $\exp(Vt)$ can be found in terms of the eigenvalues and eigenvectors of V, provided V admits a spectral decomposition (see e.g. [8]). Note that in the case when any individual ultimately leaves the population, in the limit as $t \to \infty$ the population consists entirely of new individuals and the sizes of the m colonies follow independent Poisson distributions, with means given by $-\boldsymbol{\eta}^{\mathrm{T}} V^{-1}$, where $\boldsymbol{\eta}^{\mathrm{T}} = (\eta_1, \eta_2, \ldots, \eta_m)$.

An extension of the above model, in which the immigration, emigration, and migration intensities are time-dependent is considered by Faddy [6]. The independent decomposition (16) into original and new individuals still holds, and the distributions of $\boldsymbol{Y}(t)$ and $\boldsymbol{Z}(t)$ can still be described in terms of independent multinomial and Poisson distributions. However, the time-dependent nature of the intensities implies that $p_{ij}(t)$ has to be replaced by $p_{ij}(s, t)$ $(t > s)$, where $p_{ij}(s, t)$ is the probability that an individual that is in colony i at time s is in colony j at time t. Moreover, $p_{ij}(s, t)$ can be found explicitly only in a few special cases (see e.g. [2] and [9]).

Multi-colony migration processes also find application in other settings such as **compartment models** and queueing networks. In the latter, the intensities are often functions of the population state and interest usually focuses on the equilibrium distribution of the system (see e.g. [7, Chapter 2]). The single colony model discussed earlier also describes a queue with infinitely many servers (*see* **Queuing Processes**).

Minimax Theory

Minimax strategies are a pivotal concept in the theory of games. They were independently introduced in this context in the 1920s by Borel [2, 3] and von Neumann [23]. The 1944 monograph by von Neumann & Morgenstern [24] was very influential in fostering a coherent formulation and in explaining their role in game theory and particularly in the theory of two-person, zero-sum games. For a thorough treatment of game theory and of the place of minimaxity therein, see Luce & Raiffa [18].

In statistical theory minimaxity first appears in the seminal 1939 paper of Wald [25]. This paper laid the foundations of statistical **decision theory**, and the concept of minimaxity flowed naturally after the definitions there of **loss** and **risk**. See Brown [6] for discussion of the extent this development was influenced by Wald's earlier contacts with Morgenstern.

Minimax considerations are based on the risk function. Let $\mathscr{F}$ denote the set of possible distributions in a statistical decision problem and let Δ denote the set of randomized decision functions. Then the risk, $R(F, \delta)$, is the expected loss to the statistician who uses the procedure $\delta \in \Delta$ when the true distribution is $F \in \mathscr{F}$. Conventionally, one assumes the loss is nonnegative, and hence $R \geq 0$. Small values of R are desirable to the statistician, but since F is unknown these cannot necessarily be obtained.

The minimax risk is defined to be $M = \inf_{\delta \in \Delta} \sup_{F \in \mathscr{F}} R(F, \delta)$. A procedure δ_ε with $\sup_{F \in \mathscr{F}} R(F, \delta_\varepsilon) \leq M + \varepsilon$ is called ε-minimax ($\varepsilon \geq 0$). When $\varepsilon = 0$, the corresponding δ_0 is called minimax.

Various mathematical results characterizing existence and structure of minimax procedures involve putative **prior distributions** on $\mathscr{F}$ (endowed with a suitable σ-field). Let $\mathcal{P}$ denote the class of prior distributions, let $R^*(P, \delta) = \mathrm{E}_p(R(F, \delta))$ denote the expected risk under $P \in \mathcal{P}$, and let δ_p denote a corresponding Bayes procedure, i.e. one for which $R^*(P, \delta_p) = \inf_{\delta \in \Delta} R^*(P, \delta)$.

The fundamental minimax theorem is valid under certain important regularity conditions. When valid it asserts the existence of a minimax procedure which is Bayes for a corresponding prior, P_0, called a least favorable prior. This yields the following important string of equalities:

$$\sup_{p \in \mathcal{P}} \inf_{\delta \in \Delta} R^*(P, \delta) = M = R^*(P_0, \delta_0) = \inf_{\delta \in \Delta} \sup_{p \in \mathcal{P}} R^*(P, \delta_0). \qquad (1)$$

Regularity conditions implying (1) and (2) can be found in Wald [26], LeCam [16], and Brown [4, 5]. Much milder conditions imply the existence of a minimax procedure and a least favorable sequence of priors, $\{P_i : i = 1, \ldots\}$, such that

$$\sup_i R^*(P_i, \delta_{p_i}) = M. \qquad (2)$$

Virtually all statisticians have agreed that in the presence of confidently held prior probability beliefs a Bayes procedure should be used. Of course, there has been and continues to be considerable disagreement as to how strongly and how universally held prior belief needs to be, and as to the meaning of prior probability itself.

The key equalities (1) or (2) suggest an alternative approach to the choice-of-procedure dilemma which may be appropriate in the absence of confidently held prior probability beliefs. They imply that the minimax procedure is an optimal approach against a malevolent "nature". Such a "nature" is one who could either divine the statistician's intended procedure and then pick an $F \in \mathscr{F}$ so as to maximize the statistician's risk, or one who could merely arrange always to choose F by the least favorable prior when (1) holds and by a nearly least favorable one when only (2) holds.

Because of this, some statisticians have suggested that minimaxity provides an objective criterion leading to a unique and satisfactory choice of decision procedure for each non-Bayesian decision problem. Wald may himself have felt this way in the 1940s but apparently abandoned this belief by the time of his sudden death in 1950. For further discussion, consult Savage [20, 21] and Brown [6]. One reason for the abandonment of this idea was the early realization that there are situations where an ε-minimax procedure has a risk function which would be preferred by all but the most pessimistic statistician over that of the minimax procedure. See, for example, Hodges & Lehmann [9], Robbins [19], and Wolfowitz [27].

The discovery by Stein [12, 22] that **shrinkage estimators** may dominate the usual minimax estimator of a multivariate mean is definitive evidence that, at best, the minimax principle does not provide a *unique* objective solution in many common statistical settings.

Minimaxity has been – and continues to be – an important and stimulating concept for statistics, in spite of its failure to provide universally appropriate procedures. It has played an essential role as a motivation and as an organizing principle in many important statistical areas. It often also provides a benchmark against which other proposed procedures can be measured.

Areas where minimaxity plays a key role include asymptotic analysis (via the concept of local asymptotic minimaxity) as in LeCam [15] or Lehmann [17], **robust** estimation theory as in Huber [10, 11], robust Bayesian methodology (via the notion of Γ-minimaxity) as in Berger [1], **optimal design** of experiments as in Kiefer & Wolfowitz [14] and Kiefer [13], and nonparametric function estimation as in Donoho & Liu [7] and Donoho et al. [8]. See Brown [6] as well as other references cited there for more details.

Minimum Therapeutically Effective Dose

Moore [10] indicates that the difference between a drug and a poison is the dose. Hence, it is extremely important to identify the dose range of a drug product that provides effective and safe treatment of a certain disease. The lower limit of this dose range is usually referred to as the minimum therapeutically effective dose (MTED). As a result, the MTED is defined as the lowest dose level of a drug product yielding a therapeutically significant response in average efficacy that is also statistically significantly superior to the response provided by the placebo [6, 11, 13]. According to this definition, the MTED must produce a response with a magnitude of clinical superiority over the placebo, since a small but statistically significant response resulting from either large sample sizes or small variability can be of no real therapeutical meaning (*see* **Clinical Significance Versus Statistical Significance**). Furthermore, the MTED must yield a statistically significant clinical response. This is because a large response produced at a certain dose level, if it is statistically insignificant from the placebo response, fails to establish the scientific evidence of effectiveness for that dose level. Similarly, the maximum tolerable dose (MTD) is the highest possible, but still tolerable, dose level with respect to a prespecified clinical limiting toxicity [9, 15]. The maximum effective dose (MED) is the highest dose level beyond which no additional therapeutically meaningful improvement in average efficacy can be achieved. The therapeutic range (window) is then defined as the range of the dose levels from the MTED, denoted by d_{L}, to the minimum of MTD and MED, denoted by d_{U}. If d_{L} is much smaller than d_{U}, then the corresponding drug product is said to have a wide therapeutic window. However, if the MTD is very close to, or even smaller than, the MTED, then the drug product is of no practical therapeutical use. The definition discussed above focuses on the average efficacy of a patient population. Fillon [6] gives a definition of the MTED for a particular patient as the lowest dose level that provides a prespecified therapeutical effectiveness above a predetermined percentage of patients. We refer to the first traditional definition as the population MTED (PMTED) and the second definition as the individual MTED (IMTED).

Study Design

The MTED is usually estimated from the data of primary efficacy endpoints from dose-ranging or **dose-response** clinical trials conducted during phase II clinical development of a drug product. These dose–response studies are usually randomized, double-blind, parallel-group designs with inclusion of a concurrent placebo group. Occasionally, a **crossover design** such as Williams' design [4] is employed. Many clinicians, however, find that a variety of titration designs, either with or without a concurrent parallel placebo group for dose-ranging studies, are useful because they mimic clinical practices in the real world. For details on designs for dose-response trials, see ICH E4 guideline [8].

Inclusion of a placebo is essential for estimation of the MTED, because a dose of any drug product cannot establish its therapeutical effectiveness without comparison with a placebo. In addition to choosing an appropriate statistical design, the selection of dose levels, the number of dose levels, and sample sizes for each dose group are crucial for estimation of the MTED. These issues are not only related to each other, but are also very difficult to deal with. The dose range should be chosen as wide as possible within the safety limit so that the dose–response relationship can be adequately characterized. For the same reason, the number of dose levels, including the active agent and the placebo, should be at least three. It is also preferable to select a dose level whose response is not expected to be statistically different from the placebo response, so that the MTED can be estimated more precisely. **Sample size determination** includes estimation of the total sample size and its distribution across different dose groups. As indicated by Ruberg [13], sample size should be determined on the basis of statistical tests for the hypotheses of interest for primary efficacy clinical endpoints.

Statistical Analysis

Basically, there are two commonly used approaches for estimation of the MTED. One is the method of **hypothesis testing** based on the **analysis of variance** (ANOVA). It consists of step-down, step-up, and single-step procedures. The step-down procedures include Dunnett's step-down procedure, Williams' test for ordered alternatives [17], and the step-down

linear contrasts [1, 16]. The **Bonferroni** procedure proposed by Hochberg [7], and its later refinement by Dunnett & Tamhane [5], in conjunction with the application of Helmert contrasts, are typical step-up procedures for estimation of the MTED. Ruberg [12] introduced the application of the step contrasts and basin steps as single-step procedures to estimating the MTED. The MTED estimated by the ANOVA will be one of the dose levels evaluated in the trial. An interval estimation for the MTED has not yet been developed for the ANOVA approach. Although a functional form such as the four-parameter logistic function is generally required, both point and interval estimates can be obtained by the model-based approach [14]. In addition, one can incorporate more directly the information of the therapeutically effective response into the assumed model for estimation of the MTED. Nonparametric methods for identification of MTED are also proposed [2, 3]. Ruberg [13, 14] gives a comprehensive review of the current state-of-the-art in design and estimation of the MTED.

Discussion

The therapeutically meaningful response can be expressed either as the original actual response at a particular dose level or as an additional clinically meaningful improvement over the placebo response. All approaches described above assume the therapeutically significant response a priori as a known constant. This assumption relies on the external validity of the past history, and previous experience of the disease under study, for the assumed clinically meaningful responses. This assumption is reasonable, provided that the placebo response has been well established by adequate, well-controlled studies and the medical condition is well understood for evaluation of the drug product. For internal validity, however, the therapeutically significant response should be determined by the response provided by a current placebo control group.

Minimum Variance Unbiased (MVU) Estimator

Methods for determining the minimum possible variance of an **unbiased** estimator constitute a fundamental topic in mathematical statistics. An estimator T^* is minimum variance unbiased (MVU) for $g(\theta)$ when

$$\mathrm{E}_\theta(T^*) = g(\theta)$$

and

$$\mathrm{var}_\theta(T^*) \leq \mathrm{var}_\theta(T), \quad \text{for all } T \text{ such that } \mathrm{E}_\theta(T) = g(\theta). \tag{1}$$

Two primary results that relate to MVU estimators are the **Cramér–Rao Inequality** [1, 6, 13], and the **Rao–Blackwell theorem** [3, 17].

Information Inequality

Assume that a statistic $T_n = t(X_1, X_2, \ldots, X_n)$ is an estimator of $g(\theta)$, where $X_1, X_2, \ldots$ is a sequence of independent, identically distributed **random variables** with probability density function $f(x;\theta), \theta \in \Theta$. Under certain regularity conditions (*see* **Cramér–Rao Inequality**), if $\mathrm{E}(T_n) = g(\theta)$, then

$$\mathrm{var}_\theta(T_n) \geq \frac{[g'(\theta)]^2}{n\ \mathrm{E}_\theta\left\{\left[\dfrac{\partial}{\partial\theta}\ln f(X;\theta)\right]^2\right\}}. \tag{2}$$

This result is known as the Cramér–Rao inequality (or the **information** inequality). The right-hand side (RHS) of (1) is called the Cramér–Rao (or information) lower bound.

Clearly, whenever the variance of an unbiased estimator is equal to the RHS, that estimator is MVU. The lower bound is attained if and only if

$$\frac{\partial}{\partial\theta}\ln f(X;\theta) = K(\theta, n)[T_n - g(\theta)]. \tag{3}$$

It follows from (3) that if T is an unbiased estimator of a function $g(\theta)$, and $\mathrm{var}_\theta(T_n)$ attains the lower bound in the RHS of (1), then $f(x;\theta)$ belongs to an **exponential class**:

$$f(x;\theta) = \exp[A(\theta)B(x) + C(x) + D(\theta)] \tag{4}$$

for appropriate functions A, B, C, and D. In this case, the estimator T_n is given by $\sum_{i=1}^n B(x_i)$. We see below that (4) is also a sufficient condition for MVU estimators.

In general, the Cramér–Rao inequality is not sharp, so that other methods are necessary to find lower bounds for MVU estimators. When the lower bound cannot be obtained, "better" (i.e. greater) lower bounds than (2) can be obtained. For example, Bhattacharya [2] obtains better lower bounds using higher-order derivatives of the score function (*see* **Likelihood**). However, improvements in the Cramér–Rao lower bound are only of order $O(1/n^2)$ [8] (*see* **Orders of Magnitude**). Using other methods, Kiefer [9] and Chapman & Robbins [5] derive minimum variance bounds that are better than (2) and avoid regularity conditions.

Rao–Blackwell Theorem

A statistic $S = s(X_1, X_2, \ldots, X_n)$ is **sufficient** for θ if the **conditional probability** distribution of X given S does not depend on θ for any s. If $S_1, S_2, \ldots, S_k$ are sufficient for θ and T^* is unbiased for $g(\theta)$, then the following hold:

1. Let $T^* = \mathrm{E}_\theta(T|S_1, S_2, \ldots, S_k)$. Then $\mathrm{E}(T^*) = g(\theta)$.
2. $\mathrm{var}_\theta(T^*) \leq \mathrm{var}_\theta(T)$ for all θ.
3. $\mathrm{var}_\theta(T^*) < \mathrm{var}_\theta(T)$ for some $\theta \in \Theta$ unless $T = T^*$ with probability 1.

This result is due to Rao [14] and Blackwell [3]. It supplies a method for improving the variance of any unbiased estimator of $g(\theta)$ that is not a function of a sufficient statistic.

If the family $f(x;\theta)$ is "complete", then further results are possible. A family of densities $f(x;\theta)$ is said to be complete when $\mathrm{E}_\theta[z(T)] = 0$ for all $\theta \in \Theta$ implies $\Pr_\theta[z(T) = 0] = 1$ for all $\theta \in \Theta$. If S is a complete, sufficient statistic and $\mathrm{E}_\theta[T(S)] = g(\theta)$, then $T(S)$ is MVU for $g(\theta)$ [11].

When $f(x;\theta)$ belongs to an exponential family and has the form in (4), then $\sum_{i=1}^n B(x_i)$ is a complete sufficient statistic. Thus, for exponential families, if $T_n = \sum_{i=1}^n B(x_i)$ and $\mathrm{E}_\theta(T_n) = g(\theta)$, then T_n

is MVU. In this case, however, T_n satisfies (3), so that T_n achieves the Cramér–Rao lower bound.

Large-Sample Results

For any given n, a function of the sufficient statistic will have minimum variance for estimating its expected value. For large samples (*see* **Large-sample Theory**), *any* function of the sufficient statistic will estimate its expected value at the Cramér–Rao lower bound [8]. Finally, under slightly stronger assumptions (which hold for exponential families), all **maximum likelihood** estimates asymptotically approach the lower bound as $n \to \infty$ (Serfling [17], after Cramér [7]).

Bibliography

These topics are covered to some extent in any book on mathematical statistics. Mood et al. [12] and Casella & Berger [4] both give thoughtful and cohesive discussions of MVU estimators at an undergraduate mathematical level. The presentation by Stuart & Ord [8] is more complete and more technical, but equally useful in its synthesis of the various theoretical components. Lehmann and Casella [10], Rao [15], and Rohatgi and Saleh [16] also give extensive and rigorous treatments of the topic.

Mining Time Series Data

Time series data is ubiquitous; large volumes of time series data are routinely created in medical and biological domains, examples of which include **gene expression** data [1], electrocardiograms, electroencephalograms, (*see* **Clinical Signals**), gait analysis, **growth development** charts, and so on. Although statisticians have worked with time series for more than a century, many of their techniques hold little utility for researchers working with massive time series **databases** (for reasons discussed below).

The major tasks considered by the time series data mining community are as follows:

- *Indexing* (Query by Content): Given a query time series Q, and some **similarity/dissimilarity** measure D(Q, C), find the most similar time series in database *DB* [3, 6, 10, 15].
- ***Clustering***: Find natural groupings of the time series in database *DB* under some similarity/dissimilarity measure D(Q, C) [1, 5, 11, 13].
- ***Classification***: Given an unlabeled time series Q, assign it to one of two or more predefined classes [7, 13].
- ***Prediction*** (**Forecasting**): Given a time series Q containing n datapoints, predict the value at time $n + 1$.
- ***Association*** *Detection*: Given two or more time series, find relationships between them. Such relationships may or may not be **causal** and may or may not exist for the entire duration of the time series [4].
- *Summarization*: Given a time series Q containing n datapoints, where n is an extremely large number, create an (possibly graphic) approximation of Q, which retains its essential features but fits on a single page, computer screen, and so on [9, 18].
- *Anomaly detection* (interestingness detection): Given a time series Q, assumed to be normal, and a unannotated time series R, find all sections of R, which contain anomalies or "surprising/interesting/unexpected" occurrences [8, 12, 17].
- *Segmentation*: Given a time series Q containing n datapoints, construct a model $\overline{Q}$, from K piecewise segments ($K \ll$ n) such that $\overline{Q}$ closely approximates Q [13].

Note that indexing and clustering make *explicit* use of a distance measure, and many approaches to classification, prediction, association detection, summarization, and anomaly detection make *implicit* use of a distance measure. In this article, we will not consider distance measures in depth, instead we refer the reader to **Time Series Similarity Measures**.

It is interesting to note that with the exception of indexing, research into the tasks enumerated above predate not only the decade old interest in **data mining**, but in computing itself. What then are the essential differences between the classic versions and the data mining versions of these problems? The key difference is simply one of size and scalability; time series data miners routinely encounter datasets that are gigabytes in size. As a simple motivating example, consider hierarchical clustering. The technique has a long history and a well-documented utility. If, however, we wish to hierarchically cluster a mere million items, we would need to construct a matrix with 10^{12} cells, well beyond the abilities of the average computer for many years to come. A data mining approach to clustering time series, in contrast, must explicitly consider the scalability of the **algorithm** [11].

In addition to the large volume of data, it is often the case that each individual time series has a very high dimensionality [3]. Whereas classic algorithms assume a relatively low dimensionality (for example, a few measurements such as "height, weight, blood sugar etc."), time series data mining algorithms must be able to deal with dimensionalities in the hundreds and thousands. The problems created by high dimensional data are more than mere computation time considerations; the very meanings of normally intuitive terms, such as "similar to" and "cluster forming" become unclear in high-dimensional space. The reason is that, as dimensionality increases, all objects become essentially equidistant to each other, and thus classification and clustering lose their meaning. This surprising result is known as the "curse of dimensionality" and has been the subject of extensive research [2]. The key insight that allows meaningful time series data mining is that although the actual dimensionality may be high, the *intrinsic* dimensionality is typically much lower. For this reason, virtually all time series data mining algorithms avoid operating on the original "raw" data; instead, they consider some higher-level representation or abstraction of the data.

Time Series Representations

As noted above, time series datasets are typically very large; for example, just eight hours of electroencephalogram data can require in excess of a gigabyte of storage. This is a problem because for almost all data mining tasks, most of the execution time spent by algorithm is used simply to move data from disk into main memory. This is acknowledged as the major bottleneck in data mining, because many naïve algorithms require multiple accesses of the data. As a simple example, imagine we are attempting to do k-means clustering of a dataset that does not fit into main memory. In this case, every iteration of the algorithm will require that data in main memory be swapped. This will result in an algorithm that is thousands of times slower than the main memory case.

With this in mind, a generic framework for time series data mining has emerged. The basic idea can be summarized as follows.

It should be clear that the utility of this framework depends heavily on the quality of the approximation created in step 1. If the approximation is very faithful to the original data, then the solution obtained in main memory is likely to be the same or very close to the solution we would have obtained on the original data. The handful of disk accesses made in step 2 to confirm or slightly modify the solution will be inconsequential compared to the number of disk accesses required if we had worked on the original data. With this in mind, there has been a huge interest in approximate representation of time series. Figure 1 illustrates a hierarchy of every representation proposed in the literature.

To develop the reader's intuition about the various time series representations, we have illustrated four of the most popular representations in Figure 2 (*see* **Spectral Analysis**; **Wavelet Analysis**).

Given the plethora of different representations, it is natural to ask which is best. Recall that the more faithful the approximation, the less clarification disk accesses we will need to make in step 3 of Table 1. In the example shown in Figure 2, the discrete Fourier approach seems to model the original data the best; however, it is easy to imagine other time series where another approach might work better. There have been many attempts to answer the question of which is the best representation, with proponents advocating their favorite technique [3, 6, 15, 16]. The literature abounds with mutually contradictory statements, such as "Several wavelets outperform the ... DFT" [15], "DFT-based and DWT-based techniques

Table 1 A generic time series data mining approach

1)	Create an approximation of the data, which will fit in main memory, yet retains the essential features of interest.
2)	Approximately solve the problem at hand in main memory.
3)	Make (hopefully very few) accesses to the original data on disk to confirm the solution obtained in step 2, or to modify the solution so it agrees with the solution we would have obtained on the original data.

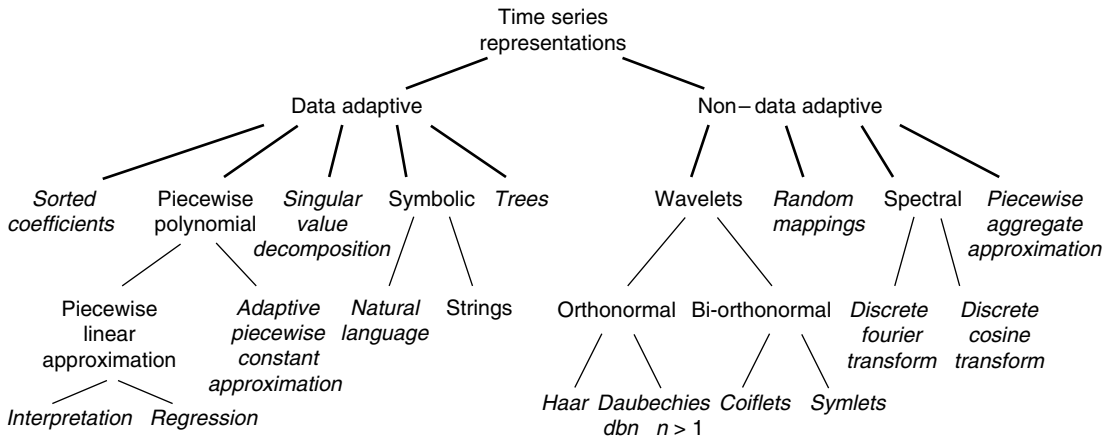

Figure 1 A hierarchy of time series representations

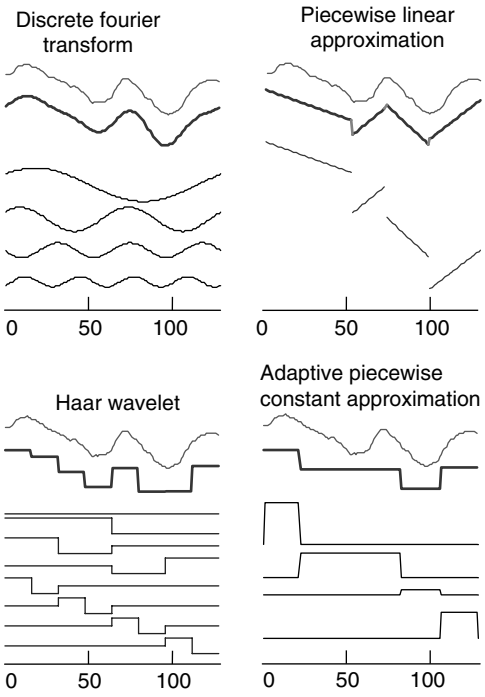

Figure 2 Four popular representations of time series. For each graphic, we see a raw time series of length 128 datapoints. Below it we see an approximation using 1/8 of the original space. In each case, the representation can be seen as a linear combination of basis functions. For example, the discrete Fourier representation can be seen as a linear combination of the four sine/cosine waves shown at the bottom of the graphic

yield comparable results" [19], "Haar wavelets perform. . . better that DFT" [10]. However an extensive empirical comparison on 50 diverse datasets suggests that while some datasets favor a particular approach, overall there is little difference between the various approaches in terms of their ability to approximate the data [14]. There are, however, other important differences in the usability of each approach [3]. We will consider some representative examples of strengths and weaknesses below.

The wavelet transform is often touted as an ideal representation for time series data mining because the first few wavelet coefficients contain information about the overall shape of the sequence, while the higher-order coefficients contain information about localized trends [15, 17]. This multiresolution property can be exploited by some algorithms, and contrasts with the Fourier representation in which every coefficient represents a contribution to the global trend [6, 16]. However, wavelets do have several drawbacks as a data mining representation. They are only defined for data whose length is an integer power of two. In contrast, the piecewise constant approximation suggested by [20], has exactly the same fidelity of resolution as the Haar wavelet, but is defined for arbitrary length time series. In addition, it has several other useful properties, such as the ability to support several different distance measures [20], and the ability to be calculated in an incremental fashion as the data arrives [3]. Choosing the right representation for the task is the key step in any time series data mining endeavor. The points above only serve as a sample of the issues that must be addressed.

Readings

The field of time series data mining is relatively new and ever changing. Because of the length of journal publication delays, the most interesting and useful work tends to appear in top-tier conference proceedings. Interested readers are urged to consult the latest proceedings of the major conferences in the field. These include the ACM Knowledge Discovery in Data and Data Mining, IEEE International Conference on Data Mining, and the IEEE International Conference on Data Engineering.

EAMONN J. KEOGH

Misclassification Error

It was recognized early [3] that misclassification of categorical variables induces problems of analysis and interpretation. In epidemiology there has been continuing interest in assessing effects of misclassification on exposure–disease **associations**. More recent attention has been paid to methodology for estimating the misclassification structure and adjusting for resulting **biases**. This involves gathering auxiliary data through validation samples (*see* **Validation Study**) and repeated measurements. Although there are immediate parallels between the rationale for handling misclassification and the discussion on measurement errors in continuous exposure variables, the two topics have different historical paths and the statistical techniques differ in technical detail. **Measurement Error in Epidemiologic Studies** deals with the case of continuous covariates. Early reviews on the effects of misclassification include a bibliography by Dalenius [8] and a paper by Chen [4]. Kuha & Skinner [26] offer a more recent account. Here we describe effects caused by misclassification and present some of the methodology for adjustment.

Effects of Misclassification

Univariate Analyses

Let A^* denote the classification variable subject to error and A the true variable that the classification variable is intended to measure. We refer to A^* as a surrogate for A. For each unit (individual) the outcome of A, and A^*, falls into one of m mutually exclusive categories. Independence between units is assumed. We write the misclassification probabilities

$$\Pr(A^* = j|A = k) = \theta_{jk}, \quad j, k = 1, \ldots m.$$

The parameters θ_{jk} governing the misclassification structure may be collected into an $m \times m$ misclassification matrix $\Theta = [\theta_{jk}]$ with nonnegative elements and columns that sum to one. For a **binary** response, where $m = 2$ and the categories indicate the presence $(A = 2)$ or absence $(A = 1)$ of disease, the misclassification matrix involves only two parameters

$$\Theta = \begin{pmatrix} \theta_{11} & \theta_{12} \\ \theta_{21} & \theta_{22} \end{pmatrix} = \begin{pmatrix} \beta & 1-\alpha \\ 1-\beta & \alpha \end{pmatrix}. \quad (1)$$

The parameter α in (1) is called the **sensitivity** of the measuring instrument and β the **specificity**.

The effect of using the surrogate classification A^* may be summarized by

$$\pi_{A^*} = \Theta\pi_A,$$

where $\pi_{A*} = (\pi_{A*}(1), \ldots, \pi_{A*}(m))'$ and $\pi_A = (\pi_A(1), \ldots, \pi_A(m))'$ are the population proportions in the categories of the surrogate variable and the true variable, respectively. Sample proportions of A^* are thus biased estimates of π_A. The nature of this bias is most easily described in the binary case, where

$$\pi_{A*}(2) = (1-\beta)\pi_A(1) + \alpha\pi_A(2) \quad (2)$$

(for example [6]). Even when the misclassification matrix differs from the identity matrix it is clear from (2) that the two errors are mutually compensating if $(1-\beta)\pi_A(1) = (1-\alpha)\pi_A(2)$. The degree of compensation depends on the true proportions $\pi_A(1)$ and $\pi_A(2)$. An instrument with given misclassification matrix can thus induce different degrees of bias in different populations.

Bivariate Analyses

2 × 2 Tables. In a **two-by-two table**, let A define the presence or absence of disease and B two exposure groups, e.g. smokers and nonsmokers. We first consider the case where the response variable is subject to misclassification, i.e. A is measured by the surrogate A^*. Let $\pi_{A|B}(j|l)$ denote the proportion of units in the population for which $A = j$ in exposure group $B = l$, and let $\pi_{A*|B}(j|l)$ denote the corresponding proportion for A^*.

When focus is on the difference in the response proportions between the two exposure groups, then an **unbiased** estimator of the surrogate difference $\pi_{A*|B}(2|2) - \pi_{A*|B}(2|1)$ will in general be biased for the true difference $\pi_{A|B}(2|2) - \pi_{A|B}(2|1)$. The argument simplifies if both exposure groups have the same sensitivity α and specificity β. In this case the misclassification mechanism for A is said to be **nondifferential** with respect to B. It follows from (2) that under nondifferential misclassification

$$\pi_{A*|B}(2|2) - \pi_{A*|B}(2|1) = (\alpha + \beta - 1)[\pi_{A|B}(2|2) - \pi_{A|B}(2|1)]. \quad (3)$$

It is reasonable to expect each of the misclassification probabilities $1-\alpha$ and $1-\beta$ to be less than 0.5, in which case the factor $(\alpha+\beta-1)$ in (3) takes values between 0 and 1. The difference measured by the surrogate A^* is thus always smaller than the true difference based on A. The effect of nondifferential misclassification is to *attenuate*, i.e. "to make seem smaller", the difference in subclass proportions. This was noted by Rubin et al. [30] as early as 1956. Nondifferential misclassification similarly attenuates the ratio $\pi_{A|B}(2|2)/\pi_{A|B}(2|1)$ toward the null value of one (see, for example, [7]) (*see* **Bias Toward the Null**).

If, instead, the response variable A is correctly classified while the exposure B is misclassified as B^*, and if the misclassification of B is nondifferential with respect to A, then

$$\begin{aligned}\pi_{A|B*}(2|2)-\pi_{A|B*}(2|1) &= \frac{(\alpha_B+\beta_B-1)\pi_B(2)\pi_B(1)}{\pi_{B*}(2)\pi_{B*}(1)} \\ &\quad\times[\pi_{A|B}(2|2)-\pi_{A|B}(2|1)], \qquad (4)\end{aligned}$$

where $\pi_B=(\pi_B(1),\pi_B(2))'$ and $\pi_{B*}=(\pi_{B*}(1),\pi_{B*}(2))'$ are the population proportions of B and B^* respectively, and α_B and β_B are the sensitivity and specificity of the classification of B. The factor multiplying $\pi_{A|B}(2|2)-\pi_{A|B}(2|1)$ in (4) is again between 0 and 1, when $0<\alpha_B+\beta_B-1\le 1$, so that the effect is a similar type of attenuation as described above.

If both the response A and the exposure B are subject to misclassification, and if the surrogate pair (A^*, B^*) is jointly determined by the pair (A, B) through the misclassification probabilities $\Pr(A^*=j^*, B^*=k^*|A=j, B=k)$, then misclassification of A and B is said to be *independent* if

$$\begin{aligned}\Pr(A^*=j^*, B^*=k^*|A=j, B=k) &= \Pr(A^*=j^*|A=j, B=k) \\ &\quad\times\Pr(B^*=k^*|A=j, B=k),\end{aligned}$$

and it is *nondifferential* if

$$\Pr(A^*=j^*|A=j, B=k)=\Pr(A^*=j^*|A=j)$$

and

$$\Pr(B^*=k^*|A=j, B=k)=\Pr(B^*=k^*|B=k).$$

Under the condition of independent and nondifferential misclassification in A and B, Gullen et al. [20] show that an unbiased estimator of $\pi_{A*|B*}(2|2)-\pi_{A*|B*}(2|1)$ again attenuates the true difference. If on the other hand A, or B, or both, are subject to *differential* misclassification, then the bias inherent in $\pi_{A*|B*}(2|2)-\pi_{A*|B*}(2|1)$ can take any arbitrary form. A clear account of the possible effects of differential misclassification is presented by Goldberg [16] (*see* **Differential Error**).

Note that changes in the categorization of a misclassified variable may turn a nondifferential misclassification into a differential one. Wachholder et al. [34] discuss the situation in which A has three categories and is subject to nondifferential misclassification with respect to B. They show that combining two of the categories of A induces differential misclassification with respect to B. On a similar note, Flegal et al. [13] show that if a nondifferentially mismeasured continuous variable is dichotomized, this may induce differential error.

$2\times m$ Tables. When comparing proportions defined by a binary response A in three or more exposure subgroups ($m>2$) defined by B, the result in (3) holds when the response A is nondifferentially misclassified with respect to B. The ordering of the response proportions over exposure subgroups is thus preserved, but the differences are attenuated.

If, instead, the response A is correctly classified but the exposure B is subject to nondifferential misclassification, then (i) measures of association for response proportions between the two extreme exposure subgroups $B=1$ and $B=m$ are again attenuated, but (ii) associations between other exposure subgroups may be biased either away from or towards null [2, 15]. Exposure misclassification can even change the ordering of the response proportions in the intermediate subgroups and distort trends. However, if misclassification is confined to adjacent exposure subgroups, then attenuation occurs, but the ordering of the response proportions is retained [28].

Hypothesis Testing for Two-Way Tables. An important consequence of the attenuation results is that if there is no association between A and B, then there will be no association between the surrogates A^* and B^* under nondifferential misclassification in one variable [29] or under nondifferential and

independent misclassification in both variables [1]. The test of no association between A and B based on A^* and B^* will thus have the correct significance level (*see* **Hypothesis Testing**), but the **power** is in general reduced. Marshall et al. [28] show similar results for a test of no trend in subclass proportions for tables where the outcome A is binary and a polytomous subgroup variable B is nondifferentially misclassified.

Multivariate Analyses

The simplest **multivariate** case involves a $2 \times 2 \times 2$ table. Let A be a binary response variable and B and C binary variables defining subgroups of the population. In particular, B may refer to an exposure and C to a potential **confounder**.

If C is correctly classified, then we can consider the two-way tables between A and B separately for the two levels of C, and apply the bivariate results of the previous section. If only A is subject to nondifferential misclassification, then the difference in response proportions between the two exposure groups is attenuated by the factor given in (3). If, however, the exposure B is nondifferentially misclassified, we have from (4) that the degree of attenuation depends on the true proportions, in this case on $\pi_{B|C}(2|2)$ for $C = 2$ and on $\pi_{B|C}(2|1)$ for $C = 1$. If there is association between B and C, then the difference in response proportions between the two exposure groups may be attenuated to a different degree in the two categories of C. Nondifferential misclassification in the exposure may thus induce spurious heterogeneity (or mask true heterogeneity) in the exposure–disease association for different levels of the confounder [17].

If C is subject to nondifferential misclassification (with $0 < \alpha_C + \beta_C - 1 \leq 1$) with respect to A and B, which are both classified without error, then $\pi_{A|B,C*}(2|k, l)$ lies between the true proportions $\pi_{A|B,C}(2|k, l)$ and $\pi_{A|B}(2|k)$ for any $k, l = 1, 2$ [17, 26]. The proportions $\pi_{A|B}(2|k)$ are obtained by summing the data over the levels of C. This form of bias is known as residual confounding (for example [31]). It occurs because the analysis is restricted to the wrong levels of the confounder C, and thus the heterogeneity in the proportions due to confounding is not fully controlled for. The bias due to residual confounding may be either away from or toward the null value, and it can even induce a exposure–response association with the wrong sign. Both the size and power of a test of no association between A and B adjusted for C are thus incorrect when C is subject to nondifferential misclassification.

The above example of misclassification in a $2 \times 2 \times 2$ table may be extended in various ways. Some of the variables in a three-way table may be **polytomous** and there may be independent and nondifferential misclassification in more than one variable. In this case the effect of misclassification is a combination of attenuation and residual confounding [14]. Misclassification that is not both independent and nondifferential can produce any kind of biases (some examples are given by Greenland & Robins [19]).

For tables involving more than three variables it is not in general possible to give even qualitative statements about how misclassification distorts the analysis. One exception is a useful result due to Korn [24]: if there is independent and nondifferential misclassification in several variables in a multiway table, and if each of these misclassified variables appears in only one term of a **hierarchical loglinear model** specifying the association structure of the table, then this association structure is preserved under the misclassification. A test of **goodness of fit** for this loglinear model will have the correct significance level but reduced power. Korn [25] evaluates the loss of power due to misclassification when using a **likelihood ratio test** for comparing two nested models where the association structure is preserved.

Auxiliary Data on Misclassification

Adjustment for potential bias due to misclassification requires some information on the misclassification structure. If the structure is known, either through prior information or by assumption, then adjustment is straightforward. In general, however, the misclassification structure is unknown and estimated from a suitable set of *auxiliary data*, which are assumed to have the same misclassification parameters as the *primary data*. We briefly describe the two main types of auxiliary data: *validation samples* and *repeated measurements*.

Validation Samples

Both the true variable A, say, and the surrogate variable A^*, possibly together with other variables, are measured on each unit in a validation sample.

This raises two important questions: (i) How does one measure the true value A? (ii) How should the units in the validation sample be selected?

A measurement of A may be possible using an instrument referred to as the **gold standard**. It may be too expensive, however, to use the gold standard on all units in the primary study, or the gold standard may be available only for a subset of the units. The gold standard is a key concept in validation studies and the assumption that it measures A accurately, or with negligible error, is crucial (cf. [33], for a discussion of bias induced by using an erroneous or "alloyed" gold standard).

Ideally the validation sample should be a subsample of the primary data, obtained by a known randomized **double sampling** scheme. **Simple random sampling** from the primary data gives an *internal validation sample*, where the proportions in the categories of A in the validation sample are **unbiased** estimates of the corresponding population proportions. Both the misclassification probabilities $\Pr(A^*|A)$ and the **predictive values** $\Pr(A|A^*)$ in the population of interest can thus be consistently estimated from internal validation data. There may, however, be practical reasons that prevent such double sampling. If validation data from an earlier study are used, or if the gold standard is available only in a specific subpopulation, or if validation data are collected after the primary data are in hand, then it may be unreasonable to assume that the distribution over the categories of A are the same for units in the validation sample and in the primary study population. We then say that the validation data are *external*, and only the misclassification probabilities are assumed to be transportable between data sets.

Instead of using simple random sampling it may be useful to draw a prespecified proportion of the validation sample units within each category of A^*. This increases the efficiency in estimating the predictive values $\Pr(A|A^*)$, and is thus useful in internal validation studies [21].

Repeated Measurements

Even without a gold standard it may be possible to estimate misclassification parameters from repeated measurements of the surrogate. The measurements may be replicates using the same instrument or they may be obtained using different instruments. The distinction between internal and external data is relevant also for repeated measures, and which of these is in question depends on how the distributions over categories of A are related in the auxiliary and primary data sets.

For models based on repeated surrogate measures to be **identifiable**, a sufficient number of the measurements should be conditionally independent given the true value A. The required number depends on the model; some simple models are identifiable from just two measurements, while three measurements are sufficient for most models (see [35] and [27] for general identifiability conditions).

Adjusting for Effects of Misclassification

Misclassification parameters estimated from auxiliary data may be used to estimate parameters of interest adjusting for the biases induced by misclassification. Here we describe three classes of adjustment methods: simple matrix methods and model-based methods using either validation data or repeated measurements.

Matrix Methods

The most straightforward way to adjust for misclassification is via simple **back-calculation**. We refer to this as the *matrix method* of adjustment. The aim is to estimate the vector of cell proportions π_A for variable A. Here A may represent one variable or the cross-classification of several variables. Suppose that a primary data set and a validation data set are available, with n_p and n_v observations, respectively. The validation data provide an estimate, denoted by $\hat{\Theta}(A^*|A)$, for the matrix of misclassification probabilities $\theta_{jk} = \Pr(A^* = j|A = k)$. A matrix estimate of π_A is given by

$$\hat{\pi}_A^m = \{\hat{\Theta}(A^*|A)\}^{-1}\hat{\pi}_{A^*}, \tag{5}$$

with $\hat{\pi}_{A^*}$ the vector of observed cell proportions for the surrogate A^* in the primary data set. The analysis of interest is performed on the transformed table $\hat{\pi}_A^m$. An estimated variance matrix for $\hat{\pi}_A^m$, or any quantities derived from it, such as **odds ratios**, can be obtained using the **delta method** [18]. The simple matrix estimator (5) is well known in the epidemiologic literature. It is straightforward to compute, but has the drawbacks that the estimated probabilities are not constrained to lie between 0 and 1, and its small

sample properties may be poor due to the matrix inversion.

The estimator (5) can also be motivated as a **maximum likelihood** estimator (MLE) of π_A under a model where (i) π_A is unrestricted, (ii) the model for the misclassification probabilities is the one under which $\hat{\Theta}(A^*|A)$ was estimated (or taken as known), and (iii) the validation data are external. For most other models the MLE needs to be computed using iterative methods described in the next section. An important exception is a case where the validation data are internal and the model structure is such that there exists a one-to-one transformation from π_A and $\Theta(A^*|A)$ to π_{A^*} and $\Lambda(A|A^*)$, where $\Lambda(A|A^*)$ denotes the $m \times m$ matrix of predictive values $\Pr(A = i|A^* = j)$. The MLE of π_A is then also a closed-form matrix estimate, given by

$$\hat{\pi}_A^c = f_p \hat{\Lambda}(A|A^*)\hat{\pi}_{A^*} + (1 - f_p)\hat{\pi}_A^{(v)} \qquad (6)$$

where $f_p = n_p/(n_p + n_v)$, $\hat{\pi}_A^{(v)}$ is the vector of observed cell proportions of A in the validation data set, and $\hat{\Lambda}(A|A^*)$ is the matrix of predictive values estimated from the validation data. Estimates of this type were proposed by Tenenbein [32] for estimating cell probabilities of a single variable when both π_A and the misclassification probabilities are unrestricted. Tenenbein also gave formulas for the **variance** of $\hat{\pi}_A^c$.

In cases where (6) is the MLE of π_A, the external validation MLE $\hat{\pi}_A^m$ in (5) is also **consistent**, but not fully **efficient**. It may even have a higher variance than $\hat{\pi}_A^{(v)}$ alone. Surprisingly, the same is also true for the estimate $\tilde{\pi}_A^c = f_p\{\hat{\Theta}(A^*|A)\}^{-1}\hat{\pi}_{A^*} + (1 - f_p)\hat{\pi}_A^{(v)}$, which appears to be a compromise between (5) and (6). This estimate should not be used, because it is inconsistent when the validation data are external and less efficient than $\hat{\pi}_A^c$ when they are internal. Its variance may even *increase* with increasing n_p [26].

Matrix adjustments for misclassification are most useful in fairly simple problems with a small number of variables and few categories per variable. The estimates imply a model where the cell probabilities of the true variables are unrestricted and the model for the misclassification structure is either saturated (*see* **Generalized Linear Model**) or has a special form such as independent and nondifferential misclassification for all variables. In large problems this may lead to sparse tables and imprecise estimates for the many parameters. It is then desirable to consider more **parsimonious** models, especially when the focus is on **inference** about the association structure between the true variables. This can be done, at the expense of further model assumptions and some extra computing, by using model-based adjustment procedures described in the next section.

Modeling

Let A denote a set of variables subject to misclassification and A^* the corresponding set of surrogate variables, and let C be variables classified without error. It is also useful to define a sample indicator variable L which identifies the data set to which a unit belongs. L is binary when there is one primary sample and one validation sample, but other study designs can also be incorporated in this framework. The joint distribution of (A, A^*, C, L) may be specified through two submodels (cf. Espeland & Odoroff [12], who consider a slightly different set of models):

1. A model for the true variables (A, C, L). **Interactions** between L and (A, C) indicate differences in the distribution of the true variables between samples such as when a validation sample is external. The model of interest is the model for (A, C) in the primary sample.
2. A model for the misclassification probabilities, specified by interactions within A^* and between (A, C) and A^*. The model is saturated with respect to the true variables (A, C). Because the misclassification probabilities are assumed to be transportable between data sets, there should not be any interaction terms between L and A^*.

Both submodels are usually taken to be hierarchical loglinear models, but the joint model generated by them will not in general be loglinear [12].

The misclassification problem may be treated as one of incomplete **contingency tables**, collapsed over the margins corresponding to the unobserved variables. Suppose that there is one primary data set and one validation data set. The log **likelihood** function for the observed variables can be written as

$$L = \sum_{\text{prim}} n_{A^*C} \log \pi_{A^*,C} + \sum_{\text{val}} n_{AA^*C} \log \pi^{(v)}_{A,A^*,C} \qquad (7)$$

where n_{A^*C} are the observed cell counts for (A^*, C) in the primary data and $\pi_{A^*,C} = \sum_A \pi_{A,A^*,C}$ are the corresponding cell probabilities satisfying the specified model, and n_{AA^*C} and $\pi^{(v)}_{A,A^*,C}$ are the cell counts and probabilities for (A, A^*, C) in the validation data. The models may be fitted by maximizing (7) using iterative techniques, especially the **EM algorithm**. At the E step of the algorithm, observations from the observed (A^*, C) table in the primary data are allocated values of A to create a notionally complete (A, A^*, C) table. This is used at the M step, together with the validation sample, to fit the required joint model, and the process is iterated until convergence. Different versions of the EM algorithm for misclassification problems have been proposed by Chen et al. [5] and Espeland & Odoroff [12], who also consider the estimation of **standard errors** for the resulting estimates. The joint likelihood can also be maximized using other **algorithms** such as direct Newton–Raphson maximization [10, 11].

Methods Using Repeated Measurements

When the misclassification parameters are estimated from repeated measurements, the true values of the misclassified variables are latent variables (*see* **Path Analysis**) which are never observed. The misclassification probabilities and models of interest can be estimated from such data subject to appropriate identifiability assumptions. The analysis proceeds by specifying models for the true variables and misclassification as above and obtaining MLEs for their parameters. In some very simple cases, such as when estimating the proportions of a single binary misclassified variable, estimates are available in a closed form [22]. It is then also possible to use external repeated measurements to estimate the misclassification matrix in the matrix estimate (5) [9]. For most models, however, estimates have to be obtained iteratively, using general techniques of **latent class** modeling (see, for example, [23]). The calculations may again be conveniently carried out using the EM algorithm.

Conclusions

Misclassification induces bias in the estimates of quantities of interest obtained from observed surrogate variables. In some special cases it is possible to characterize qualitatively the nature of the bias, such as when measures of association are attenuated. In many situations, however, biases in any direction are possible. It is then desirable to collect auxiliary data such as validation data or repeated measurements from which the misclassification probabilities can be estimated, and to use these estimates to adjust analyses explicitly for the effects of misclassification. The most straightforward adjustment methods are simple matrix methods, which may, however, be unsatisfactory in larger models. Model-based adjustment methods may then be used for **estimation**.

Misclassification Models

Classification errors in **categorical data** may distort results of statistical analyses (*see* **Misclassification Error**). Models for misclassification processes have been developed to study and compensate for the effects of such errors, and hence protect the validity of data analyses. Such models have been applied in a number of biostatistical contexts including modeling the natural history of a disease or growth process (*see* **Growth and Development**), evaluation of **diagnostic tests**, and analytic **epidemiology**. Specific scientific questions in these contexts may require inferences about (i) an underlying biological process, reflected in statistical **associations** that might be obscured or distorted by nuisance misclassification; (ii) the misclassification process itself; or (iii) both the underlying and misclassification processes.

The true underlying process involves a categorical response that may be univariate binary, nominal, ordinal, or multivariate with any of these components. In most applications, misclassification is represented by a Bernoulli or multinomial **random variable**. Commonly, the misclassification rate depends on the true underlying response. Various approaches that tie together misclassification and the true response process have been proposed. Different applications require different statistical methods, each with specific advantages and limitations. Depending on the application, the parameters of the misclassification model are estimated using data from either the current or an additional, supplementary study.

In modeling the natural history of a disease, interest usually focuses on understanding the stochastic changes in the disease process over time. The choice of models for the true disease or growth process depends on various factors including the **measurement scale** of the process and whether observations are taken at regular or irregularly spaced intervals. Unfortunately, classifications of disease severity are often subject to error, and analytic models that ignore misclassification are prone to biased inferences, particularly, if misclassification is related to the underlying disease process. Approaches to account for misclassification have been developed for modeling disease and growth processes including HIV/AIDS (*see* **AIDS and HIV**), hypertension, parasitic infection, and sexual maturation.

Investigators often wish to estimate the accuracy or, equivalently, the error rate, of a diagnostic test (*see* **Diagnostic Test Accuracy**). In this context, diagnostic error is simply another name for misclassification. For a binary disease status, error can be characterized jointly by the **false negative** and **false positive rates**, and accuracy by their respective complements: **sensitivity**, the probability of testing positive when the disease is present, and **specificity**, the probability of testing negative when the disease is absent. Sensitivity and specificity are simple to estimate when a definitive **gold standard test** exists, but not when a gold standard is nonexistent or too costly to obtain (*see* **Diagnostic Test Evaluation Without a Gold Standard**). Various **latent class** modeling approaches, in which multiple tests are used to determine a model-based consensus estimate of true disease status, have been proposed to estimate diagnostic accuracy and error rates for cancer biomarkers, diagnostic imaging, dental examinations, and pathological classification (*see* **Diagnostic Tests, Multiple**).

In analytic epidemiology, interest typically centers on assessing associations among categorical variables, of which one or more are subject to misclassification. Methods will be discussed to correct for such classification errors using error rates estimated from a subgroup or other population. For example, a **case–control study** designed to relate cervical cancer to sexual partner's circumcision status might elicit the latter by proxy report of the woman, subject to error, rather than by interview or physical examination of the male partner. Data on both proxy-reported and actual circumcision status might be obtained from a subsample or a small external population, and the observed error rates used to adjust inferences on the cancer-circumcision relationship.

Modeling Growth or the Natural History of a Disease

Let n_i be the number of observations made on the ith of N individuals, and let $\boldsymbol{X}_i = (X_{i1}, X_{i2}, \ldots, X_{in_i})'$ and $\boldsymbol{Y}_i = (Y_{i1}, Y_{i2}, \ldots, Y_{in_i})'$ be random vectors respectively of observed and true disease states at each observation time. The Y_{ij} are assumed to be values of a **binary**, nominal, or ordinal variable describing the true underlying disease course or stage of growth, and the X_{ij} are the corresponding observed states after possible misclassification. The joint probabilities of

$\boldsymbol{Y}_i$ and $\boldsymbol{X}_i$ can be written as

$$P(\boldsymbol{Y}_i, \boldsymbol{X}_i) = P(\boldsymbol{X}_i|\boldsymbol{Y}_i)P(\boldsymbol{Y}_i), \tag{1}$$

where $P(\boldsymbol{Y}_i)$ is the probability of the true underlying disease or growth trajectory and $P(\boldsymbol{X}_i|\boldsymbol{Y}_i)$, which represents the misclassification process, is the **conditional probability** of the observed given the true trajectory.

Most approaches for modeling the natural history of a disease assume that the misclassification process at time t depends on the true disease process only through Y_{it} and not on the preceding path of true $(Y_{i1}, \ldots, Y_{i,t-1})$ or observed $(X_{i1}, \ldots, X_{i,t-1})$ disease stages, and thus that

$$P(\boldsymbol{X}_i|\boldsymbol{Y}_i) = \prod_{j=1}^{n_i} P(X_{ij}|Y_{ij}). \tag{2}$$

The misclassification process $P(\boldsymbol{X}|\boldsymbol{Y})$ and disease process $P(\boldsymbol{Y})$ are tied together through shared **covariates**.

Espeland et al. [14], Nagelkerke et al. [18], and Rosychuk and Thompson [22] have proposed models for longitudinal binary data subject to misclassification (*see* **Longitudinal Data Analysis, Overview**). Espeland et al. [14] focused on modeling an underlying progressive process with an absorbing state (i.e. one that individuals may enter but not leave). The authors use an **EM algorithm** [10] for parameter estimation and apply their methodology to dichotomous maturation data. Nagelkerke et al. [18] and Rosychuk and Thompson [22] respectively proposed Markov and semi-Markov models for modeling parasitic infection with an alternating binary process (*see* **Markov Chains**; **Markov Processes**; **Transition Models for Longitudinal Data**). Applications to other chronic diseases have also been proposed [7].

Albert et al. [3] proposed a model for longitudinal ordinal data (*see* **Ordered Categorical Data**) with misclassification. Similar to Espeland et al. [14], their approach is for underlying progressive processes and is applied to longitudinal sexual maturation data. We elaborate on this example to illustrate modeling of longitudinal categorical data with misclassification. Tanner staging is an ordinal rating scale for gender-specific sexual maturation that ranges from one (no sexual development) to five (full development). The National Growth and Health Study (NGHS) followed 1155 girls from age 9 or 10 to age 16 at yearly intervals, recording growth-related measures including Tanner staging. Tanner staging is prone to misclassification; biologically impossible decreases in maturation were reported during follow-up for 45% of the 1155 girls in the NGHS data. Other errors, such as recording an increase in sexual maturation stage when a girl has not in fact progressed, are not obvious but probably occur as frequently as more blatant misclassification. Here, Y_{ij} is a latent random variable reflecting the true Tanner stage, and X_{ij} is the recorded Tanner stage measurement. Scientific interest focused on examining the effect of age at a given stage of maturation on the rate of progressing to subsequent stages, and on comparing both true sexual development and Tanner stage misclassification across racial groups.

Assuming that diagnostic error is independent across visits (i.e., $X_{ij}|Y_{ij}$ is independent of $X_{ij'}|Y_{ij'}$) and that the underlying maturation process follows a first-order Markov chain, the joint probability of $\boldsymbol{X}_i$ and $\boldsymbol{Y}_i$ can be written as

$$P(\boldsymbol{X}_i, \boldsymbol{Y}_i) = P(\boldsymbol{X}_i|\boldsymbol{Y}_i)P(\boldsymbol{Y}_i) = \left(\prod_{j=1}^{n_i} P(X_{ij}|Y_{ij})\right) \times \left(P(Y_{i1}) \prod_{j=2}^{n_i} P(Y_{ij}|Y_{i,j-1})\right). \tag{3}$$

Denote the probabilities governing the underlying maturation process as the initial state probabilities $p_l = P(Y_{i1} = l)$ and the transition probabilities from state l to state m as $p_{lm} = P(Y_{ij} = m|Y_{i,j-1} = l)$.

To exploit ordinality of the sexual development stages and obtain a parsimonious and interpretable parameterization, Albert et al. [3] used **proportional odds** parameterizations for the underlying maturation process (*see* **Proportional-odds Regression**). First, the p_l were reexpressed in cumulative form as

$$\gamma_l = \text{logit } P(Y_{i1} \le l) = \text{logit } \left(\sum_{u=1}^{l} p_u\right), \tag{4}$$

where $-\infty \le \gamma_1 \le \gamma_2 \le \cdots \le \gamma_{k-1} < \gamma_k = \infty$. Second, the transition probabilities p_{lm} were similarly reparameterized as

$$\theta_{lm} = \text{logit } P(Y_{ij} \le m|Y_{ij-1} = l) = \text{logit}\left(\sum_{i=u}^{m} p_{lu}\right), \tag{5}$$

where $-\infty = \theta_{l1} = \theta_{l2} = \cdots = \theta_{l,l-1} \leq \theta_{ll} \leq \theta_{l,l+1} \leq \cdots \leq \theta_{l,k-1} \leq \theta_{lk} = \infty$ are restrictions on the parameters such that only monotonic increases in the underlying process are possible. Further, parameter reduction was achieved by presuming the θ_{lm} for each l to be linear in stages traversed, that is,

$$\theta_{lm} = \theta_l + \alpha_l(m - l) \tag{6}$$

for $l \leq m \leq k-1$ with $\alpha_l > 0, l = 1, \ldots, k-2$. Note that $\alpha_l \geq 0$ ensures that all the transition probabilities are nonnegative, as required by $P(Y_{ij} \leq m'|Y_{i,j-1} = l) \geq P(Y_{ij} \leq m|Y_{i,j-1} = l)$ if $m' \geq m$. For each maturation level l, large θ_l corresponds to high probability of remaining in state l, while α_l determines, given θ_l, the relative probabilities that girls who mature in a given year will mature one Tanner stage, or more than one stage.

Albert et al. additionally modeled the misclassification mechanism as

$$P(X_{ij} = m|Y_{ij} = l) = \begin{cases} \dfrac{\psi(l,m)}{1 + \sum_{\substack{\omega=1 \\ \omega \neq l}}^{k} \psi(l,\omega)} & l \neq m \\ \dfrac{1}{1 + \sum_{\substack{\omega=1 \\ \omega \neq l}}^{k} \psi(l,\omega)} & l = m \end{cases}, \tag{7}$$

where $\psi(l,m) = \exp(\lambda_l + \eta_l|l-m|)$. This parameterization specifies symmetric misclassification around the true state; for example, one is just as likely to underestimate as overestimate a child's true state by one. Large negative values of λ_l reflect high probability of correctly classifying the lth state, and of η_l reflect low chance of misclassifying by more than one state. An elaboration allowing asymmetric misclassification is

$$\psi(l,m) = \exp(\lambda_l + \eta_{1l}(l-m)I_{(l>m)} + \eta_{2l}(m-l)I_{(l<m)}), \tag{8}$$

where $I_{(x)} = 1$ when x is true and 0 otherwise.

Maximum likelihood estimation may be based on the marginal distribution (*see* **Marginal Probability**) of the observed $\boldsymbol{X}_i$'s, obtained as

$$L = \prod_{i=1}^{N} P(\boldsymbol{X}_i) = \prod_{i=1}^{N} \Bigg(\sum_{i_1=0}^{k} \sum_{i_2=i_1}^{k} \cdots \sum_{i_n=i_{n-1}}^{k} P(\boldsymbol{X}_i|\boldsymbol{Y}_i = (i_1, i_2, \ldots, i_n)) P(\boldsymbol{Y}_i = (i_1, i_2, \ldots, i_n)) \Bigg). \tag{9}$$

Direct maximization of this likelihood is computationally infeasible with five categories and eight follow-up time points, as in the Tanner staging example. An EM algorithm [10], incorporating a backward–forward algorithm (originally developed for fitting **hidden Markov models**) for evaluating the E-step [6], was used. Standard errors of model parameters were estimated using the nonparametric **bootstrap**. Linear terms were added to (6) (i.e. $\beta_l \text{Age}_{ij}, l = 1, 2, 3$, and 4, where Age_{ij} is the age of the ith child at the jth follow-up time), to allow the maturation process to depend on age. Separate models fit to white and black girls showed racial differences in both maturation and misclassification processes. Relative to their white counterparts, black girls were more mature at ages 9 to 10, passed more rapidly through Tanner stages (1–2), and were misclassified more frequently (tending to be classified at higher than actual maturity).

In some settings, disease states are defined by ranges of continuous measurements. For example, various stages in the progression of HIV/AIDS are defined by intervals of CD4 counts [23] (*see* **AIDS and HIV**). Errors in the continuous measurements then induce misclassification of disease state in a straightforward fashion. Satten et al. [23] proposed a misclassification model that exploits this structure. They model both the latent true value of the continuous variable conditional on the disease stage, and error in the continuous measurement. For the jth observation on individual i, let S_{ij} be the true disease state (e.g. disease stage for HIV/AIDS by intervals of CD4 counts), Y_{ij} be the continuous observation measured without error (e.g. the true CD4 count), and X_{ij} be the continuous observation measured with error (e.g. the observed CD4 count). Satten et al. [23] modeled the $\boldsymbol{S}_i = (S_{i1}, S_{i2}, \ldots, S_{in_i})'$ using a Markov process, and the Y_{ij} given S_{ij} as uniform over each interval for all stages but the highest unbounded interval, for which they used the upper half of a **log-normal distribution**. The Y_{ij} were assumed to be

observed only after perturbation by Gaussian measurement errors ε_{ij} with mean 0 and variance σ^2: $X_{ij} = Y_{ij} + \varepsilon_{ij}$. Estimation is based on maximizing the marginal likelihood of the observed X_{ij}'s, through an EM algorithm [10] with E-step using a backward–forward algorithm [6].

Motivated by a study of hypertension using data from the **Framingham** Heart Study, Albert [1] proposed a similar model for population-based follow-up where a binary disease status variable is defined by dichotomizing a continuous variable measured with error (*see* **Categorizing Continuous Variables**). At any follow-up time, an individual is assumed to be in the disease state (e.g. hypertensive) if the continuous variable (e.g. true diastolic blood pressure, DBP) exceeds a threshold (e.g. 95 mmHg), and disease-free otherwise. The population is assumed to be comprised of three types of individuals: (i) those always in the disease state, (ii) those never in the disease state, and (iii) those who migrate between states according to a two state Markov chain; that is, the population follows a "mover–stayer" model. The density of the continuous variable Y_{ij}, conditional on the true binary disease state S_{ij}, is modeled as

$$f(y|S_{ij}) = \begin{cases} 2\phi\left(\frac{y-c}{\sigma_1}\right) & \text{if } S_{ij} = 1 \text{ and } y > c \\ 2\phi\left(\frac{c-y}{\sigma_0}\right) & \text{if } S_{ij} = 0 \text{ and } y \le c \\ 0 & \text{otherwise} \end{cases}, \tag{10}$$

where $\phi(z)$ denotes the normal density at z (*see* **Normal Distribution**), c is the established cutoff for defining disease in the true continuous measurement, and σ_0^2 and σ_1^2 characterize the variability in the true continuous measurement given the true disease status 0 or 1. Y_{ij} is assumed to be measured with Gaussian $(0, \sigma^2)$ error as described above (i.e. we observe X_{ij}, where $X_{ij} = Y_{ij} + \varepsilon_{ij}$ and where ε_{ij} is Gaussian $(0, \sigma^2)$ error). Disease incidence as well as both point and period prevalence may be obtained as functions of model parameters, and estimated after maximizing the **marginal likelihood** of the X_{ij}'s using an **algorithm** similar to that of Satten et al. [23].

Modeling Diagnostic Error without a Gold Standard

In contrast to modeling natural history of a disease or growth process, interest in this application usually focuses on estimating the diagnostic error or misclassification and not the underlying true response. Let Y_{ij} be the test result for the j^{th} of n dichotomous tests on individual i, whose true disease status is d_i, and let $\boldsymbol{Y}_i = (Y_{i1}, Y_{i2}, \ldots, Y_{in})'$. All approaches assume a latent class model, where d_i is the latent class. The elements of $\boldsymbol{Y}_i$ have joint distribution

$$P(Y_{i1}, Y_{i2}, \ldots, Y_{in}) = \sum_{l=0}^{1} P(Y_{i1}, Y_{i2}, \ldots, Y_{in}|d_i = l)P(d_i = l), \tag{11}$$

where $P(d_i = 1)$ is the **prevalence** of disease in the population. The initial work in this area [9, 15] assumed that test responses are conditionally independent given true disease status, namely,

$$P(Y_{i1}, Y_{i2}, \ldots, Y_{in}|d_i) = \prod_{j=1}^{n} P(Y_{ij}|d_i). \tag{12}$$

The parameters of the model are the true **prevalence** $P(d_i = l)$ and the sensitivities and specificities, respectively $P(Y_{ij} = 1|d_i = 1)$ and $1 - P(Y_{ij} = 1|d_i = 0)$, for each of the n tests. More than 2 tests are required (i.e. $n \ge 3$) to identify these parameters. Maximum likelihood has been proposed for parameter estimation. Vacek [27] and Torrance-Rynard and Walter [25] investigated the effect of conditional independence on estimating diagnostic error, and showed that parameter estimators of sensitivity and specificity are usually biased when conditional independence is falsely assumed.

A number of papers have incorporated dependence between tests [16]. Espeland and Handelman [11] proposed **loglinear** models with higher order interaction terms to represent associations between tests. Models that incorporate conditional dependence through the introduction of **random effects** have also been proposed [21, 26]. In one random effects formulation [21],

$$P(Y_{i1}, Y_{i2}, \ldots, Y_{in}|d_i) = \int \left(\prod_{j=1}^{n} P(Y_{ij}|d_i, b) \right) \phi(b)\, \mathrm{d}b, \tag{13}$$

where $P(Y_{ij}|d_i, b) = \Phi(\beta_{jd_i} + \sigma_{d_i} b)$ and where $\phi(x)$ and $\Phi(x)$ are the standard normal density and cumulative distribution function, respectively. This integral can be numerically evaluated using Gaussian quadrature (*see* **Numerical Integration**). The sensitivities and specificities for each test can be evaluated by marginalizing over the random effect, and prove to be $\Phi\left(\beta_{j1}/\sqrt{(1+\sigma_1^2)}\right)$ and $1 - \Phi\left(\beta_{j0}/\sqrt{(1+\sigma_0^2)}\right)$, respectively.

Albert et al. [4] proposed a finite mixture model in which some individuals are always classified correctly by any test, while others are subject to diagnostic error. Let l_{id_i} be an indicator of whether the ith individual, given disease status d_i, is always classified correctly (i.e. $l_{i1} = 1$ when a truly positive specimen always tests positive and $l_{i0} = 1$ when a truly negative test always is rated negative), where $P_0 = P(l_{i0} = 1)$ and $P_1 = P(l_{i1} = 1)$. The probabilities of testing positive given d_i and l_{id_i} are

$$P(Y_{ij} = 1|d_i, l_{id_i}) = \begin{cases} 1 & \text{if } d_i = 1 \text{ and } l_{i1} = 1 \\ 0 & \text{if } d_i = 0 \text{ and } l_{i0} = 1 \\ \rho_j(1) & \text{if } d_i = 1 \text{ and } l_{i1} = 0 \\ 1 - \rho_j(0) & \text{if } d_i = 0 \text{ and } l_{i0} = 0 \end{cases}, \quad (14)$$

where $\rho_j(d_i)$ is the probability of the jth test making a correct diagnosis given that the individual is subject to diagnostic error ($l_{i1} = 0$ or $l_{i0} = 0$). The sensitivity and specificity for the jth test are $P(Y_{ij} = 1|d_i = 1) = P_1 + (1 - P_1)\rho_j(1)$ and $P(Y_{ij} = 0|d_i = 0) = P_0 + (1 - P_0)\rho_j(0)$, respectively. This finite mixture model is closely related to a latent class model of Espeland and Handelman [11], in which latent classes corresponding to unambiguously positive and negative cases are incorporated.

In a fourth approach to incorporating conditional dependence, Yang and Becker [28] proposed a **marginal model** that assumes only second-order interactions between tests conditional on the true disease status d_i (i.e. no third- or higher-order interactions). The major advantage of their approach is that estimates of sensitivity and specificity are simple functions of estimated model parameters. Yang and Becker parameterize $P(Y_{i1}, Y_{i2}, \ldots, Y_{in}|d_i)$ in (11) in terms of $\theta_j = \text{logit } P(Y_{ij} = 1|d_i)$, $j = 1, 2, \ldots, n$, as well as in terms of all pairwise log-**odds ratio** associations between tests

$$\gamma_{j,j'}(d_i) = \log\left[\frac{P(Y_{ij} = 0, Y_{ij'} = 0|d_i)P(Y_{ij} = 1, Y_{ij'} = 1|d_i)}{P(Y_{ij} = 0, Y_{ij'} = 1|d_i)P(Y_{ij} = 1, Y_{ij'} = 0|d_i)}\right]. \quad (15)$$

Yang and Becker propose an EM algorithm for parameter estimation and illustrate their methodology with 4 different tests of HIV given to 428 patients.

Shih and Albert [24] proposed a general methodology for analyzing **correlated binary data** subject to misclassification or diagnostic error. Their approach can be applied in situations in which a binary outcome is measured repeatedly in time or space and/or evaluated by several tests or raters, and in which the true disease status may change over time or space. Let y_{ijk} denote the observed binary response of the ith individual evaluated at the jth time point or spatial location by the kth test, and let d_{ij} be the true disease status of individual i at the jth time point or spatial location. Also, let $\boldsymbol{x}_{ij}$ denote a vector of covariates that may change across individuals and time/space. The following **generalized linear mixed model** was proposed for the true, correlated disease states within individuals:

$$\text{logit}\{P(d_{ij} = 1|\boldsymbol{x}_{ij}, b_i)\} = \boldsymbol{\beta}'\boldsymbol{x}_{ij} + b_i, \quad (16)$$

where b_i is a Gaussian random effect with mean 0 and variance σ^2. The misclassification model is

$$\text{logit}\{P(y_{ijk} = 1|d_{ij}, b_i)\} = \gamma_1 d_{ij} + \gamma_2(1 - d_{ij}) + \gamma_3 b_i, \quad (17)$$

where γ_1 and γ_2 govern the false negative and false positive rates, respectively. The fact that b_i is shared between the response and misclassification models induces a relationship between the probability of a true response and the probability of a misclassification. Specifically, the probability of a misclassification conditional on b_i is given by

$$P(d_{ij} = 0|b_i)P(y_{ijk} = 1|d_{ij} = 0, b_i) + P(d_{ij} = 1|b_i)P(Y_{ijk} = 0|d_{ij} = 1, b_i). \quad (18)$$

After substitution of (16) and (17), careful inspection of (18) reveals that the misclassification probability is smallest when b_i is positive and large, corresponding to high probability of disease, and when b_i is negative and large, corresponding to low probability of disease. This feature is attractive, since we would expect all tests to agree in unambiguous cases in which the probabilities of disease are either very close to one or zero.

Cook et al. [8] proposed another model in which multiple raters or tests assess the status of a binary disease process at multiple time points. The disease process is modeled with a first-order Markov chain but, as the authors note, extension to a Markov process for irregularly spaced binary observations is straightforward. The model allows for conditional dependence between raters at a given time point with a loglinear formulation similar to that of Espeland and Handelman [11].

There has been some criticism of these models. Alonzo and Pepe [5] criticize latent class modeling approaches for estimating diagnostic error without a gold standard, noting identifiability problems when using a small number of tests, and questioning whether a model-based consensus of truth makes biological sense.

Epidemiology

In this context, interest centers on estimating associations between categorical variables when some or all of these variables are subject to misclassification. There is a substantial literature on the effects of misclassification in association models, such as loglinear models. Ignoring random classification errors attenuates estimates of association, and results in loss of **power** for testing statistical significance. Estimators and tests of association may be even more severely compromised when misclassification depends on the variables involved in the associations.

For instance, **logistic regression** when the outcome variable is subject to misclassification has been discussed by various authors. Neuhaus [19] showed that ignoring misclassification in the binary responses can lead to highly biased estimates of model parameters (*see* **Unbiasedness**), while analysis accounting for misclassification may sacrifice substantial **efficiency** relative to analysis of the true responses. Neuhaus [20] presents analytic expressions demonstrating bias in parameter estimates for correlated binary models. He focuses on examining bias for a generalized linear mixed model with binary response, and for marginal approaches such as **generalized estimating equations**.

Since the categories of a binary observation may always be labelled as presence and absence of an event or characteristic, it is reasonable to adopt the terminology of diagnostic testing to describe misclassification in this context. Thus, letting $Y_i = 1$ if the disease or other characteristic is truly present for the ith individual and $Y_i = 0$ otherwise, and $T_i = 1$ if the ith subject is classified as diseased and $T_i = 0$ otherwise, we define the sensitivity and specificity of the observational process as respectively $sens = \text{Prob}(T_i = 1|Y_i = 1)$ and $spec = \text{Prob}(T_i = 0|Y_i = 0)$.

Magder and Hughes [17] proposed an EM algorithm for fitting logistic regression models when sensitivity is known or can be estimated from previous studies. They showed how the approach can be implemented with standard **software**, and discussed its extension to situations in which sensitivity and specificity are both unknown, emphasizing that estimation when diagnostic error is unknown may be sensitive to modeling assumptions. Given a set of known covariates $\boldsymbol{X}_i$, Magder and Hughes proposed a latent logistic regression model

$$\text{Prob}(Y_i = 1|\boldsymbol{X}_i, \boldsymbol{\beta}) = \frac{\exp(\boldsymbol{X}_i'\boldsymbol{\beta})}{1 + \exp(\boldsymbol{X}_i'\boldsymbol{\beta})}, \qquad (19)$$

where $\boldsymbol{\beta}$ is a vector of regression coefficients. Model (19) can be fit with standard logistic regression by including each individual as both diseased and nondiseased with weights equal to $\hat{Y}_i$ and $(1 - \hat{Y}_i)$, respectively, where $\hat{Y}_i$ is the probability that the ith individual is truly diseased given the values of T_i, $\boldsymbol{X}_i$, and $\boldsymbol{\beta}$. In the diagnostic testing context, $\hat{Y}_i$ is known as the "positive **predictive value**" when $T_i = 1$, and $(1 - \hat{Y}_i)$ is known as the "negative predictive value" when $T_i = 0$. Using **Bayes Theorem**, when $T_i = 1$,

$$\hat{Y}_i = \frac{\text{Prob}(Y_i = 1|\boldsymbol{X}_i, \boldsymbol{\beta})(sens)}{\begin{array}{c}\text{Prob}(Y_i = 1|\boldsymbol{X}_i, \boldsymbol{\beta})(sens) + \\ \text{Prob}(Y_i = 0|\boldsymbol{X}_i, \boldsymbol{\beta})(1 - spec)\end{array}}. \qquad (20)$$

Similarly, when $T_i = 0$,

$$\hat{Y}_i = \frac{\text{Prob}(Y_i = 1|\boldsymbol{X}_i, \boldsymbol{\beta})(1 - sens)}{\begin{array}{c}\text{Prob}(Y_i = 1|\boldsymbol{X}_i, \boldsymbol{\beta})(1 - sens) + \\ \text{Prob}(Y_i = 0|\boldsymbol{X}_i, \boldsymbol{\beta})(spec)\end{array}}. \qquad (21)$$

When *sens* and *spec* are known, Magder and Hughes proposed computing maximum likelihood estimates of $\boldsymbol{\beta}$ by iterating between fitting (19) using standard logistic regression software (again by including each subject as both a diseased and nondiseased observation with weights $\hat{Y}_i$ and $1 - \hat{Y}_i$, respectively) and reestimating the weights $\hat{Y}_i$ using (20) and (21) until the parameter values converge. When either or both of *sens* and *spec* are unknown, Magder and Hughes proposed an additional step in the iteration, at which the unknown quantities are estimated by

$$\widehat{sens} = \frac{\sum_i \hat{Y}_i T_i}{\sum_i \hat{Y}_i}$$

$$\widehat{spec} = \frac{\sum_i (1 - \hat{Y}_i)(1 - T_i)}{\sum_i (1 - \hat{Y}_i)}. \qquad (22)$$

However, Magder and Hughes mentioned that estimating sensitivity and specificity may be problematic for a number of reasons. First, for saturated models, parameter estimates may not be identifiable. Second, estimates may strongly depend on parametric assumptions in the logistic regression model.

There is also a large literature on modeling categorical data with misclassification under **double sampling**. In this situation, expensive and presumably error free methods are used in a smaller subsample, to assess misclassification in more extensive data obtained with comparatively economical but error prone procedures. For instance, Espeland and Odoroff [13] proposed a loglinear modeling approach allowing maximum likelihood estimation via an EM algorithm, and yielding straightforward expressions for variance estimates. Specifically, let A, B, and C be categorical factors observed on a large sample of N individuals and subject to misclassification. Denote A^*, B^*, and C^* as categorical factors not subject to error measured on a subsample of n of the original N individuals. Also, denote L as a binary factor indicating whether an individual is in the subsample in which more expensive confirmatory testing is undertaken. Espeland and Odoroff parameterized three distinct components required for double sampling models:

1. The model for the subsampling process, which describes the relationship between L and the other factors, is called the *sampling model*.
2. The model for the relationship between A and A^*, B and B^*, C and C^* is called the *misclassification model*.
3. The model for the relationship between A, B, and C is referred to as the *experimental model*.

These authors proposed a loglinear model for parameter estimation and impute missing cell counts (e.g. owing to the omission of more expensive and accurate measurements for individuals outside the subsample; *see* **Missing Data**) using an EM algorithm.

Espeland and Hui [12] illustrated the loglinear modeling approach with numerous epidemiologic examples including (i) a study of the association between cervical cancer and sexual partner's circumcision status, where circumcision status is self-reported for the entire sample of male partners, and a physical exam is done on a small subsample of these partners; (ii) a case–control study of the association between peptic ulcers and stomach cancer, in which self-reported history of peptic ulcer is obtained on all subjects, and a more careful peptic ulcer history is performed on a subset of subjects in the original sample.

Conclusions

Misclassification models have been applied in various application areas; we have discussed the modeling of a disease process, diagnostic error modeling, and association modeling in epidemiologic studies. When misclassification error rates are unknown and cannot or have not been estimated in previous studies, various methods for simultaneously estimating misclassification error and true response model parameters have been proposed. Although **identifiability** of parameters has been established for many of these models, the **robustness** of inference to misclassification modeling assumptions has received little examination. However, recent work of Albert and Dodd [2] on estimating diagnostic error without a gold standard demonstrates that estimators of diagnostic error may be asymptotically biased if the conditional dependence structure is misspecified. To complicate the situation, when the number of tests is small, the expected log-**likelihoods** for models with

different conditional dependence structures may be nearly identical [2], making model selection based on likelihood comparisons difficult or impossible. Thus, unverifiable modeling assumptions may be required to make inference on diagnostic errors without a gold standard. This suggests that robustness of misclassification error estimation to modeling assumptions in other contexts is an important area for future research.

Missing Data Estimation, "Hot Deck" and "Cold Deck"

The terms *hot deck* and *cold deck* refer to two related classes of methods used for imputation of missing values in sample surveys (*see* **Multiple Imputation Methods**; **Missing Data**). Many methods of imputation, especially those developed and used before the 1980s, involve direct "donation" of the value of a specific item from a record that has a measured value for the item to a record having nonresponse on the particular item. In his monograph entitled *Compensating for Missing Data in Surveys*, Kalton [2] defines the class of *hot deck* methods as any method involving such "donation" that takes the "donors" from the same sample survey as the recipients. The class of *cold deck* methods refers to analogous methods that take the donors from past data. As noted by Kalton [2], however, the term *hot deck* more often refers to a more specific set of sequential methods that has been used extensively for the imputation of items in the *Current Population Survey* [1]. We use it in this more restrictive sense and describe one variation of it below.

Description of the Hot Deck Method

In the hot deck method, cells are defined on the basis of variables that are considered "important" for imputation. These are generally variables that relate to the particular sample design used (e.g. **cluster**, **stratified**, etc.) or to demographic or other variables. The data are then sorted first according to these defined cells and secondly by other variables that are considered relevant for imputation. Following this, a register is then defined for each of the defined cells consisting of values of each variable that is to be imputed. The initial value of the register would consist of the value of each variable to be imputed for the first record in each cell that has recorded values for each of these variables. In a single pass through the data, the cell of each record is identified and, if a variable is missing, then it is given the value of that variable that is in the register for that cell. If, however, the record is complete on all variables to be imputed, then the values of the variables for this record replace the previous values in the registry for that cell. This process is repeated until all missing values are imputed. The process is the same for the cold deck method with the exception that the "donor" data are from a past survey.

Example

Let us consider a sample survey conducted on males 65 years of age and older in a large city and based on a two-stage cluster sample (*see* **Multistage Sampling**) in which the primary sampling units (PSUs) are blocks and the second stage units are households. The data consist of information collected from all males 65 years of age and older in 10 sample households within three sample blocks. The cell to be used in imputation are block (three categories) and age group (65–74 years/75 years and older). Data to be imputed are history of stroke ($1 = \text{yes}/2 = \text{no}$) and history of hypertension ($1 = \text{yes}/2 = \text{no}$). The data for each person, sorted by block and age group and listed by household within each of the six block–age group cells, are shown in Table 1. The records comprising the initial values of the register for each of the six cells are highlighted in boldface (records 2, 9, 14, 23, 26, and 34).

As one moves down the table, the first missing value is history of stroke in record 1. That value "2" is donated from record 2 (the record in the initial register for the block 1 – age group 65–74 cell). The next record having a missing value is record 5, which is also in the block 1 – age group 65–74 cell, and that record has missing values for both history of hypertension and history of stroke. The value "1" for history of hypertension and "1" for history of stroke is donated to record 5 from record 4 which comprises the registry at that point in the process. The entire imputation process proceeds in this fashion and is summarized in Table 2.

Comment

The above example illustrates one of a variety of similar methods that are generally discussed under the rubric *hot deck*. The major strengths of this category of methods are: (i) that data can be imputed very simply in a single "pass" of the data file; (ii) it always

Table 1 Data from sample survey of males 65 years of age and above

Record	Block	Age group "1" = 65–74 "2" = 75+	Household	History of hypertension "1" = Yes "2" = No	History of stroke "1" = Yes "2" = No
1	1	1	1	1	–
2	**1**	**1**	**2**	**1**	**2**
3	1	1	2	2	2
4	1	1	3	1	1
5	1	1	4	–	–
6	1	1	5	1	2
7	1	1	6	2	1
8	1	1	10	–	–
9	**1**	**2**	**1**	**1**	**1**
10	1	2	7	2	2
11	1	2	8	2	–
12	1	2	9	1	1
13	2	1	1	2	–
14	**2**	**1**	**3**	**2**	**2**
15	2	1	4	–	2
16	2	1	5	2	2
17	2	1	5	–	–
18	2	1	7	2	2
19	2	1	8	1	1
20	2	1	8	1	2
21	2	1	9	–	1
22	2	1	10	2	2
23	**2**	**2**	**2**	**1**	**1**
24	2	2	6	1	1
25	2	2	10	1	–
26	**3**	**1**	**1**	**1**	**1**
27	3	1	2	2	1
28	3	1	3	2	2
29	3	1	6	1	2
30	3	1	7	1	1
31	3	1	8	2	2
32	3	1	8	1	1
33	3	1	9	1	2
34	**3**	**2**	**4**	**1**	**2**
35	3	2	5	1	–
36	3	2	10	1	1
37	3	2	10	1	–

uses data that have been observed in the same data set; and (iii) imputation can generally be performed on records that have missing values for several variables more easily by this method than by methods based on more explicit **regression** models. The major weaknesses are: (i) it is not based on an explicit model; (ii) the values that are imputed depend on the ordering of records within cells, which gives them an aura of being somewhat arbitrary; and (iii) in subsequent analyses, the imputed values are considered as "real", and this often has an unpredictable effect on the estimated **standard errors** of statistics generated from the sample survey.

In summary, the class of hot deck methods is of importance not only historically but also in situations where resources or time are not available to consider more rigorous contemporary methods such as multiple imputation. Further discussion of this method, especially as used in conjunction with more contemporary methods, is presented in texts by Little & Rubin [3], Rubin [5], and in a chapter by Little & Schenker [4].

Table 2 Hot deck imputation process for data in Table 1

Record having missing value ("recipient")	Cell	Record comprising register ("donor")	Imputed value(s)
1	block 1, age group 1	2	history of stroke = 2
5	block 1, age group 1	4	history of hypertension = 1 history of stroke = 1
8	block 1, age group 1	7	history of hypertension = 2 history of stroke = 1
11	block 1, age group 2	10	history of stroke = 2
13	block 2, age group 1	14	history of stroke = 2
15	block 2, age group 1	14	history of hypertension = 2
17	block 2, age group 1	16	history of hypertension = 2 history of stroke = 2
21	block 2, age group 1	20	history of hypertension = 1
25	block 2, age group 2	24	history of stroke = 1
35	block 3, age group 2	34	history of stroke = 2
37	block 3, age group 1	36	history of stroke = 1

Missing Data in Clinical Trials

Missing data are a fact of life in **clinical trials**, and it is important that we have statistical techniques that can accommodate incomplete data. Missing data arise for a multiplicity of reasons, and indeed are so common that one should be highly suspicious of any clinical trial report that claims to have no missing data! An unusual reason for missing data occurred when a set of case record forms was destroyed in an explosion [1]. More commonly, a patient fails to attend a scheduled study visit, or a blood sample goes astray or is inadequately refrigerated. Sometimes, patients retrospectively withdraw their consent to participate in a trial. Equally, since **clinical trials protocols** tend to evolve over time, a new baseline **covariate** may be added to the record form, or a simplified **quality of life** questionnaire replaces a version that was unacceptable to the patients. Of course, such problems should be identified during pilot studies, but time constraints are such that it is not always possible to conduct adequate pilot tests. If there are changes to data collection during the course of a trial, then relevant data may not be recorded for the early patients. Another very common example of missing data is in trials where the outcome measure is a survival time. It would be unusual and generally rather inefficient to continue a trial until all of the recruited patients had died. Instead, we fix a final closing date, and analyze the data, accepting that the actual survival times are missing for the patients who are alive at the close of study (*see* **Censored Data**).

Types of Missing Data

There is no single approach that can cope with this variety of missing data. Before attempting to discuss solutions to the handling of missing data, it is helpful to classify different types of "missingness". Rubin [13] gives a useful taxonomy, and his terminology for the different mechanisms that can generate missing data is widely accepted (*see* **Missing Data**).

The first class comprises data that are "missing completely at random" (MCAR). Here, the presence or absence of an observation is completely unrelated to the value that might have been observed. For example, if a new question is added to a record form, then the data for early patients are expected to be MCAR. However, even in this simple situation, the missing data could fail to be MCAR if there is some underlying secular trend in the prognosis of the condition being studied. Similarly, if a laboratory test is not performed because equipment is out of order, then the data are most likely MCAR. In contrast, if a patient fails to attend an appointment, this might be, for example, because the patient feels too ill to travel, and since this reason is likely to be related to the outcome of the missing examination, it would be inappropriate to regard the data as MCAR.

Note that one must be very careful in interpreting the term MCAR. Even when the data are MCAR, the pattern of missing data can be systematic, as in the above example of a new question being added to a record form.

Data that are MCAR are generally straightforward to handle. For example, it would be valid to exclude the patients with incomplete data from analysis. This would not necessarily be efficient, but the approach would not introduce a systematic **bias** into the comparison of the treatments.

The second class comprises data that are "missing at random" (MAR). In this class, the fact that an observation is missing, after conditioning on the observed data, provides no further information. Murray & Findlay [11] give an example of a study of hypertension, in which patients were withdrawn from the study if, at a study assessment, their diastolic blood pressure (DBP) exceeded 110 mmHg. Thus, the fact that an individual's DBP was not recorded at the eight-week assessment provided no additional information to the observation that, at the four-week assessment, the DBP exceeded the threshold of 110 mmHg. Unlike for data that are MCAR, if the data are MAR, then it is not generally valid to exclude from the analysis the patients with incomplete data.

The key point when data are MAR is that there is no need to model the "missingness" mechanism explicitly. Provided that an appropriate statistical model can be developed to describe the observed data, then valid **inferences** can be made using **maximum likelihood** methods applied to the observed, incomplete data.

The final class comprises "nonignorable missing data". The most familiar example here is censored data, where it would be invalid to base inferences on

a **likelihood** function that incorporated data only from the uncensored observations. In the case of survival data, special techniques such as the **Kaplan–Meier estimator** have been developed which take due account of censoring, but any more advanced **parametric model** or semi-parametric model must incorporate a factor in the likelihood function which derives from the censored observations.

The fundamental point about nonignorable missing data is that it is not sufficient simply to model the observed data, but rather that the statistical model must incorporate the "missingness" mechanism.

Testing for Type of "Missingness"

In general, it is not possible to perform a formal test of the assumption that data are MAR, and instead one must rely on information that is external to the observed data [14]. Diggle & Kenward [4] give a special case of a model for **longitudinal data** with drop-outs, which allows one to test whether missing data are MCAR or MAR, but the method is heavily dependent on the validity of the general model within which the special cases of MCAR and MAR are nested. Thus the situation is circular, as the observed, incomplete data are insufficient to test the general model [14]. Nonignorable missing data mechanisms, and tests for types of "missingness", are areas of very active research. See, for example, Baker [2], and the references mentioned in that publication, for a lead into the current research.

Approaches to Analyzing Incomplete Data

A large number of techniques are available for analyzing incomplete data, ranging from *ad hoc* "fixes" to sophisticated modeling. The techniques can be grouped under three headings: analysis of complete cases, imputation, and modeling.

Analysis of Complete Cases

The simplest approach to handling missing data is to analyze only those individuals with complete data. Disadvantages of this approach are, first, that it is inefficient because we discard potentially useful information and, secondly, that we potentially introduce a bias if the incomplete cases are atypical of the study population. This second point cannot occur, by definition, if the data are MCAR; but in other situations, including when the data are MAR, an analysis based solely on complete cases is likely to be misleading.

Imputation

"Imputation" is the general term given to the process of filling in missing values. This approach can be very valuable, especially when the proportion of missing values is very low but, as with all missing data methods, should be used with care. Little & Rubin [8] give a good account of the different procedures and their limitations. A missing value can be replaced by an overall **mean** of the missing variable, or, using a **regression** approach, by its conditional **expectation** given the data observed for that individual. A further approach, popular within the pharmaceutical industry, is "last value" imputation [7]. This is generally used when there are drop-outs from longitudinal trials. In this approach, a missing value is replaced by the last observed value of that variable for the individual in question.

Imputations generally lead to a systematic underestimation of variability, if we proceed to analyze the completed data set as if all the data, including those imputed, were actually observed. The effects of this problem can be minimized by replacing each missing value with a value simulated from its conditional distribution, or by using the idea of **multiple imputation** [8]. With multiple imputation, the data set is completed several times over, and each completed data set is analyzed using standard complete-data techniques. The results of all of these analyses are then merged to give a final inference. If the imputed values are all derived from a single model of "missingness", the final inference incorporates the impact of the incomplete data under this model. If the completed data sets derive from different possible models of "missingness", then the final inference also reflects the uncertainty associated with model selection.

Modeling

Imputation procedures generally suffer from the lack of a sound theoretic basis. If, instead, we have a suitable statistical model, then inferences can be made using the maximum likelihood method. Indeed, if we have data which are MAR, then we need only

model the observed data. In this situation, the very flexible **EM algorithm** [3] allows maximum likelihood estimates to be derived. However, even in the most regular of situations, likelihood surfaces can be "badly behaved" when data are incomplete. Murray [9] gives an example with **bivariate normal** data, in which the likelihood surface has a saddle point.

With nonignorable missing data mechanisms, the statistical model must go further and include explicit assumptions about these mechanisms. As already mentioned, survival models that can incorporate censored observations are a good example of this approach. All such analyses are likely to be based on assumptions that can only be assessed using external information. A crucial part of any such analysis is a detailed **sensitivity analysis**, exploring the impact of departures from these assumptions [12].

As illustrated by Murray & Findlay [12], the appropriate handling of missing data can have a profound impact on the results of an analysis. The paper reports the results of a comparative trial in hypertension, where 131 of 429 (31%) patients had incomplete data, usually the result of being withdrawn according to the protocol when their blood pressure was inadequately controlled. In an analysis comparing the mean diastolic blood pressure in the two treatment groups at the end of the study, an inappropriate assumption of MCAR gave a difference of 1.2 mmHg in one direction, when the more appropriate assumption of MAR gave a difference of 1.2 mmHg in the other direction. The **standard error** was 1.1 mmHg, so the **bias** arising from the inappropriate assumption of MCAR was in excess of two standard errors.

Formulating the Question

Within the problem of identifying a suitable statistical approach to the analysis there often lies an issue of problem formulation [6]. What precise question is the analysis trying to address? The key distinction is between pragmatic and explanatory questions [10, 15] which, in the context of a clinical trial, is reflected in the distinction between "**intention-to-treat**" and "as-treated" analyses.

The explanatory approach asks a "what if" question. What would have been observed if patients had not withdrawn with side effects? What would have been observed if we had kept patients in the trial, even though their blood pressure was not controlled? The analysis referred to above [11], in which patients were withdrawn from a hypertension trial if their blood pressure was uncontrolled, leading to the data being MAR, addressed an explanatory "what if" question.

The pragmatic approach asks instead about the overall impact of a treatment on a patient. The fact that a patient is withdrawn from a trial is regarded as important in itself. The key to handling missing data in a pragmatic trial is somehow to include unfavorable events leading to withdrawals as part of the primary endpoint. For example, a patient who withdraws with side effects might be classified as a failure, whereas a patient who withdraws because all symptoms have resolved might be classified as a success.

An example of this approach is a trial of exercise tolerance in patients with heart failure following myocardial infarction. This was an ancillary protocol to the AIRE Study [16], a large mortality study in which patients were randomized to receive either placebo or an angiotensin-converting enzyme inhibitor. In the exercise substudy, patients undertook an exercise test six months after starting their randomized treatment. The active treatment proved very effective in reducing mortality (a reduction in hazard of 27%), which could potentially have invalidated the analysis of the exercise data. In theory, the least fit placebo patients, having died, may have left a selected healthy subset to undertake the exercise tests; whereas in the active group, more of the acutely ill patients may have survived, albeit with a limited ability to exercise. A simple comparison of average exercise duration in the two groups would then be misleading, as it would not compare like with like. The missing data process is nonignorable, since a missing value tells us that a patient was too unwell to exercise, or had already died. The analysis was therefore not based on average exercise duration. Instead, a threshold was set which defined a successful exercise test. A patient who died, or was unable to achieve the threshold exercise duration, was classified as a failure. This newly defined endpoint lost some efficiency, moving from a continuous outcome (exercise duration) to a **binary** one (success/failure), but assured no missing data and an **unbiased** analysis. Another example of this approach, which is close to a proposal of Gould [5], is reported by the Xamoterol in Severe Heart Failure Study Group [17].

GORDON D. MURRAY

Missing Data in Epidemiologic Studies

In analytic epidemiologic studies, such as **case–control studies**, **cohort studies** and related designs, data are usually collected by questionnaire or interview, or are abstracted from existing records, such as hospital records on treatment or diagnosis, personnel employment records on occupational exposures, or death certificates. Except in studies with a two-stage design (see below), complete information is sought for all subjects included in the study.

In case–control studies, one requires data on previous exposures that may have occurred long before the study. Adequate planning and organization are required to try to ensure that data are collected in an identical way for diseased persons (cases) and for healthy subjects (**controls**). Data are also collected on known or suspected **confounding** variables in order to adjust for these variables in the analysis. Preliminary data on matching variables, such as information on sex and age, are needed for matched case–control designs (*see* **Matching**). In cohort studies personal interviews are carried out infrequently, but data are often abstracted from existing files or records. In occupational cohort studies one can use personnel records to obtain data on the occupational history and sometimes on specific exposures; sometimes records from the office of the occupational hygienist or routinely collected data from the medical officer will be useful (*see* **Occupational Epidemiology**). The quality and completeness of such data may differ substantially between companies or even departments of the same company. Data quality may also differ for different job categories and could therefore depend on the exposure of interest. Disease information in cohort studies is sometimes abstracted from hospital records or from cancer registry files (*see* **Disease Registers**). In mortality studies, the date and **cause of death** are abstracted from official death certificates or from other sources. An important issue in planning and organizing cohort studies is to try to guarantee a nonselective retrieval of information for the personal history (occupational history, lifestyle, residential history). It is also important to avoid any selective follow-up to obtain the date of diagnosis or date of death. The diagnosis and/or the causes of death should be assessed in a comparable way for exposed and nonexposed subjects (*see* **Bias in Case–Control Studies**; **Bias in Cohort Studies**).

Sources of Missing Values in Epidemiologic Research

Unplanned Missing Values

Despite well-organized data collection efforts, data may contain errors, the data collection is sometimes incomplete, and missing values occur. Missing data can arise as total **nonresponse** or as item nonresponse. Total nonresponse results from refusal of subjects to participate in the study or from inability to locate the selected subjects. For example, in **population-based case–control studies,** controls may have been selected but are not accessible because they have recently moved. Total nonresponse is a frequent source of **selection bias**. In this article we restrict ourselves to item nonresponse, which refers to the lack of data on one or several items from a study participant but not on all items.

Item nonresponse may arise because a person refuses to answer certain questions. For example, if the question is too sensitive (e.g. alcohol consumption, sexual behavior, income, or health-related questions), a study participant may refuse to answer that item. What is regarded as sensitive may differ from one person to the next, and it may vary with personal behavior and/or depend on the answer to the sensitive question. Older people may be more willing to answer a certain question than younger people. Persons with a very high or very low income may not be willing to report it. Another reason for missing values is that subjects do not know the answer because they are unable to recall certain events. It also happens that a given answer is inconsistent with other answers and can therefore not be used in the analysis, as when a person says on one part of the questionnaire that she never smoked but later reports a consumption of 20 cigarettes daily. Missing values can also occur if the interviewer fails to ask all questions, as may happen if the interview is interrupted. Parts of the questionnaire may not be readable or may be destroyed during the process of editing. If data are abstracted from records, these records may be incomplete, illegible, or simply missing. Operating procedures in some departments of an industrial setting or a hospital may require records to be destroyed. In many situations, records include gaps or insufficient or uninterpretable

information, resulting in missing values. Similarly, measures based on chemical or physical procedures may fail to produce a value because required amounts of blood or tissue are not available, or because of a laboratory accident or technical failure. In all these cases the missing values are unplanned, and we usually have limited information on why the data are missing. This lack of information on the mechanism of missingness makes this type of missing value problematic during an analysis.

Planned Missing Values

Because epidemiologic studies may require thecollection of data on many variables for many subjects some sampling strategies have been developed that require less data. A two-stage design (*see* **Case–Control Study, Two-phase**) may be performed in which first-stage data on the disease and crude exposure status are collected for many subjects, but additional information on detailed exposure or on confounding variables is collected only for a subsample in a second stage. The second stage may include equal numbers of crudely exposed and unexposed subjects. In a two-stage design, a large amount of data can be missing, but the missingness is understood and under the control of the investigator. The probability that a value is missing is known or can be calculated easily and can be used for the analysis. Simple and efficient procedures to estimate exposure effects for such designs were proposed by White [60] already in 1982. Closely related ideas of planned missingness are found in **validation studies** in which an easy-to-measure surrogate variable is collected for all subjects, and "**gold standard**" measurements are made only for a subsample.

Missing Value Mechanisms

Whenever we want to handle a data set with missing values appropriately, the probability law generating the missing values will be of importance. Formally, this law, usually called the missing value mechanism, is the conditional distribution of the missing indicators, given all variables considered. To facilitate the discussion, we introduce some notation and consider here the situation with one exposure and one **confounder** variable, where only the confounder variable may be missing. Hence we consider for each subject four variables: the disease status D, the exposure E, the confounder C, and the response indicator R, such that we actually observe C if and only if $R = 1$. This situation is complex enough to explain most problems and the basic approach to solutions. Some solutions, however, do not generalize to settings with several exposures and/or confounders, especially in the case of arbitrary missing patterns; we will point this out where it is necessary. Also, one can exchange the role of E and C.

Now, the missing value mechanism is given by the **conditional probabilities** of observing C, that is, by

$$q(d, e, c) := \Pr(R = 1 | D = d, E = e, C = c).$$

To understand the possible dependencies of the observability of C on D, E and C, we shall discuss some specific situations. In case–control studies, missingness often depends on the disease status, as cases and controls may differ in their behavior and willingness to participate in the investigation and to respond to specific questions. For example, Schlehofer et al. [49] report results of a case–control study on risk factors for brain tumor, including blood group among other factors. For controls, only interview data were available, but for cases hospital records could be used in addition. This results in missing rates of 9% for cases, but of 46% for controls. By contrast, in a prospective cohort study one can usually exclude a dependence of the response probabilities on the disease status, if all **covariate** data are collected at the start of the study. Retrospective cohort studies (*see* **Cohort Study, Historical**) and most hybrid designs, such as **nested case–control studies**, often exhibit a dependence of missingness probabilities on the disease status.

Also, the exposure variable may have an influence on observability of the confounder. In an investigation of the risk of radiation therapy, a given therapy may be associated with hospital records containing detailed information on potential confounders. In studies of exposure in nuclear plants, higher exposure levels may be associated with frequent medical examinations and increased chance to assess information on confounders.

There exist a variety of settings in which the probability of observing a variable depends on the value of the variable itself. In interviews or studies by questionnaire, heavy drinkers or smokers may refuse to

answer questions about such behavior, and very poor or very rich people may refuse to give information on their income. Likewise, long-term unemployed subjects may refuse to give information on their working history. Often the value of a variable may influence the probability of knowing or remembering it. For example, if we ask subjects to recall whether there is any case of a disease among their first and second degree relatives, and if there is no such case, he or she will often answer "I don't know", because he or she does not know all the relatives. But if there is one case, it suffices to know this one to give an answer. Even "objective" sources like hospital records do not guarantee that there is no dependence on the true value. In looking for exposure to a specific therapy, it is often easy to detect such a treatment if it has been given, but to assert that the treatment has not been given requires a complete search of hospital records over the time period of interest.

In epidemiology we may often have rather complicated missing mechanisms. For example, in case–control studies, cases may refuse more often to admit an unhealthy lifestyle than controls, because they feel guilty. On the other hand, they may remember previous exposures better because they have sought reasons for their illness. Similarly, the willingness to admit to specific sexual behaviors may differ among sex and age groups. As another example, the availability of information on confounder variables may depend both on the disease status and the exposure level. If exposed subjects and cases are willing subjects, only unexposed controls may yield missing values. These possible interactions make handling of incomplete data especially difficult.

So far, we have described possible scenarios. Some of them are more dangerous than others, however, depending on the type of analysis. If one wants to make efficient use of subjects with incomplete confounder information, the missing at random (MAR) assumption is of central importance. In our context, the MAR assumption is

$$q(d, e, c) = q(d, e),$$

namely that the true value of C is conditionally independent of R given D and E. This assumption allows one to estimate the conditional distribution of C, given D, E and $R = 0$ from those subjects with $R = 1$, which is the key to efficient use of all data. Note that the MAR assumption allows a dependence of the occurrence of missing values on D and E. In two-stage designs we can exclude a dependence on C by design, but sampling fractions typically depend on D and E. In the literature on missing values, one sometimes finds the missing completely at random (MCAR) assumption, $q(d, e, c) = q$, but this is seldom realistic in epidemiology.

If one wants to ignore the subjects with incomplete covariate data in the analysis, it is essential to assume that the selection of such subjects introduces no **bias**, which leads to different requirements as discussed later. We should finally mention that in a case–control study the definition of $q(d, c, e)$ refers to the selected subjects, but it coincides with the values in the total population, provided that selection probabilities really depend only on the case–control status, and not on other information which is a requirement for any well-conducted case–control study.

Fitting Logistic Regression Models with Incomplete Covariate Data

For epidemiologic investigations, **logistic regression** is an important tool to analyze the joint effect of one or several exposure variables on the disease risk adjusted for one or several confounding variables. In the case of one exposure and one confounder variable, the logistic model for risk in the underlying population assumes that the conditional probability of disease given the exposure value e and the confounder value c is given as

$$\begin{aligned}\Pr(D = 1 | E = e, C = c) &= \Lambda(\beta_0 + \beta_E e + \beta_C c) \\ &=: p_\beta(e, c),\end{aligned}$$

with $\Lambda(t) = 1/[1 + \exp(-t)]$. As suggested by this formula, E and C may be **binary** or continuous variables, extensions to **polytomous** variables are straightforward, and most statements in this article are valid for any type of covariates.

With complete data we can estimate the parameters β_0, β_E, and β_C by the **maximum likelihood** principle. There are several proposals of different quality to cope with incomplete data. To understand the behavior of most simple methods for handling incomplete covariate data, we examine the conditional probabilities of the disease status given the

actual information we observed. Considering only subjects in the cohort with complete data, we have

$$\Pr(D = 1|E = e, C = c, R = 1) = \Lambda\left(\beta_0 + \log\frac{q(1, e, c)}{q(0, e, c)} + \beta_E e + \beta_C c\right), \quad (1)$$

which can be derived by analogy with the justification of logistic regression models for case-control data, as given by Breslow & Day [5, p. 203]. This result follows by noting that $q(d, e, c)$ are nothing other than the probabilities of selecting these subjects, just as cases and controls have selection probabilities from the base population in a case-control study. Eq. (1) implies that fitting a logistic regression model to the subjects with complete data only will give valid estimates for β_E and β_C, provided $q(d, e, c)$ can be decomposed into $q(d) \cdot q(e, c)$. For subjects with a missing confounder value we have

$$\Pr(D = 1|E = e, R = 0) = \int \Lambda\left(\beta_0 + \log\frac{1 - q(1, e, c)}{1 - q(0, e, c)} + \beta_E e + \beta_C c\right) \mathrm{d}F(c|E = e, R = 0). \quad (2)$$

Most simple methods to handle incomplete covariate data try to approximate (1) and (2) by simple logistic models, and the resulting **misspecification** can cause serious bias. In contrast, methods relying on the **likelihood** or on appropriately chosen **estimating** equations have the potential to produce **consistent** estimates. Hence we now consider the likelihood in the incomplete data case. From the joint distribution of the observed variables, subjects without a missing value contribute

$$q(d, e, c) \times p_\beta(e, c)^d \times [1 - p_\beta(e, c)]^{1-d} \times \Pr(C = c|E = e) \times \Pr(E = e),$$

and subjects with a missing value contribute

$$\int [1 - q(d, e, c)] \times p_\beta(e, c)^d \times [1 - p_\beta(e, c)]^{1-d} \times \Pr(C = c|E = e) \times \Pr(E = e)\,\mathrm{d}c.$$

If the MAR assumption $q(d, e, c) = q(d, e)$ holds, not only $\Pr(E = e)$ but also the terms involving q can be removed from the likelihood. However, the likelihood still depends on $\Pr(C = c|E = e)$; hence the classical maximum likelihood principle requires specifying the distribution of the covariates, at least in part, which is fundamentally unlike the complete data case. Trying to avoid these difficulties leads to **semiparametric** approaches. The likelihood presented above is based on a prospective sampling scheme. In the case of complete data, it is well known that such a likelihood also yields valid estimates of β_E and β_C in the analysis of case–control studies [32]. This is also true for incomplete data, as shown by Carroll et al. [9].

In the following we outline the main simple and sophisticated methods for handling incomplete covariate data.

Complete Case Analysis

In a complete case analysis all subjects with a missing value are omitted from the analysis. The validity of this approach is based on the implicit assumption that the **regression** model for the subjects with complete data is identical to the model for all subjects, i.e. that

$$\Pr(D = 1|E = e, C = c, R = 1) = \Pr(D = 1|E = e, C = c)$$

holds. Using (1), this is true, if $q(d, e, c) = q(e, c)$, i.e. if missing probabilities do not depend on the disease status. This is also intuitively clear; if missing probabilities depend only on the covariate values, restriction to subjects without missing values changes only the population, but not the regression model, whereas missing probabilities depending additionally on the outcome introduce some type of **selection bias**. An isolated difference between the missingness probabilities for cases and controls affects the estimation of the intercept but does not affect the estimation of β_E and β_C; in general consistent estimation of the latter is guaranteed if $q(d, e, c) = q(d) \cdot q(e, c)$, which follows directly from (1) [19].

Therefore a complete case analysis has the favorable property that it yields consistent estimates of the regression parameters, even if the MAR assumption is violated. It has the unfavorable property that consistency of parameter estimates depends on the assumption that missingness probabilities do not depend jointly on the disease status and the covariate values. The latter is however often questionable for case–control studies (cf. final section). The bias of the **odds ratio** based on a complete case analysis

can be easily computed [55], and it can be shown that realistic differences in the missingness probabilities can lead to substantial bias. For example, if exposed cases are better documented than controls and unexposed cases such that the missingness probability for the exposed cases is 10% and 40% for the other groups, then the odds ratio for exposure is overestimated by a factor of 1.5.

Additional Category or Missing Indicator Method

Epidemiologists often work with categorical variables and sometimes define an additional category for missing observations. Such coding suggests that we analyze the data under the implicit assumption that

$$\Pr(D = 1|E = e, C = c, R = 1) = \Lambda(\beta_0 + \beta_E e + \beta_C c)$$

and

$$\Pr(D = 1|E = e, R = 0) = \Lambda(\beta_0 + \beta_E e + \beta^*).$$

Equivalently we can impute for the missing values of C the value 0 and add the missing indicator $M = 1 - R$ to the regression model. This "missing indicator method", which is also applied to continuous covariates, results in the same specification and hence the same estimates. The approach is inappropriate, as one cannot expect to achieve good estimates for the adjusted risk β_E if adjustment for the unobserved values of the confounding variable is attempted by introducing the additional parameter β^* in the second equation above. To see this, let us assume that $q(d, e, c) \equiv q$, i.e. MCAR, such that the subjects with and without missing values form two random subsamples. Then in the first equation above β_E corresponds to the adjusted log-odds ratio (OR) of the exposure, whereas in the second line β_E corresponds to the unadjusted log-OR, because $\beta_0 + \beta^*$ can be regarded as one intercept. Consequently, the quantity $\exp(\hat{\beta}_E)$ estimates a quantity between the adjusted and unadjusted odds ratio. Hence the goal of obtaining realistic odds ratios that describe the effect of exposure adjusted for confounding variables cannot be achieved if missing values in the confounding variables are regarded as an additional category. Moreover, if the missingness probabilities are allowed to depend on the disease status and/or exposure status, then $\exp(\hat{\beta}_E)$ can lead to values outside the range between the adjusted and unadjusted odds ratio. The bias is often accompanied by underestimation of the variability; Greenland & Finkle [20] report the results of a **simulation** study with two Gaussian (*see* **Normal Distribution**) covariates, where the missing indicator method results in true coverage probabilities of 55% for nominal 95% **confidence intervals**.

So far we have considered the effect of coding missing values as an additional category on the estimation of β_E. In the epidemiologic literature the estimate of β^* is often reported, too, and compared to the value of $\hat{\beta}_C$. Often there is an implicit assumption that $\hat{\beta}^*$ has to be between 0 and $\hat{\beta}_C$, or, in the case of several categories, within the range of the effect estimates (including 0 for the baseline category). If missing probabilities depend only on the exposure, and the degree of **correlation** between confounder and exposure is small, then this is approximately true, as can be shown using the approximation discussed in the next section. However, if missingness probabilities depend on the disease status, the relative disease frequency among subjects with complete data differs from the relative disease frequency among subjects with incomplete data, and β^* mainly reflects this difference.

Although regarding missing values as an additional category cannot be recommended in general, it can be appropriate in special settings, where missing values characterize a meaningful subset of all individuals. For example, Commenges et al. [11] report a study comparing different procedures to diagnose dementia in a screening setting. They found missing values in those variables corresponding to the results of two tests to be highly predictive, because the missing values reflected a subject's failure to comprehend the test.

Single-Imputation Methods

This class of methods is characterized by imputing for each missing value a single value and analyzing the completed data set. If the confounder C is continuous, the simplest choice is to replace each missing value by the overall mean $\overline{C}$ of the observed values of the confounding variable. Instead of using an estimate for the overall expectation of C, one may use estimates of the conditional expectations: if E is categorical, then we can impute the mean of the observed values of C within each category of E; if E is continuous, then

we can compute a **regression** of the observed values of C on E. If C is binary, then relative frequencies replace the means, and Schemper & Smith [46] proposed the term probability imputation. The imputation of estimates for the conditional expectations yields an approximately valid **inference**, if missing probabilities do not depend on the disease state and the true, unobserved value, i.e. if $q(d, e, c) = q(e)$. In this situation, we have

$$\text{by (1)} \quad \Pr(D = 1|E = e, C = c, R = 1) = p_\beta(e, c)$$

and

$$\text{by (2)} \quad \Pr(D = 1|E = e, R = 0) = \int \Lambda(\beta_0 + \beta_E e + \beta_C c)\, \mathrm{d}F^{C|E=e}(c).$$

If we regard Λ as an approximately linear function, then we have

$$\Pr(D = 1|E = e, R = 0) \approx \Lambda(\beta_0 + \beta_E e + \beta_C \cdot E[C|E = e]).$$

Hence imputing estimates for the conditional expectation results in an approximately correct specification of the conditional disease probabilities, and hence the resulting bias of the parameter estimates is often small. One has to expect, however, that **variance** estimates tend to be too small, because the imputed values are treated as true ones and no adjustment is made for the additional variability introduced by imputing estimates. Results of simulation studies [45, 46, 53, 58] suggest that both bias and underestimation of the variance are only problematic for extreme parameter constellations with high missingness rates and very influential confounding variables.

The justification so far depends on the assumption that missingness probabilities do not depend on the disease status. This is not necessary, because imputation of conditional expectations can always be regarded as an approximation to simple semiparametric approaches [58]. However, some care is necessary; if missingness probabilities depend on the disease status, then naive estimates for conditional expectations are wrong; it is necessary to estimate the conditional expectations separately within diseased and undiseased subjects and then to form a weighted average [58]. Moreover, for extreme parameter constellations the bias can be still substantial [53].

Generalizations to several covariates with arbitrary missing patterns are straightforward, as long as there are enough subjects with complete information. But many auxiliary regression models may be required. In general, misspecification of these auxiliary regression models can be a source of additional bias in the parameter estimates, but little is known about this problem.

Modifying the Complete Case Estimates

Under the MAR assumption, the response probabilities $q(d, e)$ can be estimated from the observed data, for example by fitting a logistic regression model with outcome variable R and covariates D and E. The bias of the complete case estimates can be expressed as a function of q, and hence we can correct the bias [53, 55]. Alternatively, one may fit a logistic regression model with estimated offsets in (1) to the subjects with complete covariate data [4]. If E is categoric and a saturated model (*see* **Generalized Linear Model**) is used in estimating q, then both approaches coincide and are identical to maximum likelihood estimates [57]. As simple expressions for the corresponding asymptotic variances can be provided [7], this is a simple method to achieve **consistent** and **efficient estimates** in this special setting if the MAR assumption is tenable. Unfortunately there is no simple generalization for arbitrary missingness patterns.

Estimation of the Score Function: Weighting, Filling, and the Mean Score Method

In the complete data case, maximization of the likelihood is equivalent to finding a root of the **score** function

$$S_n(\beta) = \frac{1}{n} \sum_{i=1}^{n} S_\beta(D_i, E_i, C_i),$$

with

$$S_\beta(d, e, c) = \frac{\partial}{\partial \beta} \{d \log p_\beta(e, c) + (1 - d) \log(1 - p_\beta(e, c))\}.$$

In the incomplete data case the contribution to the score function is unknown for subjects with a missing value. Nevertheless, one can try to estimate $S_n(\beta)$. A

first approach is to regard the subjects with complete covariate information as a subsample with selection probabilities $q(d, e, c)$ and to try to estimate the "population average" $ES_\beta(D, E, C)$. The classical **Horvitz–Thompson estimator** satisfies this task by weighting each contribution of the subsample with $q(d, e, c)^{-1}$. However, $q(d, e, c)$ is unknown, and only under the MAR assumption can we arrive at estimates $\hat{q}(d, e)$ and at a weighted score function

$$\tilde{S}_n(\beta) = \frac{1}{n} \sum_{\substack{i=1 \\ R_i=1}}^{n} \frac{S_\beta(D_i, E_i, C_i)}{\hat{q}(D_i, E_i)}.$$

Solving $\tilde{S}_n(\beta) = 0$ results in consistent estimates of β. Solving $\tilde{S}_n(\beta) = 0$ can be done by any software package for logistic regression that allows arbitrary weights (*see* **Software, Biostatistical**). However, variance estimates obtained this way are invalid, and can be much too small [53, Section 5.11]. If a parametric model $q_\alpha(d, e)$ is used in estimating the response probabilities, explicit estimates of the variance can be provided [33, [53], p. 17], but they cannot be computed with standard software. If E and C are both categorical, then the approach is equivalent to distributing subjects with a missing value to the cells of the **contingency table** of subjects without a missing value with fractions equal to estimates of the conditional probability for the true value. This intuitive method was called "filling" by Vach & Blettner [55]. The idea to weight contributions to the score function reciprocally to the response probabilities was also used by Flanders & Greenland [15] and Zhao & Lipsitz [61]. However, they consider the analysis of designs for which the response probabilities were known.

An alternative approach to estimating S_β is to replace each unknown contribution $S_\beta(D_i, E_i, C_i)$ for subjects with unknown C_i by an estimate for $\mathrm{E}[S_\beta(D_i, E_i, C_i)|D_i, E_i]$, i.e. an estimate for the conditional expectation of the score function given the observed variables. Reilly & Pepe [34] investigate this approach in detail for the special case where E is categorical. In that case, estimates of the conditional expectations are simple averages over the subjects without missing values, and the approach is equivalent to weighting. However, whereas the weighting approach is difficult to generalize to the case of several covariates with arbitrary missingness patterns, this is in principle possible for the individual estimation of the conditional expectations by **nonparametric regression**.

Finally, estimates based on the weighting or the mean score approach are consistent under the MAR assumption but not always efficient. Especially if missingness rates are large, there can be a substantial loss in comparison to efficient approaches [38; 53, Section 5.2; 61].

Maximum Likelihood Estimation

Application of the maximum likelihood (ML) principle requires a parametric specification $f_\alpha(c|e)$ for the conditional distributions $\Pr(C = c|E = e)$ (cf. above). Then under the MAR assumption the contributions to the likelihood are given by

$$p_\beta(e, c)^d (1 - p_\beta(e, c))^{1-d} f_\alpha(c|e), \text{if } R = 1,$$
$$\int p_\beta(e, c)(1 - p_\beta(e, c))^{1-d} f_\alpha(c|e)\, \mathrm{d}c, \text{if } R = 0.$$

The integral in the likelihood makes maximization a little bit cumbersome. The **EM algorithm** [12] is a standard tool to maximize the likelihood in incomplete data problems. However, if C is continuous, even the EM algorithm may require numerical integration. If C is categorical, integration reduces to summation, and both the EM algorithm [24] or a direct maximization using the Newton–Raphson method are feasible. The latter has the advantage of automatically computing the quantities necessary to estimate the variance of the parameter estimates, whereas use of the EM algorithm requires additional effort [30, 52]. The ML principle is also applicable in the general setting with several covariates and arbitrary missingness patterns, as long as we are able to specify a parametric family for the conditional distribution of the covariates affected by missing values given the unaffected covariates.

The ML estimates are consistent and efficient as long as the MAR assumption is valid and the true distribution of the covariates is within the specified family. This specification is a crucial point of the ML approach, because this requirement is not necessary in the complete data case, and our knowledge about the distributions of and dependencies between the covariates is usually limited. Misspecification of the distribution of the covariates, however, can induce a bias in the regression parameter estimates. Thus it becomes necessary to model nuisance features of

the problem carefully. If all covariates are categorical, loglinear models provide a simple framework to describe the joint distribution [56], but if continuous covariates are involved, parametric models flexible enough seem to be hard to specify.

If all covariates are categorical, one can also fit a **loglinear model** to the joint distribution of all variables [16, 59] and use relationships between loglinear and logistic models.

Semiparametric Maximum Likelihood Estimation

We have seen in the last section that maximum likelihood estimation requires specification of a parametric family for the conditional distribution of C given E. It is an appealing idea to avoid this unpleasant task by replacing $f(c|e)$ by a **nonparametric** estimate. Pepe & Fleming [31] consider the case of a categorical exposure, such that the empirical distribution within each exposure stratum can be used; Carroll & Wand [8] consider a continuous exposure and use kernel estimates (*see* **Density Estimation**). Both approaches rely on the assumption that missingness probabilities do not depend on the disease status, but they can be generalized to this setting (Vach & Schumacher [58]). Computations of the resulting estimates of β require special software, as does estimation of the variance. The resulting estimates are not fully efficient in comparison to the estimates of the next section. It is also difficult to generalize these approaches to settings with several covariates and arbitrary missingness patterns, because this requires nonparametric estimation of high-dimensional **multivariate** conditional distributions.

Semiparametric Efficient Estimation

The last two sections have suggested that the handling of incomplete covariate data is ideally a **semiparametric** problem; we are interested in the parameters of the regression model describing the conditional distribution of disease status given all exposure and confounding covariates, but the distribution of the covariates, in spite of being essential for the likelihood, should be left unspecified. In recent years there has been substantial progress (for example [3]) in the general field of efficient semiparametric estimation. Robins et al. [38] used this theory to fit generalized linear models with incomplete covariate data. They showed that roughly any consistent estimator for β is asymptotically equivalent to one defined as the solution of an estimating equation $\sum_{i=1}^{n} S_\beta(D_i, E_i, C_i) = 0$, where

$$S_\beta(D, E, C) = R\frac{h(E, C)(D - p_\beta(E, C))}{q(D, E)} - \frac{\varphi(D, E)(R - q(D, E))}{q(D, E)}.$$

They were also able to characterize functions h_{opt} and φ_{opt} which lead to a semiparametric efficient estimate, i.e. the asymptotic variance of this estimate is exactly the supremum of the asymptotic variances of all maximum likelihood estimators based on parametric families $f_\alpha(c|e)$ covering the true $f(c|e)$. Of course, this is the best we can expect without imposing parametric assumptions. Unfortunately h_{opt} and φ_{opt} depend on the true values of β and the true distribution of C given E and are moreover not available in closed form.

However, an adaptive procedure is possible which starts with a parametric assumption on the distribution of the covariates, then estimates all parameters, uses an iterative procedure to compute $\hat{h}_{\text{opt}}$ and $\hat{\varphi}_{\text{opt}}$ based on the assumption that the estimates correspond to the true parameters, and finally solves the estimating equations with h and φ replaced by $\hat{h}_{\text{opt}}$ and $\hat{\varphi}_{\text{opt}}$, and q replaced by an appropriate estimate. In contrast to ML estimation, a misspecification of the covariate distribution does not result in inconsistent estimates, and, in spite of the adaptive steps, the estimates are efficient, if the specification of the covariate distribution was correct. Details of this adaptive procedure can be found in Robins et al. [38] and Rotnitzky & Robins [40]. The approach can be also generalized to several covariates with arbitrary missingness patterns; however, here the computation of $\hat{h}_{\text{opt}}$ and $\hat{\phi}_{\text{opt}}$ is more difficult.

Multiple Imputation

Multiple imputation is a general technique for statistical inference with incomplete data. The basic idea is to create several data sets with different values imputed for the missing values, and to analyze each data set by standard software, such as software for logistic regression. If the imputations are generated in a so-called "proper" manner, the average of the parameter estimates provides a consistent estimate.

Furthermore, the average of the variance estimates and the empirical variance of the multiple parameter estimates can be combined to form a total variance estimate; confidence intervals and ***P* values** can be computed, too. Rubin & Schenker [44] present an overview of the basic techniques.

It seems reasonable to generate imputations from estimates of the conditional distribution of the unobserved values. However, this is an improper method in the sense that variance estimates tend to be too small, because they do not take into account the variance due to estimating the conditional distribution. Proper methods can be defined by additionally estimating the conditional distribution in each imputation step based on a **random sample** with replacement of the subjects without missing values [14, 42, 43]. Of course, any attempt to estimate the conditional distribution of the missing values from the observed values depends on the MAR assumption.

With respect to our setting, Reilly & Pepe [34, 35] have considered the special case where E is categoric. Values to be imputed for missing values in C are drawn from the empirical distributions of C within the strata defined by D and E. This hot-deck imputation method is improper, although Reilly & Pepe [35] provided a valid variance estimator. Moreover they showed that hot-deck multiple imputation with infinite imputations is asymptotically equivalent to the mean-score method. In particular, this implies that the hot-deck method has the same deficiencies with respect to efficiency. Greenland & Finkle [20] report results of a simulation study with E and C both continuous and affected by missing values. Imputations were drawn from estimated conditional distributions resulting from fitting **bivariate normal distributions** within the diseased and undiseased subjects. Although this is an improper method, they observed that confidence intervals keep their nominal level. They also observed a loss of efficiency in comparison to maximum likelihood estimation (*see* **Missing Data Estimation, "Hot Deck" and "Cold Deck"**).

Multiple imputation can be also applied in general settings with arbitrary missingness patterns. The crucial point is the choice of the procedure to estimate the necessary conditional distribution. If we rely on parametric assumptions on the distribution of the covariates, we have the same unpleasant situation as with ML estimation. However, one can alternatively draw imputations from a set of nearest neighbors, i.e. subjects with complete information and similar values with respect to the observed variables. The choice of an appropriate distance measure requires some knowledge about the distribution of the covariates, but not necessarily an explicit model. Heitjan & Little [22] give an illuminating example.

Methods Based on the Retrospective Likelihood

The methods considered so far rely on a prospective sampling scheme implying independence of the disease status among different subjects. In case–control studies this assumption is violated. However, in incomplete data problems the use of the prospective likelihood can also be justified for retrospective data [9]. The resulting estimates are consistent, the estimated **standard errors** are never too small, and they are correct if we make no assumptions on the distribution of the covariates. Nevertheless, methods based on the retrospective likelihood are of interest, especially for the analysis of two-stage designs. In such a design, the number of subjects with complete data is fixed in advance, and hence missingness indicators are not independent, which is a further violation of the prospective sampling scheme.

Maximum likelihood estimation with respect to the retrospective likelihood is considered by Scott & Wild [51] and Breslow & Holubkov [6]. Two different **pseudo-likelihood** approaches, in which some parameters are pre-estimated in a naive manner, are considered by Breslow & Cain [4] and Schill et al. [48]. A weighting approach is due to Flanders & Greenland [15]. Comparisons with respect to the **asymptotic relative efficiency** and simulation studies [6, 47, 61] often reveal large inefficiencies of the weighting approach and some inefficiencies of the two pseudo-maximum likelihood approaches.

Handling of a Questionable MAR Assumption

All sophisticated, and especially all efficient, approaches to handle incomplete covariate data rely on the MAR assumption. In many applications this assumption is questionable, but one may still want to use methods relying on it. In that case, it is necessary to think about or investigate the possible impact of a violation. One may argue that if there is a pure violation, in the sense that missingness depends only

on the true value of the covariate, then the impact must be small, because the association between the covariates and the outcome is not changed. Schemper & Smith [46] provide an informal argument for this conjecture. Investigations for the special case of categorical C and E [57] corroborate the conjecture. These studies further demonstrate that the impact on the exposure effect estimate can be substantial if there are differences in the degree of violation between diseased and undiseased or between exposed and unexposed subjects, which is also intuitively clear, because such differences change the observed association.

If one does not want to rely on such general, theoretical considerations, one may try to investigate the impact of an invalid MAR assumption for a particular data set. This can be easily done within the multiple imputation framework, for example by drawing more larger values for a variable or more values from a specific category (cf. [44]). Vach & Blettner [56] present a framework to specify violations within the framework of ML estimation and perform a **sensitivity analysis** for two case–control studies. Baker [2] takes an additional step and does not specify, but tries to estimate, the parameters of the non-MAR mechanism. Rotnitzky & Robins [40] consider this step within the framework of semiparametric efficient estimation. However, a (saturated) logistic model and a (saturated) non-MAR model are in general not jointly **identifiable**; hence any attempt to estimate non-MAR mechanisms relies on restrictions of the two models allowing identifiability. This alone, however, is not enough, as identifiability does not imply reasonable properties of resulting estimates in this setting; Rotnitzky & Robins [40] show in the semiparametric setting that in spite of identifiability there need not exist a $\sqrt{n}$-consistent estimator. Hence, the usefulness of these approaches has to be investigated further before recommendations can be made.

Robins & Gill [37] point out that in settings with arbitrary missingness patterns, the MAR assumption as defined by Rubin [41] allows some configurations of no practical relevance. This fact can be used to change the MAR assumption, allowing some special non-MAR mechanisms to be estimated without problems of identifiability. Robins & Gill [37] and Robins [36] present two examples of this kind.

Handling of Incomplete Data in other Models Used in Analytic Epidemiology

Poisson Regression, Gaussian Regression, and Generalized Linear Models

Nearly everything we have said in the last section with respect to logistic regression is also valid for other regression models where parameters are estimated by maximum likelihood. In particular, the difficulties with maximum likelihood estimation in the incomplete data case are the same, and the semiparametric approaches work in the general setting of generalized linear models. With respect to the simple methods, there are two differences. First, there is no general analogy to the modifications of the complete case estimates. Second, the single imputation methods need more care. We can expect nearly unbiased estimates of the regression parameters after imputation of conditional means, as this implies a roughly correct specification of the conditional expectation of the outcome variable. Indeed, in the case of Gaussian regression one can prove consistency [18]. However, only in binary regression models does correct specification of the conditional mean imply correct specification of the conditional variance. In general, the conditional variance of the outcome increases if some covariate values are missing; hence, after the imputation of conditional means, a further analysis should be based on a heteroscedastic model. For this reason, weighted **least squares** estimates are advocated in Gaussian regression after imputation of conditional means. An overview of this and other techniques suitable for Gaussian regression models is given by Little [27]. Some of the proposals depend on the assumption of a **multivariate normal distribution** of all variables and hence have limited application in epidemiology. The impact of the variance heterogeneity for other types of regression models, especially **Poisson regression**, has not been investigated. Thus we recommend that the single imputation method should be used with caution.

Cox Regression with Incomplete Covariate Data

For the analysis of (censored) survival times the **proportional hazard** model [10] is widely used in epidemiology. Simple methods to handle incomplete covariate data are subject to the same criticism as for logistic regression, with the additional difficulty

that, especially in **retrospective studies**, censoring may be associated with missingness in covariates. Even in a complete case analysis, the assumption of noninformative **censoring** can be violated. With respect to more sophisticated approaches, it is difficult to extend the maximum likelihood approach to survival models (*see* **Survival Analysis, Overview**), as the **nuisance parameter** involves the baseline hazard, although a semiparametric partial maximum likelihood approach is possible [62]. A weighting approach has been proposed by Pugh et al. [33], and Lin & Ying [26] consider an appropriately modified score function, but their approach requires MCAR. None of these approaches can be easily generalized to situations with general missingness patterns. Robins et al. [38] also point out the difficulty of obtaining a feasible solution from the theory of semiparametric efficient estimation. In the face of this problem, one may be willing to use alternative fully parametric regression models for survival data, such that, especially in the case of categorical covariates, the ML principle can be used. In this spirit, Schluchter & Jackson [50], Baker [1] and Vach [54] suggest approximating the **Cox regression model** by a logistic model for grouped survival data, and Lipsitz & Ibrahim [29] consider **Weibull** models. The use of single imputation methods has been considered by Schemper & Smith [46].

Analysis of Matched Case–Control Studies

The handling of incomplete covariate data in matched case–control studies has received little attention. Haber & Chen [21] consider the case of a single exposure variable as the only covariate and compare the matched and unmatched odds ratio estimator. They conclude that in the case of missing exposure information for some cases and controls, the advantages of the unmatched estimator increase in comparison to the complete data case. **Conditional logistic regression** (*see* **Matched Analysis**) is a standard tool for the analysis of matched case–control studies. Missing values in the covariates constitute an even greater problem with **conditional logistic regression** than with ordinary logistic regression, as a complete case analysis with one-to-one-matching causes loss of the complete pair if the covariate is missing in either the case or the control. Despite a small simulation study [17], a systematic investigation is still needed.

Regression Models for Longitudinal and Multivariate Data

Regression models for longitudinal or clustered data (*see* **Clustering**), especially **marginal models**, are proving useful in epidemiology for the analysis of familial aggregation and of environmental studies (*see* **Environmental Epidemiology**) as well as for studies of biochemical markers. With respect to incomplete covariate data, there is little to add to what we have said previously. However, in these applications outcome variables may also be missing, especially from drop outs in longitudinal studies. We want to restrict ourselves to some basic comments, especially on the differences with the incomplete covariate problem.

First, the MAR assumption is again of central importance. In the case of drop outs, the question is whether we are able to observe the crucial event causing the drop out, or whether the drop out hides this event. Secondly, if the MAR assumption is tenable and if we consider regression models specifying the joint conditional distribution of the outcome variables and allowing the use of the ML principle with complete data case, then the ML principle can also be used in the presence of missing values in the outcome variables and reduces usually to an analysis of all units with measured outcome. Thirdly, the popular marginal models [25] do not belong to this class, and for them the MAR assumption is not sufficient to exclude a bias due to missing values, if only the available units are used; a solution has been provided by Robins et al. [39]. Finally, if the MAR assumption is violated, we have often some rather precise ideas on the drop out mechanism, which may permit adjustment by choosing an appropriate model [13, 23, 28].

Strategies to Cope with Incomplete Data

The best advice is to minimize the possibility for missing values. We should plan appropriate data collection procedures and design interviews and questionnaires so that subjects have little reason to refuse an answer. Adequate planning can also help to avoid differential missingness with respect to disease status or exposure status. The same data collection procedures should be used for cases and controls in case–control studies, and exposed and unexposed subjects should be followed using similar procedures

and effort in cohort studies. Usually one knows in advance which variables are most likely to have missing values. Then a fruitful strategy can be to collect data on a surrogate variable that is available on most subjects and to collect the variable of interest with additional effort only in a randomly selected subsample, assuring that the MAR assumption holds. Then it is possible to use statistical methods very similar to the sophisticated methods discussed earlier, except that the surrogate variable is not included in the regression model (*see* **Validation Study**). A general idea is to collect additional data to predict missingness. By incorporating such variables in the analysis, the MAR assumption may become more reliable. Finally, one can try to recontact a representative sample of the nonresponders, and try to collect the missing data. If this succeeds, a valid analysis becomes possible in principle.

If these approaches are infeasible or unsuccessful, then one should at least discuss the possible impact of the missing values on the analysis. The first step is to report the missing rates for all variables, stratified by disease status and exposure levels, and to summarize major associations of missingness with other variables. The second step is to justify the analytical approach. If a complete case analysis is applied in a case–control study, then one should give arguments to exclude an important difference in the missing value mechanism between cases and controls. If one uses methods relying on the MAR assumption, then the latter must be justified or a sensitivity analysis should be conducted.

Conclusions

Missing values are a common problem in the analysis of epidemiologic studies. The problem should be addressed in planning the study so as to minimize their occurrence. Careful planning may also allow one to control or to understand the missingness mechanism and thereby to facilitate valid inference. If one has sufficient insight into the missingness mechanism, then one can take advantage of efficient statistical methods, although there remains a need for more practical experience with these techniques and improved availability of software. Such analytical methods cannot salvage a poorly planned and executed study, however, that has many missing values and offers little insight into the missingness mechanism.

Missing Data

This article concerns the analysis of biostatistical data that are subject to missing values. It builds on earlier research [63, 65–67]. Missing values arise in biostatistics for many reasons. For example:

1. In longitudinal studies, data are missing because of *attrition*, i.e. subjects drop out prior to the end of the study (*see* **Longitudinal Data Analysis, Overview**).
2. In sample surveys, some individuals provide no information because of noncontact or refusal to respond (*unit* **nonresponse**). Other individuals are contacted and provide some information, but fail to answer some of the questions (*item* nonresponse). For example, the National Health and Nutrition Examination Survey (NHANES) includes data from an individual interview and a health examination. Some survey respondents miss particular variables because they refused to answer sensitive questions, or measurements were not carried out or were incorrectly recorded, for example they lie outside allowable ranges. Other individuals are missing all the recordings from the health examination since they failed to show up, but have information from the individual interview recorded.
3. Information about a variable is partially recorded. A common example in biostatistics is *right censoring* (*see* **Censored Data**), where times to an event (death, progression of disease) are being recorded, and for some individuals the event has still not taken place when the study is terminated. The times for these subjects are known to be greater than that corresponding to the latest time of observation, but the actual time is unknown. Another example of partial information is **interval censoring**, where it is known that the time to an event lies in an interval. For example, in a longitudinal study of a chronic disease, it may be established that some event (such as reinjury of hip after hip replacement surgery) took place some time between two visits to the doctor for checkups. The time to reinjury is then known to lie in an interval determined by the two checkups. If the interval is narrow compared with the distribution of event times themselves, then the simple approach of locating the event at the midpoint of the interval may be a good approximation, but otherwise methods that treat the event time as partially missing data may be important [13, 19, 38].
4. In clinical studies that involve chart review, charts are often incomplete or lacking in sufficient detail to determine particular items. Often indices are constructed by summing values of particular items, and if any of the items that form the index are missing, then some procedure is needed to deal with the missing data.
5. Missing data can arise by design. For example, suppose one objective in a study of obesity is to estimate the distribution of a measure Y_1 of body fat in the population, and correlate it with other factors. Since Y_1 is expensive to measure, it can only be obtained for a limited sample, but a crude proxy measure Y_2, such as body mass index, can be obtained for a much larger sample. A useful design is to measure Y_2 and **covariates** for a large sample and Y_1, Y_2, and covariates for a smaller subsample. The subsample allows predictions of the missing values of Y_1 to be generated for the larger sample, using one of the methods of analysis described below, yielding more efficient estimates than are possible from the subsample alone.

Unless missing data are deliberately incorporated by design, the most important step in dealing with missing data is to try to avoid it during the data-collection stage. Given that data are likely to be missing after data collection, however, it is also useful to try to collect covariates that are likely to be predictive of the missing values, so that an adequate adjustment can be made. In addition, the process that leads to missing values should be determined during the collection of data if possible. This assists in modeling the missing-data mechanism when an adjustment for the missing values is performed [62].

Three major approaches to the analysis of missing data can be distinguished:

1. discard incomplete cases and analyze the remainder (complete-case analysis):
2. impute or fill in the missing values and then analyze the filled-in data; and
3. analyze the incomplete data by a method that does not require a complete (that is, a rectangular) data set.

With regard to point 3, I focus on powerful **likelihood**-based methods, specifically **maximum likelihood** (ML) and **Bayesian** simulation. The latter is closely related to **multiple imputation** [96], an extension of single imputation that allows uncertainty in the imputations to be reflected appropriately in the analysis. Approaches to longitudinal data with missing values are considered in the concluding section.

A basic assumption in all our methods is that missingness of a particular value hides a true underlying value that is meaningful for analysis. This may seem obvious but is not always the case. For example, consider a longitudinal analysis of CD4 counts in a **clinical trial** for **AIDS** [9]. For subjects who leave the study because they move to a different location, it makes sense to consider the CD4 counts that would have been recorded if they had remained in the study. For subjects who die during the course of the study, it is less clear whether it is reasonable to consider CD4 counts after time of death as missing values. Rather, it may be preferable to treat death as a primary outcome and restrict the analysis of CD4 counts to individuals who are alive. A more complex missing data problem arises when individuals leave the study for unknown reasons, which may include relocation or death.

Pattern and Mechanism of Missing Data

It is useful to distinguish the *pattern* of the missing data and the missing data *mechanism*. The pattern simply defines which values in the data set are observed and which are missing. Specifically, let $Y = y_{ij}$ denote an $n \times p$ rectangular data set without missing values, with ith row $y_i = y_{i1}, \ldots, y_{ip}$, where y_{ij} is the value of variable Y_j for subject i. With missing data, define the *missing-data indicator matrix* $M = m_{ij}$, such that $m_{ij} = 1$ if y_{ij} is missing and $m_{ij} = 0$ if y_{ij} is present. The matrix M then defines the pattern of missing data.

When a data set contains missing values, it is important that information is coded so that M can be determined, even if it is not specifically created. This is usually done by designating a special missing-value code for missing values (such as 9999) that lies outside the allowable range for the variable. It is important to distinguish between zero values and missing values, since failure to do this creates considerable problems in analysis.

Some methods for handling missing data apply to any pattern of missing data, whereas other methods assume a special pattern. An important example of a special pattern is *univariate* nonresponse, where missingness is confined to a single variable. Another is *monotone* missing data, where the variables can be arranged so that $Y_{j+1}, \ldots, Y_p$ is missing for all cases where Y_j is missing, for all $j = 1, \ldots, p - 1$ (see Figure 1). This pattern arises commonly in longitudinal data subject to attrition.

The missing-data mechanism concerns the reasons why values are missing, and in particular whether these reasons relate to values in the data set. For example, a subject in a longitudinal study may be more likely to avoid a treatment and drop out of a study because (s)he felt the treatment was ineffective, which might be related to a poor value of an outcome measure. Rubin [93] treated M as a random matrix, and characterized the missing-data mechanism by the conditional distribution of M given Y, say $f(M|Y, \phi)$, where ϕ denotes unknown parameters. If missingness does not depend on the values of the data Y, missing or observed, that is:

$$f(M|Y, \phi) = f(M|\phi), \quad \text{for all } Y, \phi,$$

then the data are called missing completely at random (MCAR) – note that this assumption does not mean that the pattern itself is random, but rather that missingness does not depend on the data values. An MCAR mechanism is plausible in planned missing-data designs as in example 5 above, but is a strong assumption when missing data do not occur by design because missingness usually depends on recorded variables. Let Y_{obs} denote the observed values of Y and Y_{mis} the missing values. A less restrictive

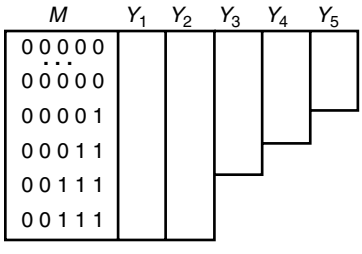

Figure 1 Schematic of a monotone missing data pattern, with rows representing cases, $Y_1, \ldots, Y_5$ repeated measures at five time points, and blocks representing data. M is the missing-data indicator matrix

assumption is that missingness depends only on values Y_{obs} that are observed, and not on values Y_{mis} that are missing. That is:

$$f(M|Y, \phi) = f(M|Y_{\text{obs}}, \phi), \quad \text{for all } Y_{\text{mis}}, \phi.$$

The missing data mechanism is then called missing at random (MAR). Murray & Findlay [80] provided an instructive example of MAR for data from a study of hypertensive drugs where the outcome was diastolic blood pressure. By protocol, the subject was no longer included in the study when the diastolic blood pressure got too large. This mechanism is not MCAR, since it depends on the values of blood pressure. But blood pressure at the time of drop out was observed before the subject dropped out. Hence the mechanism is MAR, because drop out only depends on the observed part of Y. Many methods for handling missing data assume the mechanism is MCAR or MAR, and yield **biased** estimates when the data are not MAR.

Complete-Case Analysis

A common and simple method is complete-case (CC) analysis, also known as *listwise* deletion, where incomplete cases are discarded and standard analysis methods applied to the complete cases. In many statistical packages (*see* **Software, Biostatistical**) this is the default analysis. Valid (but often suboptimal) inferences are obtained when the missing data are MCAR, since then the complete cases are a random subsample of the original sample with respect to all variables. However, even when MCAR holds, the rejection of incomplete cases seems an unnecessary waste of information: if the number of variables is large, then even a sparse pattern of missing values can result in a substantial number of incomplete cases. One approach to incorporating the incomplete cases is to drop variables with high levels of nonresponse; Rubin [92] provides systematic methods in the **regression** context.

Aside from efficiency considerations, a serious problem with dropping incomplete cases is that the complete cases are often a biased sample, i.e., the missing data are not MCAR. The size of the resulting bias depends on the degree of deviation from MCAR, the amount of missing data, and the specifics of the analysis. In particular, the bias in estimating the **mean** of a variable is easily shown to be the difference in the means for complete and incomplete cases multiplied by the fraction of incomplete cases. Thus, the potential for bias increases with the fraction of missing data (*see* **Bias from Nonresponse**). In sample surveys this motivates strenuous attempts to limit unit nonresponse through multiple follow-ups, and surveys with high rates of unit nonresponse (say 30% or more) are often considered unreliable for making inferences to the whole population. For comparisons of means [69] and more generally regression analysis [59], the bias from CC analysis is often smaller. Specifically, it yields valid **inferences** in regression provided the model is correctly specified and missingness depends on the predictor variables, observed or missing, but not on the outcome.

When data are MAR but not MCAR, a useful modification of CC analysis is to assign a nonresponse weight to the respondents to remove or reduce nonresponse bias. In **probability sampling**, a sampling weight inversely proportional to the probability of selection is often used to adjust for differential selection probabilities. If nonresponse is viewed as another stage of probabilistic selection of units, then the product of the probability of selection by design and the probability of response given selection is the probability of being observed, and the inverse of this can be used as a weight in the analysis. Whereas sample design probabilities are known, nonresponse probabilities are unknown and need to be estimated from the data. A standard approach is to form adjustment cells (or subclasses) on the basis of background variables measured for respondents and nonrespondents; for unit nonresponse adjustment these are often based on geographical areas or groupings of similar areas based on aggregate socioeconomic data. All nonrespondents are given zero weight and the nonresponse weight for all respondents in an adjustment cell is then the inverse of the response rate in that cell. If more than one background variable is measured, then adjustment cells can be based on a joint classification, collapsing small cells as necessary. For a health survey application (*see* **Surveys, Health and Morbidity**), see Ezzati & Khare [15]. This method removes the component of nonresponse bias attributable to differential nonresponse rates across the adjustment cells, and eliminates bias if within each adjustment cell respondents can be regarded as a random subsample of the original sample within that cell (i.e. the data are MAR given indicators for the adjustment cells).

A useful alternative approach with more extensive background information is *response propensity* **stratification**, where (i) the indicator for unit nonresponse is regressed on the background variables, using the combined data for respondents and nonrespondents and a method such as **logistic regression** appropriate for a **binary** outcome; (ii) a predicted response probability is computed for each respondent based on the regression in (i); and (iii) adjustment cells are formed on the basis of a categorized version of the predicted response probability. Theory [56, 90] suggests that this is an effective method for removing nonresponse bias attributable to the background variables. For a health survey application, see [30]. Robins et al. [89] and Robins & Rotnitsky [88] apply a similar weighting approach in the more general settings of **generalized estimating equations** for repeated measures analysis (*see* **Longitudinal Data Analysis, Overview**) and **multivariate regression**.

Weighting methods can be useful for removing or reducing nonresponse bias, but they do have serious limitations. First, information in the incomplete cases is still discarded, so the method is inefficient. Weighted estimates can have unacceptably high **variance**, as when outlying values of a variable are given large weights. Secondly, variance estimation for weighted estimates with estimated weights is problematic. Explicit formulas are available for simple estimators such as means under **simple random sampling** [82], but methods are not well developed for more complex problems, and often ignore the component of variability from estimating the weight from the data. Bias and variance considerations aside, statisticians rightly resist attempts to analyze data selectively, and hence aim to analyze all the data to the extent possible; alternatives to CC analysis that incorporate the incomplete cases in a satisfactory way are recommended unless the fraction of incomplete cases is very small, say 10% or less.

Available-case (AC) analysis [65, section 3.3] is a straightforward attempt to exploit the incomplete information by using all the cases available to estimate each individual parameter. For example, suppose the objective is to estimate the correlation matrix of a set of continuous variables $Y_1, \ldots, Y_p$. Complete-case analysis uses the set of complete cases to estimate all the **correlations**; AC analysis uses all the cases with both Y_j and Y_k observed to estimate the correlation of Y_j and Y_k, $1 \leq j, k \leq p$. Since the sample base of available cases for measuring each correlation includes the set of complete cases, the AC method appears to make better use of available information. The sample base changes from correlation to correlation, however, creating potential problems when the missing data are not MCAR or variables are highly correlated. In the presence of high correlations, there is no guarantee that the AC correlation matrix is even positive definite. Haitovsky's [32] simulations concerning regression with highly-correlated continuous data found AC markedly inferior to CC. However, Kim & Curry [44] found AC superior to CC in **simulations** based on weakly correlated data. Simulation studies comparing AC regression estimates with maximum likelihood (ML) under **normality** suggest that ML is superior even when underlying normality assumptions are violated [4, 58, 81]. Although AC estimates are easy to compute **standard errors** are more complex [109]. The method cannot be generally recommended.

Imputation

Methods that impute, or fill in, the missing values have the advantage that, unlike CC analysis, observed values in the incomplete cases are retained. A common naive approach imputes missing values by their simple unconditional sample means (i.e. marginal means). Wilks [111] and Afifi & Elashoff [1] discussed this method in **bivariate** settings. Unconditional mean imputation can yield satisfactory point estimates of some parameters such as unconditional means and totals, but it yields inconsistent estimates of other parameters, even if the data are MCAR. In particular, sample variances from the data filled in by means clearly underestimate actual variances, since the imputed cases contribute zero to the sum of squared deviations from the sample mean. Unconditional mean imputation yields an inconsistent estimate of the **covariance matrix** and distorted estimates of **association** [65, Chapter 3]. **Inferences** (tests and **confidence intervals**) based on the filled-in data are seriously distorted by bias and overstated precision. Thus, unconditional mean imputation cannot be generally recommended.

An improvement over unconditional mean imputation is *conditional mean* imputation, in which each missing value is replaced by an estimate of its conditional mean given the values of the observed

values. For example, in the case of univariate nonresponse with $Y_1, \ldots, Y_{p-1}$ fully observed and Y_p sometimes missing, one approach is to classify cases into cells on the basis of similar values of observed variables, and then to impute missing values of Y_p by the within-cell mean from the complete cases in that cell. A more general approach is regression imputation, in which the regression of Y_p on $Y_1, \ldots, Y_{p-1}$ is estimated from the complete cases, including **interactions** as needed, and the resulting prediction equation is used to impute the estimated conditional mean for each missing value of Y_p. For a general pattern of missing data, the missing values for each case can be imputed from the regression of the missing variables on the observed variables, computed using the set of complete cases. Iterative versions of this method lead (with some important adjustments) to ML estimates under **multivariate normality** [6, 84].

Although conditional mean imputation incorporates information from the observed variables and yields best predictions of the missing values in the sense of **mean square error**, imputations should be judged in terms of the quality of inferences about population parameters from the filled-in data. From this perspective, conditional mean imputation leads to distorted estimates of quantities that are not linear in the data, such as percentiles (*see* **Quantiles**), correlations and other measures of association, and variances and other measures of variability. A solution to this problem is to use random draws rather than best predictions to preserve the distribution of variables in the filled-in data set. An example is *stochastic regression* imputation, in which each missing value is replaced by its regression prediction plus a **random error** with variance equal to the estimated residual variance.

In other approaches, imputations are drawn from the actual values in the data set. A common version of this method in longitudinal studies subject to attrition is to carry the last observation forward in time to fill out the dataset [87]. Clearly, this method is making a very strong assumption about missing data: that the missing values in a case are all identical to the last observed value. Even if we accept the notion that the average level of the variable does not change after drop out, there is no fluctuation about that average. Little & Su [69] suggested better methods for longitudinal imputation based on simple row and column fits. Another method that imputes respondent values is the *hot deck*, as used by the Census Bureau for imputing income in the Current Population Survey (CPS) [33]. For each nonrespondent on one or more income items, the CPS hot deck finds a matching respondent on the basis of variables that are observed for both; the missing items for the nonrespondent are then replaced by the respondent's values. For matching purposes in the CPS, all variables are categorized, and the number of variables used to define matches is large. When no match can be found for a nonrespondent based on all of the variables, the CPS hot deck searches for a match at a lower level of detail, obtained by omitting some variables and collapsing the categories of others. David et al. [8] compared imputations from the CPS hot deck with imputations using a more parsimonious regression model for income.

A more general approach to hot deck imputation is to define a distance function on the basis of the variables that are observed for both nonrespondents and respondents. The missing values for each nonrespondent are then imputed from a respondent that is close to the nonrespondent in terms of the distance function. One such method is *predictive mean matching* [57, 95]. Consider, for simplicity, univariate nonresponse, and suppose that a model predicting Y_p from the other variables $Y_1, \ldots, Y_{p-1}$ has been estimated using the complete cases. For each nonrespondent, predictive mean matching finds a respondent whose predicted value of Y_p is close to the predicted value of the nonrespondent. The respondent's observed value of Y_p is then imputed to the nonrespondent. Lazzeroni et al. [51] showed in simulations that this method in somewhat **robust** to **misspecification** of the model used for matching.

The imputation methods discussed so far assume the missing data are MAR. In contrast, models that are not missing at random (NMAR) assert that even if a respondent and nonrespondent to Y_p appear identical with respect to observed variables $Y_1, \ldots, Y_{p-1}$, their Y_p values differ systematically. Greenlees et al. [31] and Lillard et al. [54] discussed how imputations for missing CPS data can be based on NMAR models. It is also possible to create an NMAR hot deck procedure; for example, respondents' values that are to be imputed to nonrespondents could be multiplied by an inflation or deflation factor that depends on the variables that are observed. A crucial point about the use of NMAR models is that often there is no direct evidence in the data to address the validity of their underlying assumptions. Thus, whenever NMAR models are being considered

it is prudent to consider several NMAR models and explore the sensitivity of analyses to the choice of model [94] (*see* **Sensitivity Analysis**). See Little & Wang [70] for an application of this idea to a longitudinal study of treatments of schizophrenia.

A serious defect with imputation is that it seems to be inventing data. More specifically, a single imputed value cannot represent all the uncertainty about which value to impute, so analyses that treat imputed values just like observed values generally underestimate uncertainty, even if nonresponse is modeled correctly and random imputations are created. **Large-sample** results [97] show that for simple situations with 30% of the data missing, single imputation under the correct model results in nominal 90% confidence intervals having actual coverages below 80%. The inaccuracy of nominal levels is even more extreme in multiparameter testing problems.

A modification of imputation that fixes this problem is **multiple imputation** (MI) [96, 98]. Instead of imputing a single set of draws for the missing values, a set of M (say $M = 5$) data sets are created, each containing different sets of draws of the missing values from their predictive distribution. We then apply the analysis to each of the M data sets and combine the results in a simple way. In particular for scalar estimands, the MI estimate is the average of the estimates from the M data sets, and the variance of the estimate is the average of the variances from the five data sets plus $1 + 1/M$ times the sample variance of the estimates over the M data sets (the factor $1 + 1/M$ is a small-M correction). The last quantity here estimates the contribution to the variance from imputation uncertainty, missed by single imputation methods. Another benefit of multiple imputation is that the averaging over data sets results in more efficient point estimates than does single random imputation. Often MI is not much more difficult than doing a single imputation – the additional computing from repeating an analysis M times is not a major burden and methods for combining inferences are straightforward. Most of the work is in generating good predictive distributions for the missing values.

Maximum Likelihood for Ignorable Models

Complete-case analysis and imputation both result in rectangular data sets for analysis. But there are statistical methods that let us analyze a nonrectangular data set without having to impute the missing values. One such approach is the method of maximum likelihood (ML) with associated **large-sample** standard errors based on the **information matrix**.

The ML approach avoids imputation by formulating a statistical model and basing inference on the likelihood function of the incomplete data. Define Y and M as above, and let $X = x_{ij}$ denote an $n \times q$ matrix of fixed covariates, assumed fully observed, with the ith row $x_i = x_{i1}, \ldots, x_{iq}$, where x_{ij} is the value of covariate X_j for subject i. Covariates that are not fully observed should be treated as **random variables** and modeled with the set of Y_js [64]. The data and missing-data mechanism are modeled in terms of a joint distribution for Y and M given X. *Selection models* specify this distribution as

$$f(Y, M|X, \theta, \Psi) = f(Y|X, \theta) f(M|Y, X, \Psi), \quad (1)$$

where $f(Y|X, \theta)$ is the model in the absence of missing values, $f(M|Y, X, \Psi)$ is the model for the missing-data mechanism, and θ and Ψ are unknown parameters. The likelihood of θ and Ψ given the data Y_{obs}, M, and X is then proportional to the density of Y_{obs} and M given X regarded as a function of the parameters θ and Ψ, and is obtained by integrating out the missing data Y_{mis} from (1), i.e.

$$L(\theta, \Psi|Y_{\text{obs}}, M, X) = \text{const} \times \int f(Y, M|X, \theta, \Psi)\, dY_{\text{mis}}. \quad (2)$$

The likelihood of θ *ignoring the missing-data mechanism* is obtained by integrating the missing data from the marginal distribution of Y given X, i.e.

$$L(\theta|Y_{\text{obs}}, X) = \text{const} \times \int f(Y|X, \theta)\, dY_{\text{mis}}. \quad (3)$$

The likelihood (3) is easier to work with than (2) since it is computationally simpler and, more importantly, avoids the need to specify a model for the missing-data mechanism, about which little is known in many situations. Hence it is important to determine when valid likelihood inferences are obtained from (3) instead of the full likelihood (2). Rubin [93] showed that valid inferences about θ are obtained from (3) when the data are MAR, i.e.

$$p(M|X, Y, \Psi) = p(M|X, Y_{\text{obs}}, \Psi), \quad \text{for all } Y_{\text{mis}} \text{ and } \Psi.$$

If, in addition, θ and Ψ are distinct in the sense that they have disjoint sample spaces, then likelihood inferences about θ based on (3) are equivalent to inferences based on (2); the missing-data mechanism is then called *ignorable* for likelihood inferences. Large-sample inferences about θ for an ignorable model are based on ML theory, which states that under regularity conditions

$$\theta - \hat{\theta} \sim \mathrm{N}_k(0, C), \tag{4}$$

where $\hat{\theta}$ is the value of θ that maximizes (3), and $\mathrm{N}_k(0, C)$ is the k-variate normal distribution with mean zero and covariance matrix C given by the inverse of an information matrix; for example, $C = I^{-1}(\hat{\theta})$, where I is the observed information matrix $I(\theta) = -\partial^2 \log L(\theta|Y_{\mathrm{obs}}, X)/\partial\theta\,\partial\theta^{\mathrm{T}}$, or $C = J^{-1}(\hat{\theta})$, where $J(\theta)$ is the expected value of $I(\theta)$. As in [65], (4) is written to be open to a frequentist interpretation if $\hat{\theta}$ is regarded as random and θ fixed, or a **Bayesian** interpretation if θ is regarded as random and $\hat{\theta}$ fixed. Thus, if the data are MAR, the likelihood approach reduces to developing a suitable model for the data and computing $\hat{\theta}$ and C.

Likelihoods based on incomplete data often have complicated forms and require iterative maximization algorithms. In some situations the method of *factored likelihoods*, first described by Anderson [3], yields explicit ML estimates. The idea is to **transform** θ to $\phi(\theta) = [\phi_i(\theta), \ldots, \phi_Q(\theta)]$, where the components $\phi_1, \ldots, \phi_Q$ are distinct, and the likelihood of ϕ factors into the product $L(\phi|Y_{\mathrm{obs}}, X) = \prod_{q=1}^{Q} L_q(\phi_q|Y_{\mathrm{obs}}, X)$, where each factor $L_q(\phi_q|Y_{\mathrm{obs}}, X)$ corresponds to a complete-data problem or a simpler incomplete-data problem. The ML estimate $\hat{\phi} = (\hat{\phi}_1, \ldots, \hat{\phi}_Q)$ of ϕ is found by maximizing each factor $L_q(\phi_q|Y_{\mathrm{obs}}, X)$ separately, and the ML estimate of θ is then $\hat{\theta} = \theta(\hat{\phi})$, where $\theta(\phi)$ is the inverse transformation from ϕ to θ. Consider, for example, **bivariate normal** data:

$$\begin{pmatrix} y_{i1} \\ y_{i2} \end{pmatrix} \sim_{\mathrm{ind}} \mathrm{N}_2\left(\begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{12} & \sigma_{22} \end{pmatrix}\right),$$

and a monotone pattern with m complete cases $\{(y_{i1}, y_{i2}) : i = 1, \ldots, m\}$ and $n - m$ incomplete cases $\{y_{i1} : i = m + 1, \ldots, n\}$ with Y_2 missing. Let $\theta = (\mu_1, \sigma_{11}, \mu_2, \sigma_{22}, \sigma_{12})$ and $\phi = (\phi_1, \phi_2)$, where $\phi_1 = (\mu_1, \sigma_{11})$, $\phi_2 = (\beta_{20.1}, \beta_{21.1}, \sigma_{22.1})$, and $\beta_{21.1} = \sigma_{12}/\sigma_{11}$, $\beta_{20.1} = \mu_2 - \beta_{21.1}\mu_1$, $\sigma_{22.1} = \sigma_{22} - \sigma_{12}^2/\sigma_{11}$ are, respectively, the slope, intercept, and residual variance of the regression of Y_2 on Y_1. The ignorable model likelihood of ϕ based on Y_{obs} then factorizes into the complete-data likelihood of ϕ_1 based on the n observations $\{y_{i1} : i = 1, \ldots, n\}$ and the complete-data likelihood of ϕ_2 for the regression of Y_2 on Y_1 based on the m complete cases $\{(y_{i1}, y_{i2}) : i = 1, \ldots, m\}$. Explicit expressions for the ML estimates of ϕ and hence θ are readily obtained. In particular:

$$\begin{aligned} \hat{\mu}_2 &= \hat{\beta}_{20.1} + \hat{\beta}_{21.1}\hat{\mu}_1 = \overline{y}_2 - b_{21}\overline{y}_1 + b_{21}\hat{\mu}_1 \\ &= \overline{y}_2 + b_{21}(\hat{\mu}_1 - \overline{y}_1), \end{aligned}$$

where $\overline{y}_1$, $\overline{y}_2$ and b_{21} are the sample means of Y_1 and Y_2 and **least squares** slope of Y_2 on Y_1 based on the m complete cases and $\hat{\mu}_1$ is the sample mean of Y_1 based on all n cases. This is known as the regression estimate (*see* **Ratio and Regression Estimates**) of the mean of Y_2, and is a well-known estimator from **double sampling** in sample surveys. It is also the average of observed and imputed values from regression imputation, discussed before. For further details on this example, and applications to multivariate normal and **multinomial** data with a monotone missing data pattern, see [91] or [65, Chapter 6].

The factored likelihood method does not work in the above problem if incomplete cases on Y_2 are also available. Here, and in many other problems, maximization of the likelihood requires numerical methods. Standard optimization methods such as Newton–Raphson or Scoring can be applied; for example, Hartley & Hocking [34] applied a scoring algorithm to multivariate normal data with missing values, and Jennrich & Schluchter [42] applied modified scoring to unbalanced repeated-measures data. Alternatively, the **EM algorithm** [10] can be applied, a general algorithm for incomplete data problems that provides an interesting link with imputation methods. The history of EM, which dates back at least to McKendrick [73] for particular problems, is sketched in [65]. For more recent work on extensions, see [77].

For ignorable models, let $L(\theta|Y_{\mathrm{obs}}, Y_{\mathrm{mis}}, X)$ denote the likelihood of θ based on the hypothetical complete data $Y = (Y_{\mathrm{obs}}, Y_{\mathrm{mis}})$ and covariates X. Let $\theta^{(t)}$ denote an estimate of θ at iteration t of EM. Iteration $t + 1$ consists of an E-step and an M-step. The E-step consists of taking the **expectation** of $\log L(\theta|Y_{\mathrm{obs}}, Y_{\mathrm{mis}}, X)$ over the conditional distribution of Y_{mis} given Y_{obs} and X, evaluated at $\theta = \theta^{(t)}$. That is, the expected log likelihood $Q(\theta|\theta^{(t)}) = \int \log L(\theta|Y_{\mathrm{obs}},\ Y_{\mathrm{mis}}, X)\, f(Y_{\mathrm{mis}}|Y_{\mathrm{obs}},\ X,\ \theta^{(t)})\, \mathrm{d}Y_{\mathrm{mis}}$.

is formed. When the complete data belong to an **exponential family** with complete-data **sufficient statistics** S, the E-step simplifies to computing expected values of these statistics given the observed data and $\theta = \theta^{(t)}$, thus in a sense "imputing" the sufficient statistics [105].

The M-step determines $\theta^{(t+1)}$ to maximize $Q(\theta|\theta^{(1)})$ with respect to θ. In exponential family cases this step is the same as for complete data, except that the complete-data sufficient statistics S are replaced by their estimates from the E-step. Thus, the M-step is often easy or available with existing software, and the programming work is mainly confined to E-step computations. Under very general conditions, each iteration of EM increases the log likelihood, and under more restrictive but still general conditions EM converges to a maximum of the likelihood function [112]. If a unique finite ML estimate of θ exists, then EM will find it.

Little & Rubin [65] provided many applications of EM to particular models, including: (i) multivariate normal data with a general pattern of missing values and the related problem of multivariate linear regression with missing data [6, 84]; (ii) robust inference based on **multivariate *t*** models [50, 58]; (iii) **loglinear models** for multiway **contingency tables** with missing data [21]; and (iv) the general location model for mixtures of continuous and categorical variables [68, 83], which yields ML algorithms for logistic regression with missing covariates [108]. Schluchter & Jackson [102] provided an EM algorithm for **survival analysis** with missing covariates. An extensive bibliography of the myriad of EM applications is given in [74].

The EM algorithm is reliable, but has a linear convergence rate determined by the fraction of missing information, as defined in [10]. When the fraction of missing information is large, convergence can be painfully slow. Meng & Van Dyk [77] showed how the clear choice of the missing data can be used to speed convergence. There is an extensive literature on extensions and enhancements of EM for cases where the E- or M-step is hard or slow [17, 18, 41, 47, 48, 71, 76, 77]. EM does not involve computation and inversion of an information matrix based on the observed data. This makes the algorithm particularly attractive in problems where the number of parameters is large, as in ML algorithms for biomedical imaging, such as positron emission tomography [17, 18, 49, 103] (*see* **Image Analysis and Tomography**). This feature of EM has the disadvantage that asymptotic standard errors based on the inverse of the information matrix are not an output. An information matrix can be computed and inverted separately. Alternative approaches to computing standard errors are to use the formulas in [72], to build an information matrix from supplemental EM steps [75], to use **bootstrap methods** [14, 58], or to switch to a Bayesian simulation method that simulates the posterior distribution of θ (see below).

Maximum Likelihood for Nonignorable Models

Ignorable ML is appropriate when the data are MAR. Nonignorable, non-MAR models apply when missingness depends on the missing values. For example, if a subject dropped out of the longitudinal study when his/her blood pressure got too high and we did not observe that blood pressure, or if in an analgesic study measuring pain, the subject dropped out when the pain was high and we did not observe that pain value, missingness depends on the missing value. A correct likelihood analysis must be based on the full likelihood from a model for the joint distribution of Y and M. The standard likelihood asymptotics apply to nonignorable models provided the parameters are identified, and computational tools such as EM also apply to this more general class of models. However, often information to estimate simultaneously the parameters of the missing-data mechanism and the parameters of the complete-data model is limited, and estimates are sensitive to **misspecification** of the model. Often a **sensitivity analysis** is needed to see how much the answers change for various assumptions about the missing-data mechanism.

There are two broad classes of models for the joint distribution of Y and M. *Selection* models model the joint distribution as in (1). *Pattern-mixture* models specify

$$f(Y, M|X, \pi, \phi) = f(Y|X, M, \phi) f(M|X, \pi), \quad (5)$$

where ϕ and π are unknown parameters and now the distribution of Y is conditioned on the missing-data pattern M [29, 60, 65, 94]. Eqs (1) and (5) are simply two different ways of factoring the joint distribution of Y and M. When M is independent of Y the two specifications are equivalent with $\theta = \phi$

and $\psi = \pi$. Otherwise (1) and (5) generally yield different models.

Most of the literature on missing data has concerned selection models of the form (1) for univariate nonresponse. Examples are the probit selection model [2, 36], and the closely related logit model of Greenlees et al. [31], extended to repeated-measures data in [11]. The sensitivity of answers to model misspecification is discussed in [[29; 55; 65], Chapter 11; [104]] and the discussion in [11]. Nonignorable models for contingency tables are discussed in [5; 16; 65, Chapter 9; [86]].

Pattern-mixture models seem more natural when missingness defines a distinct stratum of the population of intrinsic interest, such as individuals reporting "don't know" in an opinion survey. However, pattern-mixture models can also provide inferences for parameters θ of the complete-data distribution by expressing the parameters of interest as functions of the pattern-mixture model parameters ϕ and π. An advantage of the pattern-mixture modeling approach over selection models is that assumptions about the form of the missing-data mechanism are sometimes less specific in their parametric form, since they are incorporated in the model via parameter restrictions. This idea is explained in specific normal models in [61] and [70].

Heitjan & Rubin [40] and Heitjan [39] extended the formation of missing-data problems via the joint distribution of Y and M to more general incomplete data problems involving coarsened data. The idea is to replace the binary missing-data indicators $M = \{m_{ij}\}$ by random coarsening (*see* **Coarsening at Random**) variables $G = \{g_{ij}\}$, which map the y_{ij} values to coarsened versions $z_{ij}(y_{ij})$. Particular values of g_{ij} could map y_{ij} to "completely observed" and "completely missing", as with m_{ij} above, but other values of g_{ij} might map y_{ij} into other sets, for example a finite interval would correspond to interval censoring. The data are then defined as *coarsened completely at random* or *coarsened at random* depending on whether the distribution of G is independent of Y, or depends on Y only through observed data. Full and ignorable likelihoods can be defined for this more general setting. This theory provides a bridge between missing-data theory and theories of censoring (*see* **Censored Data**) in the survival analysis literature. For biomedical applications, see [38].

Bayesian Simulation Methods

Maximum likelihood is most useful when sample sizes are large, since then the log likelihood is nearly quadratic and can be summarized well using the ML estimate θ and its large sample variance–covariance matrix. When sample sizes are small, a useful alternative approach is to add a **prior distribution** for the parameters and compute the posterior distribution of the parameters of interest. For ignorable models this posterior is

$$p(\theta|Y_{\text{obs}}, M, X) \equiv p(\theta|Y_{\text{obs}}, X) = \text{const} p(\theta|X) \times f(Y_{\text{obs}}|X, \theta),$$

where $p(\theta|X)$ is the prior and $f(Y_{\text{obs}}|X, \theta)$ is the density of the observed data. Since the posterior distribution rarely has a simple analytic form for incomplete-data problems, **simulation** methods are often used to generate draws of θ from the posterior distribution $p(\theta|Y_{\text{obs}}, M, X)$. I outline two of these simulation methods for the ignorable case, although the techniques can also be applied to nonignorable models.

For missing data problems where the likelihood can be factored into complete-data components, $L(\phi|Y_{\text{obs}}, X) = \prod_{q=1}^{Q} L_q(\phi_q|Y_{\text{obs}}, X)$ and the parameters $\phi_1, \ldots, \phi_Q$ are also a priori independent, the posteriors of $\phi_1, \ldots, \phi_Q$ are also independent, and draws $\phi^{(d)} = (\phi_1^{(d)}, \ldots, \phi_Q^{(d)})$ can be obtained directly from the complete-data posterior distributions. Draws of θ are then obtained as $\theta^{(d)} = \theta(\phi^{(d)})$, where $\theta(\phi)$ is the inverse **transformation** from ϕ to θ. This method is analogous to the factored likelihood method for ML estimation described above. For an application to normal data see [65, Chapter 6].

Data augmentation [107] is an iterative method for simulating the posterior distribution of θ that combines features of the EM algorithm and multiple imputation, with M imputations of each missing value at each iteration. It can be thought of as a small-sample refinement of the EM algorithm using simulation, with the imputation step corresponding to the E-step and the posterior step corresponding to the M-step. An important special case of data augmentation arises when M is set equal to one, yielding the following special case of the Gibbs' sampler [22, 25] (*see* **Markov Chain Monte Carlo**). Start with an initial draw $\theta^{(0)}$ from an approximation

to the posterior distribution of θ. Given a value $\theta^{(t)}$ of θ drawn at iteration t:

1. draw $Y_{\text{mis}}^{(t+1)}$ with density $p(Y_{\text{mis}}|Y_{\text{obs}}, X, \theta^{(t)})$;
2. draw $\theta^{(t+1)}$ with density $p(\theta|Y_{\text{obs}}, Y_{\text{mis}}^{(t+1)}, X)$.

The procedure is motivated by the fact that the distributions in 1 and 2 are often much easier to draw from than the correct posterior distributions, $p(Y_{\text{mis}}|Y_{\text{obs}}, X)$ and $p(\theta|Y_{\text{obs}}, X)$. The iterative procedure can be shown in the limit to yield a draw from the joint posterior distribution of Y_{mis} and θ given Y_{obs} and X. The algorithm was termed *chained data augmentation* in [106]. This algorithm can be run independently K times to generate K i.i.d. draws from the approximate joint posterior distribution of θ and Y_{mis}. A number of articles [23, 24, 26, 107] have discussed techniques for monitoring the convergence of the algorithms. Schafer [100] developed algorithms that use iterative Bayesian simulation to multiply impute rectangular data sets with arbitrary patterns of missing values when the missing-data mechanism is ignorable. The methods are applicable when the rows of the complete-data matrix can be modeled as i.i.d. observations from the multivariate normal, multinomial loglinear, and general location models.

Methods for Unbalanced Repeated-Measures Data

I conclude by reviewing methods for longitudinal data with unequal numbers of measurements between subjects. For normal outcomes and ignorable missing data, a wide range of problems can be tackled using the random-effects model:

$$(y_i|X_i, \beta_i) \sim_{\text{iid}} \text{N}_k(X_{1i}\alpha + X_{2i}\beta_i, \Sigma),$$
$$\beta_i|X_i \sim_{\text{iid}} \text{N}_q(0, \Gamma),$$

where $\text{N}_p(\alpha, B)$ denotes the p-variate normal distribution with mean α covariance matrix B; X_{1i} is a known $(K \times p)$ design matrix containing fixed within-subject and between-subject covariates, with associated unknown $(p \times 1)$ parameter vector α; β_i is an unknown $(q \times 1)$ random-coefficient vector; and X_{2i} is a known $(K \times q)$ matrix for modeling the random effects. Estimation for this model is discussed in [35, 42, 46], and ML estimation is currently available in SAS Proc Mixed [99], or the BMDP program BMDP5V [12] (*see* **Software, Biostatistical**). For Bayesian inference using the Gibbs' sampler, see [28].

For longitudinal categoric data with unequal numbers of measurements, standard loglinear models are unsatisfactory because of the conditional interpretation of the parameters. ML methods have been proposed on the basis of marginal multinomial models (*see* **Marginal Models**) [43, 115]. An alternative approach is to assume categoric outcomes are indicators for underlying continuous outcomes that follow a normal model [27, 37]. Nonlikelihood approaches include the weighted **least squares** methods [45], and iterative methods based on generalized estimating equations [20, 52, 53, 85, 89]. Another approach is analysis by summary measures, in which we obtain a summary measure for each individual and then analyze it across the subjects.

A variety of nonignorable pattern-mixture and selection models for drop outs in longitudinal data have been proposed, including models for informative drop out where drop out depends on underlying unobserved slopes characterizing a patient's decline [9, 62, 79, 101, 110, 113, 114]. An advantage of pattern-mixture models in this setting is that this part of the model can usually be fit using standard software such as PROC MIXED [99] by simply including the drop out indicator as a covariate in the model for the distribution of the y_is. Nonignorable models for repeated-measures categorical data are considered in [7] and [78].

RODERICK J. LITTLE

Misspecification

Statistical models specify the density of a **response random variable** Y. This density depends on parameters which often relate to a specified function of **explanatory variables**, or **covariates** X. The parameters of the density and of the function of covariates are typically unknown and the statistical problem is to use a sample of data to calculate accurate estimates of the unknown parameters along with measures of uncertainty associated with the estimates.

In practice, data analysts often choose a particular statistical model because it is easy to work with mathematically or is simple to fit using easily available **software**. For example, when one wants to assess the association of an explanatory variable with an outcome, it is tempting to fit a **linear regression** model, since this model is easy to fit and describe.

However, there may exist a more accurate specification of a statistical model than that chosen by an analyst. That is, there may be densities that fit the data better and functions of the covariates that better describe their relationship with the response. When this occurs, we have misspecified the statistical model. This misspecification may be due to either an incorrect conceptual understanding of the phenomenon under study or an inability to collect data on all the relevant factors related to the outcome under study. Model misspecifications include choosing the incorrect link function or omitting important covariates with **generalized linear models**, incorrectly assuming independence of observations or misspecifying the within-cluster dependence structure with clustered data (*see* **Cluster Analysis of Subjects, Hierarchical Methods**), misspecifying the mixing distribution in generalized linear mixed models, and wrongly assuming **proportional hazards** with survival data.

Effects of Model Misspecification

Model misspecification can produce **biased** or inefficient estimates (*see* **Efficiency and Efficient Estimators**) of the associations of covariates with the response, invalid variance estimates, and less powerful tests of hypotheses concerning covariate–response associations (*see* **Power**). To examine effects of model misspecification such as bias and loss of efficiency, we must calculate the expected value and variance of estimators obtained from the misspecified model with respect to the true, underlying density of the responses. When we obtain estimators by maximizing an assumed likelihood, further theory is available. Suppose that we use **maximum likelihood** to fit a model that assumes that the response Y follows a distribution F with parameter vector $\boldsymbol{\xi}^*$ and covariates X_F, while, in truth, Y follows a distribution G with parameter vector $\boldsymbol{\xi}$ and covariates X_G such that X_F is a subset of X_G. The work of Huber [3], Akaike [1] and White [10, 11] shows that the "maximum likelihood" estimator, $\hat{\boldsymbol{\xi}}^*$, under the false model **converges** to the value $\boldsymbol{\xi}^*$ that minimizes the **Kullback–Leibler** divergence [4] between the true and misspecified models. That is, $\boldsymbol{\xi}^*$ minimizes

$$\mathrm{E}_{X_G}\mathrm{E}_{Y|X_G} \log\left\{\frac{g(y|\boldsymbol{\xi}, X_G)}{f(y|\boldsymbol{\xi}^*, X_F)}\right\}, \tag{1}$$

where g and f are the true and misspecified response densities, and one takes the expectation with respect to the true model. Thus, when we maximize the incorrect likelihood, we obtain the parameters of the misspecified model that minimize the average difference between the logarithms of the true and misspecified densities. White [10, 11] further showed that $\hat{\boldsymbol{\xi}}^*$ has an asymptotic normal distribution with $\mathrm{var}(\hat{\boldsymbol{\xi}}^*)$ given by a matrix product of the form

$$\mathrm{var}(\hat{\boldsymbol{\xi}}^*) = \mathbf{A}^{-1}(\boldsymbol{\xi}^*)\mathbf{B}(\boldsymbol{\xi}^*)\mathbf{A}^{-1}(\boldsymbol{\xi}^*), \tag{2}$$

where

$$\mathbf{A}(\xi^*) = \mathrm{E}_{X,Z}\mathrm{E}_{Y|X,Z}\left[\frac{\partial^2 \log P_F(Y = y|\xi^*, X)}{\partial\xi_i^*\partial\xi_j^*}\right],$$

$$\mathbf{B}(\xi^*) = \mathrm{E}_{X,Z}\mathrm{E}_{Y|X,Z}\left[\frac{\partial \log P_F(Y = y|\xi^*, X)}{\partial\xi_i^*} \times \frac{\partial \log P_F(Y = y|\xi^*, X)}{\partial\xi_j^*}\right],$$

and expectations are with respect to the true model with G. The matrix $\mathbf{A}$ involves the **information** from the misspecified likelihood, while the matrix $\mathbf{B}$ involves the true variance–covariance structure of the responses. Under correct model specification, i.e. $f = g$, $\mathbf{A} = \mathbf{B}$.

Further results are available in other settings. For example, Li & Duan [5] considered the case where

the responses follow a generalized linear model with slope parameter vector $\boldsymbol{\gamma}$, but one fits a model that misspecifies the link function. Li & Duan showed that the estimated slope $\hat{\boldsymbol{\gamma}}^*$ from the misspecified model typically **consistently** estimates $\boldsymbol{\gamma}$ up to a scale factor. That is, $\mathrm{E}(\hat{\boldsymbol{\gamma}}^*) = c\boldsymbol{\gamma}$, for a constant c. Thus, one can still consistently estimate ratios of slope coefficients, γ_i/γ_j with a misspecified link function.

Solomon [8] and Struthers & Kalbfleisch [9] derived analogous results for survival models. These authors considered the effect of fitting a proportional hazards model when the data actually follow an **accelerated failure–time model** and vice versa, and found that the asymptotic expectation of the estimated regression coefficients of the misspecified models was approximately proportional to the true coefficients.

An Example: Omitted Covariates

We illustrate these results by examining the effects of omitted covariates in **logistic regression** models. We suppose that Y is a **binary** outcome, X and Z are covariates, and that the true model for the probability of response is

$$\operatorname{logit}\Pr(Y = 1|X, Z) = \mu + \beta X + \gamma Z. \quad (3)$$

To these data we fit the misspecified model

$$\operatorname{logit}\Pr(Y = 1|X) = \mu^* + \beta^* X. \quad (4)$$

Minimizing the Kullback–Leibler divergence, given in (1), in μ^* and β^*, we obtain

$$\mathrm{E}_{X,Z}\mathrm{E}_{Y|X,Z}\left\{\frac{1}{[1+\exp(-\mu-\beta X-\gamma Z)]} - \frac{1}{[1+\exp(-\mu^*-\beta^* X)]}\right\} = 0,$$

$$\mathrm{E}_{X,Z}\mathrm{E}_{Y|X,Z}\left\{\frac{X}{[1+\exp(-\mu-\beta X-\gamma Z)]} - \frac{X}{[1+\exp(-\mu^*-\beta^* X)]}\right\} = 0.$$

Thus, μ^* and β^* will depend on the true values μ and β and the joint distribution of X and Z. If X and Z are independent, then it follows that

$$[1+\exp(-\mu^*-\beta^* X)]^{-1} = \mathrm{E}_Z[1+\exp(-\mu-\beta X-\gamma Z)]^{-1} \quad (5)$$

and that $\beta^* = 0$ solves (5) when $\beta = 0$. Expanding the logit of (5) in a Taylor series about $\beta = 0$ yields

$$\mu^* + \beta^* X \approx \log\left[\frac{\mathrm{E}(p)}{\mathrm{E}(q)}\right] + \beta X\left[1 - \frac{\mathrm{var}(p)}{\mathrm{E}(p)\mathrm{E}(q)}\right], \quad (6)$$

where $\operatorname{logit}(p) = \mu + \gamma Z$ and $q = 1 - p$. Since $\mathrm{var}(p) \le \mathrm{E}(p)\mathrm{E}(q)$, we have $|\beta^*| \le |\beta|$, so omitting the covariate Z leads to attenuated estimates of the effect of X (*see* **Shrinkage**).

We compute variances of the estimators obtained from the misspecified, omitted covariate model using (2) and calculate the **asymptotic relative efficiency** (ARE) of $\hat{\beta}^*$ to $\hat{\beta}$ as

$$\mathrm{ARE}(\hat{\beta}^* \text{ to } \hat{\beta} \text{ at } \beta = 0) = \left[\lim_{\beta\to 0}\left\{\frac{\partial}{\partial\beta}\beta^*\right\}\left\{\frac{\partial}{\partial\beta}\beta\right\}^{-1}\right]^2\left[\lim_{\beta\to 0}\frac{\mathrm{var}(\hat{\beta})}{\mathrm{var}(\hat{\beta}^*)}\right].$$

The ARE involves the variances of $\hat{\beta}$ and $\hat{\beta}^*$ as well as the relationship between the parameters that these estimators estimate. Since $\beta^* = 0$ when $\beta = 0$, it is appropriate to compare variances and estimation efficiency at this value. When X and Z are independent, these calculations yield

$$\mathrm{ARE}(\hat{\beta}^* \text{ to } \hat{\beta} \text{ at } \beta = 0) = 1 - \frac{\mathrm{var}(p)}{\mathrm{E}(p)\mathrm{E}(q)}. \quad (7)$$

Thus, misspecifying a logistic regression model by omitting a covariate Z, that is independent of the included X, leads to attenuated estimates of the association of X with the response and less powerful tests of the hypothesis that X is not associated with the response.

The **two-by-two tables** in Tables 1 and 2 further illustrate this special form of model misspecification. Suppose that Y is a binary outcome, X and Z are binary covariates, and that the true model for the

Table 1 Hypothetical data from a logistic model

	$Z=0$			$Z=1$			
	$X=1$	$X=0$			$X=1$	$X=0$	
$Y=1$	90	75	165	$Y=1$	50	25	75
$Y=0$	10	25	35	$Y=0$	50	75	125
	100	100	200		100	100	200

Table 2 Data from Table 1 combined over levels of Z

	$X = 1$	$X = 0$	
$Y = 1$	140	100	240
$Y = 0$	60	100	160
	200	200	400

probability of response follows (3). Suppose, furthermore, that the observations arising from this model are as given in Table 1.

Each two-by-two table in Table 1 leads to an estimate $\hat{\beta} = \log 3$ and a fitted logistic regression model using both X and Z as covariates yields $\hat{\beta} = \log 3$ with associated standard error $\text{se}(\hat{\beta}) = 0.244$ and statistic for a Wald test (*see* **Likelihood**) of $H_0 : \beta = 0$ of $[\hat{\beta}/\text{se}(\hat{\beta})]^2 = 20.29$. Note that $\Pr(X = 1)$ is the same for $Z = 0$ and $Z = 1$, indicating that X and Z are independent. Combining the data over Z, that is, omitting Z and fitting the model given in (4) using the combined table, as given in Table 2, leads to an attenuated estimate of $\hat{\beta}^* = \log 7/3$ with associated standard error $\text{se}(\hat{\beta}^*) = 0.209$ and Wald test of $H_0 : \beta = 0$ of $[\hat{\beta}^*/\text{se}(\hat{\beta}^*)]^2 = 16.44$. Omitting Z not only leads to an attenuated estimate of the effect of X on Y but also to a less powerful test of the hypothesis that X has no effect on Y. To illustrate the quality of the approximation given in (6), applying the Taylor approximation in (6) to the data from Tables 1 and 2 suggests that $\beta^*/\beta = 0.75$, which corresponds closely to the observed value of 0.77. Applying the ARE formula given in (7) to Tables 1 and 2 yields an ARE value of 0.79. This closely corresponds to the observed ratio of the Wald test based on $\hat{\beta}^*$ to that based on $\hat{\beta}$ of 0.81. The analogous ratio of **likelihood ratio test** statistics is 0.78.

Detection of Model Misspecification

One uses **diagnostic** methods such as **residual** plots to examine whether a statistical model adequately describes a given data set; that is, whether one has correctly specified the model. Chapter 12 of McCullagh & Nelder [6] and Chapter 4 of Fahrmeir & Tutz [2] describe many such approaches. These diagnostic procedures include plots to examine the adequacy of assumed link and variance functions and the scale of the model covariates, as well as methods in which one embeds the chosen model within a larger class and tests to see whether a model in the larger class provides a much more accurate description of the data (*see* **Goodness of Fit**).

Since the matrices $\mathbf{A}$ and $\mathbf{B}$ in the variance formula given in (2) are equal with correct model specification, one could compare estimates of these two matrices to examine model adequacy. Indeed, Royall [7] recommends estimating variances of estimated model parameters by plugging estimates $\hat{\mathbf{A}}$ and $\hat{\mathbf{B}}$ into (2) to provide inference that is **robust** to model misspecification.

Mode

The population mode of a variable is that value of the variable which is possessed by the greatest number of members of the population. Empirically, the mode may be described as the most frequently occurring value in a sample of observations. It is much used to summarize **nominal data**; for example, the most common blood group, most common eye color, most common type of operation carried out in a particular hospital, and so on. It is occasionally used as a measure of location for continuous variables, but is only really suitable for those with symmetric **unimodal** distributions. For a symmetric distribution, the **mean**, **median**, and mode coincide.

In more formal terms, if $f(x)$ is a **probability** density function with continuous first derivative, a mode is a value of x for which

$$\frac{\mathrm{d}f(x)}{\mathrm{d}x} = 0, \qquad \frac{\mathrm{d}^2 f(x)}{\mathrm{d}x^2} < 0.$$

Thus there may be more than one mode of a distribution. An example of a *bimodal distribution* is shown in Figure 1. Empirical examples of such distributions are not common, but an example of a histogram with two distinct modes is shown in Figure 2. The data here correspond to the sizes of myelinated lumbosacral ventral root fibers taken from a kitten of a particular age. The first mode is associated with axons of gamma neurons and the second with alpha neurons.

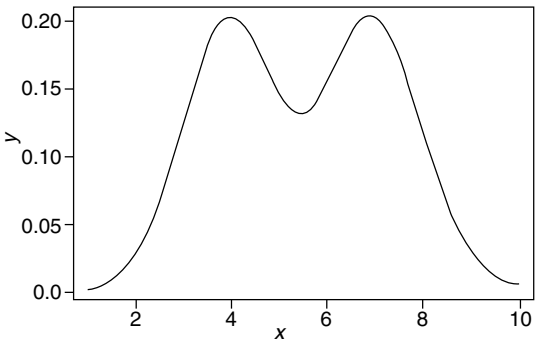

Figure 1 A bimodal density function

Tests for modes and for possible multimodality of density functions are important in, for example,

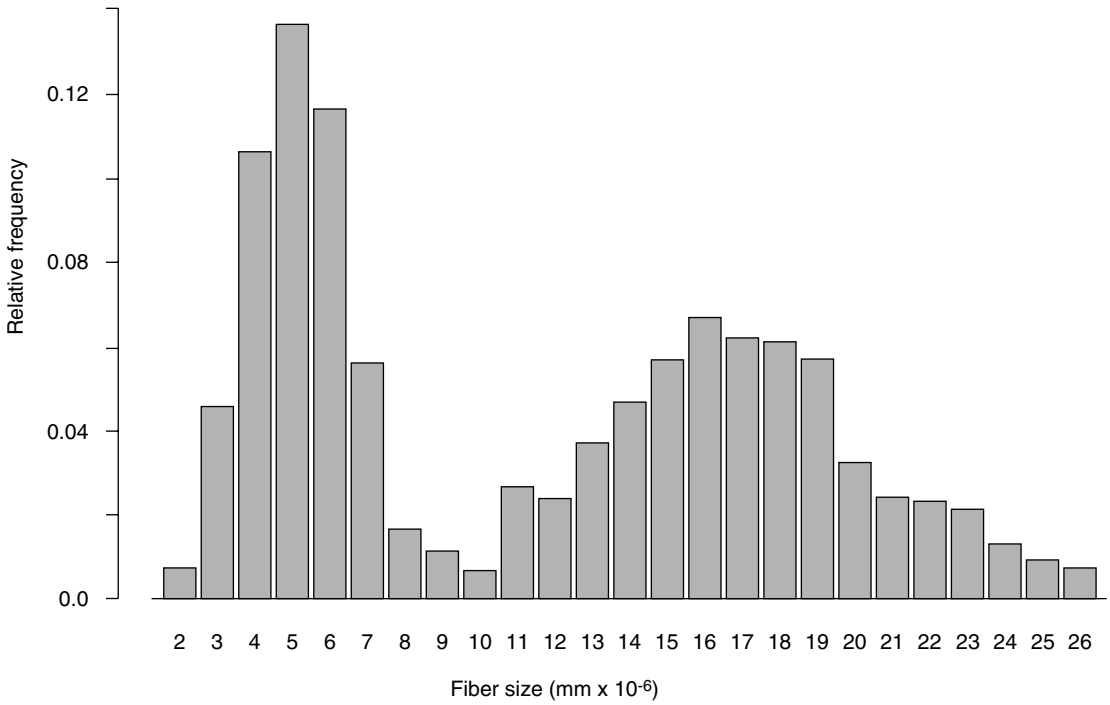

Figure 2 A histogram of myelinated lumbosacral ventral root fiber sizes from a kitten of a particular age

cluster analysis; a number of such tests are described in [1, 2], and [3].

Model Checking

A statistical model is an artificial construction and, as such, must be tested before use – indeed, it is often the deficiencies of a "first-guess" model which point the way towards an increased understanding of the behavior of a system. Modeling is (or should be) an iterative process, successively updating and checking a model until it is deemed to be adequate. Note that the adequacy of a model generally depends on its intended use – the question is not, "Is the model correct?" but rather, "Will it do the job?".

All models aim to describe, or explain, the behavior of some quantities of interest (the *outcome* or **response variable** in a statistical context), usually in terms of their relationship to other quantities (*predictor* or **explanatory variables**). Checking a model, therefore, involves asking two questions:

1. Is the model structure realistic (in the sense that it either reflects prior knowledge of the system being studied, or represents relationships that are empirically observed)?
2. How closely does it describe the observed behavior of the response variables?

Answering the first of these questions is largely a subjective affair requiring expert knowledge of the system being modeled; however, there are simple basic checks that can be made – for example, if one of the response variables is a proportion, does the model always yield values between 0 and 1? A good model should have such features built into it by design (*see* **Model, Choice of**), so this will not be discussed further here.

Answering the second question requires data analysis. In ideal circumstances, it may be possible to fit a model using one set of data and calibrate it using another. However, in biostatistical applications data are usually sufficiently scarce that this is not possible, and model fitting and checking are carried out using the same data. Techniques for assessing model adequacy are wide-ranging, and may be formal or informal. They all involve some measure of (dis)agreement between data and model – whether through some sort of residual analysis (*see* **Residuals**), where agreement equates to having observed data values which are similar to those predicted by the model, or through **likelihood**-based methods, where agreement is synonymous with the data values having high plausibility under the model. Departures from the model may be either *isolated*, where individual data points fall outside the general pattern, or *systematic*. We briefly outline techniques which may be appropriate for detecting these departures from the fitted model. Good accounts of the general ideas may be found in [6] and in [11, Chapter 12].

General Methods

When the response variable(s) are continuous (or ordinal with several categories; *see* **Ordered Categorical Data**), perhaps the simplest informal checks of a model are provided by visual inspection of residual plots. The most common plots show appropriately standardized residuals as some function of the model fitted values, or of explanatory variables. Isolated departures from the model are easily spotted using such plots; systematic departures may be indicated if any pattern is discernible, although a merely visual assessment can be misleading. A thorough treatment is given in [2].

Closely related to the idea of residual plots is that of comparing predicted responses from the fitted model with those obtained from the same data using nonparametric methods. This approach allows formal diagnostic procedures (*see* **Diagnostics**) to be established for checking the validity of a parametric model. Examples of these ideas may be found in [3, 4], and [7]; a straightforward overview is given in [1].

When a response variable is discrete, graphical methods of model checking are usually less straightforward. If the predictor variables are also discrete so that the data arise as a contingency table, standardized residuals may be computed for each cell in the table, and the resulting table of residuals inspected visually. The model may be inadequate if any residuals deviate significantly from zero, or if there appears to be a pattern to the residuals in some part of the table (for example, if there is a block of cells where all the residuals are negative). In cases where the predictor variables are continuous (for example, in **logistic regression**) residuals are harder to define – some techniques are given in [9].

Finally, goodness-of-fit tests (*see* **Goodness of Fit**) provide a quick and simple method of checking the fit of a model, although it should be stressed that these tests are usually quite general and may lack

power; they should always be supplemented by an examination of residuals.

Isolated Departures

Isolated departures from a model may not, in themselves, indicate that the model is a poor one for the purposes for which it was intended: it may be, for example, that data values have been wrongly recorded, or that the discrepancies occur at the extremes of the available data where the model is not expected to apply. It is always worth examining the original data record in such cases, as this can often provide an insight into why the model is failing. Many of the considerations which arise in the detection and assessment of **outliers** apply equally well in this context.

When an individual data point is suspect, yet is not obviously wrong, its effect upon the fitted model must be examined. In general, techniques for determining the influence of an individual point involve removing it and refitting the model. The *deletion residual* for a case is defined as the difference between the observed data value and that predicted by the refitted model, and is a measure of the *consistency* of that case with the rest of the data. Other statistics, such as the Cook statistic [11, p. 406], seek to quantify the effect of a point upon the estimated model parameters.

If individual cases are found to have a significant effect upon the fitted model, it may be worth refitting the model using some robust estimation procedure (*see* **Robustness**; **Robust Regression**) so as to downweight the contribution of the suspect points. This usually entails some modification of the classical distribution theory used in procedures such as goodness-of-fit testing; discussion of these issues may be found in [5, 12, 14].

Systematic Departures

Plotting residuals against predictor variables can be very helpful in identifying systematic discrepancies between model and data – if there is pattern in the plot of residuals against a predictor X, this implies that it is some function of X, rather than X itself, which should be used as a predictor.

Systematic discrepancies generally indicate that the overall pattern of a system's behavior is not adequately represented by the modeled relationships between the various components of that system. To check formally for such discrepancies requires some intuition regarding directions in which the model may be improved. Formal methods for checking the adequacy of a model involve embedding it in a wider class of models, and carrying out hypothesis tests to determine whether or not anything is to be gained from extending the model. Clearly, the wider class of models needs to be chosen with some care to yield informative results.

The references below describe techniques for model checking across a broad range of subject areas. In addition to those already cited, [15] is included for its comprehensive survey of the literature in a **time series** context, [10] contains material that is of use in survival analysis (*see* **Survival Analysis, Overview**), and [8] and [13] give a Bayesian perspective (*see* **Bayesian Methods**).

Model, Choice of

Choosing and fitting statistical models to data occupies a large proportion of the time of many medical statisticians. It is an activity that requires the use of many specific and well-defined techniques, such as using a certain **algorithm** to fit a model or calculating a particular **diagnostic**. However, the sequence of techniques used to select a model and decide its suitability will owe more to experience and judgment than technical expertise. Statistical modeling provides one of the best illustrations of Healy's remark that the practice of statistics is not a science but "that blend of knowledge and practical know-how" that he describes as a technology [15]; in this respect statistics has much more in common with medicine than is often supposed.

The present article describes, in broad outline, the issues that surround the choice of a statistical model. It has already been mentioned that experience and judgment play a greater role in this area of statistics than in many others, so many of the views expressed will inevitably have a marked personal component. On the other hand, while all the examples are medical, many of the issues discussed will be familiar to statisticians, whatever their area of application. Cox [10] provides a more general view of statistical modeling.

Constraints on space mean that most of the article will concentrate on the position when the data have been collected. The reader should, however, be aware that the design of a study can be greatly enhanced if the nature of the model that will be used is borne in mind at that stage (*see* **Experimental Design**).

In practical terms, a statistical model can be thought of as a tool that allows the statistician to determine and describe the relationships between variables in the data, and to quantify the variation present. At a deeper level there remains some uncertainty surrounding modeling [20]. The choice of a model depends on many things, but in most instances, the purpose of the study, the existing knowledge about the system under investigation, and how well the model fits the data are likely to be paramount.

Modeling in Clinical Trials and Epidemiology

Randomized Controlled Trials

Randomized controlled trials do not, as a rule, require much by way of statistical modeling (*see* **Clinical Trials, Overview**). The comparison of randomized groups can be based on a very general model of unit treatment additivity and the act of **randomization**. **Crossover** trials are not considered because they have special problems; similar concerns apply to cluster-randomized studies (*see* **Group-randomization Designs**), which are also excluded.

Some aspects of model choice do arise in connection with the outcome variable. For example, is a **proportional hazards** model suitable for an outcome that is a survival time, and, if so, is a fully parametric specification such as a **Weibull distribution** to be preferred to a semiparametric **Cox regression model**? The choice in this example may be based on how well the Weibull model fits, although other considerations, such as whether **predictions** of survival times are required, may also play an important role.

In smaller trials, the investigators may be reluctant to rely wholly on the randomization to produce comparable treatment groups. In these circumstances important prognostic variables can be used in an **analysis of covariance**. Decisions on which variables to include as **covariates** are usually not based on the data but have been identified a priori, in the trial protocol, where the considerations will have had a medical rather than statistical emphasis. This approach simplifies and strengthens the statistical analysis but it does not settle the matter entirely; for example, it may not be practical to specify, before the data are collected, the form in which the prognostic variables should enter the model. However, even in small studies, randomization should have produced groups that are fairly closely matched, and it is probably reasonable to view the model as providing a correction to a small imbalance, and the form of the variables is unlikely to be a major problem.

Although there are aspects of randomized controlled trials that may require some statistical modeling, it is of the utmost importance to remember that these are secondary considerations. The primary aim of the trial is to provide an estimate of the treatment effect and there is no direct interest in the model. If a model has been used in the analysis, then it is likely that some aspects of the model, such as the

inclusion of a variable the prognostic value of which is widely accepted, will be unchallenged, whereas other aspects, such as the inclusion of other variables, the form in which they are included (e.g. linear or quadratic), or the use of a Weibull distribution, may be less widely accepted. The trial will be weakened if the size of the estimate is crucially dependent on less well-founded aspects of the model; if the direction of the effect is dependent on these aspects, then the trial will be seriously undermined. In practical terms, the analyst can simply try a range of plausible models and observe their effect on the size and precision of the estimate of the treatment effect.

Modeling in trials is relatively straightforward, because the primary aim of the analysis is clear and because randomization should have relegated modeling to a subsidiary role.

Epidemiologic Studies

The discussion in this section is restricted to various types of **case–control** and **cohort studies**. Other forms of study could, undoubtedly, qualify under this heading and some of these, for example **screening** programs and **projections** of the number of AIDS cases, are considered in later sections.

In common with clinical trials, these studies usually have a clear aim that is readily summarized, usually by a **relative risk** or **odds ratio**. For example, they may be concerned with quantifying the risk of contracting some disease in those exposed to some hazard, relative to those not exposed. Unlike the situation in clinical trials, randomization cannot be used to produce groups that are comparable in all respects except exposure. Consequently, the investigator must rely on **matching** and on statistical modeling to adjust for differences in **confounding** variables. Deciding which variables to include in the model can be problematic, and some relevant issues of more general application will be touched on later. However, attempts to specify as much as possible of the model a priori can help. Also, considering the effect on important relative risks of using different plausible models is useful.

In a particular application it is likely that the problems of **variable selection** will be the main concern of the statistician. Apart, perhaps, from paying some attention to **additive** and **multiplicative** risks, the underlying form of the models will not be seriously questioned. This is because the considerations which have shaped these models tend to occur at a more general level than the individual study. **Poisson regression** or Cox regression for cohort studies and conditional or unconditional **logistic regression** for case–control studies arise because of the sampling schemes, general properties of **binary data** and statistical theory [5, 6]. In some areas of application, deeper, subject-specific justification of statistical models may be available, such as cancer epidemiology, in which **multistage carcinogenesis models** can provide guidance.

Modeling in General Biostatistics

The primary aims of randomized trials and epidemiologic investigations differ little from study to study. Other kinds of medical investigation, or even secondary analyses of trials or epidemiologic studies, can have much more diverse aims and, accordingly, the way in which models are chosen is much more varied. In choosing a model the analyst is guided by two distinct sets of considerations; namely, the purpose to which the model will be put, and the amount of quantitative information about the structure of the system being modeled. It is possible that quite different models of the same system may be needed for different purposes.

If we are trying to understand the relationship between some outcome, y, and other variables, written as a vector $\mathbf{x}$, then a common approach is to assume that

$$\mathrm{E}(y) = \mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}, \tag{1}$$

where $\boldsymbol{\beta}$ is a vector of regression coefficients. This may be adequate, but there is usually no reason why this form of relationship should hold. Such empirical models inevitably fail to carry much conviction; models which are based on a deeper consideration of the underlying system are intrinsically more compelling. For example, predictions based on such models will be grounded not only in the data used to fit the model, but also in the theory which gave rise to it. Likewise, associations between y and an element of $\mathbf{x}$ may be missed by (1) because of its linear form. Even if an association is found using (1), it may have limited value because the mechanism of the association has not been elucidated. Finally, fitting a theoretically based model allows the theory to be examined and possibly extended.

The main obstacle to the high-sounding sentiments just expressed is that in most areas of biostatistics

there is no suitable theory, and even when a semblance of one does exist, the guidance it offers is often partial. To illustrate this, three examples of models that are, to varying extents, based in theory are presented.

Example 1: Fetal Mandible Length

Data relating fetal mandible length to gestational age [8] were analyzed by Appleton [3] using a model that related mandible size to the process of cell proliferation that gave rise to its growth. He took the length to be $k(P + Q)^{1/3}$, where P and Q represent the number of proliferative and nonproliferative cells, and which obey

$$\frac{\mathrm{d}P}{\mathrm{d}t} = 2\alpha\eta P, \qquad \frac{\mathrm{d}Q}{\mathrm{d}t} = 2\alpha(1-\eta)P,$$

where α is the cell birth rate and η is a decreasing function of Q. The biology has brought us so far, but the precise form of $\eta(Q)$ is not specified: this type of shortfall is not untypical. Nevertheless, the form for $\eta(Q)$ may not be crucial (Appleton used a negative exponential) and the model certainly provides insight into how parameters, *the biological meaning of which is clear*, affect the data.

However, from a statistical point of view the approach is difficult; parameters were estimated using an *ad hoc* procedure and centiles (*see* **Quantiles**) would be awkward to calculate. One of the aims of the initial investigators was to construct centile charts, so for this purpose the simpler, empirical approach of Royston & Altman [25] may be both adequate and preferable.

The above example illustrates clearly how model choice needs to be related to the purpose of the study, as well as to the data. Of course, there would be no objection to the use of the cell-proliferative model to produce centiles, had it been straightforward to do so. However, it is doubtful whether the analyst would wish to embark on an elaborate analysis, whatever its advantages, if a more familiar and simpler approach could provide the required solution. More generally, it almost goes without saying that model choice must acknowledge what is feasible: much of the **mathematical biology** that might be called upon to provide the theory to underpin models is cast in terms of differential equations, as this example illustrates. Unless these equations have closed-form solutions, present statistical theory is not well equipped to take advantage of the insights they may offer.

Example 2: Compartmental Models

The class of compartmental models provides a good illustration of the utility of a theory based on differential equations with a closed-form solution. Many biological systems, mostly in pharmacology and drug metabolism but also in areas such as dialysis medicine, can be represented as several notional compartments, with a substance of interest (e.g. a drug or metabolite concentration) diffusing between the compartments at rates proportional to the existing concentrations. This gives rise to linear differential equations with fixed coefficients the solutions of which are of the form

$$\text{concentration} = A\exp(-\alpha t) + B\exp(-\beta t) + \cdots,$$

where the number of exponentials is equal to the number of compartments in the model. There is no need to use the differential equations directly in the analysis of the data – the theory has been used to indicate that a model of the above form should be fitted. Moreover, the theory shows how biological meaning can be ascribed to functions of the parameters (*see* **Pharmacokinetics and Pharmacodynamics**). Although this kind of model has been very successful, it may represent a theory that is further from reality than the model in the preceding example. The compartments are usually notional parts of the anatomy of a patient, and often give rise to volumes of distributions that greatly exceed the volume of the patient. This illustrates that even successful models which possess a biological foundation may need some tolerance in their interpretation.

From a statistical viewpoint, compartmental models are susceptible to theoretical ambition: it is often much easier to extend a model by adding extra compartments than it is to collect data to sustain the resulting model. An example arises in dialysis medicine, where it is thought that creatinine clearance follows a two-compartment model, $A\exp(-\alpha t) + B\exp(-\beta t)$, with $\alpha \gg \beta > 0$. Any information on α is in the creatinine concentrations measured in the first 10–20 minutes of dialysis, but it is precisely in this period that measured creatinine concentrations are completely unreliable, due to the conditions of mixing that prevail in the early stages of dialysis. It is thus virtually impossible to fit the model that theory indicates is appropriate.

Example 3: Measurement of Cerebral Blood Flow

A more esoteric example concerns the measurement of cerebral blood flow rate using the Kety–Schmidt technique [17]. A low concentration of an inert gas (nitrous oxide) is introduced into the breathing mixture of the subject and the arterial and venous concentrations of the gas are each measured several times (about eight times) over the next 20–30 minutes. Both concentrations rise to the same equilibrium level, A, but the arterial level, $C_a(t)$ rises faster than the venous level, $C_v(t)$; this is illustrated in Figure 1, in which is shown both the fitted model and a typical set of data. Fick's principle of diffusion indicates that the cerebral blood flow rate can be calculated from these quantities as

$$K \frac{A}{\int_0^\infty C_a(t) - C_v(t)\,\mathrm{d}t},$$

where K is a known constant. A theory has led thus far, but more detailed specification is not provided. We know that $C_a(t) \geq C_v(t) > 0$, $C_a(0) = C_v(0) = 0$, and that both curves increase monotonically to a limit of A, but many functional forms are still open; for example,

$$C_x(t) = A[1 - \exp(-k_x t)] \qquad \text{or}$$

$$C_x(t) = A\left(1 - \frac{k_x^2}{(t + k_x)^2}\right).$$

In the absence of a specific prescription, choosing between these, or other models, must be based on whatever guidance – biological, practical, or statistical – is available.

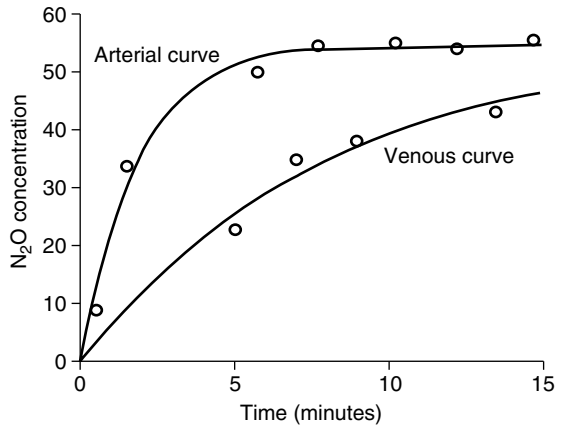

Figure 1

Kety [16] provides a detailed description of diffusion processes between different organs in the body that are related to, but not identical with, those involved in producing $C_a(t)$ and $C_v(t)$, and all of these use exponential functions. Although the arguments are not directly relevant, in the absence of other guidance, expressions for $C_a(t)$ and $C_v(t)$ based on exponential functions seem preferable.

Of course, whatever the nature of the background information on which a model is based, there is still a need to assess the performance of a model in practice. It is shown in Figure 1 that $C_a(t) = A[1 - \exp(-k_a t)]$ and $C_v(t) = A[1 - \exp(-k_v t)]$ provides a reasonable fit, so the estimated cerebral blood flow rate is found to be $K[k_a k_v/(k_a - k_v)]$, and this can be estimated by substituting estimates for the ks. When assessed over many more determinations, this model performs well, giving an example of a model that is specified by clear but incomplete theory and then supplemented by a number of *ad hoc* steps that are typical of the statistician's task in this type of analysis. A more detailed discussion of this example is available in Matthews et al. [21].

It is shown in Figure 1 that the model chosen in the final example fits the data well. Clearly, a model will not be acceptable unless it fits the data adequately, even if the model has a sound theoretical basis. However, how well a statistical model fits is often a relative matter, and it may well be sensible to use a model which has a sound basis and appears to offer a reasonable fit, in preference to an unfounded model which happens to offer a better fit to a particular dataset. Moreover, what constitutes an adequate fit is likely to be intimately bound up with the purpose of the analysis, and is an issue which can require careful judgment. Of course, determining *why* a theoretically based model does not fit can be a very informative exercise.

Models for Imputation

A rather different use of a model is to attempt to estimate some quantity which is not directly estimable on the basis of the collected, or collectable, data; three examples serve to illustrate this type of model.

Example 1: Lead Time in a Screening Program

One of the aims of screening a well population is to identify individuals with pre-clinical disease so that treatment can be instituted earlier; the time gained by use of a screening program (*see* **Screening, Overview**) is known as the *lead time*. Clearly, for any individual identified by the program as having the disease, the lead time cannot be observed. However, the mean lead time achieved may be of importance for assessing the value of the program.

Walter & Day [26] derive a method for estimating the mean lead time which involves postulating the density $f(\cdot)$ for the *sojourn time* of the disease in the population, which is the time during which the pre-clinical disease is potentially detectable by the program. An important component in the final choice of density is how well it fits the data, but it must also be recognized that the data may not be able to provide precise information on the form of f. As no fundamental guidance on the form of f is likely to be available, a choice that reflects features such as the generally skewed nature of waiting times must be made; Walter & Day considered **exponential**, **lognormal** and step functions. However, it is the mean lead time, not the form of f, that is of primary interest, and it is the sensitivity of this quantity, amongst sensible choices of f, that will determine how much reliance can be placed on the results of this analysis.

Example 2: Reporting Delays in Projection of Numbers of AIDS Cases

Amongst other things, the Cox Report [9] attempted to predict the number of **AIDS and HIV** cases likely to arise in the UK over a 2–5 year period, starting in 1988 (*see* **Projections: AIDS, Cancer, Smoking**). The prediction turned out to be highly influenced by the numbers of recently reported new cases. However, these cases were the ones that were most affected by delays in reporting to the Communicable Disease Surveillance Centre. To examine the effect of the delay, simple models of the delay process were constructed (see Appendices 7 & 8 of the Cox Report) and predictions on the basis of models incorporating this feature were proposed.

In both of these examples, calculations to permit the estimation of quantities of interest require the specification of the distribution $f(t)$ of some other quantity, such as sojourn time or reporting delay. In neither case is this distribution itself of primary interest nor is there any substantial guidance from the context of the application on the appropriate form of $f(t)$. Consequently the prudent analyst would pay attention to the effect of perturbations in the form of $f(t)$ on the quantities of direct interest.

Example 3: Proportion of Divided Cells in Thin Section

A slightly different form of imputation is reported by Wheeler and her colleagues [27]. Here interest centers on the proportion of labeled cells that divide at different times after labeling (*see* **Cell Cycle Models**). Labeled cells are visible under the microscope and it might be thought that cells which divide would appear as pairs of cells. However, counting such pairs suggested that only about 30% of all labeled cells eventually divided. It was thought that this unexpectedly low value (100% was expected) might be due to a geometrical artifact, namely that some cells divided in such a way that only one of the daughter cells was visible in the thin section of tissue which was scrutinized; see Figure 2.

A model was derived to take account of this feature; the model makes simple assumptions about the shapes of the cells and their relative positions after division and proceeds to use geometrical arguments to find an expression for

$$\Pr(\text{both daughter cells visible in section} \mid \text{cell has divided}).$$

Application of this formula indicated that the proportion of cells dividing was close to 100%. This model is, perhaps, less abstract than those in the previous examples but it does make several important simplifying assumptions. However, the simple model is probably quite sufficient. The main aim here is to investigate whether the artifact illustrated in Figure 2 is of sufficient magnitude to explain the discrepancy between observed and expected proliferation rates of

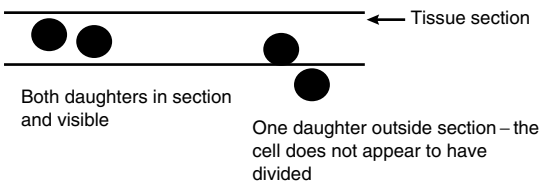

Figure 2

30% and 100%. Once a plausible model has shown that this is indeed possible, the histologist is unlikely to require information from more refined models.

Empirical Models

The preceding sections have discussed the way in which modeling can proceed when substantial guidance exists about the way the process being modeled "works". In medicine this is very much the exception rather than the rule. It is far more common that the statistician must assume that some quantity related to the outcome y and covariates x, usually $\mathrm{E}(y|x)$ or some function thereof, can be modeled as a smooth function of x. The rest of this section concerns models where the dependence on covariates is through a linear predictor, $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}$, where $\boldsymbol{\beta}$ represents unknown parameters that usually have to be estimated. Models of this form have proved very useful over the years, but their form can be rather restrictive, and alternative approaches, such as graph-theoretic models [11], **neural networks** and **tree-structured statistical methods** are becoming more widespread.

When constructing a model empirically, the form of the model is often largely dictated by whether the outcome is continuous, categorical, ordinal, and so on. Of course, many matters of detail arise, such as the need to transform a continuous variable or whether the variance or link function of a **generalized linear model** is correct. However, the main problem faced by the analyst is how to construct $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}$. It should be noted that this choice will generally be influenced by decisions made on such matters as **transformations** or link functions, and both these different facets of the model need to be considered and reconsidered as the modeling progresses.

Many studies in which an empirical approach to modeling is used are concerned with identifying associations between an outcome and a series of variables that are thought to affect the outcome. Other studies aim to build a model that is subsequently used to make predictions for new patients. Other kinds of study are possible and, because empirical modeling is used so widely, there are many approaches to the problems of **variable selection**: only a few general points are made here.

Studies seeking associations are very far from the well-specified models described in the earlier sections. Here it is likely that the investigator will have collected many covariates, with up to 50 or even 100 variables being commonplace. Such studies must be approached with caution, as many models will be possible, and little guidance is available as to when a satisfactory model has been found. In many cases it is prudent to await the collection of new data in order to assess the model; if the initial data set is sufficiently large, then the model might be determined on a random subset of the data and assessed on the remaining cases. This is especially important if the model is to be used for prediction [23].

Stepwise methods (*see* **Variable Selection**), such as forward selection or backwards elimination, are widely used, and have their uses. They aim to select the most important variables, with respect to some purely statistical criterion such as "proportion of variance explained", provided that the contribution of the variable can be distinguished from background noise. However, being chosen on solely statistical criteria, the resulting models may be difficult to interpret and may be at odds with existing knowledge. Miller [22] gives valuable information on the limitations of this approach; in particular, he points out that the estimates of $\boldsymbol{\beta}$ obtained after stepwise selection will be biased away from $\mathbf{0}$, sometimes by very substantial amounts.

The form of the model may be constrained by sensible pre-selection, perhaps by grouping variables according to type; for example, hematological, biochemical, performance status, and so on. Only simple summaries or representative members of each group are then entered into the model selection. Other *ad hoc* measures can be useful: if they have a common scale, highly **correlated** variables x_1 and x_2 might more profitably be entered as $\frac{1}{2}(x_1 + x_2)$, $x_1 - x_2$ and so on (*see* **Collinearity**).

Some attention needs to be given to the form in which variables are entered into the linear predictor. Categorical variables will be entered as **dummy variables**, as will ordinal variables (*see* **Ordered Categorical Data**), although in the latter case it will often be sensible to extract a trend that reflects the ordered nature of the categories (*see* **Trend Test for Counts and Proportions**). Continuous variables are usually entered in $\mathbf{x}^{\mathrm{T}}\boldsymbol{\beta}$ as a linear term, but this may not always be appropriate. Non-linearity in the effect of a variable can be accommodated by first turning it into a categorical variable defined by suitably chosen "cut-points" (*see* **Categorizing Continuous Variables**). The following is a good example of how

such effects might be anticipated: the risk to a baby of infection with respiratory syncytial virus is affected by the age of the mother [24], but it is clear that the effect of a change from 16 to 20 is likely to be much greater than a change from 24 to 28, and a categorized version of maternal age may well be the most sensible approach. However, in general the pre-specification of cut-points is difficult, and there are considerable dangers with data-dependent specification [2]. Adding nonlinear terms is certainly a possibility, but polynomial terms often have undesirable properties and more imaginative functions, such as fractional polynomials [25], may be needed (*see* **Polynomial Regression**). Another approach is to use the data to determine the form of dependence: **generalized additive models** replace $x_{i1}\beta_1 + x_{i2}\beta_2 + \cdots + x_{ip}\beta_p$ with $f_1(x_{1i}) + f_2(x_{2i}) + \cdots + f_p(x_{pi})$, where the f_js are data-derived smooth functions [14].

In empirical modeling generally, and stepwise selection methods in particular, little attention is paid to the possibility of **interactions** between variables. The problems of selecting variables have already been stressed, and to entertain the possibility of interactions inevitably complicates matters. However, if attention is restricted to two-way interactions, and then only to those that a priori are strongly plausible, considerable improvements in the fit and realism of models can be achieved.

Modeling Variance

The modeling described thus far usually relates, either explicitly or implicitly, to the mean response, but modeling of other aspects of the response, in particular its **variance**, is certainly possible. Explicit modeling of both mean and variance, by linear predictors in two sets of covariates, namely $\mathbf{x}_i$ and $\mathbf{z}_i$, as

$$\mathrm{E}(y_i|\mathbf{x}_i) = \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}, \qquad \mathrm{var}(y_i|\mathbf{z}_i) = \exp(\mathbf{z}_i^{\mathrm{T}}\boldsymbol{\lambda})$$

is described by Aitkin [1]. Such models can be useful, for example when deriving centile charts, but are not widely used. In practice, many nontrivial variance structures do not arise because of explicit modeling but, rather, as an implicit consequence of the need to take account of some aspect of the structure of the data. A simple example of this is a generalized linear model, where the variance function reflects the choice of outcome distribution.

More complicated examples can be found in spatial statistics (*see* **Epidemic Models, Spatial**) and data from complex surveys (*see* **Sample Surveys in the Health Sciences**). Perhaps the most common example that arises in medical statistics is **longitudinal data analysis**, in which an individual is measured on successive occasions. The measurements on an individual are likely to be correlated, and any analysis which does not acknowledge this aspect of the data will be flawed; in particular, it is likely to exaggerate the amount of information in the data. To overcome this, the outcomes on an individual can be modeled by $\mathbf{y} = \boldsymbol{\mu} + \boldsymbol{\varepsilon}$, where $\boldsymbol{\mu}$ is the mean response, usually modeled in terms of some covariates, and the residuals $\boldsymbol{\varepsilon}$ have a dispersion matrix $\mathbf{V}$ which reflects the nonindependence of the responses. This approach may seem attractive, but can have practical drawbacks: if $\mathbf{V}$ is unstructured it will depend on many parameters, or a more **parsimonious** model, such as an **ante-dependence model**, will need to be chosen. In many applications the number of observations per individual may make this level of modeling difficult.

An indirect way of introducing dependence within an individual which has some intrinsic appeal is through **random coefficient** models (*see* **Random Effects**; **Multilevel Models**). Suppose that the outcome being measured is fetal heart-rate during the second stage of labor, and it is thought that this increases with time. A possible model is

$$y_{ik} = \alpha_i + \beta_i t_{ik} + \varepsilon_{ik},$$

where y_{ik} is the heart-rate of the ith fetus on the kth occasion that the fetus was measured, being at time t_{ik}. The residual terms ε_{ik} are assumed to be *independent* with variance σ^2. Rather than taking the parameters α_i and β_i to be fixed, they are now assumed to be realizations from a **bivariate distribution** with mean α and β and dispersion matrix

$$\begin{pmatrix} \sigma_\alpha^2 & \sigma_{\alpha\beta} \\ \sigma_{\alpha\beta} & \sigma_\beta^2 \end{pmatrix}.$$

This model induces a covariance of $\sigma_\alpha^2 + \sigma_\beta^2 t_{ik} t_{ik'} + \sigma_{\alpha\beta}(t_{ik} + t_{ik'}) + \sigma^2$ between the kth and k'th outcomes on an individual, so a nontrivial dependence structure has emerged simply from the random coefficients. Models of this type have been used widely under a variety of names, but perhaps their most unified exposition and most powerful advocacy is given

by Goldstein [13], who calls them **multilevel models**. The rather specific forms of dispersion induced by these techniques may not be suitable for all applications but with sufficient ingenuity these can be amended, and in practice they have been found to be very flexible.

Multilevel models can also be adapted for use with noncontinuous outcomes. Hierarchical generalized linear models constitute an alternative line of development, which can accommodate a variety of dispersion structures and types of outcome. Further details of this class of models can be found in [19] and in the references therein.

The analysis of longitudinal data illustrates the following general point about the use of more elaborate models. It is important that the statistician should be convinced of the necessity of using more complicated models: simpler approaches will generally be easier to implement and, crucially, they may be much easier to explain to medical colleagues. The use of **summary measures** is a simple and readily understood approach to the analysis of longitudinal data, which will often circumvent the need for more complicated models of any description.

Some Modeling Pitfalls

Although statistical modeling has been very useful in many areas of medical statistics, the foregoing discussion has shown that selecting a model is far from an exact and precisely defined procedure. As such, it is important to keep in mind ways in which the process can go astray.

An obvious way in which things can go wrong is by selecting the wrong model: for example, if the data really follow the model $\mathrm{E}(y|x_1, x_2) = x_1^{\mathrm{T}}\beta_1 + x_2^T\beta_2$ and $\mathrm{E}(y|x_1) = x_1^{\mathrm{T}}\beta_1$ is fitted, then it is well known that the resulting parameter estimates will be **biased** (*see* **Misspecification**). Of course, there probably is no model which the data *really follow* and a good discussion of the practical attitude to a 'true model' is provided by Chatfield [7]. In most cases, the best we can hope for is a model that is consistent with what is already known and is adequate for the purpose to hand. This view of what forms an acceptable model is very much in keeping with Healy's notion of technology, where the practitioner is less concerned with some notion of "absolute truth" than with making the most of what truth is available.

Other, less philosophical, problems abound, and it would be impossible to give a complete catalog. However, two problems – namely, model uncertainty and mathematical coupling – are sufficiently general that they deserve special mention.

It will be clear from the preceding discussions that a good deal of uncertainty attends the process of deciding on the model, M, that will ultimately be used to fit the data. However, when presenting the results of model-fitting, it is customary to ignore this source of variability: so, for example, when quoting the uncertainty of parameter estimates, it is $\mathrm{var}(\hat{\beta}|M)$, not $\mathrm{var}(\hat{\beta})$ that is used. Ignoring the uncertainty in model selection can be very misleading, and there is much interest in ways in which this source of variation can be acknowledged [7, 12].

However, the appropriate level of formality necessary for this task needs careful consideration. Appleton [3] presents an example which is concerned with the estimation of cell growth rates at a given time; cross sectional data on numbers of cells at different times were available and several plausible growth curves were fitted. Although all curves appeared to provide reasonable fits to the data, the rate of growth differed substantially between the curves. A formal approach might attempt to amalgamate these estimates, and include the inter-model variation in the final interval estimate. However, presenting all the individual fits and rates may be more informative; this approach could lead the investigators to the disappointing but possibly sensible conclusion that their data were unable to answer their question. Both approaches are far preferable to simply selecting a model and providing an estimate with no further comment.

Another potential pitfall for the statistical modeler is mathematical coupling [4]. Essentially, it arises when attempts are made to relate an outcome variable to a covariate used in the definition of the outcome. For example, suppose that blood glucose concentration is measured at midnight (x) and at 0600 (y), and it is required to relate the change in concentration, $y - x$, to the initial value x: a spurious relationship can be caused by the presence of x on both sides of the equation. Related problems abound in analyses involving ratios, and are particularly hazardous for the unwary analyst [18] (*see* **Baseline Adjustment in Longitudinal Studies**).

No general solutions to either of these problems exist, but it is important that the statistician should

be aware of these and many other subtle traps that abound, and which can only be avoided by the exercise of shrewd judgment, as well as technical expertise. It is perhaps appropriate to end on this note, because much of this article has illustrated that many of the difficult problems encountered in modeling call on the statistician's judgment, common sense, and knowledge of the scientific discipline in which he works, and not just on his statistical expertise.

JOHN N.S. MATTHEWS

Molecular Epidemiology

Molecular epidemiology (ME) refers to the use of biomarkers in epidemiologic study designs, with emphasis on markers designed to measure exposure, to characterize host susceptibility, and to measure disease. Other terms involving closely related types of studies include biochemical epidemiology [16], pharmacogenetics [5], ecogenetics [10], and transitional studies [4], the last term referring to studies designed to bridge the gap between laboratory investigations and population studies. The first systematic description of the approach was provided by Perera & Weinstein [11]. They defined "molecular cancer epidemiology" as "advanced laboratory methods in combination with analytical epidemiology to identify at the biochemical or molecular level specific exogenous agents and/or host factors that play a role in human cancer causation". Consistent with the broad contribution of molecular biology to a more profound understanding of human disease, laboratory markers have been increasingly integrated into epidemiologic studies.

Objectives

Molecular epidemiology can be viewed as a synthesis involving the application of the methods of molecular biology to the study of disease on the population level. The contribution of molecular biology during the last third of the twentieth century has resulted in a redefinition of our basic understanding of human disease. **Population-based studies** have also grown in size and sophistication as the need to understand the cause of disease has been better appreciated, especially in an era where high costs for medical care indicate a need for expanded efforts at disease prevention.

Biological markers used in classical epidemiologic study designs can contribute to understanding **dose–response** relationships by assessing biologically effective dose, making interspecies comparisons, quantifying human interindividual variability, and identifying subsets at altered risk [13, 16]. In addition, biomarkers may provide more sensitive, specific, quantitative, or reproducible indications of study endpoints than traditional approaches, and therefore may in theory improve both study efficiency and validity. Such markers might provide early or specific indications of disease, and thereby identify a cancer at an earlier more treatable stage, or even in time for a preventive intervention. The mechanistic insight gained from biomarkers study may enhance disease understanding in profound ways.

Types of Biomarkers

Biomarkers are used to make three general types of measurements: (i) internal exposure, often measuring a compound of interest bonded to a macromolecule (i.e. hemoglobin or DNA, a critical "target"), but also including substances or their metabolites such as nicotine or its metabolite cotinine as a marker for exposure to tobacco smoke; (ii) host susceptibility factors, typically metabolic traits that are due to hereditary variation; and (iii) early biologic effects, mutations or cytogenetic damage – these are "effect" markers, that is indicators of disease or biological effects of pathologic significance.

Although for discussion purposes these categories are considered distinct, there is overlap. For example, detection of nicotine in the blood might be considered a marker of smoking (exposure), or an indicator of potential pathologic effects (early effect or disease marker), or might comprise part of a phenotype (e.g. ratio of nicotine to its metabolites) reflecting activity of a metabolizing enzyme (susceptibility factor).

Exposure Markers

The first category, exposure markers, offers the possibility of extending the reach of classic epidemiology beyond traditional questionnaire or external exposure monitoring. The actual dose of a compound of interest in the organism is assessed by the biomarker. Much attention has focused on measurement of adducts to DNA and other macromolecules, as it has been hypothesized that these might reflect both the relevant exposure, metabolic activation (generally considered an obligate step in carcinogenesis), and the actual quantity of compound that has reached a critical cellular target. In light of the target (i.e. DNA) involved, it is plausible that these compounds reflect a biologically relevant measure on the pathway to malignancy. The use of biomarkers is of course not new in the history of epidemiology. Examples include the use of polio antibody patterns to detect

Table 1 Conventional and molecular epidemiology

Feature	Conventional	Molecular
Use of biomarkers	Incidental	Systematic
Size	Varies, but often large	Varies, but typically small
Type of biomarker	Well established measures of exposure or disease	New or investigational markers of exposure, effect, or susceptibility
Cost	Low per subject	High per subject
Goals	Identify relationship between exposure and disease	Clarify mechanism and identify high-risk subgroups
Advantages	Historically the major method used to identify external cancer causes Public health orientation	Enter the "black box", i.e. elucidate mechanism Reduce interindividual variation Identify subsets at risk Potentially refine risk estimates Facile link to animal studies
Disadvantages	For certain cancers no cause is known, in spite of study Variable susceptibility is poorly understood Poor record at identifying reasons for individual susceptibility	Costly and complex Misclassification increased due to laboratory error Biomarker collection compromises validity Little public health benefit has resulted Ethical concerns

immunity. Some of the features of this approach that contrast with conventional epidemiology are indicated in Table 1.

"Susceptibility Markers" and Genetic Studies

The second category of markers involves host susceptibility factors, typically but not always genetic (hereditary) traits that control the metabolism of substances involved directly or indirectly with human disease. A susceptibility factor modifies the disease risk conferred by a specific exposure. It is further distinguished from exposure because susceptibility is generally preexisting and nontransitory. An early focus of molecular epidemiologic studies was a hypothesized genetic component in cancer. In contrast to earlier studies that searched for an obvious hereditary factor that accounted for the aggregation of specific cancers in families, these studies hypothesized that an influence of certain **genes** would exist for common apparently sporadic cancers in the general population as well.

Four studies in the 1980s laid the groundwork for the study of genetic susceptibility using epidemiologic study designs. This first generation of studies all involved a determination of a "metabolic phenotype", i.e. a pattern of metabolism of a test substrate that would reflect the underlying inherited genetic trait. In 1979, Lower et al. reported a relationship between the acetylation phenotype and incidence of urinary bladder cancer [8]. This early report was an early example of a study involving a relationship between a common genetic factor that controls the metabolism of an environmental contaminant and a disease in a case and control population. The term "molecular epidemiology" appeared in the title. The hypothesis was that "slow acetylators", a group comprising 50% of Western populations, would be less able to acetylate and thereby inactivate carcinogenic aromatic amine carcinogens. The second study examined aryl hydrocarbon hydroxylase (AHH) inducibility in relation to lung cancer [6]. The 20% of the population with the high inducibility phenotype were thought to convert carcinogens in tobacco to their active form at an accelerated rate, accounting for their increased risk of lung cancer. Ayesh et al.studied the relationship of debrisoquine metabolism (*CYP2D6*), to lung cancer [1]. A fourth genetic factor, glutathione *S*-transferase (*GSTM1*) was studied in relation to lung cancer. Subjects without this activity, who were presumably deficient in ability to eliminate carcinogenic epoxides from cigarette smoke, exhibited excess lung cancer risk [14]. All of these studies relied on a

laboratory measurement of a phenotype to infer the genetic susceptibility factor. In contrast, more recent studies directly identify the **genotype** through the study of an individual's DNA. Some of the advantages and disadvantages of the phenotype and genotype approaches are indicated in Table 2. Each of the four genetic traits initially approached with phenotypic measurements is under continued study today.

A major evolution over this period is the superseding of phenotype probe drug approaches by direct genotype assays. The genotype approach has distinct advantages and drawbacks (summarized in Table 2), but generally genotyping is increasingly the study approach of choice. Acetylation phenotyping, originally accomplished by administering sulfa drugs or caffeine, is now performed using a direct genotyping approach that detects the major mutations in the *NAT2* gene. The association of slow acetylators (*NAT2*-deficient subjects) with bladder cancer has been repeatedly observed in subjects with occupational exposure to arylamines. The debrisoquine phenotype can likewise be accurately detected by genotyping of the *CYP2D6* gene. The genotype determination is more complex since partially activating and inactivating mutations exist, and many minor variants must be tested. The degree of **association** of this trait with lung cancer is controversial. It appears most likely that elevated risk for smoking-related cancer in extensive metabolizers is limited to subjects with heavy smoking histories [2]. Investigators have attempted to understand the relationship of AHH activity to **polymorphisms** of both the *CYP1A1* and *Ah receptor* genes. The precise relationship of the gene polymorphisms to enzyme activity (and presumably to the ability to activate carcinogens in tobacco, thereby accounting for lung cancer risk) is incompletely understood, and may involve other genes such as the Ah receptor. Studies of the phenotype are subject to **bias** (see Table 2) but have often shown an effect, while genotype studies have been negative in Western studies, but positive in Japan. These differences may reflect the fact that both the mutation frequency (i.e. gene frequency) and mutation type (allelic heterogeneity) exhibit ethnic variation. Finally, a summary of the available literature suggests that individuals that lack *GSTM1* activity (i.e. without at least one functional *GSTM1* allele) exhibit consistently increased risk of both lung and bladder cancer (relative risk 1.2–1.6) [3] (*see* **Genetic Epidemiology**).

Effect Markers

Effect markers comprise the third category. These include nonspecific markers such as mutations in *Salmonella typhimurium* detected in urine or feces, various assays for chromosomal abnormalities (e.g. micronuclei, sister-chromatid exchange), as well as more specific findings, such as the specific chromosome translocations that characterize hematologic malignancies. These markers complement better

Table 2 The phenotype and genotype approaches in molecular epidemiology

Consideration	Phenotype	Genotype
Advantage	Approach is historically tested Reflects physiologic, *in vivo* disposition of drug Inducers, inhibitors, substrates all combine to reflect physiology	Identifies heterozygotes Simple, requires only germline DNA sample Unaffected by illness, diet, medications, etc. Can be performed with microquantities Noninvasive samples (i.e. DNA obtained from mouth wash, hair follicles, or standard blood sample)
Disadvantage	Numerous factors may distort measurements, e.g. drug–drug interaction More complex analysis Patient cooperation required Phenotyping protocols difficult to adapt to field study Time-consuming nature of test results in refusal to participate	Functional status of mutations may be unknown Risk of exposure to blood-borne pathogens Ethical questions arise since DNA may be used for other tests Allelic heterogeneity Ethnic differences

known histologic and cytologic markers such as dysplasia or increased mitotic frequency.

Related Approaches

Inborn errors of metabolism were described by Garrod in the early twentieth century and are distinct from the genetic traits of interest to ME in that they invariably produced phenotypic manifestations and clinical consequences. In genetic terms, the associated condition was fully **penetrant** given the genotype. Most of the genetic traits of interest in ME are not highly penetrant. In pharmacogenetics, an area closely related to ME, the phenotype is detected with laboratory probes and does not always result in clinical sequelae, i.e. the condition is not fully penetrant. Sequelae result after specific exposures, typically to pharmaceutical agents (but also xenobiotics, carcinogens, or endogenous compounds) whose metabolism is dependent upon the enzyme (or receptor, immune factor, or other element) that is subject to pharmacogenetic variability. Chronic conditions are thought to occur with altered frequency based on long-term exposures to specific agents subject to this type of variability.

Criticism

The field has attracted much attention and methodological critique. First, there are those who have questioned whether ME is a true subdiscipline with substantive new content [9]. While no one distinguishing factor can uniquely identify ME studies, the alteration of study design to allow the use of biomarkers is probably characteristic. A second area that has generated negative comment is the small size and inadequate attention to design issues in some studies. The size of certain studies has been constrained by the cost of specific assays. For example, a newly developed or expensive gas chromatography/mass spectroscopy assay could cost over $1000 per sample. Given this limitation it is axiomatic that proper design of a study should be a major concern in order to achieve maximum efficiency. Certain goals of ME such as identifying subsets of the population at elevated risk will necessitate large sample size. Some studies have placed emphasis on the "molecular" aspects but with minimal "epidemiology" or sophistication in the statistical treatment. Both the quality and the co-opting of the "epidemiology" label to cover such studies are unfortunate, but some bad studies do not invalidate the proper use of the approach. Some have also dismissed the "molecular" modifier for epidemiology as unnecessary, stating that it is improper to identify a component of epidemiology based on a measurement technique, compared with recognized fields of epidemiology such as "pediatric", "infectious", "occupational", or "clinical". Such a complaint seems churlish given that the growth of scientific inquiry does not follow a set pattern and nomenclature is anything but consistent.

A more basic issue to emerge is that some goals of ME may not be attainable with the designs being used. For example, some proponents of ME would like to estimate the **absolute risk** of cancer in an individual associated with a specific set of genetic factors. While the general direction of inquiry is laudable, the hospital-based case–control approach (*see* **Case–Control Study, Hospital-based**) often advocated is incompatible with this goal, and population-based case–control (*see* **Case–Control Study, Population-based**) or **cohort** designs will be required. In addition, much larger studies (i.e. thousands of subjects rather than hundreds) will be required to detect **gene–environment interactions** of medical interest. The idea that combinations of factors (i.e. genetic factors plus mutation load) will refine individual risk [15] challenges the traditional public health advocacy of epidemiology and refocuses emphasis on "individual" clinical risk in a way that is disturbing to many [7, 9]. The implicit reductionism of the approach raises worrisome ethical issues. In particular, the improper use of genetic information derived from these studies in an increasing concern.

Two critiques finally emerge as central. The first is that historically, all the major etiologic environmental factors known to cause cancer have been identified not through mechanistic or animal studies, but through **observational studies** in humans. Smoking and lung cancer is a paradigmatic example. Case–control and cohort studies unequivocally demonstrated the association of tobacco use and lung cancer a least a decade before Aurbach's smoking beagles were shown to exhibit characteristic preneoplastic changes in the respiratory tract (*see* **Smoking and Health**). Moreover, the history of epidemiology demonstrates that public health and prevention can be accomplished in the absence of detailed mechanistic understanding.

Secondly, it is difficult to demonstrate that specific biomarkers are superior to properly designed traditional questionnaire approaches to exposure assessment. A carefully designed smoking questionnaire (*see* **Questionnaire Design**) will demonstrate a stronger association of tobacco use with lung cancer then either serum cotinine (nicotine metabolite marker of recent smoking) or smoking-related carcinogen adducts of hemoglobin (e.g. 4-aminobiphenyl, a marker of intermediate exposure). It can be argued that these markers relate to recent or intermediate time periods, and the exposure that caused the disease is remote. Nevertheless, without a clear public health benefit, one might ask whether ME studies are worth the cost in time, resources, lost eligible subjects (some will refuse a biospecimen request), and new sources of bias. The roles of questionnaire information and biomarkers are complementary, and there are clearly settings where questionnaire approaches are not suitable. Nevertheless, the tacit assumption that biomarkers are universally superior requires critical scrutiny [12].

Summary

The advances of molecular biology have transformed science in the late twentieth century and may ultimately be more far-reaching than the revolutionary advances of physics in the first half of the century. It is inevitable that this understanding must permeate scientific investigation involving human disease, including the study of disease on the population level. Epidemiology provides the tools for such study, and it is fitting that these tools will be transformed and adapted to optimize the use of biomarkers. The trend towards increasing emphasis on laboratory methods in clinical medicine shows no signs of declining, and such approaches will find application in the studies that define both the diseases and the factors that cause them. Seen in this context, the growth of molecular epidemiology is both natural and inevitable. To achieve the full potential of the ME approach, however, investigators will need to pay close attention to issues of study design and quality control.

Moment Generating Function

Moment generating functions are used to derive **moments** of distributions, establish the distributions of sums and differences of independent **random variables**, and derive limiting distributions of sequences of random variables. We say that a variable X with distribution function $F(x) = \Pr(X \leq x)$ has a moment generating function $M_X(t)$, i.e. the moment generating function exists if

$$M_X(t) = \mathrm{E}[\exp(tX)] = \int_{-\infty}^{\infty} \exp(tx)\, \mathrm{d}F(x) \quad (1)$$

is finite for any real number t in some open interval $-T < t < T$. For a continuous distribution with density function $f(x)$,

$$M_X(t) = \int_{-\infty}^{\infty} \exp(tx) f(x)\, \mathrm{d}x, \quad (2)$$

and for a discrete random variable taking values $a_1, a_2, \ldots, a_m$ with probabilities $p_1, p_2, \ldots, p_m$, respectively,

$$M_X(t) = \sum_{j=1}^{m} \exp(ta_j) p_j. \quad (3)$$

When it exists, $M_X(t)$ is a strictly positive and continuously differentiable function of t, for $|t| < T$. Moreover, $M_X(0) = 1$ and moments of any order exist. Using $M_X^{(r)}(t)$ to denote the rth derivative of $M_X(t)$ with respect to t, we may obtain the rth moment of X about the origin from

$$\mathrm{E}(X^r) = M_X^{(r)}(0) \quad \text{for } r = 1, 2, \ldots, \quad (4)$$

and a Taylor series expansion about the origin yields

$$M_X(t) = 1 + \sum_{r=1}^{\infty} \frac{\mathrm{E}(X^r) t^r}{r!}. \quad (5)$$

Moments of positive random variables involving non-integer powers may be obtained from a corresponding result derived by Cressie & Borkent [1]. Central moments, $\mu_r = \mathrm{E}[(X - \mu)^r]$, $r = 1, 2, \ldots$, may be obtained by evaluating derivatives of the central moment generating function,

$$\mathrm{E}\{\exp[(X - \mu)t]\} = \exp(-\mu t) M_X(t) = 1 + \sum_{r=1}^{\infty} \frac{\mu_r t^r}{r!}$$

at $t = 0$.

The existence of the moment generating function uniquely determines a distribution. If X and Y are random variables with respective distribution functions $F(x)$ and $G(y)$ and moment generating functions $M_X(t)$ and $M_Y(t)$, then $F(x) = G(x)$ for all real x if and only if $M_X(t) = M_Y(t)$ for all t in some open interval $-T < t < T$.

Another important use of the moment generating function is to establish the limiting distribution for a sequence of random variables. Let $X_1, X_2, \ldots$, denote a sequence of random variables with distribution functions $F_1(x_1), F_2(x_2), \ldots$, respectively, and suppose the moment generating function $M_{X_n}(t)$ exists for each X_n. Then, the pointwise **convergence** of $M_{X_n}(t)$ to some function $M_\infty(t)$ for all $|t| < T$ implies $F_n(x)$ converges to $F_\infty(x)$, the distribution function corresponding to $M_\infty(t)$, as $n \to \infty$, for all points x for which $F_\infty(x)$ is continuous. $F_\infty(x)$ will be a proper distribution, however, if and only if $M_\infty(0) = 1$. Conversely, the pointwise convergence of $F_n(x)$ to some limit $F_\infty(x)$ implies the pointwise convergence of the corresponding sequence of moment generating functions to the moment generating function for $F_\infty(x)$ for any t in any open subset of R in which the $M_{X_n}(t)$ are uniformly bounded.

A multiplicative property provides convenient derivations of sums or differences of independent random variables. If $X_1, X_2, \ldots, X_n$ are independent random variables, for example, then

$$M_{X_i - X_j}(t) = M_{X_i}(t) M_{X_j}(-t) \quad (6)$$

and

$$M_{X_1 + X_2 + \cdots + X_n}(t) = M_{X_1}(t) M_{X_2}(t) \cdots M_{X_n}(t). \quad (7)$$

We can establish the distribution of a difference or sum by recognizing the product on the right of (6) or (7) as the moment generating function for a specific distribution.

Koopmans [3] derived a basic probability inequality from the existence of the moment generating

function. For independent and identically distributed random variables $X_1, X_2, \ldots, X_n$, where the common moment generating function $M_X(t)$ exists for $|t| < T$, we have

$$\Pr(X_1 + X_2 + \cdots + X_n > 0) \leq [M_X(t)]^n$$

for any $0 < t < T$. Koopmans used this result to investigate **laws of large numbers**.

The joint moment generating function of a multivariate random variable $\mathbf{X} = (X_1, \ldots, X_k)$, defined as

$$M_{\mathbf{X}}(t) = \mathrm{E}\left[\exp\left(\sum_{j=1}^{k} t_j X_j\right)\right], \qquad (8)$$

is said to exist if it is finite for all $-T < t_j < T$, $j = 1, \ldots, k$. Mixed moments such as $\mathrm{E}(X_i^r X_j^s)$ may be obtained by differentiating (8) r times with respect to t_i and s times with respect to t_j, and evaluating the resulting derivative at the origin. Moment generating functions for marginal distributions are obtained by setting appropriate t_js equal to zero; for example,

$$M_{X_2}(t_2) = M_{X_1, X_2, X_3}(0, t_2, 0).$$

Random variables $X_1, X_2, \ldots, X_k$ are mutually independent if and only if

$$M_{\mathbf{X}}(t) = M_{X_1}(t_1) M_{X_2}(t_2) \cdots M_{X_k}(t_k).$$

For nonnegative integer-valued random variables, it is sometimes convenient to derive factorial moments

$$\mu_r{}^* = \mathrm{E}[X(X-1)\cdots(X-r+1)], \quad r = 1, 2, \ldots$$

from the derivatives of the factorial moment **generating function**

$$G_X(t) = \mathrm{E}(t^X) = \mathrm{E}\{\exp[X \ln(t)]\} = M_X[\ln(t)] \quad (9)$$

evaluated at $t = 1$. $G_X(t)$ is also called the probability generating function because it uniquely determines the probability function for X through the relationship

$$\Pr(X = r) = \frac{G_X^{(r)}(0)}{r!}.$$

Johnson et al. [2] and Smith [4] provide more extensive reviews of the uses and properties of various types of generating functions.

KENNETH KOEHLER

Moments

Moments are used to quantify and summarize the **mean** value, level of dispersion, and other features of a **probability** distribution. The rth moment of a **random variable** X about zero is simply the average value (or expected value) of X^r. It is defined by the Riemann–Stieltjes integral

$$\mathrm{E}(X^r) = \int_{-\infty}^{\infty} x^r \, \mathrm{d}F(x), \tag{1}$$

where $F(x) = \Pr(X \leq x)$ is the distribution function for X. We take r to be a positive integer, but this is not a requirement. When X is a continuous random variable with density function $f(x)$, we have

$$\mathrm{E}(X^r) = \int_{-\infty}^{\infty} x^r f(x) \, \mathrm{d}x.$$

For a discrete distribution on the nonnegative integers,

$$\mathrm{E}(X^r) = \sum_{k=0}^{\infty} k^r \Pr(X = k).$$

Moment formulas may also be obtained from derivatives of **moment generating functions** or from derivatives of **characteristic functions**.

The first moment about zero ($r = 1$) is the mean of the distribution of possible values for X. It is also called the expected value (or **expectation**) of X. We use the symbol μ to denote the mean.

The rth moment about a constant c is $\mathrm{E}[(X - c)^r]$. Taking $c = \mu$, we have the rth central moment

$$\mu_r = \mathrm{E}[(X - \mu)^r] = \int_{-\infty}^{\infty} (x - \mu)^r \, \mathrm{d}F(x), \tag{2}$$

which is also called the rth moment about the mean. For a discrete distribution on the nonnegative integers,

$$\mu_r = \sum_{k=0}^{\infty} (k - \mu)^r \Pr(X = k),$$

and for a continuous distribution with density function $f(x)$,

$$\mu_r = \int_{-\infty}^{\infty} (x - \mu)^r f(x) \, \mathrm{d}x.$$

The first central moment is zero by definition. The second central moment, usually denoted by σ^2, is called the **variance** of X, and its positive square root, $\sigma = (\mu_2)^{1/2}$, is called the **standard deviation**. As the square root of the average squared deviation from the mean, the standard deviation provides a measure of the level of dispersion in the distribution of the possible values of X. It can also be given a probability interpretation. When X has any **normal** (Gaussian) distribution, for example, the probability that an observed value for X lies in the interval $(\mu - \sigma, \mu + \sigma)$ is approximately 0.68 and the probability that it lies in the interval $(\mu - 2\sigma, \mu + 2\sigma)$ is approximately 0.95.

Central moments are obtained from moments about zero by the formula

$$\mu_r = \sum_{j=0}^{r} (-1)^j \binom{r}{j} \mu^j \mathrm{E}(X^{r-j}), \tag{3}$$

where $\binom{r}{j}$ is a binomial coefficient. For example,

$$\begin{aligned}
\mu_2 &= \mathrm{E}(X^2) - \mu^2, \\
\mu_3 &= \mathrm{E}(X^3) - 3\mu\mathrm{E}(X^2) + 2\mu^3, \\
\mu_4 &= \mathrm{E}(X^4) - 4\mu\mathrm{E}(X^3) + 6\mu^2\mathrm{E}(X^2) - 3\mu^4.
\end{aligned}$$

Inverse formulas are

$$\begin{aligned}
\mathrm{E}(X^2) &= \mu_2 + \mu^2, \\
\mathrm{E}(X^3) &= \mu_3 + 3\mu_2\mu + \mu^3, \\
\mathrm{E}(X^4) &= \mu_4 + 4\mu_3\mu + 6\mu_2\mu^2 + \mu^4.
\end{aligned}$$

Ratios of moments, or ratios of functions of moments, are also used to help characterize the level of dispersion and the shape of a probability distribution. The coefficient of variation, σ/μ, may be used to quantify variation in an assay method or some other measurement technique relative to the mean size of the quantity to be measured. It is often expressed as percentage by multiplying by 100%. We may describe the shape of a distribution with the **skewness** index

$$[\beta_1(X)]^{1/2} = \mu_3(\mu_2)^{-3/2} \tag{4}$$

and the **kurtosis** index

$$\beta_2(X) = \mu_4(\mu_2)^{-2} \tag{5}$$

Although these quantities may not uniquely determine the shape of a distribution, moments above the fourth order are rarely used to summarize properties of distributions.

If a random variable can only take values in a finite interval, then knowledge of all of the moments completely determines the distribution. This may not be true for some unbounded distributions, however, without imposing further constraints, but the most commonly used families of distributions, such as **Pearson distributions**, are characterized by no more than four parameters, which are usually uniquely determined by no more than four moments. We refer the reader to Johnson et al. [1, 2] for reviews of such families. We may estimate parameters from observed data by deriving a formula for each parameter as a function of the moments and substituting estimates of moments into the formulas (*see* **Method of Moments** estimation).

We define joint moments for an n-dimensional random vector $\mathbf{X} = (X_1, \ldots, X_n)$ as expectations of products. Quantities like $\mathrm{E}\left(\prod_{j=1}^{n} X_j^{r_j}\right)$, for example, are called product moments about zero. Central product moments (also called central mixed moments) are defined by

$$\mu_{r_1 r_2 \ldots r_n} = \mathrm{E}\left[\prod_{j=1}^{n} (X_j - \mu_j)^{r_j}\right], \tag{6}$$

where $\mu_j = \mathrm{E}(X_j)$. A special case,

$$\mathrm{cov}(X_j, X_k) = \mathrm{E}[(X_j - \mu_j)(X_k - \mu_k)] \tag{7}$$

is called the covariance of X_j and X_k (*see* **Covariance Matrix**). We can characterize the strength of the linear relationship between X_j and X_k with the **correlation** coefficient

$$\rho_{jk} = \frac{\mathrm{cov}(X_j, X_k)}{\{\mathrm{E}[(X_j - \mu_j)^2]\,\mathrm{E}[(X_k - \mu_k)^2]\}^{1/2}}, \tag{8}$$

which achieves its bounds of 1 (or -1) when all possible values for (X_j, X_k) lie on a straight line with a positive (or negative) slope. When X_j and X_k are mutually independent, then $\mathrm{cov}(X_j, X_k) = \rho_{jk} = 0$, but the converse is not always true.

Other types of moments are sometimes considered. The rth *absolute moment* about zero, $\mathrm{E}(|X|^r)$, and the rth absolute central moment, $\mathrm{E}(|X - \mu|^r)$, are examples. For integer valued discrete random variables, it may be convenient to derive *factorial moments* instead of central moments or moments about zero. The rth descending factorial moment of a random variable X is defined as

$$\mu_{(r)} = \mathrm{E}[X(X-1)\ldots(X-r+1)], \tag{9}$$

the expectation of a product of r incrementally decreasing terms, for $r = 1, 2, 3, \ldots$. Moments about zero are obtained from descending factorial moments through the formula

$$\mathrm{E}(X^r) = \sum_{k=1}^{r} \frac{\mu_{(k)}}{k!} \sum_{j=0}^{k} (-1)^j \binom{k}{j} (k-j)^r. \tag{10}$$

In particular,

$$\begin{aligned}
\mathrm{E}(X) &= \mu_{(1)}, \\
\mathrm{E}(X^2) &= \mu_{(2)} + \mu_{(1)}, \\
\mathrm{E}(X^3) &= \mu_{(3)} + 3\mu_{(2)} + \mu_{(1)}, \\
\mathrm{E}(X^4) &= \mu_{(4)} + 6\mu_{(3)} + 7\mu_{(2)} + \mu_{(1)}.
\end{aligned}$$

Cumulants are an alternative to moments that have historically played a prominent role in the study of probability distributions. While moments about zero are obtained from coefficients in a power series expansion of the characteristic function of a distribution, cumulants are obtained from coefficients in a power series expansion of the natural logarithm of the characteristic function. Cumulants have some convenient theoretical properties, but moments are more frequently used in practical applications. We refer the reader to Stuart & Ord [3] for additional definitions and formulas and a good account of the relationships between various types of moments and cumulants.

KENNETH KOEHLER

Monte Carlo Methods

Monte Carlo techniques are used in situations in which the analytic solution of the problem is either intractable or time consuming. Instead of calculating exact quantities, simulation is used to produce stochastic approximations to the solution.

In practice, Monte Carlo methods are discussed interchangeably with **simulation**. Useful discussions can be found in a variety of monographs, such as [7, 8], and [9], to which the reader is referred for a thorough review.

Monte Carlo techniques are used in a wide range of problems. Common uses are the construction of Monte Carlo **hypothesis tests**, **bootstrap** distributions, and for **numerical integration** in **Bayesian** calculations. More specialized uses are the analysis of complex stochastic systems.

Monte Carlo techniques have a long history in mathematics. An early example is Buffon's Needle dating from 1733, described in [7]. Realistically, the widespread application of Monte Carlo techniques has only become feasible with the availability of cheap and efficient computing since the 1970s. In fact, the exponential increase in available computing power has led to Monte Carlo techniques facilitating major statistical advances.

As a trivial example of a Monte Carlo method we consider the calculation of the mean μ of a density $g(x)$. The analytic solution is

$$\mu = \int x g(x)\, \mathrm{d}x,$$

which may be difficult to evaluate. In the Monte Carlo approach, we sample k observations, $X_1, \ldots, X_k$, from $g(x)$ and form the Monte Carlo estimate

$$\hat{\mu} = \frac{\sum_{i=1}^{k} X_i}{k}.$$

A **law of large numbers** can be used to show that this estimate will converge strongly to the true value, provided the integral exists (*see* **Convergence in Distribution and in Probability**). Thus, we can produce an estimate of a required accuracy by manipulating k.

An important point to note is that the term Monte Carlo does not refer to a particular stochastic **algorithm**, only to the fact that a stochastic algorithm has been used. For instance, in the previous example there is an infinite number of different stochastic algorithms that we could use to sample the observations and estimate μ.

The choice of algorithm depends on a variety of factors. In many problems there is a "natural" formulation. For example, we estimate the mean of a distribution by taking the mean of a sample from the distribution. Another criterion that should be considered when choosing an algorithm is the **efficiency** of the method. This leads to the contemplation of variance-reduction techniques, which are used to produce more accurate estimates for the same computational effort (*see* **Simulation**).

In practice there is a tradeoff between the use of an inefficient algorithm that is easy to design and implement and an efficient algorithm that could take detailed analysis to design. Provided that the inefficient algorithm is not pathological, it is sufficient merely to run the algorithm for an appropriately longer period of time, to obtain results comparable to those with the efficient algorithm. An important caveat is that great care must be taken to ensure that satisfactory convergence has occurred. In any application the relevant literature should be consulted.

We now briefly describe several important examples of the use of Monte Carlo techniques.

Monte Carlo Hypothesis Testing

The first technique considered is that of Monte Carlo **hypothesis testing**. Assume we have a statistic T, and a simple null hypothesis H_0 and composite alternative H_a. Consider constructing a test of size $1 - \alpha$. If the sampling distribution of $T|\mathrm{H}_0$ is known and analytically tractable, then we can use standard calculus methods to construct a **critical region** for rejecting H_0.

Alternatively, we consider constructing a Monte Carlo test of H_0. Specification of the rejection region involves the calculation of a **quantile** of the null distribution of T. In the Monte Carlo approach we estimate the required quantile stochastically. To do this we sample from the distribution $h(t)$ of $T|\mathrm{H}_0$, to produce $T_1, \ldots, T_k$. Depending on the alternative, we reject H_0 if the observed t is more "extreme" than

$100(1-\alpha)\%$ of the combined simulated values and the observed t.

As a simple example we consider the one sample t test that the mean of a normal distribution is μ against the alternative that it is less than μ. If we observe a sample $X_1, \ldots, X_n$, then our statistic is

$$T = \frac{\overline{X} - \mu}{\text{se}},$$

with

$$\text{se} = \frac{\sum_{i=1}^{n}(X_i - \overline{X})^2}{n(n-1)},$$

the standard error of the mean. Using the classical approach, we calculate that the rejection region under the null is $t < t_{\alpha,n-1}$, where $t_{\alpha,n-1}$ is the α quantile of **Student's *t* distribution**, with $n-1$ degrees of freedom.

Under a Monte Carlo approach we could sample $T_1, \ldots, T_k$ from a t distribution with $n-1$ degrees of freedom. We would then reject H_0 if T was less than $T_{[\alpha]}$, where $T_{[\alpha]}$ is the α quantile of $(T_1, \ldots, T_k, T)$. Thus we use the sample from the t distribution to estimate the α quantile.

Alternatively, we can consider the problem of estimating the P value of the test. In the example given, this is equivalent to finding the value of the integral

$$\int_{-\infty}^{t} h(x)\,\mathrm{d}x,$$

which is consistently estimated by

$$\hat{P} = \frac{\sum_{i=1}^{k} I(T_i \le t)}{k+1},$$

where $I(T_i \le t)$ is the indicator function for the event $T_i \le t$, and $\hat{P}$ is the Monte Carlo estimate.

In practice, the Monte Carlo approach to hypothesis testing is advantageous if the distribution of the chosen test statistic is intractable but it is convenient to sample from this distribution. Some practical examples can be found in [1].

Jöckel [6] has investigated the properties of Monte Carlo hypothesis tests under quite general conditions and produces the following conclusions. First, if we choose large enough samples (k) to produce our Monte Carlo quantities, then the results will be equivalent to the analytic results, with high probability. Secondly, the power of the Monte Carlo test is an increasing function of k.

Bootstrap

The second example we will consider is the bootstrap [2]. The bootstrap is a simple but powerful idea that is applicable to a wide range of problems. The central idea of the bootstrap is the following [3]. Suppose we wish to estimate some functional θ of a distribution $F(\beta; x)$,

$$\theta = \int g(x)\,\mathrm{d}F(\beta; x).$$

The bootstrap estimate is found by replacing the unknown population distribution in the integral with the sample's empirical distribution, as follows:

$$\hat{\theta} = \int g(x)\,\mathrm{d}\hat{F}(x),$$

where $\hat{F}(x)$ is the empirical distribution of the observed sample.

Now consider estimating the variability of this statistic. To estimate the variance of the sampling distribution of our estimate, we again replace the population distribution with the sample distribution, to give

$$\hat{\sigma}^2 = \mathrm{E}_{\hat{F}}[\hat{\theta} - \mathrm{E}_{\hat{F}}(\hat{\theta})]^2,$$

where $\hat{\sigma}^2$ is called the bootstrap estimate of the sampling variation of $\hat{\theta}$, and $\mathrm{E}_{\hat{F}}$ denotes expectation over the empirical distribution of the sample. This calculation could be performed analytically, and requires tabulating a complicated set of permutations. Instead, we can form a Monte Carlo estimate by generating draws of the same size as the original sample from the empirical distribution of the sample. For each such draw we calculate this statistic. We iterate this procedure k times to obtain $\theta_1^*, \ldots, \theta_k^*$, and then calculate

$$\hat{\sigma}^2 = \frac{1}{k}\sum_{i=1}^{k}(\theta_i^* - \overline{\theta}^*)^2,$$

where $\overline{\theta}^*$ is the mean of the bootstrap samples.

This is equivalent to drawing with replacement from the original sample, which is how the bootstrap is sometimes described.

Complex Systems

Another example of the use of Monte Carlo methods is in the analysis of complicated systems. Simulation methods are often used to explore the properties of complex systems, **likelihoods**, or estimators. Deterministic simulation systems are frequently used in areas such as finance where the impact of varying input parameters is assessed by changing the values in a **spreadsheet** [10].

Simulations involving stochastic components are often called Monte Carlo simulations. In many situations, uncertainty or randomness plays a key part in the dynamics of the system. Examples include queuing for operations and the demand for inventory items. Mathematical models can be proposed and analytical solutions can be sought, but in any realistic formulation the mathematics quickly becomes intractable.

Epidemic theory has been a fertile area for Monte Carlo simulations (*see* **Epidemic Models, Stochastic**). A recent epidemic that has received considerable attention is the HIV/AIDS (*see* **AIDS and HIV**) epidemic. Monte Carlo methods have been used to build realistic behavior patterns into a model for this epidemic and to explore its evolution based on those assumptions. Monte Carlo has also been used as an estimation technique. Often, good information exists for some aspects of the model. The other parameters of the model are varied until the results of the simulation agree best with the observed data.

An example of this methodology was given in [4] and [5]. Data from homosexual men in San Francisco provided input parameters for several aspects of the model. The model was a compartmental one with different levels of sexual activity, immigration, emigration, and death. Data on the probability of transmission related to sexual activity collected from several other studies were used to complement the primary data set.

The simulation study generated incidence projections for HIV and AIDS. A **sensitivity analysis** was conducted to see the range of behavior variables that were consistent with the observed incidence patterns. The conclusion was that there was a range of parameter values which could generate the observed data. The most important outcome of the analysis was the flagging of the most influential parameters for further collection of data.

Markov Chain Monte Carlo

The final example we will consider is the use of **Markov chain Monte Carlo** (MCMC) techniques such as Gibbs sampling. These techniques use stochastic simulation to explore and summarize a multivariate density which may not be analytically tractable. This problem arises often in the area of Bayesian statistics.

With MCMC techniques, standard results [9] are used to construct **Markov chains** with the required stationary distributions. Popular choices are variants on the Metropolis–Hastings algorithm. From an initial state vector, the chain is simulated until the sequence has reached approximate stationarity. This is the Monte Carlo part of the algorithm. The resulting sequence is used to make stochastic approximations to any required functional of the multivariate distribution.

T.J. O'NEILL, S.C. BARRY & BOREK PUZA

Moran, Patrick Alfred Pierce

Born: July 14, 1917, in Sydney, Australia.
Died: September 19, 1988, in Canberra, Australia.

Pat Moran was an Australian statistical scientist with an enormous breadth and depth to his research interests. During his prolific career, Moran made substantial contributions to **population genetics**, medical statistics (particularly **psychiatry**), geometric probability, mathematical statistics, **time series**, and applied probability. He received numerous scientific honours, and now is commemorated by two Australian awards for young research statisticians.

After graduating in 1937 with First Class Honours in Mathematics from Sydney University, Moran went to Cambridge, England, where in 1939 he took Part III of the Mathematics Tripos. World War II interrupted further studies, and initially Moran had a job with the Ministry of Supply where he worked with D.G. Kendall and M.S. Bartlett. Then he joined the Australian Scientific Liaison Office in London, where reporting on all manner of wartime matters developed his clear and concise writing style as well as his breadth of scientific interests. Over these years he came to appreciate the importance of statistical methods; in fact he began reading **M.G. Kendall's** *Advanced Theory of Statistics* during the flying bomb raids on London. At the end of the war, Moran accepted the Baylis research studentship at St Johns College, Cambridge, to do a Ph.D. in Mathematics. He never did complete a Ph.D. (a fact which later on he would relate with pride), instead preferring a reasonable income to support his wife and then their children. From 1946 to 1951 Moran was a Senior Research Officer at the Institute of Statistics, Oxford, and was attached to Balliol College. He lectured at Trinity College (1949–1951) and was made a University Lecturer in 1951.

In 1952, Moran was appointed to the first Chair of Statistics at the Australian National University (ANU), which was established postwar as a research and graduate training institution in Canberra. He held this position until his retirement thirty years later. Although Moran preferred to maintain a small department, nevertheless he attracted first-rate faculty and visitors, as well as many graduate students, and the Department became "the cradle of modern Australian Statistics" [2]. From this position, Moran's influence on statistical science in Australia was profound: in an obituary Hall [2] noted that "ten out of the present seventeen professors of Statistics in Australia have been associated with the Department as either students or staff".

Moran's first papers written during the war were on Hausdorff measure (from his earlier research at Cambridge) and on convex sets. One of these was motivated by a problem posed by the Bomb Fragmentation Committee, and the resulting principle was used much later with a scanning beam electron microscope [2]. After the war, Moran published papers on **rank correlation**, and at Oxford became interested in the analysis of animal populations. In Canberra, Moran initiated the study of dam and storage system theory, publishing a monograph in 1959 which later was translated into Russian and Czech. Geometrical probability was an enduring interest from his war years, and his 1963 monograph with M.G. Kendall [3] was later translated into Russian. Some of his papers in this area were stimulated by problems posed by immunologists at the John Curtin School of Medical Research, ANU, such as the determination of the random pattern of antibodies attached to a spherical virus. Moran did not begin his influential research in genetics until the late 1950s, producing a major monograph [4] in 1962, giving a systematic account of the mathematical aspects of the genetics of natural populations (also translated into Russian) (*see* **Genetic Epidemiology**). Moran's 1967 [5] **probability** text was written to provide an outline of probability theory which can be both "generalized in a highly abstract manner" and can be used to describe many "complicated phenomena in natural science". This treatise lies usefully between an elementary introduction and deep abstract analysis, and was reprinted in 1984. Moran's list of over 180 publications can be found at [1], supplemented at [2].

Moran was a Roman Catholic, and much enjoyed turning his intellectual powers to theological discussions with clergy. He was a modest person who thought deeply about many matters, with his familiar pipe never far away. His criticism was always direct, and his insightful comments were a source of stimulation for many researchers, in statistics and mathematics, biology, and medicine.

SUSAN R. WILSON

Morbidity and Mortality, Changing Patterns in the Twentieth Century

The twentieth century has been a period of unprecedented gains in longevity and health status. At the turn of the twentieth century, **life expectancy** at birth in Europe, North America, and Australia and New Zealand was typically around 45–50 years, similar to levels prevailing in Africa today, and not much greater than the levels of 35–40 years which had prevailed in Europe for centuries. As the twentieth century draws to a close, life expectancy in most industrialized countries is of the order of 75–80 years, or even higher for females in some countries. In other words, life expectancy has increased by more than 50% over the last 100 years or so in the industrialized world, but these gains have not been enjoyed equally by all population groups. The twentieth century has seen the emergence of dramatic inequalities in survival, notably between men and women, but also between the better educated and poorer sectors of society.

In this brief review of 100 years of epidemiologic history, trends and differentials in mortality will be presented to the extent that data are available to document them, and the emergence (or decline) of major epidemics and endemic conditions will be discussed. Much of the analysis will be limited to mortality data since this is the most comprehensive, comparable, and unambiguous source of information on health status. With the exception of cancer registries (*see* **Disease Registers**) for some (generally subnational) populations, and **surveillance** sites for vascular events included under the **World Health Organization** (WHO) MONICA project, there are no comparable, standardized data on morbidity from which comparative trend analyses can be made. (MONICA is a 10-year (1984–94) epidemiologic surveillance system established in 35 countries, mostly industrialized, to monitor vascular disease incidence and mortality in defined populations, hence the name *Moni*toring of Cardiovascular Diseases and Risk Factors.) Equally importantly, there are no comparable data to investigate whether the extra years of life gained, particularly at older ages, have been accompanied by a rise, or fall, in disability. Data sources for assessing disability vary among countries and even within a population over time. Therefore little can be said, with any confidence, about changing patterns of disability, although this information is clearly required to assist policy and program formulation.

Data Sources for Mortality

Vital registration of births and deaths is the most useful source of mortality data for populations where complete recording of events has been achieved (*see* **Vital Statistics, Overview**). Where the death certificate includes diagnosis of the underlying **cause of death**, certified by a registered medical practitioner in accordance with the principles and procedures of the revision of the **International Classification of Diseases (ICD)** currently in force (*see* **Death Certification**), the information can also be used for epidemiologic assessments. Complete (or virtually complete) vital registration exists for industrialized countries, including Eastern Europe and the former USSR. In addition, several countries in developing regions of the world, including Argentina, Chile, Cuba, Mexico, Singapore, Uruguay, and some countries in the Caribbean have virtually complete registration and medical certification of deaths. Of the developing regions, medical certification of deaths is most advanced for Latin America and the Caribbean (43% of deaths), and least advanced in Sub-Saharan Africa (1% of deaths) [2].

Even in the absence of reliable vital registration data, patterns and levels of mortality can still be usefully ascertained through less expensive systems covering a sample of the population. For example, China has established a network of 145 Disease Surveillance Points (DSP) which record over 50 000 deaths annually in a population of 10 million people, representative of mortality conditions throughout China. Causes of death among the rural population in India are assessed via a "verbal autopsy" system operating from 1300 primary health care centers throughout the country. ("Verbal autopsy" is a method for diagnosing the approximate cause of death through a structured interview with relatives of the deceased. The interview is usually administered by a nonmedical person some weeks or months after death. Relatives are asked about a series of symptoms prior to death from which a diagnosis of the cause of death is made, preferably by a qualified physician.) While not as

reliable as the DSP system in China, the Indian data are nonetheless useful for delineating broad cause of death patterns throughout the country [2].

Issues of Comparability

The interpretation of analyses of vital registration data on causes of death must be made with caution since the comparability of data is undoubtedly affected by many factors (*see* **Mortality, International Comparisons**). Even among the developed nations, where causes of death over the course of the twentieth century have generally been classified according to standards and principles agreed upon by various international committees (since 1948, under the auspices of WHO), variations in diagnostic practice among countries affect data comparisons. A WHO international comparative study carried out in the 1960s reported significant variations in certification practices among six European countries with major differences in the proportion of deaths which were certified by pathologists [10]. No doubt these differences have diminished in recent decades, but the practice of autopsy still varies substantially among industrialized countries, with implications for data comparability [11].

Cultural differences also no doubt are a significant factor in the coding of injuries. Suicides in particular are undoubtedly underreported in some countries owing to the social or religious stigma associated with the act, with the death in such cases usually being coded to accidental injuries [6]. Studies have also revealed "diagnostic preferences" for chronic diseases. For example, in the 1950s and early 1960s, deaths which were coded to chronic respiratory diseases in the UK, Australia, and New Zealand may well have been coded to a cardiovascular disease in the US [5].

The statistical comparability of cause of death data has certainly been affected by the successive revisions of the ICD. The most profound change occurred with the introduction of the Sixth Revision around 1950, in which major alterations to the format of the list of causes were made to accommodate the sweeping changes in the principles of cause of death classification introduced with that revision. The introduction of the Eighth Revision in 1968 substantially affected the **time series** comparability of certain major causes of death, particularly ischemic heart disease (IHD), with up to 15% more deaths being coded to IHD than to the most comparable cause in the Seventh Revision [9].

The comparability of epidemiologic analyses of mortality data is also very much affected by the extent to which deaths are coded to ill-defined and unspecified diagnoses. This affects both comparisons among countries as well as trends within a country over time. For example, around 1950, approximately 15%–20% of all deaths in Belgium, France, Greece, Poland, and Spain were coded to ill-defined causes, compared with 1%–2% in Australia, Austria, Canada, Denmark, New Zealand, Switzerland, the UK, and the US. Without adjustment for diseases coded to ill-defined conditions, cross-national comparisons might be very misleading [4]. By the early 1990s, ill-defined causes throughout the industrialized world had declined to about 1%–3% of all deaths. For countries where this practice was common four decades ago, time series analyses for specific causes (especially cardiovascular diseases) must be interpreted with great prudence.

Trends in Life Expectancy and Age-Specific Mortality Rates

Life Expectancy

Life expectancy at birth is a convenient summary index of prevailing mortality conditions at each age. The measure is not a linear function of age-specific death rates and hence equal reductions in mortality at different ages will not have an identical impact on life expectancy – a reduction in death rates at younger ages will result in a larger gain in life expectancy at birth than a similar reduction in death rates at older ages. Despite this feature, life expectancy is widely understood and is perhaps still the most commonly used indicator to summarize overall mortality levels in a population.

Table 1 provides an overview of the gains in life expectancy in selected countries over the course of the twentieth century. By far the largest absolute increase has been enjoyed in Japan (34 years for males, 39 years for females), followed by Italy. Much less progress has been registered in Eastern Europe although national trends are not strictly comparable owing to differences in time period, **life table** methodologies, and population coverage around the turn of the century. What the table does suggest, however, is that the pattern of mortality reduction

Table 1 Life expectancy at birth, 1900–95, selected countries

[a]Annual average.

among the industrialized countries is extremely heterogeneous and that, while significant progress has been achieved, there has been more divergence than convergence among the industrialized countries.

Viewing trends in life expectancy over almost a century can conceal significant time trends that have characterized this century of mortality change. Life expectancy at birth has not increased monotonically since the early 1900s. Rather, significant gains were achieved virtually everywhere until the beginning of the 1950s. From the mid-1950s, male life expectancy stagnated, or even declined modestly in some Western European countries, as well as in Australia and North America (see Figure 1). Meanwhile, female life expectancy continued to rise. From the mid-to-late 1960s, male life expectancy began to rise again, quite sharply in some countries. At about the same time, one of the most remarkable reversals in life expectancy began throughout Eastern Europe with male life expectancy declining by up to 4–5 years in most countries, and by even more (7 years) in Russia [8]. Even this general trend has been accompanied by significant national variations with male life expectancy beginning to show signs of a renewed rise in the Czech Republic, Hungary, and Poland, but deteriorating markedly in Russia since 1988, having risen sharply in the former USSR between 1980 and 1987 [8].

Demographers and epidemiologists have been studying these remarkable changes in Eastern Europe for more than two decades. Most would agree that the trends are real and not due to sudden changes in the completeness or accuracy of reporting of deaths following widespread social and political change in the late 1980s. Epidemiologic research suggests that much of the pervasive increase in male mortality in Eastern Europe since the late 1960s is due to tobacco usage [3] or, in the case of the recent dramatic mortality increases in Russia, alcohol abuse [7].

Age-Specific Mortality Change

Given the very close relationship between the age-pattern of mortality and the prevailing cause of death structure – infectious diseases tend to kill many more children than adults, while chronic diseases do the converse – the conquest of the communicable diseases such as tuberculosis, measles, malaria, diarrheal diseases, and acute respiratory infections, which had largely been completed in the industrialized countries by 1950 or thereabouts, has resulted in massive declines in **infant mortality** and child mortality, and a significant reduction of death rates among young adults.

Around 1900, infant mortality rates in Australasia, Europe, or North America typically hovered around 100–150 deaths per 1000 live births, similar to levels currently prevailing in many African countries (see Table 2). Overall child mortality rates (measured as the probability of a newborn infant dying before age 5) were of the order of 200 per 1000 live births. In 1995, infant mortality rates in the industrialized countries are typically around 10 or less per 1000 live births, reaching as low as 4–5 per 1000 in Japan and parts of Scandinavia.

Although less dramatic, and with some interruptions for men as noted earlier, adult mortality levels have also declined more or less continuously since the beginning of the twentieth century. This decline has been much more evident for women, although evidence of a stagnation in mortality rates for women in some Eastern European countries first became evident in the early 1970s. Since the late 1970s, several countries, including Australia, the Netherlands, the UK, and the US, have seen further substantial reductions in male (and female) mortality, both in middle and old age. Much of this recent decline in death rates can be attributed to further declines in ischemic heart disease and stroke mortality, continuing a trend which began in the late 1960s.

From this brief analysis, one may conclude that adult mortality rates tend to be higher in populations with higher overall mortality and tend to decline (more or less monotonically) with declines in general mortality levels. This is perhaps counterintuitive, but is confirmed by recent global mortality analyses which suggest that the risk of adult death throughout the developing world is substantially higher than in Australasia, North America, Japan, and Western Europe [2].

Demographers have developed methods to decompose or disaggregate changes in life expectancy at birth into contributions due to changes in mortality at different ages. These can be either positive contributions (in which case mortality rates in the age group have declined), or negative, whereby life expectancy has increased despite an increase in mortality rates in a given age group. To illustrate the utility of these methods, the age pattern of contributions to life expectancy trends for males in three populations, Australia, England and Wales, and Hungary, are shown in Table 3 for the period 1950–79.

The very substantial contribution (in years) from post-1950 declines in infant and child mortality is evident in all three populations (1.37 years out of a 3.0 year increase in life expectancy in England and Wales, 4.32 years of a 4.9 year increase in Hungary, and 1.48 years out of a 4.2 year gain in Australia) [1]. Since mortality rates at ages 15–34 years were already comparatively low in the early 1950s, further declines at these ages did not contribute greatly to changes in life expectancy. Reductions in mortality for higher age-groups resulted in similar absolute contributions to increasing life expectancy in both England and Wales, and Hungary, at least until the mid-1960s.

Given the abrupt cessation of overall male mortality decline in Hungary and neighboring countries from the mid-1960s and the rapid increase in male life expectancy in Australia (and other Western countries) since the early 1970s, analyses for these subperiods are also presented in the table.

The complexity of age patterns of mortality change and their influence on overall life expectancy is well illustrated by these two examples which, in many respects, are representative of recent mortality trends in the industrialized countries. In Hungary, male life expectancy remained unchanged between 1960–64 and 1975–78 (but declined subsequently). This was due to rises in mortality (i.e. negative contributions to life expectancy) at all ages 25 years and older, and particularly at ages 45–54 years. Conversely, further declines in infant and child mortality, and, to a much lesser extent, at ages 15–24 years, acted to increase life expectancy but were exactly counteracted by rising death rates at older ages. The pattern of mortality change in Australia over the same period was exactly the reverse. Between 1950–54 and 1970–76, male life expectancy hardly changed at all (up by 1.3 years), almost all of which (0.9 years) was due to declines in infant and child death rates, with only small (positive or negative) contributions from relatively stable adult death rates. During the 1970s, however, male death rates at ages 45 and over declined dramatically in Australia, accounting for 1.9 years of the 2.9 year increase in life expectancy at birth, with much of the remainder (0.6 years) being due to continued declines in infant and child mortality.

Sex Differentials in Mortality

One of the most remarkable features of twentieth century mortality decline in the industrialized countries has been the dramatic widening of male–female differentials in mortality. Around the turn of the century, life expectancy for females was typically 2–3 years higher than for males, and in some countries, such as Ireland and Italy, the gap was less than 1 year. Female mortality rates exceeded those of males in many countries at various ages up to the end of the childbearing period. Indeed, the contribution of **maternal mortality** to the sex mortality differential around the turn of the century was sufficiently high

Table 3 Age components of changing life expectancy at birth, selected nations, 1950–54 to 1979

Country	Life table periods	Sex	Contribution (in years) to change in life expectancy at birth due to mortality trends at ages								Interaction	Total increase in life expectancy (in years)[a]

[a]The age components and the interaction contribution may not sum exactly to the total due to rounding.

to reduce the female advantage in life expectancy over males by 0.3 to 0.5 years [1]. Conversely, accidents and violence were a major cause of male excess mortality, typically accounting for about half of the female advantage in life expectancy at birth.

By far the largest contribution to the increase in male excess mortality by the mid-1960s was the diverging mortality trends for men and women from cardiovascular diseases, at least in Australia and the US. A similar pattern is also evident in the Scandinavian countries (and indeed in most other industrialized nations) after 1950.

The contribution of cancer to widening sex mortality differentials is rather more complex. Prior to about 1930, female mortality from cancer exceeded that for men, largely due to cancers of the genital tract. By the mid-1960s, about half a year had been added to the gap in life expectancy in Australia and Scandinavia due to differential male–female trends from cancer, and almost a full year in the US. Much of this, and subsequent increases after 1960, can be attributed to the massive increase in male lung cancer mortality (see next section). Finally, it is also interesting to observe the growth in the contribution of male excess mortality from motor vehicle accidents. Around 1910, there were too few cars for this to be a significant cause of death. Since then death rates from car crashes rose dramatically, especially for males, so that by 1964, this cause alone contributed about half a year to the gap in life expectancy between the sexes.

Sex differentials in mortality have continued to widen in recent decades with the result that average life expectancy at birth for females is currently typically about 6–7 years higher than for males, and in some countries (e.g. Hungary and France) the gap is closer to 9 years. In others, e.g. Australia and the UK, there is evidence that the sex differential in mortality is no longer increasing. This is due to the very substantial declines in male mortality from lung cancer, ischemic heart disease, and stroke in these countries, following widespread reductions in smoking by men which began several decades ago.

Cause of Death Trends

The twentieth century has been characterized by a massive decline in **communicable diseases** and maternal and perinatal causes in industrialized countries, and increasingly in many developing countries as well. The extent of this reduction is well illustrated in Figure 2, which shows the **proportionate mortality** for males in selected countries from various broad causes over the last 100 years or so. The pattern for females is broadly similar, with the added feature that maternal deaths have declined from around 2%–5% of female deaths in the early 1900s to less than one-tenth of 1% today. From causing about 30% of deaths around 1900, infectious and parasitic diseases now cause less than 5% of deaths in the industrialized countries, and this figure would be even lower were it not for the **AIDS** epidemic. Noncommunicable diseases have emerged as the leading causes of death by far as the twentieth century draws to a close, despite the very substantial reductions in vascular disease mortality in some developed countries in recent decades.

The trends in accidents and violence (external causes) are particularly interesting. Although the proportionate contribution of these nonmedical causes to overall mortality has remained relatively constant at around 6%–8%, the composition of causes within the category of accidents and violence has changed dramatically. For example, earlier in the century, industrial accidents were the leading cause of male deaths from external causes, reflecting the risks associated with several occupations commonly practiced at that time (*see* **Occupational Mortality**). Subsequently, with the modernization of the labor market and legislative reform for occupational safety, these accidents have greatly diminished in frequency. For males, at least, motor vehicle accidents have emerged as the principal cause of death from nonmedical causes, rising from virtually zero around 1900 to account for about 30% of violent deaths among males in many industrialized countries, and an even higher proportion (50% or so) of violent deaths at the young adult ages (15–34 years) (see Figure 3).

An overview of mortality change in the industrialized countries since 1950 is given in Figure 4, which shows the *relative* change (death rate in 1950–54 = 100) in age-standardized death rates from selected leading causes of death for men and women separately (*see* **Standardization Methods**). The graph shows the average experience of 22 industrialized countries and demonstrates the varied epidemiologic history of the world's richest countries over the last

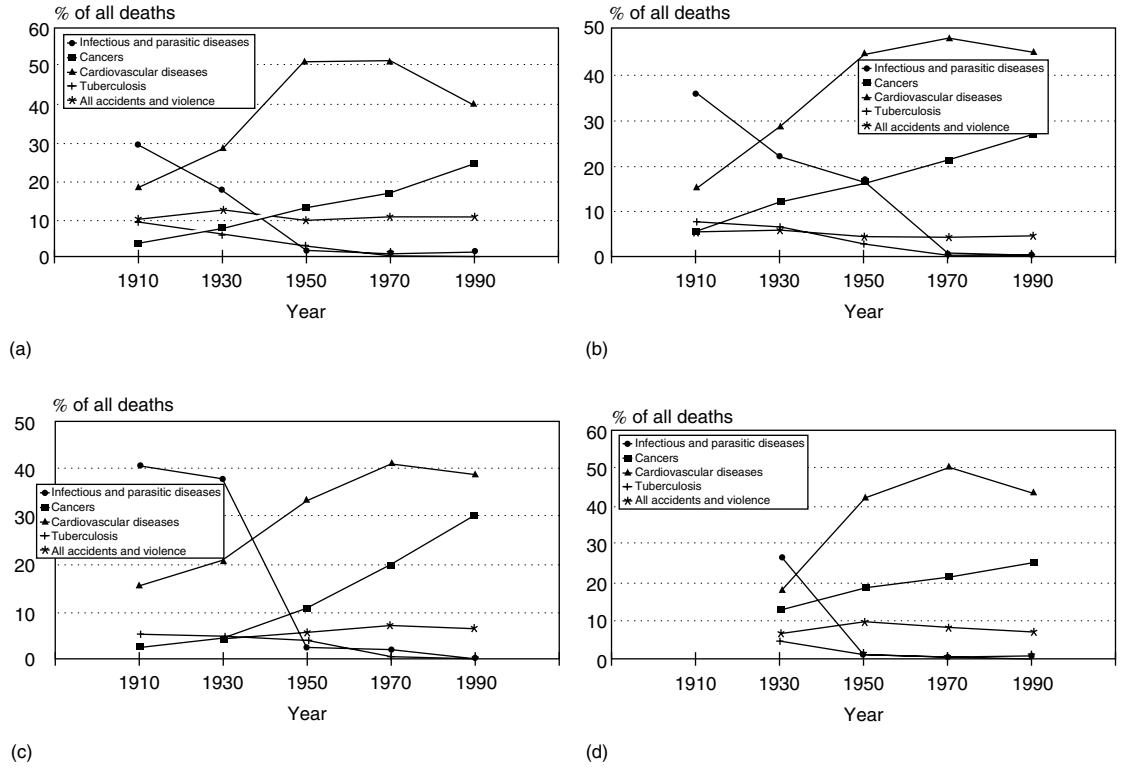

Figure 2 Proportionate mortality (in %) from broad causes, selected countries, males, 1910–90. (a) US, (b) England and Wales, (c) Italy, and (d) Denmark

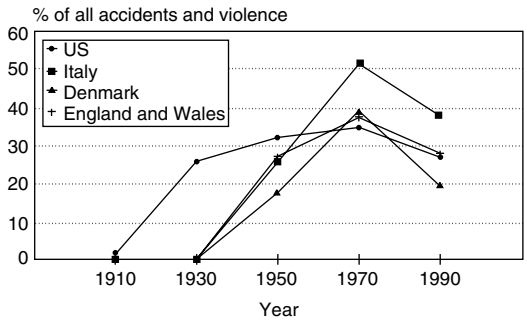

Figure 3 Proportion of all violent deaths due to motor vehicle accidents, selected countries, males, 1910–90

few decades. The rise (for men) and then steady decline in ischemic heart disease and stroke mortality is clear, as is the peak in motor vehicle accident mortality in the early 1970s. Since then, death rates from traffic crashes have returned to levels last seen in the 1950s for women, and 25% lower than the 1950–54 level for males. This has occurred despite a dramatic increase in the number of motor cars. This remarkable reversal is due to a number of factors, including improved highway conditions and stricter measures to control drunken driving in these countries.

But perhaps the most dramatic change in mortality since the middle of the century has been the extraordinary growth in lung cancer mortality, for both males and females. Male lung cancer rates have increased, on average, by almost 200% since 1950–54, while for females, the rise, in relative terms at least, has been even greater (more than 300%). Even though the relative increase in lung cancer rates has been higher for females, the absolute level of rates is still much higher in males owing to their longer smoking history. The enormity of the lung cancer epidemic in the industrialized countries during the course of the twentieth century is perhaps best summarized by the trends for the US (see Figure 5).

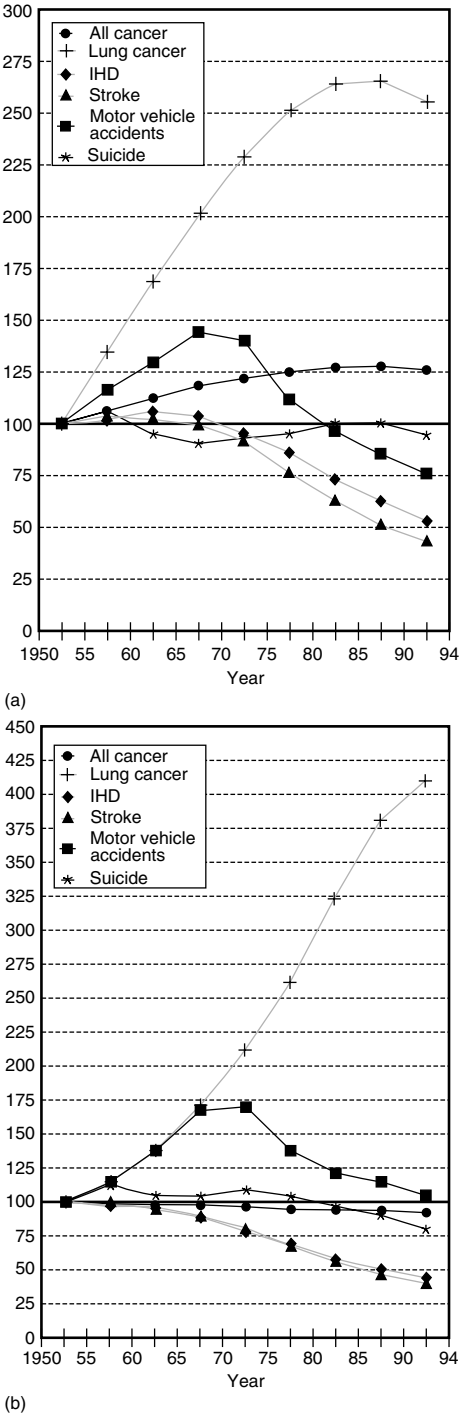

Figure 4 Relative change in mortality (1950–54 = 100) for selected causes of death in 22 industrialized countries, 1950–54 to 1990–94, (a) males, (b) females

From a level of around five deaths per 100 000 in 1930, US male lung cancer rates have risen about 15-fold to peak in the early 1990s. Other cancers have remained relatively stable, or, in the case of stomach cancer, declined substantially. For women, the rise in lung cancer only began in the early 1960s, some decades after American women began to smoke in large numbers.

There have been notable successes in reducing lung cancer mortality, particularly in Australia, Finland, the Netherlands, and the UK, where death rates from the disease have been steadily declining and are now at levels 20%–40% below their peaks. Male lung cancer rates in some industrialized countries are still rising, most notably in Japan (an increase of over 1000% since 1950), but also in Greece, Hungary, Portugal, Poland, and Spain. Indeed, lung cancer mortality in Hungary in 1994 reached 122 deaths/100 000 population (age-standardized), exceeding even the highest level reported for UK men (111/100 000) at the height of their epidemic (1974) [11].

Lung cancer death rates for women are rising everywhere except in Australia, New Zealand, and the UK, where death rates appear to have stabilized. The highest mortality rate for women in the early 1990s is reported for American women (38/100 000), closely followed by Denmark (36/100 000). Indeed, in several populations (see Figure 5), lung cancer now exceeds breast cancer as the leading site for mortality from the disease (*see* **Smoking and Health**).

Along with the reversal in lung cancer rates for men in some countries, the other great public health success of the second half of the twentieth century has been the extraordinary decline in ischemic heart disease mortality and stroke (cerebrovascular disease). Beginning in the mid-to-late 1960s, death rates from these diseases began to decline following a decade or more of rising rates in many countries. Death rates are now less than half their post World War II peak levels and are still declining. Largely as a result of these declines in major vascular diseases, overall mortality levels have fallen by up to 40% in many Western countries.

The other major disease for which significant progress in reducing mortality has been achieved is cirrhosis of the liver. In countries such as Australia, France, Germany, Portugal, and Spain, male death rates from the disease rose steadily during the 1950s and 1960s and reached a peak level of 45–55 deaths/100 000 population in the mid-1970s. Since

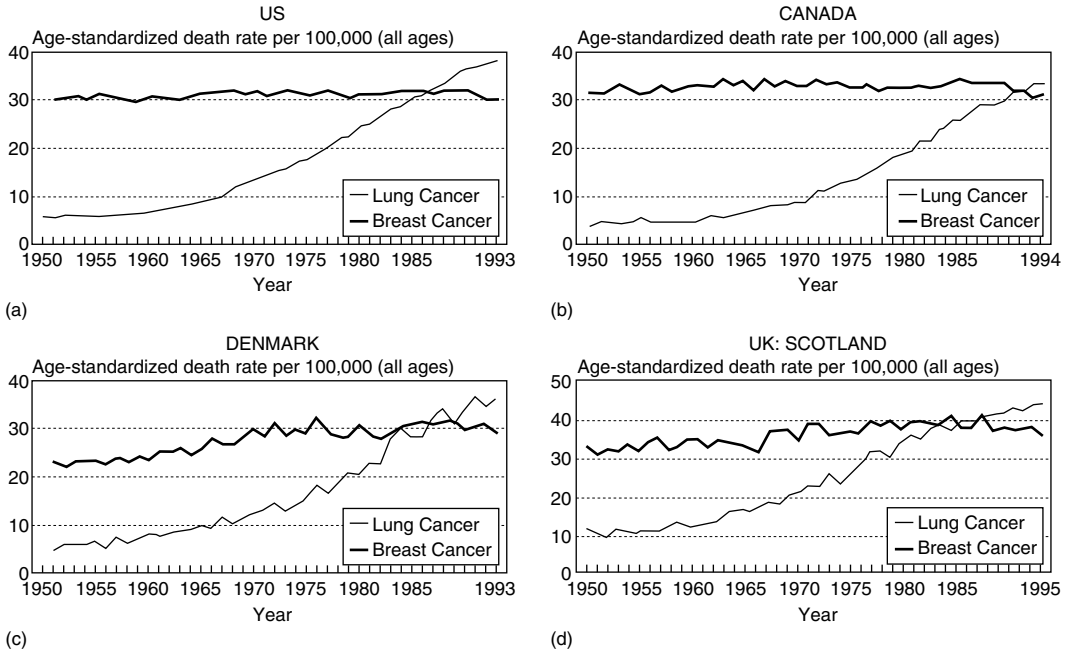

Figure 5 Trends in breast and lung cancer mortality among women, selected countries, 1950–95. (a) US, (b) Canada, (c) Denmark, and (d) UK (Scotland)

then, death rates have halved in France and Portugal, and have declined by 20%–30% in the other countries where death rates from the disease have been comparatively high. On the contrary, there is no evidence that mortality has declined among men in Eastern Europe, and indeed it appears to be rising in several of these countries.

Whither the Future: Mortality and Causes of Death in the Twenty-First Century

As the twentieth century draws to a close, it is perhaps important to reflect briefly on major threats to health in the first decades of the twenty-first century. Unquestionably, the two epidemics of greatest public health concern must be use of *tobacco* and *HIV* infection. Between 1950 and 2000, tobacco will have caused over 60 million deaths in the developed countries of the world, more than 50 million men and about 10 million women [3]. In 1995, tobacco was estimated to have caused about 3 million deaths globally, about 2 million in the developed countries and about a million, but with substantial uncertainty, in less developed countries. In the twentieth century, most of the deaths from tobacco have been in developed populations, but in the twenty-first century the opposite will be true. The annual numbers of deaths are still increasing in developed populations but they are increasing even faster elsewhere. Over the past few decades there has been a massive rise in global cigarette consumption, particularly in developing countries, where 50% of men smoke. On current trends, annual global tobacco deaths are likely to reach 10 million in the 2020s or early 2030s. The chief uncertainty is not whether, but when, annual mortality will reach this level. On present smoking patterns, half a billion of the world's current population will eventually be killed by tobacco. These predictions will be substantially wrong only if there are substantial changes in global smoking patterns.

AIDS caused by the human immunodefeciency virus (HIV), is the only other major cause of death that is rising rapidly. First diagnosed in the early 1980s, the disease is estimated to have caused about 400 000 deaths in 1990, the majority in Sub-Saharan Africa [2]. **Epidemic modeling** of the disease suggests that the peak in global mortality will be attained

sometime between 2005 and 2010, when annual deaths are predicted to reach about 1.7 to 1.8 million a year [2]. Beyond then, the epidemic is expected to decline slowly due to the past (and projected) efforts at prevention. As with tobacco, these projections could be gross underestimates if HIV incidence were to increase rapidly in some large population groups. If this were to happen, it would most probably occur in Asia where seroprevalence has been increasing dramatically in some high-risk populations (*see* **Projections: AIDS, Cancer, Smoking**).

The third area for concern is the emergence, or reemergence, of various infectious diseases which, if uncontrolled, could cause a substantial number of deaths in the future. The reemergence of tuberculosis as a significant health issue in the developed countries is an object lesson for the public health profession not to become complacent about past successes in disease control. Equally, the ebola virus as well as significant cholera outbreaks attest to the need for continual vigilance in **surveillance of diseases**. Finally, the very large unfinished agenda of controlling the leading causes of child mortality in developing countries, particularly diarrheal diseases, acute respiratory infections, the vaccine-preventable diseases, and malaria, which each year collectively kill more than 12 million infants and young children [2], must remain a major global public health priority into the next century.

Mortality, International Comparisons

The international comparison of mortality or other health-related statistics is probably the most useful, simple, and widely used method to assess the health status of the population of a particular country. In most cases health can be measured only in relative terms, by placing the country on a scale between the best and worst achievements being observed in other countries. Most often, comparisons are made between countries in a specific geographic region or with similar level of socioeconomic development. Such comparisons form an important part of national public health reports or documents on national health policies. Publications and reports of international organizations active in the field of health are usually also largely based on international comparisons of health statistics including mortality data. International mortality comparisons are often the subject of research papers.

To make international comparisons of health data possible, there are several essential and obvious conditions. Data have to be available from a sufficient number of countries and they must be based on the same definitions in order to be comparable. In this respect, mortality statistics are probably the best presently available health data for international comparisons. The **World Health Organization** has been collecting mortality information since the early 1950s, just after the establishment of the Organization. Currently, about 70 countries are regularly reporting detailed data to the WHO on an annual basis. These statistics are based on the concept of the underlying cause of death (*see* **Death Certification**) and are usually coded using the **International Classification of Diseases** (ICD). Generally, these data can be estimated as being of good quality (accuracy) particularly in developed countries with well established and functioning systems of **vital statistics**. However, there are many potential methodologic problems limiting the comparability of mortality data even among developed countries. These problems are mostly related to the coding of the underlying cause of death (*see* **Cause of Death, Underlying and Multiple**). However, the impact of variations in coding procedures on actual cause-specific mortality statistics is very difficult to measure regularly in quantitative terms, as it requires special studies to compare actual methods and practices of coding death certificates between countries. Studies which have been carried out so far have confirmed the perception that in some cases differences in the coding methods and practices may cause significant **bias** in the number of deaths from specific diseases. There are several elements in death registration which may have an influence on the international comparability or may cause an artifact in the trend of particular cause-specific mortality within the country. At least the following could be mentioned:

1. the level of training and corresponding practices in filling in death certificates by health professionals;
2. the form of the certificate itself – for example, the number of lines provided to list underlying and intermediate causes of death;
3. the regulations and administrative structures defining further transfer and processing of death certificates – for example, whether completeness and quality are controlled locally;
4. the coding of the cause of death from the written textual form into the ICD code – for example, whether it is done locally or centrally, manually or automated.

Another factor that is often forgotten, but which may cause significant bias in mortality rates used for international comparisons, is related to the population estimates used as a **denominator** to calculate mortality rates; for example, the number of deaths per 100 000 population. The total resident population in a given country is counted more or less accurately only during population **censuses**, which in most countries are carried out once every 10 years. In between census periods, population estimates are calculated on the basis of births, deaths, immigration, emigration, and aging of the population (*see* **Demography**). In practice, these estimates may not be accurate enough. When such estimates are used to calculate mortality rates, these inaccuracies can cause distortion in mortality trends and, correspondingly, in international comparisons.

Usually it is difficult to detect whether there is any bias in the mortality data of a particular country as compared to other countries. However, one has to keep in mind this possibility while making international comparisons.

There are also several statistical aspects that have to be taken into account in order to avoid the possibility of misleading conclusions based on international comparisons. First of all, the absolute number of deaths, without taking into account the size of the population, should not be used. Mortality rates or other indices should normally be used. In cases in which mortality for all ages or for a wide age band is compared, appropriate mortality rates have to be age-standardized beforehand (*see* **Standardization Methods**). Comparisons of crude death rate (i.e. a simple ratio of the number of deaths to the population size) are often misleading, particularly when one compares countries with different population age structures. For example, the crude death rate is usually higher in developed countries compared to developing ones, although an opposite situation should be expected when considering the health of the population in general. This happens purely because of differences in population structure; that is, developed countries have a much higher proportion of older people with, naturally, high mortality. There are two methods (direct and indirect) to age-standardize mortality rates in order to eliminate the influence of differences in population age structure between countries. If there is a sufficient amount of data for each age group, usually the direct method is used. Mortality rates are calculated for each age group and then are combined into the one index, assuming that the given country has the "standard" population structure. There are two commonly used standards for international comparisons: the world and the European standard populations (see Table 1).

The indirect method of standardization is usually used in cases in which relatively rare causes of deaths are compared, or there are not enough data due to other reasons, to estimate mortality in each age group. This standardization is based on the assumption that the age-specific mortality is the same – that is, "standard" – in each country. These "standard" age-specific mortality rates are usually calculated using combined data from all countries included in the comparisons. The expected number of deaths is calculated on the basis of the above "standard" mortality rates and the actual age distribution of the population in a given country. The ratio of actually observed and calculated expected cases is used as the standardized mortality ratio.

One also has to be careful when comparing countries with small populations. Mortality indices for these countries are less stable, and the position of such countries may change significantly from one year to the next because of random variations.

Table 1 Standard populations (world and European)

Age group (years)	World	European
0	2 400	1 600
1–4	9 600	6 400
5–9	10 000	7 000
10–14	9 000	7 000
15–19	9 000	7 000
20–24	8 000	7 000
25–29	8 000	7 000
30–34	6 000	7 000
35–39	6 000	7 000
40–44	6 000	7 000
45–49	6 000	7 000
50–54	5 000	7 000
55–59	4 000	6 000
60–64	4 000	5 000
65–69	3 000	4 000
70–74	2 000	3 000
75–79	1 000	2 000
80–84	500	1 000
85+	500	1 000
Total	100 000	100 000

Sources: (a) Waterhouse et al. [1]; (b) *World Health Statistics Annual*, Geneva, WHO (any issue). Reproduced by permission of the IARC and the WHO.

For international comparisons, it is preferable to use mortality rates or other mortality based indices which are calculated centrally; for example, by the World Health Organization. Indices calculated individually by each country may have some bias due to the different calculation methods and **software** used in each country. This may happen particularly in the case of **life expectancy** as there are several different mathematical methods and software packages to calculate this index from the raw, age-disaggregated mortality data.

Mortality data are collected by and are available from several international organizations and agencies (e.g. the United Nations, the World Health Organization, the Statistical Office of the European Communities, and the Organization for Economic Cooperation and Development). The database maintained by the WHO is probably the most comprehensive and widely used. Detailed mortality data are published yearly in the *World Health Statistics Annual* [2]. Copies of the database with raw mortality data are available on request in computer-readable form from

the WHO headquarters [3]. For European countries, this information in the form of age-standardized mortality rates is also available as a part of the "Health for All" statistical data base maintained by the WHO Regional Office for Europe in Copenhagen. These data, together with user-friendly data presentation software which facilitates international comparisons, can be downloaded from the **Internet** (`www.who.dk`).

R. PROKHORSKAS

Most Powerful Test

Random phenomena abound in biological and medical studies. When a biological researcher monitors whether an experimental unit in a tumorgenicity study will develop a tumor, the researcher will not be certain whether such an event will occur. Rather, his/her knowledge will be represented by the probability that the event will occur. Let $X = 1(0)$ whenever the event occurs (does not occur). Then the researcher's knowledge concerning the occurrence of a tumor will be represented by the Bernoulli probability mass function (pmf)

$$f_X(x|\theta) = \Pr_{\theta}(X = x) = \theta^x(1-\theta)^{1-x}, x = 0, 1, \tag{1}$$

where $\theta \in \Theta = [0, 1]$ is the probability of a tumor occurring (*see* **Binary Data**). The extreme values $\{0, 1\}$ of θ represent certain knowledge, while $\theta = 1/2$ represents the least amount of knowledge concerning the event. In this example, X is the variable of interest, $\mathcal{X} = \{0, 1\}$ is the range space of X, θ is the relevant parameter, $\Theta = [0, 1]$ is the parameter space, and $f_X(\cdot|\theta)$ is the pmf of X for the parameter value θ.

Another situation is when a medical researcher observes the time of occurrence X of some event such as the onset of AIDS for HIV-infected individuals. In contrast to the first example, the variable X takes values in an uncountable range space $\mathcal{X} = (0, \infty)$, and knowledge of this event is specified by a probability density function (pdf) $f_X(\cdot|\theta)$, where θ is a parameter. As h approaches 0, the pdf has the interpretation

$$f_X(x|\theta)h = \Pr_{\theta}(x < X \leq x + h) + o(h).$$

A specification that arises in many survival time studies is provided by the **exponential** density function

$$f_X(x|\theta) = \theta \exp(-\theta x), x > 0.$$

Thus, generally, a researcher will be interested in some characteristic represented by a variable X. Uncertain knowledge concerning this characteristic is represented by a family of pmfs or pdfs given by $\mathcal{P} = [f_X(\cdot|\theta) : \theta \in \Theta]$, where θ is a parameter taking values in a parameter space Θ. Summary measures about X needed for making important decisions, such as the mean, standard deviation, median, or quartiles, are functions of θ. The true value of θ, denoted by θ_0, is unknown, and it is a goal of the researcher to gain knowledge concerning this value to further his/her knowledge concerning X. To achieve this goal, either through scientific experimentation, clinical trials, etc., he/she observes the **random variables** $X_1, X_2, \ldots, X_n$ which are identically and independently distributed (iid) from $f_X(\cdot|\theta_0)$. The joint pmf or pdf of $(X_1, X_2, \ldots, X_n)$ is therefore

$$f_{(X_1,\ldots,X_n)}(x_1, \ldots, x_n|\theta) = \prod_{i=1}^{n} f_X(x_i|\theta).$$

Statistical Hypotheses and Tests

The problem of statistical **hypothesis testing** is to decide, on the basis of a realization $(x_1, x_2, \ldots, x_n)$ of $(X_1, X_2, \ldots, X_n)$, whether to reject a **null hypothesis** in favor of an **alternative hypothesis**, or fail to reject it. These hypotheses, which are statements concerning the value of θ, are generally chosen so that the alternative represents change. They are written symbolically as

$$\text{(null)}\mathrm{H}_0 : \theta \in \Theta_0 \text{ and } \text{(alternative)}\ \mathrm{H}_1 : \theta \in \Theta_1,$$

where $\{\Theta_0, \Theta_1\}$ is a partition of Θ. A statistical test of H_0 vs. H_1 requires a statistic $\delta(X_1, \ldots, X_n)$, i.e. a function of $(X_1, \ldots, X_n)$ and possibly other known constants, taking values in [0, 1]. For a realization $(x_1, \ldots, x_n)$, $\delta(x_1, \ldots, x_n)$ is the probability of rejecting H_0 given $(x_1, \ldots, x_n)$. For a test δ, its **power** function $\pi_\delta : \Theta \to [0, 1]$ is

$$\pi_\delta(\theta) = \mathbf{E}_\theta[\delta(X_1, \ldots, X_n)],$$

where $\mathrm{E}_\theta[\cdot]$ represents expectation with respect to the joint pmf or pdf $f_{(X_1,\ldots,X_n)}(\cdot, \ldots, \cdot|\theta)$. The power function is the expected probability of rejecting H_0 when the parameter value is θ. Ideally, we would want $\pi_\delta(\theta) = 0$ whenever $\theta \in \Theta_0$, and $\pi_\delta(\theta) = 1$ whenever $\theta \in \Theta_1$; however, such an ideal situation is seldom achieved except in artificial and/or trivial problems. The size of a test δ is

$$\text{size}(\delta) = \sup_{\theta \in \Theta_0} \pi_\delta(\theta),$$

and δ is of **level** $\alpha (0 \leq \alpha \leq 1)$ if $\text{size}(\delta) \leq \alpha$. $\text{Size}(\delta)$ can be interpreted as the maximum expected probability of committing an *error of type I*, which is committed when the test rejects H_0 when in reality H_0

is true. On the other hand, when $\theta \in \Theta_1$, $1 - \pi_\delta(\theta)$ represents the average probability of committing an *error of type II*, which is committed when the test fails to reject H_0 – a wrong decision, since in such a case H_1 is true.

If $\Theta_0 = \{\theta_0\}$ and $\Theta_1 = \{\theta_1\}$, we say that Θ_0 and Θ_1 are simple hypotheses. In such a situation, given an $\alpha \in [0, 1]$, a test δ^* is a most powerful α-level (MP-α) if

1. $\text{size}(\delta^*) = \pi_{\delta^*}(\theta_0) \le \alpha$, and
2. for any other test δ with size $(\delta) = \pi_\delta(\theta_0) \le \alpha$, $\pi_{\delta^*}(\theta_1) \ge \pi_\delta(\theta_1)$.

If either Θ_0 or Θ_1 is not simple, the hypothesis is composite. When the null or the alternative hypothesis is composite, a test δ^* is a uniformly most powerful test of level α (UMP-α) if

1. size $(\delta^*) = \sup_{\theta \in \Theta_0} \pi_{\delta^*}(\theta) \le \alpha$, and
2. for any other test δ with size $(\delta) = \sup_{\theta \in \Theta_0} \pi_\delta(\theta) \le \alpha$, $\pi_{\delta^*}(\theta) \ge \pi_\delta(\theta)$ for every $\theta \in \Theta_1$.

Neyman–Pearson Fundamental Lemma

For testing a simple $H_0 : \theta = \theta_0$ vs. a simple $H_1 : \theta = \theta_1$, the **Neyman–Pearson** fundamental lemma (Neyman & Pearson [4]; see also Lehmann [3]) guarantees the existence of an MP-α test which is of the form

$$\delta^*(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } L(\theta_1|x_1, \ldots, x_n) \\ & \quad > cL(\theta_0|x_1, \ldots, x_n), \\ \gamma, & \text{if } L(\theta_1|x_1, \ldots, x_n) \\ & \quad = cL(\theta_0|x_1, \ldots, x_n), \\ 0, & \text{if } L(\theta_1|x_1, \ldots, x_n) \\ & \quad < cL(\theta_0|x_1, \ldots, x_n), \end{cases}$$

where $L(\theta|x_1, \ldots, x_n) = f_{(X_1, \ldots, X_n)}(x_1, \ldots, x_n|\theta)$ is the **likelihood** function, and $c \in [0, \infty)$ and $\gamma \in [0, 1]$ are some constants which are chosen so that $\text{size}(\delta^*) = \alpha$. The fundamental lemma furthermore guarantees that if δ^{**} is an MP-α test for H_0 vs. H_1, then for some $c \in [0, \infty)$, it is of the form

$$\delta^{**}(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } L(\theta_1|x_1, \ldots, x_n) \\ & \quad > cL(\theta_0|x_1, \ldots, x_n), \\ 0, & \text{if } L(\theta_1|x_1, \ldots, x_n) \\ & \quad < cL(\theta_0|x_1, \ldots, x_n). \end{cases}$$

To illustrate, consider the Bernoulli example above, and let $X_1, \ldots, X_n$ be iid from $f_X(x|\theta) = \theta^x(1-\theta)^{1-x}$, $x \in \{0, 1\}$. Suppose interest is in testing $H_0 : \theta = \theta_0$ vs. $H_1 : \theta = \theta_1$, where $\theta_0 < \theta_1$. The likelihood function, given $(X_1, \ldots, X_n) = (x_1, \ldots, x_n)$, is $L(\theta|x_1, \ldots, x_n) = \theta^{\Sigma x_i}(1-\theta)^{n - \Sigma x_i}$. Since

$$\log\left[\frac{L(\theta_1|x_1, \ldots, x_n)}{L(\theta_0|x_1, \ldots, x_n)}\right] = \left(\sum_{i=1}^n x_i\right) \log\left[\frac{\theta_1(1-\theta_0)}{\theta_0(1-\theta_1)}\right] + n \log\left(\frac{1-\theta_1}{1-\theta_0}\right),$$

and noting that $\theta_1(1-\theta_0)/\theta_0(1-\theta_1) > 1$, then the MP-$\alpha$ test is of the form

$$\delta^*(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } \sum x_i > k, \\ \gamma, & \text{if } \sum x_i = k, \\ 0, & \text{if } \sum x_i < k. \end{cases}$$

If the true value of the parameter is θ, the statistic $T = \sum X_i$ has a **binomial distribution** with parameters n and θ, so

$$\Pr_\theta(T = j) = b(j; n, \theta) \equiv \binom{n}{j} \theta^j (1-\theta)^{n-j}, \quad j = 0, 1, \ldots, n.$$

To satisfy the requirement that the size of the test is α, one could take

$$k = \min\left[j \in (0, 1, \ldots, n) : \sum_{i=j+1}^n b(i; n, \theta_0) \le \alpha\right]$$

and

$$\gamma = \frac{\alpha - \sum_{i=k+1}^n b(i; n, \theta_0)}{b(k; n, \theta_0)},$$

so the MP-α test for $H_0 : \theta = \theta_0$ vs. $H_1 : \theta = \theta_1$ becomes

$$\delta^*(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } \sum x_i > k, \\ \gamma, & \text{if } \sum x_i = k, \\ 0, & \text{if } \sum x_i < k. \end{cases}$$

Since the test δ^* does not depend on θ_1, it is also an MP-α test for $H_0 : \theta = \theta_0$ vs. $H_1' : \theta = \theta_1'$ provided that $\theta_1' > \theta_0$. Consequently, it is a UMP-α test for testing H_0 vs. $H_1'' : \theta > \theta_0$. Furthermore, since $\pi_{\delta^*}(\theta_0') \le \pi_{\delta^*}(\theta_0)$ for every $\theta_0' \le \theta_0$, then, as a test

for $H_0' : \theta \leq \theta_0$ vs. H_1'', δ^* is of level α and hence is UMP-α for testing H_0' vs. H_1''.

For the exponentially distributed time-to-event example at the beginning of this article suppose one wants to test $H_0 : \theta = \theta_0$ vs. $H_1 : \theta = \theta_1$ based on the values of $X_1, \ldots, X_n$ which are iid from $f_X(x|\theta) = \theta \exp(-\theta x)$, $x > 0$. The likelihood function is $L(\theta|x_1, \ldots, x_n) = \theta^n \exp(-\theta \sum x_i)$. By the fundamental lemma the MP-α test is

$$\delta^*(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } \sum x_i < c', \\ 0, & \text{if } \sum x_i > c', \end{cases}$$

since

$$[(x_1, \ldots, x_n) : L(\theta_1|x_1, \ldots, x_n) > cL(\theta_0|x_1, \ldots, x_n)]$$

is equivalent to

$$\left[(x_1, \ldots, x_n) : \sum_{i=1}^{n} x_i < c'\right]$$

for some c', and with the change in direction of the inequality due to the inequality $\theta_0 - \theta_1 < 0$. Under $H_0 : \theta = \theta_0$, the statistic $2\theta_0 \sum_{i=1}^{n} X_i$ has a central **chi-square distribution** with $2n$ **degrees of freedom**, whose quantiles are well-tabulated for small to moderate values of $2n$ (cf. [1] and [5]) or are obtained easily using a computer. Consequently, if one sets $c' = \chi^2_{2n;1-\alpha}$, where $\Pr(\chi^2_{2n} \geq \chi^2_{2n;1-\alpha}) = 1 - \alpha$, where χ^2_k is a central chi-square distributed variable with k degrees of freedom, then the test

$$\delta^*(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } 2\theta_0 \sum x_i \leq \chi^2_{2n;1-\alpha}, \\ 0, & \text{if } 2\theta_0 \sum x_i > \chi^2_{2n;1-\alpha}, \end{cases} \tag{2}$$

is an MP-α test for $H_0 : \theta = \theta_0$ vs. $H_1 : \theta = \theta_1$ with $\theta_1 > \theta_0$. Again, since δ^* does not depend on θ_1, it is an MP-α test for H_0 vs. $H_1' : \theta = \theta'$ with $\theta' > \theta_0$. Consequently, it is a UMP-α test for H_0 vs. $H_1'' : \theta > \theta_0$. Furthermore, since for any other $\theta_0' \leq \theta_0$

$$\begin{aligned} \pi_{\delta^*}(\theta_0') &= \mathrm{E}_{\theta_0'}[\delta^*(X_1, \ldots, X_n)] \\ &= \Pr_{\theta_0'}\left(2\theta_0 \sum X_i \leq \chi^2_{2n;1-\alpha}\right) \\ &= \Pr\left\{\chi^2_{2n} \leq \frac{\theta_0'}{\theta_0}\chi^2_{2n;1-\alpha}\right\} \\ &\leq \Pr\left\{\chi^2_{2n} \leq \chi^2_{2n;1-\alpha}\right\} \text{ since } \theta_0' \leq \theta_0 \\ &= \alpha, \end{aligned}$$

so, as a test for $H_0' : \theta \leq \theta_0$ vs. H_1'', it is therefore of level α. Consequently, δ^* in (2) is a UMP-α test for H_0' vs. H_1''.

In the above examples, the MP-α Neyman–Pearson tests turn out to be UMP-α tests for testing one-sided alternatives. These are particular cases of testing problems where the monotone likelihood ratio (MLR) property holds. When the parameter $\theta \in \Theta \subseteq \Re = (-\infty, \infty)$ is one-dimensional, the family $\mathcal{P}$ possesses the MLR property in a (one-dimensional) statistic $S(X_1, \ldots, X_n)$ if, for every $\theta_1, \theta_2 \in \Theta$ with $\theta_1 < \theta_2$:

.

1. $L(\theta_2|x_1, \ldots, x_n)/L(\theta_1|x_1, \ldots, x_n) = h[S(x_1, \ldots, x_n); \theta_1, \theta_2]$ for some function $h(\cdot; \cdot, \cdot)$; and
2. $h(s; \theta_1, \theta_2)$ is a monotone nondecreasing function in s.

Under this situation, the MP-α test for testing $H_0 : \theta = \theta_0$ vs. $H_1 : \theta = \theta_1$, where $\theta_0(<, >)\theta_1$, is also the UMP-α test for $H_0' : \theta(\leq, \geq)\theta_0$ vs. $H_1' : \theta(>, <)\theta_0$, and it is of the form

$$\delta^*(x_1, \ldots, x_n) = \begin{cases} 1, & \text{if } S(x_1, \ldots, x_n)(>, <)c, \\ \gamma, & \text{if } S(x_1, \ldots, x_n) = c, \\ 0, & \text{if } S(x_1, \ldots, x_n)(<, >)c, \end{cases}$$

where constants c and γ are chosen in order for $\pi_{\delta^*}(\theta_0) = \alpha$. For more details concerning this MLR property and its consequences, we refer the reader to Lehmann [3], pp. 78–86. Finally, we remark that, for two-sided types of alternatives, e.g. $H_1 : \theta \neq \theta_0$, UMP-$\alpha$ tests generally do not exist, and hence there is usually a need to restrict the search for a "best" test to a smaller class, such as the class of **unbiased** tests and/or invariant tests. An in-depth treatment of such tests can be found in Lehmann [3], Chapters 4–6. Some other references which discuss optimal hypothesis tests and provide numerous examples are the books by Bickel & Doksum [1], Casella & Berger [2], and Rohatgi [5].

Moving Average

Moving averages are operations applied to **time series** to achieve smoothing. The aim is usually to smooth the series enough to distinguish particular features of interest. A simple but effective model of a time series is to regard it as being made up of a long-term trend, a cycle and random effects. Symbolically,

$$X_t = m(t) + g(t) + e_t,$$

that is,

$$\text{observation} = \text{trend} + \text{cycle} + \text{random variation}.$$

Moving averages are often used to eliminate the seasonal or cyclic effects (*see* **Circadian Variation**) and hence to emphasize the trend terms, but this is not their only use.

Suppose we have a time series, i.e. a series of measurements taken over time, say

$$X_1, X_2, X_3, \ldots, X_N.$$

Define a new series by averaging the first s values, then deleting the first value from this group, adding the $(s+1)$th observation to the group and averaging, then deleting the first value from this group, adding the $(s+2)$th and averaging, then ... and so on. Symbolically,

$$\begin{aligned}
X^*_{(s+1)/2} &= \frac{(X_1 + X_2 + \cdots + X_s)}{s},\\
X^*_{(s+3)/2} &= \frac{(X_2 + X_3 + \cdots + X_{(s+1)})}{s},\\
X^*_{(s+5)/2} &= \frac{(X_3 + X_4 + \cdots + X_{(s+2)})}{s},\\
&\cdots\\
X^*_{N-(s-1)/2} &= \frac{(X_{N-s+1} + \cdots X_{N-1} + X_N)}{s}.
\end{aligned}$$

The new series, X^*_t, has been obtained from the original by applying a *moving average of length s* to the original series. All that we have done is to average successive blocks of s terms. This is easier to see for specific values of s; for $s = 3$ and 4 we have

$$\begin{aligned}
&s = 3\\
&X^*_2 = \frac{(X_1 + X_2 + X_3)}{3},\\
&X^*_3 = \frac{(X_2 + X_3 + X_4)}{3},\\
&X^*_4 = \frac{(X_3 + X_4 + X_5)}{3},\\
&\cdots.
\end{aligned}$$

$$\begin{aligned}
&s = 4\\
&X^*_{5/2} = \frac{(X_1 + X_2 + X_3 + X_4)}{4},\\
&X^*_{7/2} = \frac{(X_2 + X_3 + X_4 + X_5)}{4},\\
&X^*_{9/2} = \frac{(X_3 + X_4 + X_5 + X_6)}{4},\\
&\cdots.
\end{aligned}$$

The smoothed values, X^*_t, are assumed to be at the mean of the time values in each block. When s is even we see that the smoothed series lies between the original time points, which may be inconvenient. We can overcome this by applying a further two-point average to the "badly sited" series to give a new smoothed version called the "centered" moving average. The numerical example below uses this method.

It is straightforward to show that if a series has a cyclic effect of period s, then the application of an s-term moving average will remove it and will leave locally linear effects unchanged. Suppose in our model above that $X_t = g(t) + m(t) + e_t$, and $g(t)$ is periodic with period s. We assume that $\sum_{k=1}^{s} g(k) = 0$, since we can adjust any constant terms in the trend function. Then it follows that $\sum_{k=1}^{s} g(t+k) = 0$, so the effect of averaging s successive terms is to remove the $g(t)$ terms. For details, see [3] or [1].

As an example of the kind of calculation in Table 1, we demonstrate the effect of taking a four and then a two-point moving average of some the mortality rates in Baltimore, USA. The data are from Bliss [2]. Only part of the calculation is displayed.

The whole series is given in Figure 1. As we can see from the figure, the quarterly oscillations in the original data are suppressed by the moving average to give the smoothed series. The application of the quarterly average of length four, coefficients [1/4, 1/4, 1/4, 1/4] followed by the application of a moving average [1/2, 1/2] is equivalent to a five-point moving average with coefficients [1/8, 1/4, 1/4, 1/4, 1/8].

	0.8332	
0.8270		0.8327

The bracket notation here is a useful one in that it gives the number of terms in the average and the individual coefficients. The terms in the bracket are used to give a weighted average.

Once the cyclic effects are removed, the trend is easily seen. The cyclic component is evaluated by taking the cycle-free smoothed series from the original X_t. Of course, we are assuming that the effects are additive, that is,

$$X_t = \text{cyclic term} + \text{trend} + \text{other terms}.$$

However, if we have multiplicative effects, say

$$X_t = \text{cyclic term} \times \text{trend} \times \text{others},$$

then it is clearly necessary to take logs. We can then apply the moving average to the log series.

In addition to the removal of cyclic effects, moving averages arise in a natural way in the piecewise fitting of polynomials to time series. Suppose we decide to fit a polynomial of degree 3, say, $a_0 + a_1 t + a_2 t^2 + a_3 t^3$, to five points of our series. We know it is very much simpler to transform our time scale so that our points are X_{-2}, X_{-1}, X_0, X_1, X_2 at times -2, -1, 0, 1, 2.

The usual regression normal equations are

$$\sum_{t=-2}^{2} X_t = 5a_0 + a_1 \sum_{t=-2}^{2} t + a_2 \sum_{t=-2}^{2} t^2 + a_3 \sum_{t=-2}^{2} t^3,$$

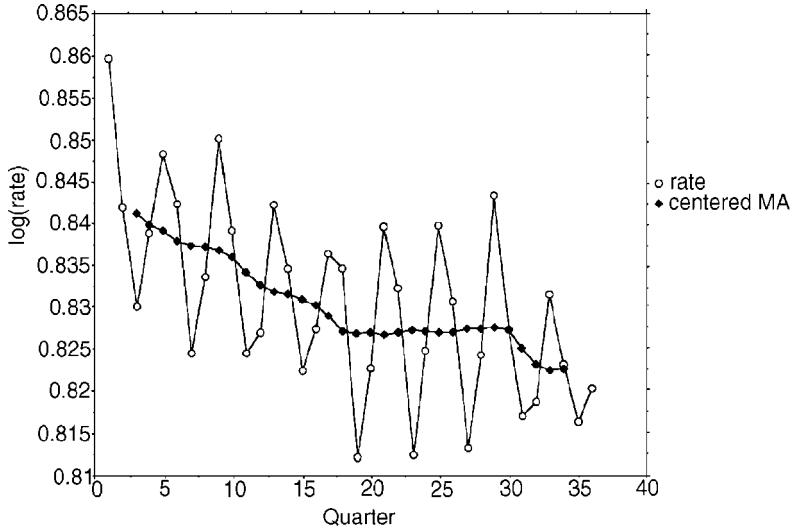

Figure 1 Log death rates and a moving average

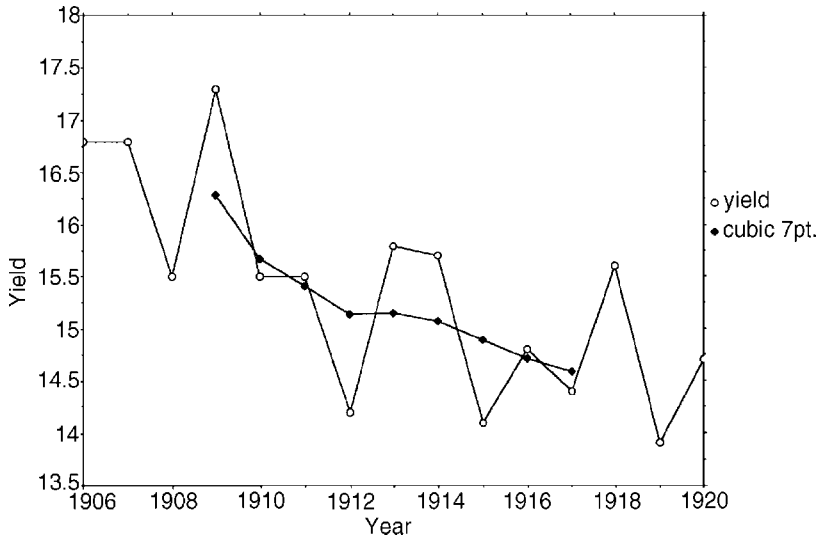

Figure 2 Barley yield in the UK, 1906–1920 and seven-point cubic

$$\sum_{t=-2}^{2} tX_t = a_0 \sum_{t=-2}^{2} t + a_1 \sum_{t=-2}^{2} t^2 + a_2 \sum_{t=-2}^{2} t^3 + a_3 \sum_{t=-2}^{2} t^4,$$

$$\sum_{t=-2}^{2} t^2X_t = a_0 \sum_{t=-2}^{2} t^2 + a_1 \sum_{t=-2}^{2} t^3 + a_2 \sum_{t=-2}^{2} t^4 + a_3 \sum_{t=-2}^{2} t^5,$$

$$\sum_{t=-2}^{2} t^3X_t = a_0 \sum_{t=-2}^{2} t^3 + a_1 \sum_{t=-2}^{2} t^4 + a_2 \sum_{t=-2}^{2} t^5 + a_3 \sum_{t=-2}^{2} t^6,$$

but

$$\sum_{t=-2}^{2} t = \sum_{t=-2}^{2} t^3 = \sum_{t=-2}^{2} t^5 = 0 \text{ and}$$

$$\sum_{t=-2}^{2} t^2 = 10, \qquad \sum_{t=-2}^{2} t^4 = 34, \qquad \sum_{t=-2}^{2} t^6 = 130,$$

so we have

$$\begin{aligned}
\{X_{-2} + X_{-1} + X_0 + X_1 - X_2\} &= 5a_0 \qquad 10a_2\\
\{-2X_{-2} - X_{-1} \quad + X_1 - 2X_2\} &= \qquad 10a_1 \qquad 34a_3\\
\{4X_{-2} + X_{-1} \quad + X_1 + 4X_2\} &= 10a_0 \qquad 34a_2\\
\{-8X_{-2} - X_{-1} \quad + X_1 - 8X_2\} &= \qquad 34a_1 \qquad 130a_3,
\end{aligned}$$

giving $a_0 = (1/35)[-3X_{-2} + 12X_{-1} + 17X_0 + 12X_1 - 3X_2]$.

If we fit this polynomial in piecewise segments and use the constant term as the smoothed values, this is equivalent to a moving average of length 5 with unequal weights that we write as (1/35) [−3, 12, 17, 12, −3].

This is sometimes abbreviated to (1/35) [−3, 12, **17**] where only half the bracket is given. When in doubt, note that the terms in the bracket must sum to the denominator of the divisor. So, in (1/35) [−3, 12, 17, 12, −3], $-3 + 12 + 17 + 12 - 3 = 35$.

We can find moving averages for all such polynomials; thus, for cubics:

5 points	(1/35) [−3, 12, 17, 12, −3],
7 points	(1/21) [−2, 3, 6, 7, 6, 3, −2],
9 points	(1/231) [−21, 14, 39, 54, 59, 54, 39, 14, −21],
11 points	(1/429) [−36, 9, 44, 69, 84, 89, 84, 69, 44, 9, −36],
13 points	(1/143) [−11, 0, 9, 16, 21, 24, 25, 24, 21, 16, 9, 0, −11],

15 points (1/1105) [−78, −13, 42, 87, 122, 147, 162, 167, 162, 147, 122, 87, 42, −13, −78],

while similar expressions are available for quintic curves. The effect of the seven-point cubic is shown in Figure 2.

Such averages are useful in giving a way of smoothing series that requires very few assumptions and that is reasonably simple to use, especially with a spreadsheet. The drawbacks are precisely the same; the informal procedure does not lend itself to testing or model building. It is difficult to make a rational choice of polynomial and moving-average length. Some theory is possible, see [1]. Thus, for a fixed-length moving average the variance increases with polynomial order, while for fixed order the bias decreases with length, but this result is of limited use. Also, one needs to take care, since cavalier use of successive moving averages may well lead to induced cyclic effects in the smoothed series (*see* **Slutzky–Yule Effect**).

Moving averages have a long history linked to interpolation from tables, especially actuarial tables. Many interpolation formulas involve differences, and smoothing formulas are used to give a graduation with smooth successive differences. A moving average is said to be correct to order q if differences of polynomials of this order remain unaffected. One popular example is Spencer's 15-point formula, which consists of applying (1/4) [−3, 3, 4, 3, −3], then (1/5) [1, 1, 1, 1, 1], then (1/4) [1, 1, 1, 1], followed by (1/4) [1, 1, 1, 1].

Multicenter Trials

A multicenter **clinical trial** is defined in this article to be a study involving two or more field sites that is conducted according to a common protocol (*see* **Clinical Trials Protocols**) and that uses a single data coordinating center to receive, process and analyze study data. In conformity with terminology adopted in [1], field sites are the primary sites of participant accrual, intervention, data collection and follow-up. For example, in trials comparing alternative treatments for a specific disease, the field sites may consist of hospitals, clinics or other locations that provide patient care. The number of field sites varies greatly across studies according to their size, complexity and purpose. For example, the Beta-Carotene and Retinol Efficacy Trial (CARET), a **prevention trial** in men and women at high risk for lung cancer, involves six field sites, whereas, in the cooperative oncology group setting, it is common for trials to encompass hundreds of sites.

In this article we provide several examples of multicenter trials, and discuss the rationale for conducting them. We also describe organizational, structural, and analytic aspects of multicenter trials. Finally, we suggest guidelines for the conduct of such studies.

More comprehensive discussions can be found in the books by Meinert [7] and Pocock [11], and in a special edition of *Controlled Clinical Trials* edited by Wittes [15].

Examples of Multicenter Trials

There are currently thousands of active multicenter trials designed to evaluate treatment or prevention strategies for every major disease. Examples from three different areas are discussed below to indicate the diverse nature of multicenter trials, and their impact on the practice of medicine.

Breast Cancer

In the past quarter-century there has been a profound change in the surgical treatment of breast cancer. Radical (Halstedian) mastectomy has been replaced by less extensive surgery, and, today, lumpectomy (local excision), together with radiation, may be recommended for the majority of women with early-stage breast cancer [10]. This shift in treatment strategy was supported by a series of multicenter randomized (*see* **Randomization**) trials comparing less-extensive to more-extensive surgery, which found no survival benefit to the more extensive forms of surgery [2]. One of the early studies in this series was conducted by the National Surgical Adjuvant Breast and Bowel Project (NSABP) and compared radical mastectomy to total mastectomy with and without post-operative breast irradiation [3]. Between July 1971 and September 1974, 1765 women with operable breast cancer entered this study at 34 institutions throughout the US and Canada. After publication of the five-year results, which demonstrated no difference in survival between treatments, the percentage of radical mastectomies done as the surgical procedure for primary operable breast cancer in the US dropped from 75% to less than 5%.

Coronary Disease

Not all multicenter trials have survival or disease-free survival (*see* **Survival Analysis, Overview**) as their primary endpoint (*see* **Outcome Measures in Clinical Trials**). An example is given by a multicenter, randomized placebo-controlled trial of the angiotensin-converting enzyme inhibitor cilazapril, designed to assess its efficacy in reducing the rate of restenosis following percutaneous transluminal coronary angioplasty [9]. Seven hundred and thirty-five patients were randomized to receive either 2.5 mg cilazapril in the evening following angioplasty and 5 mg b.i.d. for six months, or placebo. Patients also received aspirin for six months. The primary endpoint was defined to be the difference in minimal coronary lumen diameter, post-angioplasty to six months follow-up. The average change in minimal coronary lumen diameter did not differ between controls and patients treated with cilazapril, nor did the frequency of serious clinical events (death, myocardial infarction, coronary revascularization, recurrent angina). These findings were confirmed in a subsequent, larger study [8].

Prevention

Two trials that were of importance in assessing the efficacy of beta-carotene as a preventive agent against lung cancer in high-risk participants were the Alpha-Tocopherol, Beta-Carotene Cancer Prevention

Trial (ATBC) [14] and the Beta-Carotene and Retinol Efficacy Trial (CARET) [13]. In the ATBC trial, 29 133 male smokers in Finland were randomized to receive daily 50 mg alpha tocopherol (vitamin E), 20 mg beta-carotene, both drugs or placebo. Participants remained on treatment for five to eight years. In the CARET trial, 18 314 high-risk participants were randomized to receive either daily beta-carotene (30 mg) and vitamin A (retinyl palmitate 25 000 IU) or placebo. This study was terminated ahead of schedule in January 1996 after about four years of treatment. In both studies, more lung cancers were diagnosed and there were more deaths among participants receiving beta-carotene than among those participants not receiving the drug. The two multicenter trials illustrate the not uncommon occurrence of large randomized trials refuting an effect suggested by **nonrandomized** studies.

Rationale for Conducting Multicenter Trials

Adequacy of Accrual

The decision to mount a large-scale multicenter study is driven by the need to recruit subjects at a faster rate than can be accomplished at a single center. This will be the case when anticipated treatment differences are important but relatively small, or only a minority of participants are likely to experience the outcome(s) in question. Thus, prevention studies are almost always organized as multicenter trials (*see* **Prevention Trials**). In trials investigating the efficacy of treatments against established disease, the multicenter approach is common in the design of Phase III trials, which involve the randomized comparison of new treatments against a currently accepted standard. **Phase I trials** (assessment of toxicity) and **Phase II trials** (preliminary establishment of clinical activity) require many fewer patients, and are often carried out within a single institution. However, in rare diseases the multicenter approach may be necessary, even for Phase I and II trials.

Increased Generalizability of Study Conclusions

If the protocol is crafted to define clearly the patient population of interest without arbitrary exclusion of potential participants (*see* **Eligibility and Exclusion Criteria**), then the use of multiple field sites will normally result in a more heterogeneous population of participants (both patients and physicians) and will enhance the generalizability of the results. Of equal importance is the fact that widespread participation in the trial will ensure greater acceptance of the study results in the community, without which the conclusions of the study cannot be translated into standard medical practice.

Broad-Based Clinical Trials Bring State-of-the-Art Treatment to the Community

Most current therapies, at least in cancer treatment, are first made available to patients through the clinical trials process. In the Phase III setting, it is an ethical requirement that unproven treatments have a reasonable probability of improving on the current standard of care, and a low probability of being materially inferior (*see* **Ethics of Randomized Trials**). Furthermore, the care of patients enrolled on multicenter trials is governed by a carefully designed protocol, and standards of patient management, testing, and follow-up are arguably better than might be expected outside the clinical trials process. Additionally, participation in clinical trials gives community-based physicians and other care-givers the opportunity to learn about newly evolving strategies of treatment and patient management. This should have a positive effect on the care received by all patients, including those who choose not to participate in clinical trials.

A Caveat

A community-based multicenter trial is not the optimal setting to compare complicated regimens that require intensive training on the part of the treating physicians. Accrual to such studies may be difficult, and it is possible that patient care could be compromised. Furthermore, if a complicated treatment appears to provide no benefit on the basis of the trial data, the interpretation of these results will be ambiguous if there is any question regarding protocol adherence (*see* **Compliance Assessment in Clinical Trials**).

Organizational Structure and Personnel

All multicenter trials share a common structure involving distributed field sites responsible for participant accrual, intervention, primary data collection, and follow-up. These activities are directed through a coordinating center, and overall

responsibility for the conduct of the trial is generally assumed by a study chairman. The coordinating center serves numerous critical functions, as detailed by Meinert [7]; these include study design; the development of a protocol document; recruitment, training, and coordination of accrual sites; patient randomization; data entry and processing (*see* **Data Management and Coordination**); ongoing monitoring of toxicity data; periodic interim analyses of study endpoints (*see* **Data and Safety Monitoring**); auditing of field sites (*see* **Clinical Trials Audit and Quality Control**); regulatory reporting; final data analyses; and preparation of abstracts and manuscripts. While there is considerable efficiency to be gained by having all components of the coordinating center in one place, it may be the case that an institution that has expertise in one function fails to have expertise in another. Thus, coordinating center staff will not always be located at the same institution. In fact, a common model is to divide the coordinating center into an operations office having responsibility for logistical aspects of the trial and a data center responsible for data management and statistical reporting. Often, these two functions are physically separated.

The major personnel involved in conducting a multicenter trial are listed below, together with brief summaries of their functions:

Study Chairman

The study chairman is responsible for the overall project. Ideally, the individual will be involved from the time the study is first conceptualized until the final analyses are performed and results reported. This individual should be an expert in the disease being studied, should have previous clinical trial experience, and must be strongly committed to the success of the study. He or she must have the time and commitment to address key issues, particularly regarding recruitment and compliance. For large studies, a steering committee may assist the study chairman in overseeing the design and conduct of the trial.

Trial Statistician

A statistician should be identified to participate in and be responsible for the statistical design, monitoring, and analysis of the study. Responsibilities include preparation and presentation of interim endpoint analyses, preparation of toxicity tables for ongoing review, tracking of accrual, monitoring of follow-up to assure no **biases** are occurring and, ultimately, collaboration in the preparation of manuscripts summarizing trial results. The trial statistician also has general responsibility for the statistical design of ancillary studies and any related data transfers.

Operations Officer

For large trials, an operations officer should be appointed to oversee the study logistics, often with the assistance of the study chair and coordinating center support staff. The logistical considerations to be addressed include protocol development, regulatory compliance, communication with field sites, drug distribution, trial participant meetings, medical review, and interactions with the steering committee, trial sponsors, and vendors. For small studies, many of these duties may be assumed by the study chairman or trial statistician.

Data Manager

The data manager assures that quality data are entered into the research database in a timely manner. He or she participates in the design of forms (*see* **Questionnaire Design**), assists in determining which data are feasible to collect and the best procedures for doing so, sets and adheres to timeliness goals for data submission and entry, enters and/or checks data, queries field sites about missing or unclear data, abstracts data from medical reports, identifies items required for further medical review, and assists in the training of field site personnel.

Randomization Specialist

The randomization specialist reviews patient demographic and clinical data, verifies patient eligibility (*see* **Eligibility and Exclusion Criteria**), checks that informed consent has been properly documented, and finalizes treatment assignments (*see* **Randomized Treatment Assignment**).

Quality Assurance Officer

The quality assurance officer implements procedures to verify that field sites are in compliance with the protocol and that data processing and monitoring at the coordinating center is accurate and

timely. These procedures include centralized medical review, on-site audits, data entry verification, data flow monitoring, computerized edit checks for data completeness and consistency, and procedures for assuring data **confidentiality** and security.

Computer Support Personnel

This function may be divided into three areas. The first is **database** management, including maintenance of the research database and support of computerized aspects of the data quality assurance program. A second area is applications programming in support of statistical reports, and operational functions such as drug distribution, Institutional Review Board (IRB) approvals, and field site performance monitoring. A third area is systems management, which includes the development and maintenance of internal hardware and **software** systems, intra-office communications and support systems, and the development of capabilities for communicating with field sites, such as e-mail and **Internet**.

Resource Center Directors

Many trials have centers that perform special functions, such as reading pathology slides, serum banking, or reviewing unusual toxicities. A director is required to assure quality control and to facilitate communication and data transfer with headquarters.

Training Director

An individual should be charged with the responsibility for training investigators and support personnel at the participating field sites. This function includes on-site training, workshops at one or more central locations, and preparing data management and/or treatment handbooks, videos, and centralized resources accessible by phone, e-mail or Internet. This individual may also assume responsibility for responding to questions from the field sites and soliciting input from investigators and support personnel to help identify problems with the protocol conduct and methods for reducing an administrative burden.

Field Site Personnel

Contact people should be identified at each field site. These may include both the treating physician and an individual who has primary responsibility for data submission (a clinical research associate, nurse coordinator or data manager).

Data Monitoring Board

Most trials have **data and safety monitoring boards** that review interim study data. Some are independent of the study investigators, others include both study investigators and independent members, and some boards comprise study investigators and coordinating center staff. The board reviews the progress of the trial to assure that the statistical monitoring plan is followed, that there are no dangerous trends in the toxicity or outcome data, and generally to assure that the trial is conducted according to protocol (*see* **Data and Safety Monitoring**).

Guidelines for the Conduct of Multicenter Trials

It is imperative in conducting any trial that all personnel share a common understanding of the aims, operational details, and reporting requirements. Six specific areas are summarized below.

Study Protocol

Because of the dispersed nature of a multicenter trial, it is important that a written protocol be developed that addresses all aspects of the study (*see* **Clinical Trials Protocols**). The protocol is an instrument for communicating the study requirements to the investigators; hence, must be a clear, concise document that minimizes individual interpretations. Topics to be addressed include:

1. Rationale for and specific aims of the study.
2. Patient eligibility requirements and entry procedures.
3. Study endpoint definitions.
4. Required procedures for treatment administration, including precise rules for dose determinations.
5. Patient management guidelines, including specifications for dose reductions, treatment delays and treatment terminations.
6. Schedules of required clinical tests and assessments.
7. Schedule for submission of required materials and data, including long-term follow-up.
8. Data and materials submission procedures.

9. Regulatory obligations, including informed consent and reporting of adverse events.
10. Statistical considerations, to include: method of treatment assignment; anticipated accrual pattern; **power** analysis justifying sample size requirements (*see* **Sample Size Determination for Clinical Trials**); interim monitoring and analysis plans; and planned time and methodology of final analyses. The section should also describe methods to be used to address secondary aims of the study, compare toxicities, and analyze data from any ancillary laboratory studies.

Data Requirements

Data submission requirements should be examined to eliminate unnecessary data items. Generally, data should not be required for submission unless they are required to (i) address the specific aims of the study, (ii) assure that the study is carried out in compliance with its protocol, (iii) monitor the progress of the study both with respect to toxicity and clinical outcome, or (iv) fulfill regulatory reporting requirements (*see* **Drug Approval and Regulation**). Likewise, data collection instruments should be made as simple as possible (*see* **Questionnaire Design**). Their design should consider the perspective of the clinical research associates, nurses and data managers who will be responsible for their completion (*see* **Data Management and Coordination**).

Submission of Materials

Requirements for the submission of materials such as fresh tissues or serum samples must be considered carefully. Such requirements may place undue burdens on community-based hospitals and may seriously impact patient recruitment. When designing ancillary studies requiring such materials, consideration should be given to restricting sample collection to a subset of sites experienced in processing the required material.

Communication

It is essential that channels of communication be kept open between the field sites and the coordinating center. Provision should be made for regular meetings at which investigators are apprised of the current status of the trial, and are encouraged to provide feedback to the scientific leadership regarding problems encountered at the local level. Between meetings there should be frequent communication via mail, electronic mail, fax, newsletters or other media. Field investigators should be encouraged to contribute to the scientific program of the group. Some clinical trials have benefited from encouraging the involvement of trial participants on advisory committees, in discussion groups, and in the preparation of newsletters.

Site Performance Monitoring

It is important that field site investigators have an a priori understanding of the performance standards expected of them. Acceptable standards for performance with regard to on-site audits, accrual, data submission delinquency, protocol compliance, and patient eligibility should be explicit. Standards should be realistic, so that there is an appropriate balance between quality assurance and feasibility of participation.

Special Statistical Requirements

In multicenter trials it is common practice to stratify treatment assignment by field site in addition to other relevant stratification variables. If there are only a few field sites, full stratification may be used to achieve a balanced treatment assignment within each combination of **stratification** variables. In the cooperative group setting where the number of field sites may be very large, a dynamic allocation method may be required, since stratum sizes would typically be too small to achieve treatment balance within each cell. This ensures that treatment assignments will be balanced with respect to each individual stratification variable (*see* **Adaptive and Dynamic Methods of Treatment Assignment**).

If there are only a few field sites, one should include the sites in analyses, either as stratification factors or as independent variables in a model. One might also wish to look for important **interactions** of field site with treatment (*see* **Treatment-covariate Interaction**). If there are many field sites, it may be impractical to use field sites as stratification variables in analysis. However, when there are many field sites, no one field site will be likely to influence greatly the results of the analyses. Application of **Bayesian methods** to the analysis of institutional effects in multicenter trials may provide new insight. Three fairly recent publications by Skene &

Wakefield [12], Gray [4], and Gustafson [5] describe Bayesian approaches.

Interim monitoring of toxicities and events, often done by independent data and safety monitoring boards, requires careful planning in the statistics section of the protocol. Board meetings must be planned in advance, so it is not practical to schedule interim analyses at a fixed number of events. Flexible monitoring rules like those introduced by Lan & DeMets [6] are required to adjust for the fact that analyses are based on fixed calendar times rather than a fixed number of events.

Multidimensional Scaling

Multidimensional scaling comprises a set of models and associated methods for constructing a geometrical representation of proximity or dominance relationships between elements in one or more sets of entities. While this characterization of multidimensional scaling may seem rather abstract, any further specification would unnecessarily narrow it to certain specific types of data or representation models.

The types of data to which multidimensional scaling can be applied can be categorized in terms of three attributes: the number of ways of the data array, the number of modes, and the type of relationship expressed by the data. The *number of ways* of a data set refers to the number of dimensions or factors of the data array. When the data can be arranged in a matrix, they are called two-way data. One way corresponds to the rows of the matrix and the other way corresponds to the columns. Three-way data are arranged in a three-dimensional array – the third way referring to the slices of the array. The *number of modes* indicates the number of different sets of entities to which the ways of the data array refer. If both the rows and the columns of a two-way data matrix index the same set of entities (such as objects, subjects, etc.), then the data are called *two-way one-mode data*. A typical example of a two-way one-mode data set is a **correlation** matrix. When the rows and columns of the data matrix refer to two different sets of entities (e.g. subjects and objects), the data are called *two-way two-mode data*. A rectangular matrix with ratings indicating the extent to which certain symptoms pertain to certain diseases is an example of such a data set. The set of symptoms constitutes one mode while the set of diseases constitutes the other mode. Finally, three-way data of which the ways index one, two, or three different sets of entities, are respectively referred to as *three-way one-mode, three-way two-mode*, or *three-way three-mode data*. A set of square symmetric matrices containing the correlations between the same set of variables on a number of different occasions constitutes an example of a three-way two-mode data set. Finally, a three-way three-mode data array can, for instance, be obtained by having N_1 physicians rate the extent to which N_2 patients exhibit a set of N_3 symptoms. Each of the ways of the resulting $N_1 \times N_2 \times N_3$ data array corresponds to a different set of entities, namely physicians, patients, and symptoms.

Multidimensional scaling can be applied to data that express two *types of relationship*: proximity relations and dominance relations. In proximity data the data values indicate the proximity (similarity or dissimilarity) between the entities to which their indices refer (*see* **Similarity, Dissimilarity, and Distance Measure**). If larger values indicate a greater proximity, then the data are called *similarity data*. If larger values indicate a smaller degree of proximity, then the data are *dissimilarity data*. (Note that similarity data can always be converted into dissimilarities by subtracting all values from a suitably large constant.) Thus, a correlation matrix constitutes a two-way one-mode set of similarity data. The other type of data relationships to which multidimensional scaling can be applied are dominance relationships. In dominance data, the data values indicate how strongly one entity dominates the other. A paired comparisons matrix, where each entry shows the percentage of times the row element is preferred to the column element, is an example of a two-way one-mode dominance matrix.

Historically, multidimensional scaling was developed for constructing a spatial representation of two-way one-mode proximity data. Later, it was extended to other types of data (such as three-way proximity data and dominance data) and to other types of models (such as nonspatial models). In the next section we discuss its most common form namely multidimensional scaling of two-way one-mode proximity data. In the subsequent sections we present some of the extensions to three-way two-mode data and to nonspatial models.

Two-Way Multidimensional Scaling

Starting from two-way one-mode symmetric proximity data, two-way multidimensional scaling attempts to represent the objects indexed by the rows and columns of the data matrix by points in a multidimensional space such that the interpoint distances correspond as well as possible to the observed proximity data in some well-defined sense. Being one-mode data, the rows and columns of the data matrix refer to a common set of N entities. These entities will be generically referred to as "objects". It will be assumed that the data are dissimilarities. The $N \times N$ data matrix will be denoted $\mathbf{\Delta} = ((\delta_{ij}))$, where δ_{ij}

indicates the observed dissimilarity between object i and object j. $\mathbf{\Delta}$ is assumed to be symmetric, i.e. $\delta_{ij} = \delta_{ji}$. Usually the entries on the main diagonal of $\mathbf{\Delta}$ are not observed and hence are undefined.

Such two-way symmetric proximity data can be obtained in several ways. In the behavioral and social sciences, it is common to have subjects judge the degree of similarity or dissimilarity between all $N(N-1)/2$ pairs of distinct objects on a numerical scale, yielding so-called *direct ratings*. Ordinal proximity data can be obtained, for example, by having subjects arrange the objects in **rank** order according to their proximity to a reference object. Or, subjects can compare two pairs of objects at a time, and indicate for each couple of pairs which pair contains the most similar (or dissimilar) objects. Alternately, proximities can be derived from *co-occurrence data*. In such a case the proximity measure is based on the number of occasions on which two objects co-occur. In scientometrics, for instance, the similarity between two journals can be defined as the number of times the two journals are cited in the same list of references. Or, when subjects were asked to sort a (large) set of objects into a number of mutually exclusive and exhaustive categories such that similar objects are put in the same category, a pairwise proximity measure can be derived from the number of subjects who put the two objects in the same category. Two-way symmetric proximity data can also be computed from *confusion* or *transition frequencies*. In this case the proximity is based on the number of times one object is confused or succeeded by another object. In sociology, for instance, the proximity between two professions could be computed from social mobility data indicating the number of parents with profession i who have a child with profession j. Finally, multidimensional scaling is often applied to *derived* or so-called *second-order proximities*. Starting from multivariate data (e.g. measurements of N objects on a number of variables), correlations, profile distances, or other derived proximity measures are computed to quantify the degree of association between the objects.

In multidimensional scaling the N objects will be represented as points in a multidimensional space, such that the interpoint distances approximate the observed dissimilarities δ_{ij} as well as possible. While extensions to other kinds of spaces exist, multidimensional scaling usually constructs a representation in a *Euclidean* space. The dimensionality of the space will be indicated by R. If x_{ir} denotes the coordinate of the point representing object i on the rth dimension, the Euclidean distance between the points representing objects i and j can be written as

$$d_{ij} = \left[\sum_{r=1}^{R}(x_{ir} - x_{jr})^2\right]^{1/2} = [(\mathbf{x}_i - \mathbf{x}_j)'(\mathbf{x}_i - \mathbf{x}_j)]^{1/2},$$

where $\mathbf{x}_i$ is an R-component column vector defined as $\mathbf{x}_i = (x_{i1}, \ldots, x_{iR})'$, The purpose of multidimensional scaling is to represent the N objects in an R-dimensional Euclidean space such that the distances d_{ij} are close to the observed δ_{ij}. However, the Euclidean distances d_{ij} do not approximate the observed dissimilarities δ_{ij} directly, but approximate some permissible transformation f of the observed dissimilarities:

$$d_{ij} \approx f(\delta_{ij}).$$

The type of transformation f that is applied depends on the measurement level of the data (*see* **Measurement Scale**). If the data constitute a ratio scale (i.e. if the dissimilarities are unique up to a positive similarity transformation), f is defined as

$$f(\delta_{ij}) = b\delta_{ij}, \quad b > 0.$$

Owing to the scale indeterminacy of the representation discussed later in the article, b can be set equal to 1 without loss of generality. When the data constitute an interval scale (i.e. when the data are unique up to a positive linear transformation), f is defined as

$$f(\delta_{ij}) = a + b\delta_{ij}, \quad b > 0.$$

Finally, when the proximities are ordinal data (e.g. rank order data), f is a weak monotone transformation such that

$$f(\delta_{ij}) \geq f(\delta_{kl}), \quad \text{if } \delta_{ij} > \delta_{kl}.$$

In the case of a tie, i.e. if $\delta_{ij} = \delta_{kl}$, either no restriction is imposed on the relationship between $f(\delta_{ij})$ and $f(\delta_{kl})$ or the two transformed dissimilarities are required to be equal, i.e. $f(\delta_{ij}) = f(\delta_{kl})$. The former approach has been labeled by Kruskal [16, 17], in his breakthrough work formulating a rigorous mathematical and numerical approach to two-way nonmetric multidimensional scaling, "the primary approach to ties", while the latter is known as the "secondary

approach to ties". The transformed dissimilarities $f(\delta_{ij})$ are sometimes called *target distances* or *optimally scaled data*. Multidimensional scaling thus attempts to find coordinates $\mathbf{x}_1, \ldots, \mathbf{x}_N$ such that

$$d_{ij} \approx f(\delta_{ij}).$$

When the data are ordinal and a monotone transformation is allowed, the procedure is called *nonmetric* multidimensional scaling. When the proximities are interval or ratio level data, the procedure is referred to as *metric* multidimensional scaling.

The **goodness of fit** of a multidimensional scaling representation is based on a normalized sum of squared deviations between the transformed dissimilarities and the derived Euclidean distances:

$$\mathcal{L}_f(\mathbf{x}_1, \ldots, \mathbf{x}_N) = \frac{\sum_{i<j}^{N} [f(\delta_{ij}) - d_{ij}]^2}{\sum_{i<j}^{N} d_{ij}^2}.$$

The normalization is necessary to make the **loss function** independent of the scale of the derived space. Other normalization factors are sometimes used and may be preferable in certain cases. Note that $\mathcal{L}_f$ depends on the transformation f and that the optimal transformation f is unknown. To make the loss function independent of f, it is defined as

$$\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N) = \underset{\text{all } f}{\text{minimum}} \mathcal{L}_f(\mathbf{x}_1, \ldots, \mathbf{x}_N).$$

The square root of $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$ is known in the literature as the "stress" function [16, 17]. In two-way multidimensional scaling, given the data $\mathbf{\Delta}$ and given a dimensionality R, coordinates $\mathbf{x}_1, \ldots, \mathbf{x}_R$ are sought that minimize $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$. This optimization problem involves minimizing a nonlinear function in many variables and cannot be solved analytically. Instead iterative procedures are used. Such a procedure starts from some initial estimates of the coordinates and iteratively improves these estimates until no further decrease in $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$ is possible. While the solution obtained through such a procedure is known to be locally optimal, it is not guaranteed to be a global minimum $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$. The best way to safeguard against local optima is to carry out the analysis several times, starting each run from different initial estimates. If the same optimal solution is found repeatedly, then it is likely to constitute a global optimum.

It should be noted that $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$ is not affected by certain transformations of $\mathbf{x}_1, \ldots, \mathbf{x}_N$. More specifically, shifting the origin of the coordinates (i.e. replacing $\mathbf{x}_i$ by $\mathbf{x}_i + \mathbf{c}$, $i = 1, \ldots, N$, where $\mathbf{c}$ is an R-component constant vector) does not affect the goodness of fit of the solution. Likewise, any transformation of the form $\mathbf{x}_i \rightarrow \mathbf{T}\mathbf{x}_i$, $i = 1, \ldots, N$, with $\mathbf{T}\mathbf{T}' = \mathbf{T}'\mathbf{T} = \mathbf{I}$, leaves the Euclidean distances unchanged and so does not affect the goodness of fit. This family of transformations includes permutations, reflections, and orthogonal rotations of the configuration. Finally, owing to the normalization factor, changing the scale of the configuration (i.e. replacing all $\mathbf{x}_i$ by $\alpha\mathbf{x}_i, \alpha \neq 0$) does not alter the goodness of fit. Therefore, a solution that minimizes $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$ is only unique up to the similarity transformations mentioned above and the dimensions of such a configuration can be freely translated, permuted, reflected, orthogonally rotated, and uniformly rescaled to facilitate the interpretation.

To evaluate the goodness of fit, the minimum value obtained for the loss function should be inspected as well as scatter plots of δ_{ij} vs. d_{ij}, $f(\delta_{ij})$ vs. d_{ij} and δ_{ij} vs. $f(\delta_{ij})$. As mentioned above, the loss function $\mathcal{L}(\mathbf{x}_1, \ldots, \mathbf{x}_N)$ is minimized for a given dimensionality R. The appropriate dimensionality is usually not known a priori. Of course, the larger R, the better the goodness of fit that can be obtained, but the less data reduction will occur and the more complicated the solution will be. To select an appropriate dimensionality, the analysis is usually carried out for decreasing values of R. From a plot of the goodness of fit vs. the dimensionality, an appropriate value for R is selected (usually at the value where an "elbow" occurs).

Several software programs exist that implement two-way multidimensional scaling. One of the more often used programs is KYST-2A [19] that is fully documented in Kruskal & Wish [18].

To illustrate a two-way analysis, we apply KYST-2A to some data collected by Ekman [14], and originally analyzed by Shepard [24, 25] in his pioneering work on "analysis of proximities" describing the earliest approach to what later developed into modern two-way nonmetric multidimensional scaling. Ekman obtained similarity judgments from human subjects about 14 colors varying in wavelength from 434 mμ to 674 mμ. The colors were projected two at a time on a screen and the subjects were instructed to rate

the "qualitative similarity" on a five-point scale. The average similarity ratings are presented in Table 1. KYST-2A was applied to these data with R varying from 5 to 1, treating the data as ordinal data. The minimum values obtained for the stress function are plotted as a function of R in Figure 1. This figure clearly exhibits an "elbow" at $R = 2$. The associated two-dimensional configuration is presented in Figure 2. In the figure, the objects are labeled by their wavelength in mμ. The figure clearly reveals the well-known color circle ranging from violet (434 mμ) over blue (472 mμ), green (504 mμ), and yellow (584 mμ) to red (674 mμ). The input similarities are plotted against the resulting Euclidean distances in Figure 3. The figure clearly shows that the Euclidean distances approximate a monotonic transformation of the observed proximity data.

There is also an older (now called the "classical") approach to two-way metric multidimensional scaling, best described in Torgerson [26], that relies on a singular value decomposition (*see* **Correspondence Analysis**) of a symmetric estimated "scalar products" matrix derived via some preprocessing of the original proximity data. While this procedure, being based on the singular value decomposition, does not suffer from a local optimum problem, the loss function that it is optimizing does not have as clearly defined properties as $\mathcal{L}$ does.

The basic two-way multidimensional scaling procedure described above has been extended in many respects. Statistical formulations enabling **maximum likelihood** estimation have been developed (see [21] for a survey), as well as extensions to non-Euclidean metric (see [1] for a review of extensions to non-Euclidean Minkowski metrics). The families of permissible data transformations have been extended (e.g. [27]) and constrained procedures have been devised (e.g. [10]).

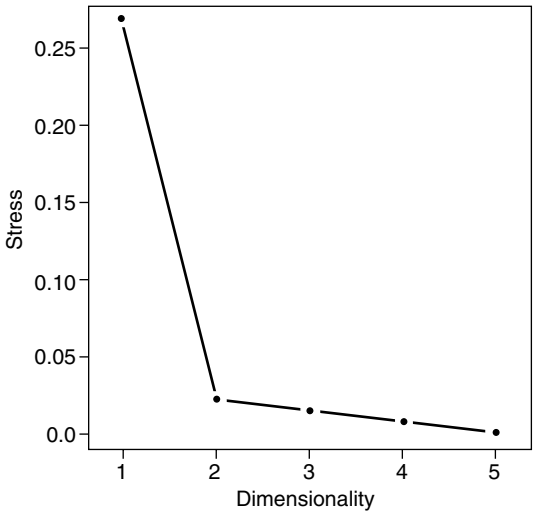

Figure 1 Minimum stress values obtained for the Ekman [14] data

One of the more important extensions of two-way multidimensional scaling has been to the case of two-way two-mode data (see [4] for a review). Such data can arise in a number of different ways; for instance, when proximity judgments are made between pairs of objects, where one object belongs to a set A and the other to a set B (with A and B disjoint sets), but

Table 1 Mean judged perceptual similarity between 14 spectral colors (data obtained by Ekman [14])

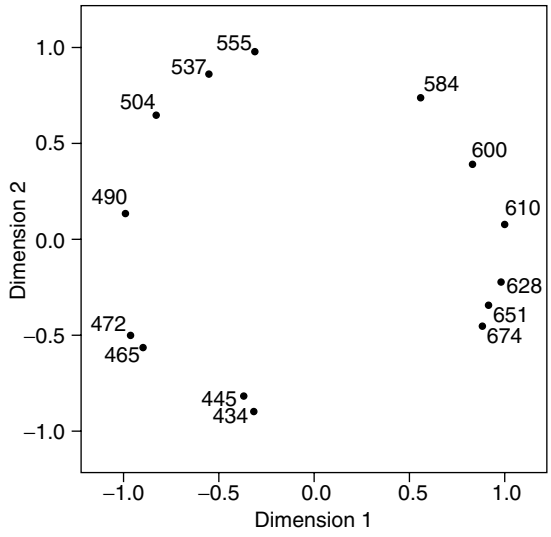

Figure 2 Two-dimensional representation of the Ekman [14] data

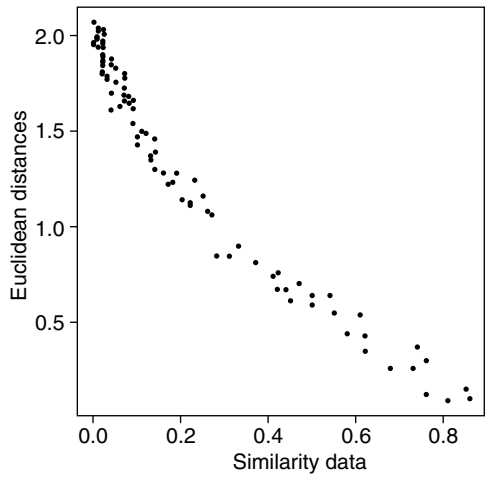

Figure 3 Plot of the similarities vs. the obtained two-dimensional Euclidean distances for the Ekman [14] data

no such judgments are made about pairs of objects both belonging to the same set. *A* and *B* may be sets of entities of basically the same kind, such as two different classes of diseases, or sets of very different types, such as a set of diseases, on the one hand, and a set of treatments on the other (where the "proximity" relation might be one of "effectiveness" of the treatment for the disease). One especially important class of two-way two-mode data to which this variant is often applied is a subjects (e.g. patients) by objects (e.g. medical practitioners) matrix with ratings or rankings of the preference for the objects by each of the subjects. This latter type of data – often called individual differences preferential choice data – can be viewed as a type of *dominance* data, measuring the relative dominance (tendency to be preferred to, or chosen over, other objects) of each of the objects, for each of the subjects. Coombs [9] has pointed out that such data can also be interpreted as *conditional* proximity data – conditional, since the ratings or rank orders of preference are comparable only *within* an individual subject (so only within the rows, of a subjects × object data matrix), but not *between* rows corresponding to different subjects. Coombs interprets preference (or other types of dominance) data as (conditional) proximities based on a very general model that assumes that a subject's preference for an object is inversely monotonically related to the distance of that object (in a subjective multidimensional space) from the subject's "ideal" (or most preferred) point. So the closer an object is to the ideal point, the more it is preferred. These are *conditional* proximities because one subject's ratings or rankings of preference (or other dominance relation) cannot be compared with those of a different subject since they are not measured on the same scale. This model is known as the *unfolding model* or *ideal point model*. Individual differences among subjects are represented in this general model by allowing for a different ideal point for each subject. Some specialized options are available in KYST-2A, entailing a different normalization or changes to the stress loss function (depending on the specific type of data being analyzed), for carrying out such an unfolding analysis. As emphasized by Carroll [4] and Kruskal et al. [19], it is important to use the *correct* options when analyzing such data, since the use of incorrect ones can lead to "degenerate" solutions that convey little or no information about the data, even though they may have a stress value indicating perfect or near-perfect fit.

It should be noted that many types of data, other than individual differences preference data, may be viewed as conditional proximities. For example, the disease × treatment matrix mentioned earlier would be of this same form if the treatments were, say, rank ordered for effectiveness separately for each disease. For reasons that will not be discussed here (but

see [4]) such analysis of two-way two-mode proximity data is often called *multidimensional unfolding*.

Three-Way Multidimensional Scaling

The extension of the basic two-way procedure that had the largest impact is the extension to three-way two-mode data. In three-way multidimensional scaling the input data consist not of a single square symmetric proximity matrix $\mathbf{\Delta}$, but of a series of matrices $\mathbf{\Delta}^{(1)}, \ldots, \mathbf{\Delta}^{(M)}$ containing dissimilarities about the same set of objects, but obtained from M different sources. The sources can be, for instance, different subjects, different occasions, etc. The INDSCAL model [6] – the most common three-way model – assumes that each source weights the dimensions of a common object space $\mathbf{x}_1, \ldots, \mathbf{x}_N$ idiosyncratically. The (nonnegative) weight that source i attaches to dimension r will be denoted w_{ir}. In the INDSCAL model, $\delta_{jk}^{(i)}$, the dissimilarity between objects j and k observed from source i, is represented by the weighted distance $d_{jk}^{(i)}$:

$$d_{jk}^{(i)} = \left[\sum_{r=1}^{R} w_{ir}(x_{jr} - x_{kr})^2\right]^{1/2}, \quad w_{ir} \geq 0,$$
$$= \left[\sum_{r=1}^{R} (y_{jr}^{(i)} - y_{kr}^{(i)})^2\right]^{1/2},$$

with

$$y_{jr}^{(i)} = (w_{ir})^{1/2} x_{jr}.$$

Thus the weighted distance $d_{jk}^{(i)}$ is equivalent to an ordinary Euclidean distance in a space $\mathbf{Y}^{(i)} = ((y_{jr}^{(i)}))$, where each dimension is rescaled by the square root of the corresponding source weight. The space defined by $\mathbf{X} = ((x_{jr}))$ is often called the *common space* or the *object space*, while $\mathbf{W} = ((w_{ir}))$ is referred to as the *source space*. $\mathbf{X}$ and $\mathbf{W}$ thus define two disjoint spaces, both having the same dimensionality R, one space (the common space) representing the objects and one space (the source space) representing the sources. The weight that source i applies to the rth dimension of the common space, w_{ir}, can be derived from the source space by simply projecting the point representing source i onto the rth coordinate axis. Finally, $\mathbf{Y}^{(i)}$, the common space rescaled for source i, is called the *private space* for source i (see, for example, Arabie et al. [2]).

Contrary to the distances obtained in two-way multidimensional scaling, the distances $d_{jk}^{(i)}$ are *not* invariant under orthogonal rotations of the object space (unless the ratio of the weights applied to a pair of dimensions is identical for all sources, in which case there exists an indeterminacy involving a generally nonorthogonal rotation in the plane defined by these two dimensions). The rotational uniqueness of the INDSCAL model often leads to representations that are easier to interpret. It is primarily this rotational uniqueness property that has made INDSCAL so popular. There are, however, some transformations of the parameters $\mathbf{X}$ and $\mathbf{W}$ that do not affect the weighted distances $d_{jk}^{(i)}$, namely permutations and reflections of the dimensions, a translation of the object space (i.e. replacing $\mathbf{x}_j$ by $\mathbf{x}_j + \mathbf{c}$ for $j = 1, \ldots, N$), and a joint transformation of the type

$$x_{jr} \rightarrow \alpha_r x_{jr}, \qquad w_{ir} \rightarrow \frac{w_{ir}}{\alpha_r^2},$$

with $\alpha_r \neq 0$ and $r = 1, \ldots, R$.

Several numerical procedures have been developed for fitting the INDSCAL model to metric or nonmetric three-way two-mode proximity data. The most widely used computer program for fitting the INDSCAL model to interval or ratio level proximity data is SINDSCAL [20], while probably the most common procedure to fitting INDSCAL to nonmetric (ordinal) data is the ALSCAL program [29]).

To illustrate the INDSCAL model, we present the results of an INDSCAL analysis originally carried out by Carroll & Chang [7] on some color perception data collected by Helm [15]. Helm [15] had 14 subjects (10 with normal color vision and four with a red–green color deficiency) judge the dissimilarity of ten colors that were approximately equally spaced on the color circle. Figure 4 displays the common space as well as the source space. The two dimensions of the common space can be interpreted as respectively a yellow–blue and a red–green dimension. As can be expected, the four color deficient subjects (labeled CD1–CD4 in the figure) clearly weight the yellow–blue dimension more heavily than the red–green dimension. Figure 5 presents the private spaces for two typical subjects, a subject with normal color vision (subject N7) and a color deficient subject (subject CD1). This figure illustrates how the private spaces are derived from the common space by idiosyncratically weighting the dimensions.

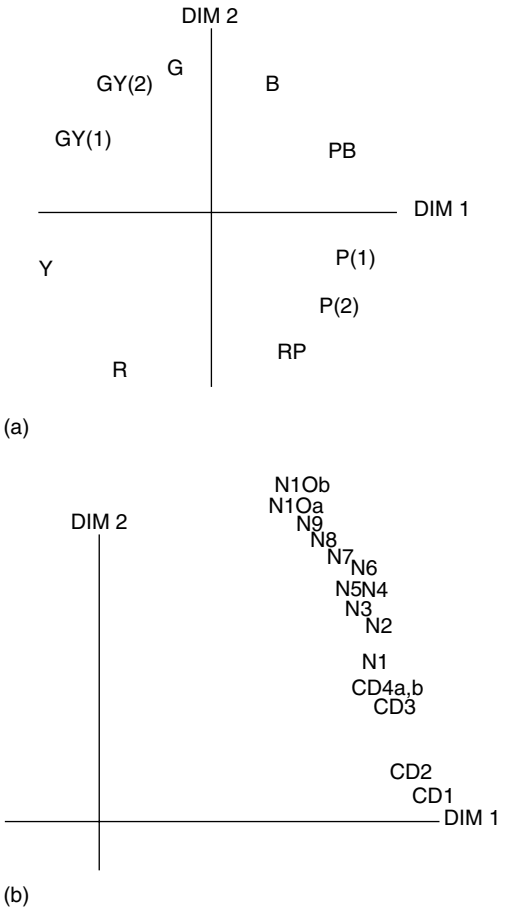

Figure 4 Two-dimensional common space (a) and source space (b) for the Helm [15] data. The objects are labeled as follows: R = red, Y = yellow, GY(1) = green yellow, GY(2) = green yellow with more green than GY(1), G = green, B = blue, PB = purple blue, P(1) = purple, P(2) = purple with more red than P(1), and RP = red purple. The subjects with normal color vision are labeled N1–N10, while the color-deficient subjects are labeled CD1–CD4

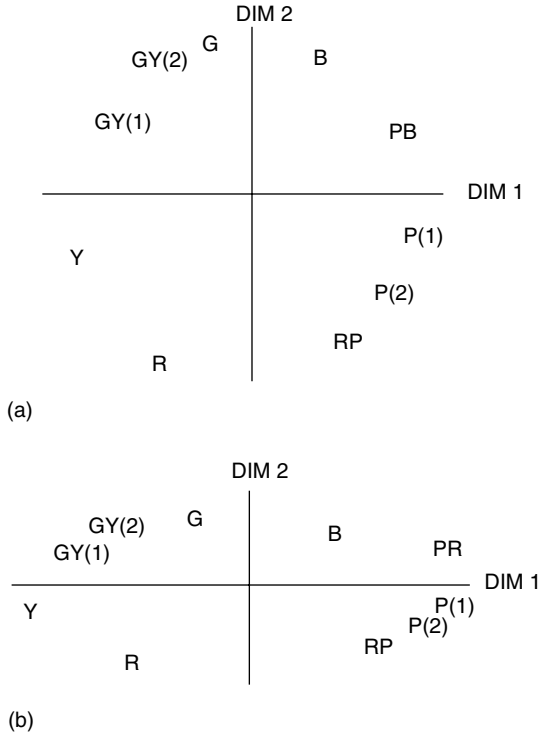

Figure 5 Private spaces for a subject with (a) normal color vision (N7) and (b) a color-deficient subject (CD1)

The basic three-way model has been extended in several ways, among others to allow for more elaborate idiosyncratic transformations of a common space (for a recent review, see [5]), to fit an "extended INDSCAL" model including "specific" as well as "common" dimensions, while allowing either metric or a special form of nonmetric fitting using a maximum likelihood criterion of fit [8], to handle individual differences in a more **parsimonious** way (for instance, through a **latent class** formulation [28]), or to accommodate other types of data such as three-way three-mode data or dominance data (for a review of three-way multidimensional scaling models for paired comparisons data, see [12]). Analysis of three-way three-mode proximity data (e.g. judgments of efficacy of each of several treatments for each of a number of diseases by different physicians), interpreted in terms of a generalization of the two-way two-mode ideal point model, is sometimes called *three-way unfolding* (see [11]).

Nonspatial Models

The multidimensional scaling methods discussed in the previous sections attempt a representation in a Euclidean or weighted Euclidean space. In addition, methods have been developed that arrive at a nonspatial representation using, instead of a Euclidean distance model, a tree or other kind of network model. The simplest and at the same time most often used nonspatial model is an ultrametric tree (*see* **Classification, Overview**). An ultrametric tree

is a rooted tree in which a nonnegative weight is attached to each node of the tree such that (i) the terminal nodes have zero weight, (ii) the largest weight is attached to the root, and (iii) the weights associated with the nodes on the path from any terminal node to the root constitute a strictly increasing sequence. In an ultrametric tree the distance between any two terminal nodes i and j, denoted d_{ij}, is defined as the maximum of the weights attached to the nodes on the path connecting i and j. These distances satisfy the so-called ultrametric inequality:

$$d_{ij} \leq \max(d_{ik}, d_{jk}),$$

for all i, j, k. Or, equivalently, the largest two of d_{ij}, d_{ik}, and d_{jk} are equal for all i, j, and k.

In an ultrametric tree representation of a set of two-way one-mode proximity data $\mathbf{\Delta}$, the objects indexed by the rows and columns of $\mathbf{\Delta}$ are represented by the terminal nodes of an ultrametric tree. The topology of the tree and the weights attached to the nodes of the tree are chosen so that the resulting ultrametric tree distances correspond as closely as possible to the observed dissimilarities. An ultrametric tree representation of $\mathbf{\Delta}$ defines a hierarchical clustering on the set of objects. Each internal node of the tree defines a partitioning of the objects represented by the terminal nodes of the subtree below that internal node. The weight attached to the internal node indicates the strength of this partitioning. The successive partitionings defined by the internal nodes are nested, thus yielding a hierarchical clustering.

This is illustrated in Figure 6, which presents the least squares ultrametric tree representation obtained by De Soete & Carroll [13] of some data collected by Rosenberg & Kim [23] concerning the similarity between kinship terms. Subjects were asked to group 15 kinship terms on the basis of their similarities in minimally two and maximally 15 categories. Dissimilarity data were derived by counting for each pair of kinship terms the number of subjects who put the two terms in different categories. Figure 6 displays the least squares ultrametric tree representation of the data obtained from the female subjects (listed in [22, Table 7.2]). As can be seen from the figure, the root node n_1 separates the direct kin (grandparents, grandchildren, parents, brother, sister) from the collaterals (uncle, aunt, cousin, nephew, niece). Within the cluster of the direct kin, node n_2 distinguishes the nuclear family from the kin that are two generations away from the ego. Within the last group,

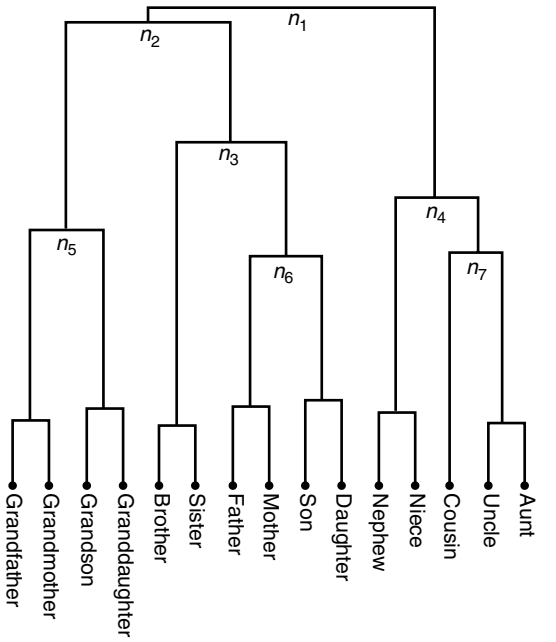

Figure 6 Ultrametric tree representation of the kinship data

node n_5 distinguishes those that are $+2$ generations (grandparents) from those that are -2 generations (grandchildren) away from the ego. Node n_3 separates the members of the nuclear family from the same generation (brother, sister) from those that are one generation apart. Within this last group, node n_6 distinguishes those that are $+1$ generation away from those that are -1 generation away from the ego. Among the collaterals, the same generation distinctions appear (nodes n_4 and n_7). At the lowest level, the kinship terms are distinguished on the basis of gender.

Besides ultrametric trees, other types of tree and network models have been used to represent proximity or dominance data. This includes nonhierarchical trees where the ultrametric is replaced by what is variously called an "additive", "path-length", or "four-point" metric (in such a tree a length or weight is associated with each branch or link and the distance between two objects is defined as the length of the unique path connecting the terminal nodes representing the two objects), as well as "multiple tree" models in which proximities are modeled via sums of distances associated with two or more distinct trees.

Also included are other network (or discrete) models such as general graph structures and overlapping or nonoverlapping clustering models. Furthermore, another class of representations of proximity data, seldom used to date, but having considerable potential for effective application, are "hybrid models" combining tree or other (discrete) network models with the (continuous) spatial dimensional models most typically associated with multidimensional scaling. Finally, tree models have been devised for analyzing various types of three-way data (for a comprehensive review, see [13]).

Concluding Comments

In this article, multidimensional scaling was introduced and its most common techniques have been described and illustrated. The reader wanting more detailed information is referred to the recent chapter by Carroll and Arabie ([5]) and to various chapters in Arabie et al. [3].

Multilevel Models

Biostatistical data often have a hierarchical structure. Typically these structures are naturally occurring ones: animal populations are characterized by individuals nested within parents, themselves often nested within groups or herds which may also be nested within spatial entities. In other cases the structure may result from research designs, as in multicenter clinical trials (*see* **Multicenter Trials**) where patients are nested within clinics. In yet other cases the data may not obviously seem to be nested, yet viewing them as such may yield new insights or more efficient analysis techniques. Examples are repeated measure designs, where measurements are "nested" within individual subjects (*see* **Longitudinal Data Analysis, Overview**), and multivariate response data, where measurements are "nested" within individuals.

In addition to nesting relationships among data units we may also have cross-classifications. For example, an individual cow may be nested within a herd of cattle, but also be the offspring of parent stock, where any parent may contribute to several herds: individual cows are thus cross-classified by parents as well as nested within their herds. A further complexity is also often present whereby individual units at one level of a data hierarchy may be nested within more than one higher-level unit. An example is spatial data, where each individual person can be classified by the geographical locality where they live, but will also be influenced in terms, say, of their health or behavior, by surrounding localities. In this case we regard them as belonging to a primary unit plus a number of secondary units.

In the following sections I develop a set of models for describing such data, increasing in complexity as they move from simple hierarchies with continuously distributed responses, to cross-classifications and multivariate data and to discrete responses. Various extensions and special cases will also be considered. The emphasis is on model specification rather than estimation, although there is a brief section on the latter.

The Basic Multilevel Model

For simplicity consider a simple data structure where an outcome is measured on patients in a number of centers, together with one or more treatments or covariates. We wish to model a relationship between the outcome and the **explanatory variables**, taking into account the possibility that this relationship may vary across centers. We shall refer to the centers as higher-level units and patients as lower-level units. In the present case we just have two levels with centers as level 2 units and patients as level 1 units. A simple such model can be written as follows:

$$\begin{aligned} y_{ij} &= \beta_0 + \beta_1 x_{ij} + u_{0j} + e_{ij}, \\ \text{var}(e_{ij}) &= \sigma^2_{e0}, \\ \text{var}(u_j) &= \sigma^2_{u0}, \end{aligned} \tag{1}$$

where y_{ij} is the response and x_{ij} the value of a single explanatory variable for the ith patient in the jth center. The slope coefficient β_1 is for the present assumed to be the same at all centers, while the random variable u_{0j} represents the departure of the jth clinic's intercept from the overall population intercept term β_0. The first two terms on the right-hand side of (1) constitute the fixed part of the model and the last two terms describe the random variation. We develop the model initially assuming that the random variables have a (multivariate) normal distribution, and discuss the nonnormal case later. This model could be viewed as a standard **analysis of covariance** if we treated each u_{0j} as a fixed parameter to be estimated. Such a model, however, often will be inappropriate, for the following reasons.

First, we may have a very large number of centers, leading to a very large number of separate parameters to estimate. Secondly, some of the clinics may have very few patients, so that their individual departures will be poorly estimated. Most importantly, we may be interested in treating the centers as a sample from a *population* of centers and wish to make general inferences about the likely behavior of other centers in this population rather than, or in addition to, providing separate estimates for each center in the sample. For all these reasons it will usually be more appropriate to regard u_{0j} as random and to write

$$u_{0j} \sim \text{N}(0, \sigma^2_{u0}), \qquad e_{0ij} \sim \text{N}(0, \sigma^2_{e0}).$$

We can also elaborate (1) by allowing the coefficient β_1 to vary across centers and rewrite the model in the more compact form

$$y_{ij} = \beta_{0ij} x_0 + \beta_{1j} x_{1ij},$$

$$\begin{aligned}
\beta_{0ij} &= \beta_0 + u_{0j} + e_{ij},\\
\beta_{1j} &= \beta_1 + u_{1j}, \qquad (2)\\
\mathbf{U} &= \{u_{0j}, u_{1j}\}, \qquad \mathrm{E}(\mathbf{U}) = \mathbf{0},\\
\mathrm{cov}(\mathbf{U}) &= \begin{pmatrix} \sigma^2_{u0} & \\ \sigma_{u01} & \sigma^2_{u1} \end{pmatrix}, \qquad \mathrm{var}(e_{ij}) = \sigma^2_e.
\end{aligned}$$

This model is often referred to as a "random coefficient model" by virtue of the fact that the coefficients β_{0ij} and β_{1j} in the first equation of (2) are random quantities (*see* **Random Effects**). It is possible, however, to have random coefficient models that are only single level (see below); we thus drop this term in order to emphasize the hierarchical data structure.

As more explanatory variables are introduced into the model we can choose to allow them random coefficients at the center level, thereby introducing further covariances as well as variances at level 2. This will lead to models with complex covariance structures. One of the aims of multilevel modeling is to explore such potential structures and also to attempt to explain them in terms of further variables. Having fitted such a model we can obtain posterior estimates for the individual "residuals" $(u_{0j}, u_{1j}, e_{0ij})$ at either level by estimating their expected values (or other functions of their distributions), given the data and model estimates. Thus, for example, we can estimate $\mathrm{E}(u_{0j}|Y, \beta, \theta)$, where

$$\boldsymbol{\beta}^{\mathrm{T}} = \{\beta_1, \beta_2\}, \qquad \boldsymbol{\theta} = \{\sigma^2_{u0}, \sigma_{u01}, \sigma^2_{u1}, \sigma^2_{e0}\}. \qquad (3)$$

The multilevel model is here described in non-Bayesian terms. For a full Bayesian specification of this model we would need to add prior distribution assumptions for the parameters in (3). The interested reader is referred, for example, to [4, 5] for details with examples.

In the next section we look at a general formulation and then some important special cases. A fully detailed treatment of the topics is not possible here and the reader is referred to [6] and [5] for details of methodology with examples and a discussion of computer software. A World Wide Web site is available which contains information about current developments, references, software, and so on, at `http://multilevel.ioe.ac.uk` (*see* **Internet**).

Cross-Classifications

Many data structures are not purely hierarchical, but mixtures of hierarchies and cross-classifications. For example, in a school health survey children may be assessed by raters, each school having just one rater. Thus we have a structure where children are grouped within cells defined by the cross-classification of raters by schools, and we wish to model the level-2 variation as a function of both the between-rater and between-school variation. If the design were changed, so that a separate team of raters visited each school and each child was measured by a single rater, then the cross-classification would be that of raters by children nested within schools. If, again, there was a single team of raters who visited every school, then the cross-classification would be of raters by children across the whole sample. In this case we have no separable hierarchy and we would wish to model the total response variation as a function of the between-child, between-school, and between-rater variation.

Rasbash & Goldstein [13] and Browne et al. [1] discuss various examples of this kind and set out the appropriate models together with procedures for efficient estimation. Corresponding to the first and second examples given above we can write the following models, using a more general notation for the fixed part of the model, where i indexes children, j_1 indexes schools, and j_2 indexes raters.

We write

$$y_{i(j_1j_2)} = X_{i(j_1j_2)}\beta + u_{j_1} + u_{j_2} + e_{i(j_1j_2)} \qquad (4)$$

for the first model with children nested within the level-2 cross-classification and with the following level-2 covariance structure

$$\begin{aligned}
\mathrm{cov}(y_{i(j_1j_2)}, y_{i'(j_1j'_2)}) &= \sigma^2_{u_1},\\
\mathrm{cov}(y_{i(j_1j_2)}, y_{i'(j'_1j_2)}) &= \sigma^2_{u_2}, \qquad (5)\\
\mathrm{var}(y_{i(j_1j_2)}) &= \mathrm{cov}(y_{i(j_1j_2)}, y_{i'(j_1j_2)})\\
&= \sigma^2_{u_1} + \sigma^2_{u_2}.
\end{aligned}$$

The second model is written as

$$y_{(i_1i_2)j} = X_{(i_1i_2)j}\beta + u_j + e_{i_1j} + e_{i_2j}. \qquad (6)$$

In both (4) and (6) we have assumed an **"additive" model** for the variance contributions, and the

adequacy of this can be tested against a model which includes an interaction term, e.g.

$$y_{(i_1 i_2)j} = X_{(i_1 i_2)j}\beta + u_j + e_{i_1 j} + e_{i_2 j} + e_{(i_1 i_2)j}. \quad (7)$$

In addition, we can have further random coefficients and levels of nesting or crossing.

Multiple Unit Membership

We have assumed so far that each lower-level unit, such as a school student or patient, belongs to just one higher-level unit of a particular kind. In many cases, however, such units may belong to more than one higher-level unit. For example, in a child growth study, children may change schools from one occasion to the next, and a particular case is that of spatial data where an individual is influenced by the geographical unit where she lives and also (with differing weights) by neighboring areas. We can write a simple two-level model of this kind as follows where, for simplicity, we suppose the maximum number of level-2 units to which a level-1 unit may belong is two:

$$\begin{aligned} y_{i(j_1 j_2)} &= X_{i(j_1 j_2)}\beta + w_{1ij_1}u_{j_1} \\ &\quad + w_{2ij_2}u_{j_2} + e_{i(j_1 j_2)}, \\ w_{1ij_1} + w_{2ij_2} &= 1, \\ \mathrm{var}(y_{i(j_1 j_2)}) &= (w_{1ij_1}^2 + w_{2ij_2}^2)\sigma_u^2 + \sigma_e^2, \quad (8) \\ \mathrm{cov}(y_{i(j_1 j_2)}, y_{i'(j_1 j_2)}) &= (w_{1ij_1}w_{1i'j_1} \\ &\quad + w_{2ij_2}w_{2i'j_2})\sigma_u^2, \\ \mathrm{cov}(y_{i(j_1 j_2)}, y_{i'(j_1' j_2)}) &= w_{2ij_2}w_{2i'j_2}\sigma_u^2. \end{aligned}$$

As before, we can further elaborate this model by allowing random coefficients, further hierarchical levels, and further crossing factors. For example, in the example of children changing schools we may cross-classify the schools by the neighborhoods where the children live with the possibility of multiple neighborhood membership in the above sense and across time. Browne et al. [1] discuss such models using MCMC estimation, with examples.

Repeated Measures Data and Multivariate Data

An interesting special case of a two-level structure is that of repeated measures models such as the following:

$$y_{ij} = \beta_{0j} + \beta_{1j}x_{ij} + e_{ij}, \quad (9)$$

where the response, say, is the weight of an animal related to a linear function of age, x, with the intercept and slope varying across animals (*see* **Random Coefficient Repeated Measures Model**).

Another important special case is that of multivariate data, where the response is a vector. Consider first a "single-level" multivariate linear model, with two responses, height and weight, measured on a sample of males and females. For the jth variable ($j = 0$ for height, $j = 1$ for weight) measured on the ith subject we have the following model equation:

$$\begin{aligned} y_{ij} &= \beta_{01}z_{1ij} + \beta_{02}z_{2ij} + \beta_{11}z_{1ij}x_j \\ &\quad + \beta_{12}z_{2ij}x_j + u_{1j} + u_{2j} \\ z_{1ij} &= \begin{cases} 1, & \text{if height,} \\ 0, & \text{if weight,} \end{cases} \\ z_{2ij} &= 1 - z_{1ij}, \\ x_j &= \begin{cases} 1, & \text{if female,} \\ 0, & \text{if male,} \end{cases} \quad (10) \\ \mathrm{var}(u_{1j}) &= \sigma_{u1}^2, \\ \mathrm{var}(u_{2j}) &= \sigma_{u2}^2, \\ \mathrm{cov}(u_{1j}, u_{2j}) &= \sigma_{u12}. \end{aligned}$$

A part of the data matrix for this structure might be as given in Table 1, so that at level 2 we have the variances and covariance of height and weight while there is no variation at level 1, and the fixed part of the model is defined using the relevant dummy variables associated with each response. Notice that in the data matrix the third individual has no weight measurement. By specifying the multivariate model as in (10) we can implicitly fit data where some responses are missing: we simply omit the relevant

Table 1 Example data for a repeated measures design

		Intercepts (z)		
Individual	Response	Height	Weight	Gender (x)
1 (female)	y_{11}	1	0	1
1	y_{12}	0	1	1
2 (male)	y_{21}	1	0	0
2	y_{22}	0	1	0
3 (female)	y_{31}	1	0	1

level-1 unit corresponding to the missing observation. The model can be generalized readily in the ways already discussed by allowing random coefficients, cross-classifications, etc. and further levels of nesting. An example of a multivariate model analysis will be given later.

Modeling Variances

In addition to specifying the average response as modeled in the fixed part of the model, we have discussed modeling the covariance structure at level 2 (and higher levels) by introducing random coefficients. We may also introduce random coefficients which vary across level-1 units and this provides a flexible general procedure for variance modeling. Consider the following model:

$$\begin{aligned} y_{ij} &= \beta_0 + \beta_1 x_{ij} + (u_j + e_{0ij} + e_{1ij} x_{ij}), \\ \mathrm{var}(e_{0ij}) &= \sigma^2_{e0}, \qquad \mathrm{var}(e_{1ij}) = 0, \\ \mathrm{cov}(e_{0ij}, e_{1ij}) &= \sigma_{e01}, \end{aligned} \tag{11}$$

so that the level-1 contribution to the overall variance is the linear function

$$\sigma^2_{e0} + 2\sigma_{e01} x_{ij}.$$

Note that we have constrained one of the "variances" at level 1 to be zero in order to give a linear rather than a quadratic variance function. In fact, the parameters $\sigma^2_{e0}, \sigma^2_{e1}$, and σ_{e01} are not to be interpreted as separate variances and covariances, but simply as parameters defining the variance structure. The variable, x, may be any kind of explanatory variable. For example, if it were a dummy variable for gender, then the model would allow a separate level-1 variance for males and females. In this way it is possible to model the variance, as well as the mean, as functions of explanatory variables. Examples are given in Goldstein [5, Chapter 3].

In some circumstances, linear models for a variance, such as implied by (11), are inappropriate because they may predict an overall level-1 variance which is negative for part of the range. In this case we can consider alternative models where the level-1 variance has the form, for example,

$$\mathrm{var}(e_{ij}) = \exp(\beta^*_0 - \beta^*_1 x_{ij}), \tag{12}$$

which is nonnegative and where we require estimates of the β^*_0 and β^*_1. Goldstein [5] shows how maximum likelihood estimates for such models can be obtained.

Nonlinear and Generalized Linear Models

We can write a two-level **generalized linear model** in the form

$$\pi_{ij} = f(X_{ij}\beta_j), \tag{13}$$

where π_{ij} is the expected value of the response for the ijth level-1 unit and f is a nonlinear function of the "linear predictor" $X_{ij}\beta_j$, where we can have random coefficients at level 2. We need to specify a distribution for the *observed* response $y_{ij}|\pi_{ij}$: where the response is a proportion this is typically taken to be binomial, and where the response is a count taken to be Poisson (*see* **Poisson Regression**). Eq. (13) is a special case of a **nonlinear regression** model which is completed by specifying a suitable link function $f(\cdot)$. Thus, for binary response data we might have a simple model:

$$\begin{aligned} \mathrm{logit}(\pi_{ij}) &= \beta_0 + \beta_1 x_{1ij} + u_{0j}, \\ y_{ij} &\sim \mathrm{bin}(1, \pi_{ij}), \end{aligned} \tag{14}$$

with a corresponding model for counts using a log link function. The random part of (14) can be elaborated with further random coefficients, cross-classifications, etc.

These models can be extended to **multinomial** (ordered or unordered) responses [5, Chapter 7].

Survival Models

Survival time data (*see* **Survival Analysis, Overview**) will often have a multilevel structure: for example we may measure illness durations within centers or waiting times in hospitals with variation across centers and hospitals. We may also have repeated duration episodes *within individuals*, for example repeated periods of disease and remission, where different kinds of episode also may exist. We briefly mention here three common types of model and their multilevel specification. Further details are given by Goldstein [5].

The first type is the extension of the semiparametric **Cox regression model**, often referred to as a **frailty** model. When defining risk sets for this model we can choose to order our failure times across the

whole data set or *within* level-2 units, say hospitals. In the former case the marginal relationship between the hazard and the covariates is not generally proportional, and in the latter case it is proportional within level-2 units.

At each failure time l we define a response variate for each member of the risk set

$$y_{ijk(l)} = \begin{cases} 1, & \text{if } i \text{ is the observed failure,} \\ 0, & \text{if not,} \end{cases}$$

where i indexes the members of the risk set, and j and k level-1 and level-2 units, respectively. The response is treated as a Poisson variate with mean function for a simple **variance components** model given by

$$\pi_{jk(l)} = \exp(\alpha_l + X_{jk}\beta + u_k), \tag{15}$$

where there is a "blocking factor" α_l for each failure time. The second type of model is a "log duration" or **accelerated failure time** model which can be written as

$$l_{ij} = \ln(t_{ij}) = X_{ij}\beta_j + e_{ij}, \tag{16}$$

for the failure times t_{ij}. This is in the standard form for a two-level random coefficient model. A complication is that we may have (level-1) censored observations, and this implies that we need a careful specification of the level-1 distribution to incorporate **censoring** information in the estimation. Some common choices are the normal, **extreme value**, and log-**gamma** distributions (*see* **Parametric Models in Survival Analysis**).

The third type of model, which leads to a particularly simple form, is the discrete time **proportional hazards model**. For a two-level model we write

$$\log[-\log(1 - \pi_{jk(l)})] = X_{jk}\beta_k + \alpha_{(l)}, \tag{17}$$

where, as before, the $\alpha_{(l)}$ are constants to be estimated, one for each time interval. This leads to a model where the response is a binomial variate, being the number of deaths divided by the number in the risk set at the start of the interval. As with the first type, any censored observations in an interval are excluded from the risk set.

Estimation

The basic model assumes multivariate normality and standard (as well as restricted) maximum likelihood methods are available using Fisher scoring, iterative generalized least squares (*see* **Generalized Linear Model**) or the **EM algorithm**. Bayesian estimation is available using **Markov chain Monte Carlo** (MCMC) methods such as Gibbs sampling [4], which is also available for generalized linear models with the appropriate distributional assumptions. An alternative in this case is to use **quasi-likelihood** estimation together with appropriate bias correction procedures [7], or the related **generalized estimating equation** (GEE) procedure, [10]. For inference, interval estimates are obtained directly from MCMC and via large sample deviance statistics or bootstrapping for likelihood estimation. Maximum likelihood procedures are also available [5].

An Example

To illustrate the flexibility of multilevel models we fit a bivariate two-level model where one response is normal and the other is binary.

The data are part of the "Health and Lifestyle Survey", a sample of 9003 individuals within households nested within 396 electoral wards in Britain and carried out in 1984/85. For present purposes data on smoking habits are analyzed using information about gender and age. Further details are given in [3]. The information about smoking behavior consists of whether or not the respondent smoked cigarettes and if they did, how many per day. Sixty-five percent did not smoke and the mean number smoked for those who did is 15.2 with a standard deviation of 9.3. The distribution of the number smoked is positively skewed which suggests a normalizing transformation. The use of this, however, does not substantially alter the results and the analysis is presented in terms of the actual number smoked.

One aim of the analysis is to ascertain how the probability of smoking and the number smoked each relate to the explanatory variables. The other is to estimate the between-area variation, and in particular to see whether areas where the proportion of nonsmokers is high are also the areas where smokers tend to smoke greater numbers of cigarettes. We write the model in two parts.

For the binary response probability

$$\begin{aligned} \text{logit}\,(\pi_{ij}) &= (x_1\beta_1)_{ij} + u_{1j} \\ y_{ij} &\sim \text{binomial}\,(1, \pi_{ij}) \end{aligned} \tag{18}$$

For the continuous response

$$y_{ij} = (x_1\beta_1)_{ij} + u_{2j} + e_{ij}$$

with

$$e_{ij} \sim N(O, \sigma_e^2), \begin{pmatrix} u_{1j} \\ u_{2j} \end{pmatrix} \sim N(O, \Omega_u),$$

$$\Omega_u = \begin{pmatrix} \sigma_{u1}^2 & \\ \sigma_{u12} & \sigma_{u2}^2 \end{pmatrix}$$

where u_{1k} and u_{2k}, respectively, refer to the ward-level contributions t o the discrete and continuous parts of the model. This model combines a model for smokers where the response is the number of cigarettes smoked and a model with a binary response which is whether or not the subject smoked. Thus, each smoker will have two responses, a "1" for the binary response variable and the number smoked for the continuous response. Each nonsmoker will have just one response, a "0" indicating that they are a nonsmoker.

This model can be fitted with the MLwiN software package [14]. The bivariate structure is modeled as level 1, where there is no random variation, so that the full model is three-level. The results are presented in Table 2.

At the electoral ward level there is a high correlation (0.81) between the proportion of smokers and the number smoked. Men are more likely to be smokers and to smoke more and there is an age effect for the number smoked, with a maximum among 50 year olds, and declining thereafter. The relationship is weaker for the probability of smoking. A model that allowed gender to have a random coefficient at level 2 was fitted, but a large sample test for the extra variance and two covariance terms gave a χ^2 value of 6.8 on three degrees of freedom ($P = 0.08$). Attempting to fit the age coefficient as random at level 2 produces a zero estimated variance. We can also test the assumption of binomial variation for the smoking response by fitting extra binomial variation. This is estimated as 0.98, where a value of 1.0 corresponds to binomial variation with a standard error of 0.015, providing little evidence of extra binomial variation (*see* **Overdispersion**).

Table 2 Bivariate model for smoking/nonsmoking and number smoked. Gender is coded 1 for male and 0 for female: age is measured about the mean of 45.9 years. The level-1 variance is constrained to 1.0 which corresponds to binomial variation

	Response	
Parameter	Binary (se)	Continuous (se)
Fixed		
Intercept	−0.54	15.7
Gender	0.14 (0.05)	2.82 (0.32)
Age	−0.03 (0.03)	1.22 (0.21)
$(\text{Age})^2$	0.0011 (0.0007)	−0.02 (0.005)
$(\text{Age})^3$	−0.000012 (0.000005)	0.00009 (0.00003)
Random		
Level 2:		
Intercept variance	0.17 (0.03)	1.45 (0.81)
covariance	0.40 (0.11)	
Level 1:		
Intercept		79.2 (2.1)

Further Topics

Finally, we mention briefly some further topics, most of which are currently the subject of methodological research.

The standard **meta-analysis** model can be viewed as a special case of a general multilevel model. For the jth study in such an analysis we can define the standardized effect d_j where this is a dimensionless quantity. It may, for example, be a correlation coefficient, a standardized regression coefficient, group difference, or weighted group difference. We can write a simple model as follows:

$$d_j = \delta + v_j + u_j, \qquad \text{var}(u_j) = \sigma_j^2,$$
$$\text{var}(v_j) = \sigma_v^2, \tag{19}$$

where in the usual case σ_j^2 is assumed known and is treated as an offset in the random part of the model, but may also in some circumstances be estimated. The parameter δ is the population parameter of interest and σ_v^2 is the between-study (level-2) variance of the standardized effect. We can add random coefficients and covariates representing study factors to (19) in an attempt to explain between-study differences, which is a further aim of meta-analysis studies. Goldstein et al. [8] give a detailed discussion.

As in single-level models, **diagnostics** are important. We can estimate standardized **residuals** at any level of a data hierarchy and study these together with looking for influential units. A detailed discussion is given in [9].

Further important issues are those concerned with missing units and missing data generally, especially where the missingness is informative, and research is being conducted in this area (*see* **Nonignorable Dropout in Longitudinal Studies**). Another topic which is actively being researched is that of multilevel structural equation modeling [11, 12, 6].

Software

Some of the major software packages, for example SAS, STATA, and GENSTAT, can handle many, although not all, of the models described in this article (*see* **Software, Biostatistical**). Several general-purpose software packages have been written, e.g. HLM [2] and MLwiN [14]. A review of these packages has been carried out by [15].

Multilocus (Gene × Gene Interaction)

The concept of multilocus (inter-locus) or **gene** × gene **interaction** is often used without being precisely defined. In essence, gene × gene interaction refers to departure from "independence" of the effects of different genetic loci in the way that they combine to cause disease. However, this concept has been confused by the fact that what is meant by independence and the precise definitions of interaction used by biologists, epidemiologists, statisticians and human and quantitative geneticists have often differed, even when using identical terminology.

Interactions between loci are sometimes referred to as *epistatic* interactions or *epistasis*. This term was first used by Bateson [1] to describe a masking effect in which a variant at one locus prevents the variant at another locus from manifesting its effect. This concept of gene × gene interaction is often employed by a biologist or biochemist when investigating biologic interaction between proteins. In quantitative genetics, however, the term *epistatic* has classically been used to refer to a deviation from additivity in the effects of alleles at different loci with respect to prediction of a quantitative phenotype, in particular by Fisher [7]. Note that this definition is NOT equivalent to the Bateson [1] definition. Epistasis in the Fisher [7] sense is closer to the usual concept of statistical interaction: departure from a (specific) linear model describing the relationship between predictive factors (here assumed to be alleles at different genetic loci) and an outcome or phenotype of interest. Note that with this definition, the choice of scale becomes important since factors that are additive with respect to an outcome measured on one scale may exhibit interaction when a different, transformed scale is used [10, 11].

Mathematically, the quantitative genetic concept of gene × gene interaction may be represented for two loci by the linear model

$$y = \beta_0 + \beta_{a_1} x_1 + \beta_{d_1} z_1 + \beta_{a_2} x_2 + \beta_{d_2} z_2 + \beta_{i_{aa}} x_1 x_2 + \beta_{i_{ad}} x_1 z_2 + \beta_{i_{da}} z_1 x_2 + \beta_{i_{dd}} z_1 z_2, \quad (1)$$

where y is a quantitative phenotype, and x_i and z_i are dummy variables related to the underlying **genotype** at locus i. For example, for a diallelic locus with alleles denoted 1 and 2, we might set $x_i = 1$ and $z_i = -0.5$ for a 1/1 homozygote, $x_i = 0$ and $z_i = 0.5$ for a heterozygote and $x_i = -1$ and $z_i = -0.5$ for a 2/2 homozygote. The coefficients β_0, β_{a_1}, β_{d_1}, β_{a_2} and β_{d_2} represent genetic parameters to be estimated corresponding to the mean effect and additive and dominance effects at loci 1 and 2; $\beta_{i_{aa}}$, $\beta_{i_{ad}}$, $\beta_{i_{da}}$ and $\beta_{i_{dd}}$ correspond to the interaction effects. The lack of a gene × gene interaction in this scenario corresponds to all interaction coefficients being equal to 0.

In **human genetics**, the phenotype of interest is often qualitative and usually dichotomous, denoting presence or absence of disease. Models for the joint action of, and interaction between, loci have typically focused on the **penetrance**, the probability of developing disease given genotype. Let p_{ij} be the probability of developing disease given that there is genotype i at locus 1 and j at locus 2. Three common models have been considered [14]: an additive model in which p_{ij} may be written as $p_{ij} = \alpha_i + \beta_j$, where α_i and β_j are parameters representing the contributions of the different genotypes at locus 1 and 2, respectively; a heterogeneity model in which p_{ij} may be written as $p_{ij} = \alpha_i + \beta_j - \alpha_i \beta_j$; and a multiplicative model in which p_{ij} may be written as $p_{ij} = \alpha_i \beta_j$. The additive and heterogeneity models are usually assumed to represent nonepistatic models and to correspond to a situation in which the biologic pathways involved in disease are at some level separate or independent. The multiplicative model is usually considered to be an epistatic model in which the loci and pathways involved are not independent. Note, however, that a multiplicative model can be considered to be an additive model when transformed to the logarithmic scale. In a statistical sense, therefore, the multiplicative model signifies independent additive effects of the loci on a logarithmic scale.

Two other models are commonly used in human genetics. A model popular with epidemiologists is an additive model for the logit or the logarithm of the odds, in which $\ln[p_{ij}/(1 - p_{ij})]$ may be written as $\ln[p_{ij}/(1 - p_{ij})] = \alpha_i + \beta_j$. The lack of an interaction term γ_{ij} (i.e. the fact that when the model is expressed as $\ln[p_{ij}/(1 - p_{ij})] = \alpha_i + \beta_j + \gamma_{ij}$, the γ_{ij} parameter equals 0) signifies independence of the locus effects on the logit scale. Another popular model from classical genetics is a threshold model, in which the loci are assumed to contribute to an underlying, unobserved, continuous trait in an additive fashion and development of disease occurs if

this trait exceeds a certain threshold [8, 13, 18, 19]. Note that both of these models, although additive and therefore expressible without interaction effects as defined on their original scales, correspond to models with interactive effects (epistasis) when transformed to the penetrance scale.

Although in human genetics the penetrance or some function of the penetrance is often used as a surrogate for a quantitative phenotype of interest, treatment of gene × gene interactions is generally easiest when the phenotype has a genuine quantitative scale of measurement. Two popular methods for analysis of quantitative traits in families using pedigree data are the *variance component method* and the *Haseman–Elston method* (*see* **Linkage Analysis, Model-free**). The variance component method models the phenotypic covariance between relatives in terms of the underlying identity-by-descent (ibd) sharing probabilities at one or more genetic loci (*see* **Identity Coefficients**). This contrasts with the Haseman–Elston method [12] and subsequent extensions [6, 9, 20] in which some function (such as the squared difference or product) of the phenotype values for a pair of relatives is modeled in a **regression** framework in terms of the underlying ibd-sharing probabilities. Both of these methods generalize quite easily to account for epistatic interactions between loci. For the Haseman–Elston method in particular, all that is required is to include products of ibd-sharing probabilities at different loci as predictors in the regression (6). Although epistatic components of variance are often ignored in initial studies of linkage to quantitative traits, in some cases these components can be relatively large, and detecting these inter-locus interactions may in fact prove to be a more powerful strategy for the detection of genetic effects than concentrating solely on the independent effects of the individual loci [17].

The relationship between the differing definitions of gene × gene interaction is quite complex, and hence the degree to which statistical modeling can elucidate underlying biologic mechanisms may be limited. The problem is one that has been recognized for some time in epidemiology, namely, that any given data pattern and statistical model can usually be obtained from a number of different underlying mechanisms or models for disease development [15, 16]. This makes biologic inference from the results of a statistical interaction test very difficult [4]. Only if a prior biologic model can be postulated in detail is it likely that statistical modeling will allow insight into the underlying biologic mechanisms. Although direct biologic inference may be limited, identification of the most parsimonious statistical model for the joint effects of several loci, including interactions, can be useful for prediction of phenotype and targeting of interventions. Moreover, the increase in power that in some cases is obtained by allowing for different modes of interaction between potential disease loci can lead to identification of disease loci that might otherwise remain undetected [2, 3, 5].

HEATHER J. CORDELL

Multinomial Distribution

The multinomial distribution is a generalization of the binomial distribution to more than two possible discrete outcomes. The roll of a die, for example, can give rise to one of six possible results. More generally, consider an experiment or survey in which there are k (≥ 2) distinct outcomes. Every realization of the experiment results in one of these k possible outcomes. The probability that each experiment results in the jth outcome ($j = 1, \ldots, k$) is denoted by p_j. The probabilities $p_1, \ldots, p_k$ are nonnegative and sum to one. In the example of the roll of a fair die, p_1 through p_6 are all equal to 1/6.

The multinomial distribution describes the joint distribution of a collection of frequencies of the k outcomes arising from n independent replications of this experiment. After n (≥ 1) independent experiments, let N_j denote the random variable counting the number of experiments that result in the jth outcome. The probability of jointly witnessing the collection of N_1 occurrences of the first categorical outcome, N_2 occurrences of the second, and so on through N_k occurrences of the kth outcome is

$$\Pr(N_1, \ldots, N_k) = \frac{n!}{N_1!N_2!\cdots N_k!} p_1^{N_1} p_2^{N_2} \cdots p_k^{N_k}. \tag{1}$$

The collection of counts $N_1, \ldots, N_k$ in (1) are said to follow a multinomial distribution. Each N_j can take on the value $0, 1, \ldots, n$ subject to the constraint that the sum of all counts $N_1 + \cdots + N_k$ is always equal to n, the number of experiments. The parameter n is referred to as the sample size or index of the distribution. When k is equal to two, (1) reduces to the probability mass function of the **binomial distribution**. There are

$$\binom{n+k-1}{k-1}$$

distinct outcomes of $N_1, \ldots, N_k$ in the multinomial distribution given by (1).

As an example of multinomial data, Robertson [5] describes the F_2 progeny of a cross between hybrid barley plants. There are four possible phenotypes (visible outcomes) from this cross: green non-two-row; green two-row; chlorina non-two-row; and chlorina two-row. According to Mendelian inheritance, these should occur in the ratio of 9 : 3 : 3 : 1 (*see* **Mendel's Laws**). The $k = 4$ probabilities $p_1, \ldots, p_4$ are then 9/16, 3/16, 3/16, and 1/16. In a total of $n = 1898$ barley plants, the counts of the four phenotypes $N_1, \ldots, N_4$ reported by Robertson [5] are 1178, 291, 273, and 156, respectively.

All marginal and conditional multinomial distributions are also multinomial. Any count N_j taken alone has a binomial marginal distribution with parameters n and p_j (*see* **Marginal Probability**). More generally, any subset of $N_1, \ldots, N_k$ also follows the multinomial distribution. The conditional distribution of the counts $N_2, \ldots, N_k$ given the fixed value of N_1 is a $k-1$ category multinomial distribution with sample size $n - N_1$ and probabilities $p_2/(1-p_1), \ldots, p_k/(1-p_1)$ (*see* **Conditional Probability**). In other words, all subsets of $N_1, \ldots, N_k$ follow a multinomial distribution. Fixing the values of a subset of $N_1, \ldots, N_k$ results in a multinomial distribution for the remaining counts.

The moments of the multinomial distribution are as follows. The mean of N_j is

$$\mathrm{E}(N_j) = np_j$$

and its variance is

$$\mathrm{var}(N_j) = np_j(1-p_j).$$

These are the same as the corresponding moments of the binomial distribution. The covariance of N_i and $N_j (i \neq j)$,

$$\mathrm{cov}(N_i, N_j) = -np_i p_j,$$

and their **correlation**

$$\mathrm{corr}(N_i, N_j) = -\left[\frac{p_i p_j}{(1-p_i)(1-p_j)}\right]^{1/2},$$

are both negative, because the frequencies $N_1, \ldots, N_k$ are constrained to sum to n. Intuitively, these negative correlations appear because increasing the count in any one of the k categories will reduce the counts in all other categories.

There is a close connection between the multinomial distribution and the **Poisson distribution**. Let $X_1, \ldots, X_k$ denote independent Poisson distributed counts with respective means $\lambda_1, \ldots, \lambda_k$. Given the value of the sum $\sum X_i$, the conditional distribution of $X_1, \ldots, X_k$ is multinomial with index $n = \sum X_i$ and probabilities $\lambda_1/\sum \lambda_i, \ldots, \lambda_k/\sum \lambda_i$.

This close connection between the Poisson and multinomial distributions is often confusing, and led to a debate between Haldane [3] and Cochran [1] over which distribution was more appropriate in determining the proper degrees of freedom for the **chi-square test**. In the barley example cited above, should the observed frequencies $N_1, \ldots, N_4$ be treated as four independent Poisson counts or as a single multinomial sample? The answer is that these counts most probably came about as independent Poisson observations. However, any inference such as estimating the p_js will always be done conditional on having observed $n = 1898$ plants. In other words, any statistical inference to be drawn from these data will be the same whether the figure of 1898 barley plants was determined before the experiment was conducted or if, in fact, this number was determined by some random process, as is more likely the case.

There are two important approximations to the multinomial distribution that are useful when the index n is large. The first of these is the joint multivariate normal distribution of the standardized counts

$$\frac{N_j - np_j}{[np_j(1-p_j)]^{1/2}}$$

obtained when $p_1, \ldots, p_k$ are held fixed and n is allowed to grow.

The second approximation points out another connection between the multinomial and Poisson distributions. This comes about in the same manner as the Poisson approximation to the binomial distribution. This approximation is obtained when n is large and a subset of the probabilities $p_1, \ldots, p_j$ $(j < k)$ become small at such a rate that the multinomial means np_i $(i = 1, \ldots, j)$ have finite, nonzero limits. In this case the frequencies $N_1, \ldots, N_j$ behave approximately as independent Poisson counts.

Estimation

The most common situation encountered in practice is when the sample size n is known and $p_1, \ldots, p_k$ must be estimated from the observed counts $N_1, \ldots, N_k$. In certain settings, however, not all of the $N_1, \ldots, N_k$ are observable and n is unknown. A problem in which both n and $p_1, \ldots, p_k$ are to be estimated often appears as **capture–recapture** surveys, in which the goal is to determine the size of a closed population. These surveys arise in wildlife management or epidemiologic studies in which there is a need to estimate the number of animals in a region or the number of diseased, but not yet diagnosed, individuals in the population. In the example of the barley data, there may be a fifth category, the genetic composition of which is always fatal to the plant resulting in an unobservable phenotype.

The usual problem assumes that n is known and estimates of $p_1, \ldots, p_k$ are needed. If nothing is known about the structure of $p_1, \ldots, p_k$, then the empirical frequencies

$$\hat{p}_i = \frac{N_i}{n}$$

are commonly used to estimate $p_1, \ldots, p_k$. The $\hat{p}_1, \ldots, \hat{p}_k$ are the maximum likelihood estimates of $p_1, \ldots, p_k$ because they maximize the probability given in (1). The $\hat{p}_1, \ldots, \hat{p}_k$ are unbiased (*see* **Unbiasedness**) for $p_1, \ldots, p_k$ and have the smallest variances of all unbiased estimators of $p_1, \ldots, p_k$.

There are many settings in which something is known about the mathematical structure of $p_1, \ldots, p_k$. This is usually expressed as a **loglinear model**. Loglinear models are multiplicative models and are so named because they are linear after taking the logarithm. These models are most useful in describing interactions of the various factors in multidimensional count data.

In the barley data, an example of a loglinear model is the model of independent linkage between color (green or chlorina) and the two-row phenotype. This model is suggested after writing the data as the two-by-two table given in Table 1. In the model of independence, $p_1, \ldots, p_4$ are estimated such that their odds ratio

$$\psi = \frac{p_1 p_4}{p_3 p_4}$$

is equal to one. The loglinear model $\psi = 1$ describes a multiplicative relationship between $p_1, \ldots, p_4$. This relationship and the corresponding estimates of

Table 1 The barley data arranged as a two-by-two table

		Two-row phenotype	
		No	Yes
Color	Green	1178	291
	Chlorina	273	156

$p_1, \ldots, p_4$ are familiar as the model of independence of rows and columns in the two-by-two table.

Bayesian methods for estimating the $p_1, \ldots, p_k$ parameters are subjective and incorporate prior knowledge. Bayesian methods require that we quantify any uncertainty the investigator may have about this knowledge before the data are observed. A general reference for Bayesian methods in the context of discrete data analysis is [4]. For the barley data, Robertson might have expected the Mendelian ratio of 9 : 3 : 3 : 1, but would have accepted another model if the data provided a large amount of evidence otherwise. A reasonable estimate for him to consider is a weighted average of the (prior) Mendelian rates p_i^{M} and the empirical frequencies $\hat{p}_i$ obtained from the data. That is, a Bayesian estimate p_i^{B} of p_i takes the form

$$p_i^{\mathrm{B}} = \left(\frac{c}{c+n}\right) p_i^{\mathrm{M}} + \left(\frac{n}{c+n}\right) \hat{p}_i \qquad (2)$$

where p_i^{M} is the Mendelian frequency, known prior to conducting the experiment. For all values of $c > 0$ and sample sizes $n > 0$, the Bayesian estimate p_i^{B} always lies between the prior (Mendelian) value p_i^{M} and the empirical fraction $\hat{p}_i$. A useful feature of the Bayes estimate given in (2) is the ability to produce nonzero estimates of p_i when the corresponding observed frequency N_i is zero.

The parameter $c > 0$ in (2) quantifies the level of certainty in the Mendelian model for the current problem. A large value of c indicates a lot of faith in this model, for which only a small amount of weight should be given to the data in the form of the empirical frequencies $\hat{p}_1, \ldots, \hat{p}_k$. On the other hand, either a large degree of uncertainty (small c) or a lot of data (large n) results in a heavy reliance on the data through $\hat{p}_1, \ldots, \hat{p}_k$ and relatively little to the prior model. A philosophical difference that many have with Bayesian methods is the subjective and seemingly arbitrary way that a value for c is assigned in (2). Different investigators will have different degrees of certainty and arrive at different Bayesian estimates of $p_1, \ldots, p_k$.

Four different estimates of the barley frequencies are summarized in Table 2. Mendel's theory of inheritance suggests that these four probabilities $p_1^{\mathrm{M}}, \ldots, p_4^{\mathrm{M}}$ should be in the ratio of 9 : 3 : 3 : 1. The maximum likelihood estimates $\hat{p}_1, \ldots, \hat{p}_4$ are the empirical frequencies N_i/n. The Bayesian estimates p_i^{B} given in (2) are a weighted average of the empirical ($\hat{p}_i$) and Mendelian (p_i^{M}) rates. The value of $c = 1000$ is used here as an illustration. The fitted loglinear model specifies that color and two-row phenotypes are not genetically linked and appear as independent characteristics.

Testing Fit

There has been a large amount of attention paid to testing the fit of the multinomial model (*see* **Goodness of Fit**). Relatively less is known about examining the adequacy of the multinomial distribution to explain the data. Instead, virtually all of this work has been directed at testing whether the $p_1, \ldots, p_k$ have been correctly estimated and appropriately explain the data. Best known in this area is the Pearson χ^2 statistic,

$$\chi^2 = \sum_{i=1}^{k} \frac{(N_i - np_i)^2}{np_i},$$

which dates back to the year 1900. Large values of χ^2 relative to its reference distribution indicate a significant lack-of-fit in the $p_1, \ldots, p_k$ parameters.

In more recent years, the χ^2 statistic has also been used to measure **overdispersion** of the multinomial model. Overdispersion refers to the situation in which the variances of the counts $N_1, \ldots, N_k$ are greater

Table 2 Four different estimates of the probabilities for the barley data

Phenotype		Observed count,	Mendelian probability,	Maximum likelihood,	Fitted loglinear	Bayesian estimate,
Color	Two-row	n_i	p_i^{M}	$\hat{p}_i$	model	p_i^{B}
Green	No	1178	0.5625	0.6207	0.5917	0.6006
Green	Yes	291	0.1875	0.1533	0.1823	0.1651
Chlorina	No	273	0.1875	0.1438	0.1728	0.1589
Chlorina	Yes	156	0.0625	0.0822	0.0532	0.0754

than predicted by the multinomial model. It is impossible to distinguish between the case of overdispersion and misspecification of the $p_1, \ldots, p_k$ parameters unless multiple samples are available.

When n is large and the $p_1, \ldots, p_k$ are replaced in χ^2 by appropriate estimates, then χ^2 behaves as χ^2 with $k - t - 1$ degrees of freedom, where t is the number of parameters estimated in $p_1, \ldots, p_k$. Under these conditions, it has long been known that there are many other statistics the behavior of which is closely tied to the χ^2 statistic. Among these test statistics are the generalized likelihood ratio

$$G^2 = 2 \sum_i N_i \log \frac{N_i}{np_i},$$

(*see* **Likelihood Ratio Tests**), the Freeman–Tukey χ^2

$$Z^2 = 4 \sum_i [N_i^{1/2} - (np_i)^{1/2}]^2,$$

and the Neyman χ^2

$$N^2 = \sum_i \frac{(N_i - np_i)^2}{N_i}.$$

All of these statistics, others not mentioned, and many not yet fully documented are contained in a family of statistics first described by Cressie & Read [2]. The power divergence statistics are of the form

$$2nI^\lambda = \frac{2}{\lambda(\lambda + 1)} \sum N_i \left[\left(\frac{N_i}{np_i} \right)^\lambda - 1 \right]$$

and are indexed by the parameter λ. Different values of λ result in many well known χ^2 equivalent statistics as special cases or as limits. For examples, the value of $\lambda = 1$ yields the χ^2 statistic; $\lambda = -1/2$ gives the Z^2 statistic; and as λ gets close to zero, $2nI^\lambda$ behaves as G^2. If n is very large and all p_i are replaced by their estimates using the correct model, then $2nI^\lambda$ should be close in value to χ^2 regardless of the value of λ.

A final method for examining goodness of fit is the use of exact tests. These computer-intensive methods involve a complete enumeration of all possible distinct outcomes of the multinomial likelihood function given in (1). This results in an exact test of significance in the sense that significance levels are determined exactly and no asymptotic approximations are needed. As an example of an exact test of significance, let us examine the fit of the barley data to the rates predicted by Mendel's model. The probability of observing the barley data assuming the Mendelian probabilities is 2.177×10^{-17}. This probability is not the significance level for testing Mendel's model. The exact significance level is obtained by enumerating all possible outcomes of the $n = 1898$ plants into the four distinct phenotypes. There are

$$\binom{n + k - 1}{k - 1} = \binom{1901}{3} = 1.143 \times 10^9$$

of these outcomes. The exact probability of an outcome with a likelihood of 2.177×10^{-17} or less is equal to 5.883×10^{-12}. This latter figure is the exact significance level and indicates a poor fit to the model of Mendelian inheritance for this data.

Multiple Comparisons

Multiplicity considerations arise in experimental research when it is desired to make inferences about several aspects of a problem simultaneously, while controlling some aspect of the frequency properties of the statistical procedure (*see* **Simultaneous Inference**). For example, observational units may generate multivariate responses and it may be of interest to examine **covariate** effects on each response (*see* **Multiplicity in Clinical Trials**) Alternatively, interest may lie in carrying out multiple analyses on the basis of subgroups of patients defined a priori. Repeated significance tests, often carried out to ensure early detection of effective treatments in **clinical trials**, also raise multiplicity issues (*see* **Data and Safety Monitoring**). In all of these cases, several tests of significance (*see* **Hypothesis Testing**) are typically carried out. If carried out naively, then the probability of making one or more false positive conclusion is typically higher than expected. This is the so-called multiplicity problem of statistical inference. Here we focus on issues pertaining to the classical multiple comparisons problem arising in the comparison of several populations with respect to a single **response variable**. For other examples of multiplicity, *see* **Simultaneous Inference**.

Consider an experiment with the objective of comparing the means of I populations. Suppose a sample of n_i subjects is available for study from the ith population. Let $n_\cdot = \sum_{i=1}^{I} n_i$, and let Y_{ij} denote the response variable for the jth subject in the ith sample. We further suppose the responses are generated according to the linear model $Y_{ij} = \mu_i + E_{ij}$, where μ_i is the mean response for the ith population, $E_{ij} \sim \mathrm{N}(0, \sigma^2)$ are independently distributed, and σ^2 is a common variance parameter reflecting the extent of the sampling variability, $j = 1, \ldots, n_i$, $i = 1, \ldots, I$. Here and throughout, we make the distinction between random variables and their realized values by using upper and lower case letters, respectively. Thus, if y_{ij} denotes a realization of Y_{ij}, then $\overline{y}_i = \sum_{j=1}^{n_i} y_{ij}/n_i$ denotes the mean of the ith sample, and s^2 the pooled estimate of the common variance (*see* **Analysis of Variance**).

Comparisons of the population means $\mu_1, \ldots, \mu_I$ may be based on tests of hypotheses or **interval estimation**. We consider issues pertaining to hypothesis tests, and point out that directly analogous issues arise in the context of interval estimation; specific comments on this follow. In this article we emphasize applications arising in **clinical trials** and related biopharmaceutical experiments in which the I samples consist of individuals randomized to one of I groups undergoing different treatment regimens. In what follows we use related terminology and will typically make reference to treatment comparisons.

There is a variety of contexts in which one might be interested in making inferences about differences in the population means, with the specific features of the problem leading to particular analysis strategies. The structure of the problem described above is that of a one-way analysis of variance (ANOVA), suggesting that if the **null hypothesis** were the equality of all I means, a corresponding statistic following the ***F* distribution** on $(I - 1, n_\cdot - I)$ **degrees of freedom** would be a natural choice. In many contexts, however, such an approach provides inadequate insight, since rejection of the null hypothesis does not furnish information regarding the nature of the treatment differences. In general, multiple comparison procedures are directed at facilitating more detailed analyses to gain such insight, while adjusting for the multiplicity by controlling certain frequency properties of the testing procedure.

Note, however, that there are many contexts in which multiple treatment comparisons can be made without the need to adopt procedures that adjust for multiplicity. Cox [7] has pointed out that probabilities regarding the simultaneous correctness of many statements may not always be of direct relevance. Dunnett [13] points out that in situations where multiple experimental treatments are used in the same study to maximize efficiency in the use of resources rather than for the purpose of making joint inferences, it is reasonable to make treatment to reference group (control) comparisons as if the data had been collected from different studies. Examples of such scenarios include Finney [19] and Redman & Dunnett [42]. This approach is consistent with the views put forth by Cook & Farewell [6] who propose that in more general contexts when multiplicities arise, such multiplicity adjustments are often adopted unnecessarily. Cook & Farewell suggest that provided a limited number of well-defined questions are posed at the design stage, and these questions relate to different features or different treatments under study, then the case can be made for avoiding multiple

testing procedures. As can be seen by the vagueness of the above statements, it remains difficult to characterize clearly situations in which multiplicity adjustments are required and when they are not, and so it is natural that some debate in this area will continue.

In what follows we discuss and contrast strategies that are generally appropriate if there is genuine concern about the need for making adjustments for multiplicity.

Overview and Terminology

Background

For the well-known case in which $I = 2$, suppose the null and **alternative hypotheses** are $H_0 : \mu_1 = \mu_2$ and $H_a : \mu_1 \neq \mu_2$, respectively. Hypothesis testing procedures are typically formulated by specification of a *discrepancy measure*, a many-to-one function of the random response variables which is a stochastic measure of the "distance" between the observed responses and what would be anticipated under the null hypothesis. A discrepancy measure must have a known distribution for specified values of the parameters of interest. Upon collecting the data, one may compute a realized value for the discrepancy measure, which is typically referred to as a *test statistic*. The ***P* value** of the test is the probability, under the null hypothesis, of observing a realized value of the discrepancy measure as extreme or more extreme than that observed. Thus, small P values indicate that the data are inconsistent with the null hypothesis. The *significance level*, denoted by α, is a specified threshold value such that if the observed P-value is $\leq \alpha$, H_0 is rejected in favor of H_a (*see* **Level of a Test**). Corresponding to a given threshold significance level is a *critical value*, c, such that test statistics larger than or equal to c lead to rejection of the null hypothesis.

A type I error is said to be committed if the null hypothesis is rejected when it is in fact true (*see* **Hypothesis Testing**). The *type I error rate*, a decision-theoretic notion introduced by Neyman & Pearson [40], corresponds to the rate with which this error would be made in a hypothetically infinite population of repetitions of the trial. A test procedure is said to control the type I error rate at α if the probability of a type I error is less than or equal to α.

The type I error rate may be interpreted probabilistically and hence one may write Pr(reject $H_0|H_0$ is true) $\leq \alpha$ (the equality will typically hold when the discrepancy measure has a continuous distribution and the null hypothesis specifies a single point in the parameter space). For the case in which $I > 2$, it might be tempting to carry out multiple hypothesis tests in an effort to learn more about the nature of any potential treatment differences. The principal difficulty with this approach is that multiple hypothesis tests at a common significance level α will result in a probability of committing *one or more* type I errors that may be substantially larger than α. Structure and rigor are added to the multiple testing procedures to ensure that the type I error rate properties are known, or at least controlled.

Formulation and Terminology of Multiple Comparison Procedures

As a first step in formalizing multiple comparison procedures, Hochberg & Tamhane [26] define a *family* as a "collection of inferences for which it is meaningful to take into account some combined measure of error". Tamhane [50] further states that there should be a "contextual relatedness" for inferences grouped into a common family. Tests pertaining to this family are directed at investigating this aspect of the treatments. Note that there may be more than one family of hypotheses in a given experiment, with each family addressing a different research question. Furthermore, since these questions may be interrelated, the families might not be disjoint (i.e. they may share one or more component hypotheses). For the purposes of this discussion it is sufficient to consider a single family, and we do so for the remainder of this article.

For concreteness we consider a family as consisting of a collection of null and alternative hypotheses $\{(H_{k0}, H_{ka}), k = 1, 2, \ldots, K\}$, where K denotes the total number of hypotheses in the family. The *familywise error rate* (FWE) is defined as the probability of making one or more false positive conclusions over all hypothesis tests in a particular family. Control of the FWE is appropriate if one cannot tolerate any type I error in the family no matter how many of the K null hypotheses are true. A procedure is said to have *strong control* of the FWE if the probability of making at least one type I error over all hypothesis tests of the family is at most α, regardless of how many component null hypotheses may be true; *weak control* of the FWE at α is achieved

if this type I error rate is guaranteed to be at most α only when all null hypotheses are true. Typically multiple comparison procedures control the FWE at α, thus satisfying Pr(at least one null hypothesis is falsely rejected) $\leq \alpha$. Procedures of this sort clearly also control the type I error rates of any subset of the family, including the component tests, while guaranteeing that the FWE does not exceed a specified level.

Another term often used is the *per-comparison error rate* (PCE). Here we restrict consideration to true null hypotheses in the family, and define the PCE as the expected number of false positive conclusions divided by the number of true null hypotheses. This error rate therefore corresponds to the usual type I error rate for individual hypotheses that are tested without any adjustment for multiplicity.

Suppose that m (which is unknown) hypotheses are true and $K - m$ are false. Denote by T the number of true hypotheses that are rejected (false positives) and by F the number of false hypotheses that are rejected (true positives). T and F are random variables. Benjamini & Hochberg [3] defined the false discovery rate (FDR) as the expected value of $T/(T + F)$. By comparison, PCE is the expected value of T/m and FWE $= \Pr(T > 0)$. They proposed that a multiple testing procedure control FDR $\leq \alpha$, instead of FWE $\leq \alpha$. They showed that FDR is equivalent to FWE when $m = K$ (all hypotheses are true). Thus, it provides weak control of FWE. When several hypotheses are false, it is less conservative than controlling the FWE and may provide a useful concept for situations where strict control of the FWE is not needed.

Multiple comparison procedures may be classified as single-step or stepwise procedures. In a *single-step procedure*, multiple tests are carried out using the same critical value for each component test. Procedures that involve carrying out multiple tests in sequence, using critical values which may be unequal, are called *stepwise* multiple testing procedures. For such stepwise procedures it is convenient to arrange the test statistics in ascending order according to their significance levels, and to arrange the component hypotheses conformably. Single-step procedures are attractive in some respects since they are simpler to apply and they have direct connections to **simultaneous confidence intervals**. They generally have lower **power** than stepwise procedures, however, and so are not desirable for the purposes of hypothesis testing.

Stepwise procedures for multiple comparisons may be further classified as step-down or step-up procedures. In *step-down* procedures, formal tests are carried out in a stepwise fashion starting with the most extreme outcome (i.e. the most significant test statistic). Testing proceeds to the hypothesis corresponding to the next most extreme outcome only upon rejection of the current hypothesis. If the current null hypothesis is not rejected, then all subsequent null hypotheses (i.e. those corresponding to the test statistics with the less extreme outcomes) are not rejected. Thus, if the first test statistic does not exceed its corresponding critical value, then the testing terminates with failure to reject any null hypothesis. Critical values are derived to ensure control of the FWE. In *step-up* testing procedures, the testing begins with the statistic corresponding to the least significant outcome. Testing continues and statistics are examined of progressively more extreme outcomes until a null hypothesis is rejected. At this point, all null hypotheses corresponding to the more extreme test statistics are also rejected. As in the step-down procedures, appropriate critical values are determined to ensure control of the FWE. Examples of single-step, step-down, and step-up multiple testing procedures are provided in subsequent sections.

In many cases an overall null hypothesis may be satisfied if and only if several less restrictive hypotheses are satisfied. Let $\mathrm{H}_0 = \bigcap_{k=1}^{K} \mathrm{H}_{k0}$ be the overall null hypothesis that all H_{k0} are true, and $\mathrm{H}_\mathrm{a} = \bigcup_{k=1}^{K} \mathrm{H}_{k\mathrm{a}}$ the corresponding alternative hypothesis that at least one H_{k0} is false. Testing H_0 against H_a is known as a **union–intersection** problem, due to Roy [44]. Denoting the test statistic for H_k by t_k for $k = 1, \ldots, K$, the test statistic for H_0 is $\max(t_1, \ldots, t_K)$. The critical value c is determined so that the type I error of the test is α, which requires that c be chosen to satisfy the following K-variate probability requirement:

$$\Pr(T_1 < c, \ldots, T_K < c | \mathrm{H}_0) = 1 - \alpha.$$

The solution, $c = c_K$ say, will be larger than the α-point of the univariate statistic, the difference representing an adjustment for the multiplicity.

For the *intersection–union* problem, where $\mathrm{H}_0 = \bigcup_{k=1}^{K} \mathrm{H}_{k0}$ and $\mathrm{H}_\mathrm{a} = \bigcap_{k=1}^{K} \mathrm{H}_{k\mathrm{a}}$, the test statistic is $\min(t_1, \ldots, t_K)$. To determine the value of the critical

constant in this case, Berger [4] demonstrated that the α-point of the univariate statistic is the correct value to use so that, in effect, no multiplicity adjustment is needed.

If $\{H_{k0}\}_{k=1}^{K}$ denotes a family of null hypotheses, then the *closure* of this family is formed by considering all intersections $H_S = \bigcap_{k \in S} H_{k0}$, where $S \subseteq \{1, 2, \ldots, K\}$. A closed testing procedure operates by rejecting any H_S if and only if every H_R is rejected by an α-level test for $R \supseteq S$. Marcus et al. [37] show that this strategy controls the FWE.

Historical Remarks

Suppose the null hypothesis consists of common means ($H_0 : \mu_1 = \mu_2 = \cdots = \mu_I$) and the alternative is that at least one mean is different. Upon application of standard ANOVA methods and rejection of the null hypothesis, it is natural to want to examine the nature of the apparent treatment differences. Fisher [20] was among the first to propose a formal multiple comparison procedure with a view to investigating potential treatment differences following a standard one-way analysis of variance. Fisher's *protected least significant difference* procedure operates as follows. If the F test from the one-way analysis of variance is carried out with a type I error rate α, and if it fails to lead to rejection of the null hypothesis of common means, the procedure terminates. If $H_0 : \mu_1 = \mu_2 = \cdots = \mu_k$ is rejected, then all pairwise tests are carried out with a PCE of α for each. This procedure can be shown to have only weak control of the FWE.

An alternative, suggested by Fisher, is to proceed directly to the K specific treatment comparisons of interest and carry out these tests with a PCE error rate α/K. This is referred to as a **Bonferroni** adjustment to the per-comparison error rates that maintains strong control of the FWE at α. It is well known to be conservative, particularly for highly **correlated** test statistics [41]. The Bonferroni procedure is an example of a single-step multiple test procedure since each test is carried out with the same critical value, regardless of the outcomes of any of the other tests.

Scheffé [46] developed an approach for simultaneous inference which follows naturally from the one-way analysis of variance. In particular, if one considers all **contrasts** of the form $\sum_{i=1}^{I} \ell_i \mu_i$, where $\sum_{i=1}^{I} \ell_i = 0$, Scheffé's multiple comparison procedure generates a set of tests (confidence intervals) that have a FWE (simultaneous coverage probability) less than or equal to $\alpha (\geq 1 - \alpha)$. Note that with the appropriate choice of coefficients these contrasts may correspond to pairwise comparisons. Finally, we note that if the F test leads to rejection of the null hypothesis of common means, then there exists a vector of coefficients $\ell = (\ell_1, \ldots, \ell_I)'$ such that a test of $H_0 : \sum_{i=1}^{I} \ell_i \mu_i = 0$ is rejected using Scheffé's procedure.

Several alternative strategies for multiple testing were proposed on the basis of **Studentized range** statistics. If $n_i = n, i = 1, \ldots, I$, then the Studentized range distribution is the probability distribution for the **range** $(\max\{\overline{Y}_i\} - \min\{\overline{Y}_i\})$ of the I independent sample means all from a standard normal distribution, divided by the pooled estimate of the standard error of a sample mean (i.e. the square root of a **chi-square distributed** random variable scaled by a factor $[I(n-1)]^{-1}$). This studentized range distribution is indexed by $[I, I(n-1)]$ and we let $q^{\alpha}_{I, I(n-1)}$ denote the corresponding upper $100\alpha\%$ point. The percentage points of this Studentized range distribution are provided in Harter [22] and many texts, and may be used to carry out tests or construct simultaneous confidence intervals for differences in means. Tukey [52] indicated that one could carry out $I(I-1)/2$ pairwise tests by comparing $z_{ii'} = n^{1/2}(\overline{y}_{i\cdot} - \overline{y}_{i'\cdot})/s$ to the critical value $q^{\alpha}_{I, I(n-1)}$; that is, if $|z_{ii'}| > q^{\alpha}_{I, I(n-1)}$, then the means μ_i and $\mu_{i'}$ can be inferred to be different with FWE controlled at α, $i \neq i' = 1, \ldots, I$.

So-called multiple range tests have also been developed by Newman [39], Keuls [34], and Duncan [9, 10]; the former two authors independently proposed the same testing procedure, which is often referred to as the Newman–Keuls test. Paraphrasing Miller [38], multiple range tests tend to declare two means in a set of I means significantly different provided the range of each and every subset containing the two means is significant according to an α_g level studentized range test, where g is the number of means in the subset at hand. The Neuman–Keuls test and Duncan's test differ in the way in which α_g is determined. For the Neuman–Keuls test, $\alpha_g = \alpha$ for $g = 2, 3, \ldots, I$, whereas $\alpha_g = 1 - (1-\alpha)^{g-1}$ in Duncan's test. Miller [38] provides a good illustration of the application of these two multiple range tests and argues that, while Duncan's test leads to larger α_g for larger group sizes (and hence greater power for detecting treatment effects), this is at the

expense of increasing the rate of false positive conclusions arising from multiple tests. Miller therefore favors the Neuman–Keuls approach over Duncan's. However, it is important to note that, in their original form, neither Duncan's nor the Newman–Keuls procedure controls the FWE; various modifications of these procedures have been proposed but are beyond the scope of this review (see [50] for details).

Generalizations to facilitate applications to the unbalanced one-way lay-out have been proposed by several authors [10, 11, 35, 52]. Dunnett [12] conducted a detailed simulation study designed to investigate the empirical type I error rates of various procedures for this context. He found that the preferred method for pairwise comparisons is the Tukey–Kramer procedure, which compares the statistic $(\overline{y}_{i\cdot} - \overline{y}_{i'\cdot})/[s(1/n_{i\cdot} + 1/n_{i'\cdot})^{1/2}]$, with $q^{\alpha}_{I,I(n-1)}/\sqrt{2}$. This was found to be slightly conservative, but less so than other procedures developed for this same context [21, 24, 49]. A proof of the conservativeness of the Tukey–Kramer method for the one-way model was obtained by Hayter [23].

Generalizations to the studentized augmented range distributions may be utilized if it is desired to test not only for the equality of all means, but whether all means share a specific value. Hence, any pair of means for which the simultaneous confidence intervals does not contain the null value of zero, say, may be declared to be significantly different. With a simultaneous coverage probability of $1 - \alpha$, the FWE of this test is controlled at α.

More Recent Developments in Multiple Comparisons

Single-Step Procedures Using P Values

The Bonferroni procedure which rejects any H_{k0} whose P value is $\leq \alpha/K$ is perhaps the most widely known single-step testing procedure. It is attractive in its generality, but improvements have been made to generate procedures that are less conservative. Šidák's inequality leads to the less conservative critical value corresponding to $1 - (1 - \alpha)^{1/K}$ instead of α/K [47]. The gain in power from this approach may be quite minimal, however, for cases when $K \leq 10$.

Simes [48] presents a multiple testing procedure applicable when $H_0 = \bigcap_{k=1}^{K} H_{k0}$ and $H_a = \bigcup_{k=1}^{K} H_{ka}$. Let $P_{(1)} \geq P_{(2)} \geq \cdots \geq P_{(K)}$ be P values arising from the K component tests ordered from largest to smallest. Then H_0 is rejected if $P_{(k)} \leq (K - k + 1)\alpha/K$ for some k. This test has higher power than the Bonferroni procedure for testing H_0. The FWE is shown to be controlled at α by arguments pertaining to **order statistics** of independent **uniform** (0, 1) random variables and is valid under the assumption that the component discrepancy measures are independent [48]. Correlations among the discrepancy measures can lead to serious inflation of the FWE [28]. This is an example of a union–intersection test procedure.

A number of more computationally intensive approaches have also been proposed. Brown & Fears [5] focused on binomial data and unadjusted P values arising from unconditional or conditional analyses. A permutation distribution (with fixed marginal frequencies) was then used to compute the adjusted P value corresponding to the probability (based on the permutation distribution) of realizing a P value smaller than that observed (*see* **Randomization Tests**). Westfall [53] proposed instead that one resample with replacement from the observed data set and determine whether the minimum P value of the new data set is, or is not, less than or equal to that observed in the sample. The frequency with which it is less is the adjusted P value for the comparison of interest. An advantage of this approach, suggested by Westfall & Young [54], is that it effectively addresses the correlation of the test statistics, particularly for multivariate outcomes, or when the comparisons of interest are all against a single control arm.

Stepwise Procedures Using P Values

Holm [27] presents a step-down multiple testing procedure, which he refers to as a sequentially rejective Bonferroni test, based on the ordered P values (*see* **Multiple Endpoints, *P* Level Procedures**). Again, let $P_{(1)} \geq P_{(2)} \geq \cdots \geq P_{(K)}$ be the ordered P values. Denote by $H_0^{(k)}$ the null hypothesis corresponding to $p_{(k)}$ for $1 \leq k \leq K$. The procedure compares the ordered P values with the sequence $\alpha, \alpha/2, \ldots, \alpha/K$ starting with $P_{(K)}$, then $P_{(K-1)}$, etc., continuing as long as $P_{(k)} \leq \alpha/k$, in which case we reject $H_0^{(k)}$ and go to the next ordered P value down; the first time we find $P_{(k)} > \alpha/k$, we stop testing and accept (do not reject) the remaining hypotheses.

Holm [27] points out that since the thresholds used to assess the strength of evidence against the null hypotheses are larger for all but the minimum P value, $P_{(K)}$, this approach has a higher probability of rejecting false null hypotheses than the standard Bonferroni procedure. This approach is attractive in that, as with the standard Bonferroni procedure, it is widely applicable.

Step-up procedures have also been proposed as improvements to the standard Bonferroni approach. Under Hochberg's [25] step-up procedure, all K P values are ordered as before, and testing begins by comparing the largest P value, which is $P_{(1)}$, with α, then $P_{(2)}$ with $\alpha/2$, and so on, continuing as long as the corresponding hypothesis is not rejected. The first time a rejection occurs, testing stops and all remaining hypotheses are rejected as well. In other words, one does not reject until $P_{(k)} \leq \alpha/k$, at which point $H_0^{(k)}, \ldots, H_0^{(K)}$ are rejected, $k = 1, \ldots, K$. Note that this procedure employs the same critical values as Holm's step-down procedure and any hypothesis rejected by Holm's procedure is also rejected by Hochberg's procedure; hence the latter is at least as powerful.

In Hommel's [29, 30] step-up procedure, one searches for the largest $m (1 \leq m \leq K)$ such that

$$P_{(k)} > \frac{(m-k+1)\alpha}{m}, \quad \text{for } k = 1, \ldots, m.$$

If such an m exists, then any hypothesis that has a P value $\leq \alpha/m$ is rejected. If such an m does not exist, then all hypotheses are rejected. Hommel's procedure coincides with Hochberg's for its first two steps, but after that it may reject additional hypotheses to those rejected by Hochberg's procedure.

Both Hochberg's and Hommel's procedures were developed by applying the closure principle to the procedure of Simes [48]. Hommel's procedure has slightly greater power, but is more complicated to apply. Another procedure that has slightly greater power but is also more complicated to apply, was given by Rom [43].

Stepwise Procedures Using Normal Theory

In multitreatment trials, the individual hypotheses $H_k, k = 1, \ldots, K$, are usually formulated in terms of parameters θ_k which are contrasts in the population means. Estimates $\hat{\theta}_k$ of these are determined from the data. Under the linear model assumptions stated at the beginning of this article, it follows that the $\hat{\theta}_k$ are normally distributed with $E(\hat{\theta}_k) = \theta_k$, $\text{var}(\hat{\theta}_k) = \tau_k^2\sigma^2$, and $\text{corr}(\hat{\theta}_i, \hat{\theta}_j) = \rho_{ij}$, where the τ_k^2 and ρ_{ij} are known constants which depend upon the design (e.g. on the sample sizes of the treatment groups). To test the hypothesis H_k that θ_k has a specified value 0 (say), a test statistic $t_k = \hat{\theta}_k/(\tau_k^2 s^2)^{1/2}$, where s^2 is an estimate of σ^2, is used. Under the normality and homogeneous variance assumptions, the t_k are **Student *t* statistics** and the joint distribution of the corresponding random variables is **multivariate *t***. This provides the underlying distribution theory for testing the hypotheses.

In stepwise testing the test statistics are ordered according to their P values as previously. Denote them by $t_{(1)}, t_{(2)}, \ldots, t_{(K)}$, where $t_{(1)}$ is the least significant and $t_{(K)}$ the most significant test statistic. These are compared in sequence with a set of critical constants $c_1 < \cdots < c_K$, determined so that the FWE is $\leq \alpha$.

In step-down testing, we start with $t_{(K)}$, then go to $t_{(K-1)}$, and so on. We continue to the next test in the sequence whenever we find $t_{(k)} \geq c_k$ and reject the corresponding hypothesis, stopping the first time $t_{(k)} < c_k$ and accepting (not rejecting) any remaining hypotheses.

In step-up testing we start with $t_{(1)}$, then go to $t_{(2)}$, and so on. We continue to the next test in the sequence whenever we find $t_{(k)} < c_k$ and accept (do not reject) the corresponding hypothesis, stopping the first time $t_{(k)} \geq c_k$ and rejecting any remaining hypotheses.

We illustrate the determination of the critical constants for the above step-down and step-up testing procedures for the case where one of the I treatment groups, say the Ith group, is to be compared with each of the other groups. Then the contrasts of interest are $\theta_k = \mu_k - \mu_I$, for $k = 1, \ldots, I-1$. Suppose, for simplicity, that each group has the same sample size, n, except for the Ith group which has sample size n_0. Then let $Y_{ij}(y_{ij})$ denote the random (realized) response for the jth subject and $\overline{y}_i$ the sample mean in group $i, i = 1, \ldots, I$; s^2 denotes the pooled estimator of the common variance based on $\nu = (I-1)(n-1) + n_0 - 1$ degrees of freedom (df).

Denote the random variables corresponding to the ordered t statistics $t_{(1)}, \ldots, t_{(K)}$ by $T_1, \ldots, T_K$, respectively. Then the critical constants for the step-down case with two-sided alternative hypotheses are

obtained by solving the following equations:

$$\Pr(-c_k < T_1 < c_k, \ldots, -c_k < T_k < c_k) = 1 - \alpha,$$
$$k = 1, \ldots, K = I - 1.$$

$T_1, \ldots, T_k$ have a k-variate central t distribution with ν degrees of freedom and common $\rho = n/(n + n_0)$ under the null hypothesis $H_0 = \bigcap_{i=1}^{k} H_0^{(i)}$. Note that since the critical value, c_K, is the same as the one derived for the single-step procedure, the step-down method may be thought of as a natural extension of the single-step procedure.

Tables of the critical values are readily available for the case in which the sample sizes for all but the reference group are the same ($n_i = n, i = 1, \ldots, I - 1$), and hence the discrepancy measures are equally correlated (see [2, 26]). In the case of unequal group sizes, good approximations can be obtained to the critical values by using the average correlation and interpolating from published tables. Alternatively, however, with a known correlation matrix, the critical values may be found by direct multivariate, or recursive, **numerical integration** [14].

For the step-up case, the values of the constants $c_1, c_2 \ldots, c_k$ are determined by solving

$$\Pr(-c_1 < T_{(1)} < c_1, \ldots, -c_k < T_{(k)} < c_k) = 1 - \alpha,$$
$$k = 1, 2, \ldots, K,$$

where $T_{(1)}, \ldots, T_{(k)}$ are the ordered values of the random variables $T_1, T_2, \ldots, T_k$ associated with the first k t statistics in order of significance. Note that the solutions here must be obtained recursively, starting with $k = 1$, then $k = 2$, and so on, since in order to solve for any c_k it is necessary to know the values of $c_1, \ldots, c_{k-1}$. Also, for both step-down and step-up testing, the value of c_1 is the α point of univariate Student's t. For $k > 1$, the constant c_k for step-up testing is slightly larger than the corresponding c_k for step-down testing. The first step of the step-up testing procedure corresponds to the Laska & Meisner [36] MIN test, which tests the intersection–union problem $H_0 = \bigcup_{k=1}^{K} H_0^{(k)}$ vs. $H_a = \bigcap_{k=1}^{K} H_a^{(k)}$; hence, the step-up procedure may be thought of as a natural extension of this test.

There are limited tables of the step-up constants given in Dunnett & Tamhane [15, 16] for the case of equal correlations; the case of unequal correlations is considered in Dunnett & Tamhane [17]. The step-down testing procedure is the normal theory analog of Holm's P value procedure, and the step-up testing procedure is the normal theory analog of Hochberg's P value procedure. The advantage of the normal theory procedures is that they utilize the correlation structure of the parameter estimates and have higher power when the normality and homogeneous variance assumptions hold. However, the P value procedures do not depend on such assumptions and can be used when they do not hold.

Comparisons with the Best Treatment

Now consider the case in which there is no specific reference group of interest and let $\mu_{(1)} \leq \cdots \leq \mu_{(I)}$ denote the I ordered population means, where we assume that larger values of μ_i correspond to preferred treatments. Since the means themselves are unknown, so too is the appropriate ordering given above. Nevertheless, one can conduct inference on the quantities $\mu_{(I)} - \mu_i$, the difference in the mean response for the ith treatment group from that of the unknown "best" treatment. Hsu [31] derives a method of constructing simultaneous joint one-sided upper confidence intervals for the $\mu_{(I)} - \mu_i$, $i = 1, \ldots, I$, and Hsu [32] extends these methods for two-sided intervals. For simplicity we focus on the case of common interest, namely where σ is unknown and upper bounds on $\mu_{(I)} - \mu_i$ are of main interest. Hsu [31] shows that if $U_1, \ldots, U_I$ are I independent and identically distributed standard normal random variables, $n_i = n$, $i = 1, \ldots, I$, $v = I(n - 1)$, and we let $d_{I,v}^{\alpha}$ be the constant such that

$$\Pr(U_I > U_i - d_{I,v}^{\alpha} s, i = 1, \ldots, I - 1) = 1 - \alpha,$$

then a set of $100(1 - \alpha)\%$ simultaneous confidence intervals for $\mu_{(I)} - \mu_i$ are given by $[0, D_i], i = 1, \ldots, I$, where

$$D_i = \max\left[\max_{j \neq i}(\overline{X}_j) - \overline{X}_i + d_{I,v}^{\alpha} s/\sqrt{n}, 0\right].$$

The constant $d_{I,v}^{\alpha}$ is the solution to

$$\int_0^{\infty} \int_{-\infty}^{\infty} \Phi^I(u + d_{I,v}^{\alpha} s)\, \mathrm{d}\Phi(u)\, \mathrm{d}\Psi_v(s) = 1 - \alpha,$$

where $\Phi(\cdot)$ and $\Psi_v(\cdot)$ are the distribution functions for a standard normal random variable and a $(\chi_v^2/v)^{1/2}$ random variable, respectively. Tables for the constant d are identical, except for a constant

$\sqrt{2}$, with those for the constants used in the normal theory step-down method described previously. For further information, see Hsu [33].

Medical and Biometric Applications

Comparisons Between Several Treatments and a Control

The problem is to compare K test treatments with a control treatment, which may be either a placebo or a standard treatment. Denote the unknown mean responses by $\mu_1, \ldots, \mu_{K+1}$, where $\mu_k, k = 1, \ldots, K$, denotes the mean for the kth test treatment and μ_{K+1} denotes the control mean. We formulate a multiple hypotheses testing problem where we test $H_{0k} : \mu_k = \mu_{K+1}$ vs. $H_{ak} : \mu_k \neq \mu_{K+1}$, for $k = 1, \ldots, K$. Rejection of H_{0k} in favor of H_{ak} leads us to conclude there is a difference between the kth treatment and the control.

The purpose of the trial may be to select the best candidate and to test the hypothesis pertaining to that particular candidate. Since there are K possible choices, we stipulate that the FWE be $\leq \alpha$ to ensure that the probability of declaring a false positive result is at most α. Since only one treatment is to be chosen, we may use a single-step procedure. If we reject this hypothesis, and wish to perform additional hypothesis tests to determine whether other candidates also differ significantly from the control, then we use the step-down procedure as described earlier. (Note that since we are only interested in finding a test treatment better than the control, we may prefer to formulate the hypotheses testing problem with one-sided alternatives instead of two-sided alternatives (*see* **Alternative Hypothesis**) in order to increase power. However, this decision must be made at the design stage.)

If the problem is to find all test treatments that can be shown to differ from the control, rather than selecting only one, then the problem may require a different formulation. Suppose the experiment is one of a series of similar experiments in which potential new treatments are compared with a control, and any test treatment showing promise is selected for further study. This is called *screening* (*see* **Animal Screening Systems**). In this case, interest would be in controlling the PCE rather than the FWE. Here the decision on each treatment does not depend on the decisions made with respect to the other treatments included in the experiment, which are included in the same experiment for reasons of experimental efficiency.

Comparisons Between a New Treatment and Several Standards

The test treatment may be a potential new treatment being compared with K standard treatments to determine whether it meets requirements for approval by the regulatory authority. The same hypotheses as before may be formulated, with μ_{K+1} now denoting the mean for the test treatment and μ_k the mean for the kth standard. Rejection of H_{0k} means that we conclude that the test treatment is different from the kth standard. To control the risk of any false claim, i.e. a claim that the test treatment differs from a particular standard when it does not, we would adopt a procedure that controls the FWE. Since the experimenter would like to find as many differences from the K standards as possible, one of the stepwise procedures, either step-down or step-up, should be used.

Superiority/Equivalence of a New Treatment Compared with K Standards

In the family of hypotheses used in the previous example, the alternative hypotheses, H_{ak}, were two-sided: rejection of H_{0k}, meant that we concluded there is a difference between the test treatment and the kth standard, but it could be either better or worse depending on the direction of the difference. Such a formulation is equivalent to testing a pair of hypotheses with one-sided alternatives, namely H_{0k} vs. $H^1_{ak} : \mu_{K+1} > \mu_k$ (test treatment is better than kth standard), and H_{0k} vs. $H^2_{ak} : \mu_{K+1} < \mu_k$ (test treatment is worse than kth standard).

Here we describe an alternative formulation, proposed by Dunnett & Tamhane [18]. We replace the hypothesis in each pair for determining whether the test treatment is worse with one which tests whether the test treatment is equivalent to the kth standard, namely

$$H'_{0k} : \mu_{K+1} = \mu_k - \delta \text{ vs. } H'_{ak} : \mu_{K+1} > \mu_k - \delta.$$

(*see* **Bioequivalence**; **Equivalence Trials**). Here, $\delta > 0$ is a prespecified value representing a difference that is clinically unimportant. Rejection of H'_{0k} leads

us to conclude that μ_{K+1} cannot be less than μ_k by more than an amount δ and hence, by definition, it is equivalent to the kth standard.

Dunnett & Tamhane [18] show how the stepwise multiple testing procedures described above can be adapted to this multiple testing problem. By using this superiority/equivalence testing formulation, we increase the power over the two-sided formulation, but of course this is addressing a slightly different problem. By testing simultaneously for superiority and equivalence, we also obtain more information than we would from a formulation that tests only for superiority using one-sided alternate hypotheses.

Comparisons with Both Active and Placebo Controls

D'Agostino & Heeren [8] described a trial where comparisons between a new treatment, T, two known active treatments, A_1 and A_2, and a placebo, P, are of interest. One proposal made was that the pairwise differences between treatment groups be tested with the *experimentwise error rate* controlled, which means that all comparisons are handled as a single family. Dunnett & Tamhane [16] pointed out that there were actually three families of comparisons, each answering a different question: (i) A_1 and A_2 vs. P to test the sensitivity of the experiment, defined as its ability to identify that the two known active treatments are efficacious; (ii) T vs. P to show that the new treatment is better than the placebo; and (iii) T vs. A_1 and A_2 to determine whether the new treatment can be shown to be superior to either of the known active treatments. Each family should be tested with FWE controlled at $\leq \alpha$. Failure to show the sensitivity of the experiment, or failure to find the new treatment better than placebo, would invalidate the comparisons made in (iii). In this case, controlling the FWE at α for each of the three families individually serves to control the overall error rate for the combined families at α as well, so there is no need to apply an experimentwise multiplicity adjustment. This is an example of what is known as *a priori ordered* families of hypotheses [1].

A single hypothesis test serves to cover (i), namely

$$\mathrm{H}_{01} : \mu_T - \mu_P \leq 0 \text{ vs. } \mathrm{H}_{\mathrm{a}1} : \mu_T - \mu_P > 0.$$

The following pair of hypotheses tests covers the comparisons in (ii):

$$\mathrm{H}_{02} : \mu_{A_1} - \mu_P \leq 0 \text{ vs. } \mathrm{H}_{\mathrm{a}2} : \mu_T - \mu_P > 0,$$

$$\mathrm{H}_{03} : \mu_{A_2} - \mu_P \leq 0 \text{ vs. } \mathrm{H}_{\mathrm{a}3} : \mu_{A_2} - \mu_P > 0,$$

while the following pair of hypotheses tests covers the comparisons in (iii):

$$\mathrm{H}_{04} : \mu_T - \mu_{A_1} \leq 0 \text{ vs. } \mathrm{H}_{\mathrm{a}4} : \mu_T - \mu_{A_1} > 0,$$

$$\mathrm{H}_{05} : \mu_T - \mu_{A_2} \leq 0 \text{ vs. } \mathrm{H}_{\mathrm{a}5} : \mu_{A_2} - \mu_{A_2} > 0.$$

To test H_{01}, we use an ordinary Student t test at level α, since there is only one hypothesis in the family. To test H_{02} and H_{03}, since we require both to be rejected to establish sensitivity, we use the MIN test of Laska & Meisner [36] or its extension, the step-up test described earlier in the article. To test H_{04} and H_{05}, we use the step-down test if we expect at most one of the two hypotheses to be rejected, or the step-up test if we expect both to be rejected.

Comparisons in a Dose Finding Experiment

In a dose finding experiment several dose levels of a compound along with a zero dose control are studied with respect to a specified response, usually some measure of efficacy or toxicity. The goal is to determine the lowest dose that produces a response that exceeds the control response (or, more generally, exceeds it by more than a specified amount, δ), denoted as the minimum effective dose (MED) [45] (*see* **Minimum Therapeutically Effective Dose**). Say there are K dose levels (usually, $K = 3$ or 4), and denote the mean responses for the control and the K dose levels by $\mu_0, \mu_1, \ldots, \mu_K$. Then we define

$$\mathrm{MED} = \min(k : \mu_k > \mu_0).$$

Ruberg [45] (see also Tamhane et al. [51]) formulates the problem of identifying the MED as the following multiple hypotheses testing problem:

$$\mathrm{H}_{0k} : \mu_0 = \mu_1 = \cdots = \mu_k \text{ vs.}$$

$$\mathrm{H}_{\mathrm{a}k} : \mu_0 = \mu_1 = \cdots = \mu_{k-1} < \mu_k,$$

for $k = 1, \ldots, K$. The estimated MED, or minimum detectable dose (MDD), is the lowest index k for which H_{0k} is rejected. Strong control of the FWE is needed in testing this family of hypotheses in order to

control the probability of obtaining an estimate that is less than the true MED. A class of test statistics which may be used are based on contrasts in the observed means. Various stepwise tests are given in Tamhane et al. [51] and compared in a simulation study with respect to their FWE and power under various forms of the dose response relationship.

General Remarks

The literature on multiple comparisons is voluminous and it is not possible to cover adequately all aspects and developments in an encyclopedia entry such as this. Two particular topics which are related, and warrant further mention, are selection and order restrictions. Selection problems have the general objective of identifying a favorable treatment or treatments from a collection of treatments. As might be expected, there are close links with multiple comparison problems and these connections are widely recognized (see [32] for example). Order restrictions in the hypotheses arise when there is added structure to the problem such as in dose-ranging studies when it is "known" that larger doses will be associated with nondecreasing means. Methods for the testing of order restricted hypotheses involve introducing constraints in the likelihood functions and so have links with **isotonic regression** (*see* **Isotonic Inference**).

It should be noted that most of the discussion thus far has assumed that two-sided tests are of interest. The methods described all apply for the case of one-sided tests following minimal modifications. In addition we have emphasized hypothesis testing throughout. Inferences regarding interval estimates are often equivalently possible, with the focus on the simultaneous coverage probability of collections of intervals, rather than FWE.

Multiple Endpoints in Clinical Trials

Many clinical trials and observational studies collect data on multiple endpoints. An example of this problem occurs in prevention trials where data are collected on the primary disease of interest in addition to diseases commonly observed and events that may occur as a result of the intervention. In this setting it is important to evaluate all the outcomes of interest, since an intervention that results in a decrease in the incidence of the targeted disease at the expense of an unacceptable increase in a detrimental outcome would require evaluation of the potential for future use of the intervention (*see* **Benefit/Risk Assessment in Prevention Trials**). Other examples of multiple outcomes data arise in family studies, clinical trials where treatment is applied to the left eye while the right eye serves as a control, and clinical trials where the side-effects of treatments result in outcomes that must also be examined.

The multiple endpoints problem occurs in many guises and includes recurrent observations, multiple endpoints, and correlated outcome data. These techniques can also be applied to data where there is clustering due to the study design (*see* **Cluster Randomization**). Additionally, several of these features may be present in a single data set, such as the multiple outcome setting where the outcomes of interest include recurrent events. There has been considerable work in this area over the past 20 years including a series of papers related to the workshop Statistical Methods for Multiple Events Data in Clinical Trials [9]. There are now methods available that can be readily implemented using existing software packages and potentially interesting approaches that require further development.

Several approaches exist for the analysis of recurrent event data. The earliest methods [7, 17] are based on modeling inter-event times and can be readily implemented using any standard statistical package. In their book, Andersen et al. [3] discuss methods for modeling recurrent events using general intensity models. This work arose naturally out of earlier work by Andersen & Gill [2] who proposed the modeling of recurrent event data by extending the Cox model. Wei, Lin & Weissfeld (WLW) [21] discuss the modeling of recurrent event data based on modeling the recurrences as marginal distributions. Prentice et al. [17] propose models for recurrent events based on modeling the data conditionally at each event point using the Cox regression model. They propose two different techniques based on two different definitions for the baseline hazard function: the first definition using total time and the second definition using the gap times between events. Lawless & Nadeau [10] discuss the modeling of recurrent events based on event counts and this work is extended by Cook & Lawless [5] to include a terminating event, in addition to the recurrent event. Therneau & Hamilton [19] compare the Andersen–Gill and WLW approaches to the modeling of recurrent data, in several different examples. They conclude that the Andersen–Gill method coupled with a robust estimator of the variance performs well in settings where the goal is a test of overall treatment effect. The WLW approach suffers from problems in the recurrent event setting due to its sensitivity to departures from proportionality in the margins. These models are also compared in Lin [11] who discusses approaches for assessing the fit of the proportional hazards model at each recurrence. Both the Andersen–Gill and WLW approaches have the advantage of ease of implementation using standard statistical software packages.

Other work in the area of recurrent events, based on parametric approaches for multitype events, is discussed in Abu-Libdeh et al. [1] and Fang et al. [6]. Abu-Libdeh et al. [1] use a mixed Poisson process with a random and fixed effect to model the data as a replicated multitype point process. Fang et al. [6] proposed a model based on a multiple renewal process allowing for time-dependent covariates. The estimators are obtained using standard maximum likelihood techniques.

For the analysis of multiple outcome data that include outcomes of several types, there are fewer available methods, with many methods applicable for the bivariate setting only. The method typically used in this setting is the method of Wei et al. [21] which is based on modeling each outcome as a separate margin assuming independence. The correlation between parameter estimates is obtained through a "sandwich" estimator. Lin & Wei [12] extended this method to incorporate linear regression methods for censored data. Prentice & Cai [16], developed estimators for the covariance and survival function for multivariate censored data with extensions to the

regression setting. Additional methods for estimating the correlation between two failure times have been developed via the copula model. This approach is discussed in Shih & Louis [18] and further studied in Phelps & Weissfeld [15]. More recently, Wang & Wells [20] have developed model selection and inference procedures for bivariate survival models based on the Archimedean copula. The introduction of random effects through a latent frailty variable has also been proposed for the analysis of bivariate survival data [8, 14]. The WLW method can be implemented in several standard statistical software packages, while the extension of Lin & Wei [12] and the copula approach require specialized software.

Methods

We first discuss models and notation for the multiple outcome approach. Assume that there are K types of failure and let T_{ki} denote the failure time for the ith individual and the kth type of failure where $i = 1, \ldots, n$ and $k = 1, \ldots, K$. Let C_{ki} denote the corresponding censoring time. The observed data are of the form $(Y_{ki},\ \Delta_{ki},\ \mathbf{X}_{ki})$, where $Y_{ki} = \min(T_{ki}, C_{ki})$, $\Delta_{ki} = 1$ if $T_{ki} = Y_{ki}$ and 0 otherwise, and $\mathbf{X}_{ki} = (X_{1ki}, \ldots, X_{pki})$ denote the p covariates for the kth event type on the ith individual. Two further assumptions are also made. The first is the assumption of independent censoring; that is, conditional on $\mathbf{X}_I, = (\mathbf{X}_{1I}, \ldots, \mathbf{X}_{Ki})$, the vectors T_I of the K failure times and the vectors C_I of the K censoring times are assumed to be independent. Additionally, it is assumed that $(\mathbf{T}_I, \mathbf{C}_I, \mathbf{X}_I)$, $I = 1, \ldots, n$, are independent and identically distributed random quantities.

For the kth type of failure on the ith subject, the hazard function $\lambda_{ki}(t)$ is assumed to be of the form

$$\lambda_{ki}(t) = \lambda_{k0}(t) \exp\{\beta_k' X_{ki}(t)\}, \quad t \geq 0, \qquad (1)$$

where $\lambda_{k0}(t)$ is an unspecified baseline hazard function corresponding to the kth failure type and $\beta_k = (\beta_{1k}, \ldots, \beta_{pk})'$ is the regression parameter corresponding to the kth failure type. To define the partial likelihood function corresponding to the kth type of failure, let $R_k(t) = \{l : X_{kl} \geq t\}$. Note that this is the risk set corresponding to all individuals who have not experienced the kth failure as of time t. Then the partial likelihood function corresponding to the kth failure type is given by

$$L_k(\beta) = \prod_{i=1}^{n} \left[\frac{\exp\{\beta' X_{ki}(Z_{ki})\}}{\sum_{l \in R_k(Z_{ki})} \exp\{\beta' X_{ki}(Z_{ki})\}} \right]^{\Delta_{ki}}. \qquad (2)$$

The maximum partial likelihood estimator, $\hat{\beta}_k$, for β_k is the solution to the standard likelihood equation $\partial \log L_k(\beta)/\partial\beta = 0$. The estimator $\hat{\beta}_k$ will be consistent for β_k if the model is correctly specified. Note that in the application of the WLW approach to recurrent event data, care needs to be taken to ensure that the model for any particular recurrence is correctly specified. The marginal models are easily fit using any standard statistical package that fits a Cox regression model. WLW show that $(\hat{\beta}_1', \ldots, \hat{\beta}_K')'$ is asymptotically normal with mean $(\beta_1', \ldots, \beta_K')'$ and covariance matrix Q which is estimated via the sandwich estimator given in the Appendix to the paper. Using these estimators, simultaneous inferences on the β_ks can be carried out, and an "average effect" of the covariates can be estimated. Software for fitting this model is available through S-PLUS and an SAS macro.

A second approach to the analysis of multiple outcome data is based on the use of a copula. The Archimedean copula is defined as

$$C_\alpha(x_1, \ldots, x_K) = \phi_\alpha[\phi_\alpha^{-1}(x_1) + \cdots + \phi_\alpha^{-1}(x_K)], \quad 0 \leq x_1, \ldots, x_K \leq 1, \qquad (3)$$

where $\phi_\alpha : [0, 1], \forall [0, 4], \phi_\alpha(1) = 0, \phi_\alpha'(x) < 0$, and $\phi_\alpha''(x) > 0$. Let $T_k, k = 1, \ldots, K$, denote distinct failure times or types and let $S_k(T_k)$ denote the continuous survival function of T_k. Then the multivariate survival function can be represented as

$$\begin{aligned} C_\alpha(S_1(T_1), \ldots, S_K(T_K)) &= \phi_\alpha[\phi_\alpha^{-1}(S_1(T_1)) \\ &\quad + \cdots + \phi_\alpha^{-1}(S_K(T_K))] \\ &= S(t_1, \ldots, t_K), \\ &\quad \text{for } t_1, \ldots, t_K \geq 0. \end{aligned} \qquad (4)$$

For the purposes of modeling, several forms of $\phi_\alpha(s)$ are useful. These include the Laplace transform,

$$\phi_\alpha(s) = \exp(-s^\alpha), \qquad (5)$$

which was studied by Hougaard [8] and the Clayton–Oakes [4, 13] gamma frailty model where

$$\phi_\alpha(s) = (1 + s)^{1/(1-\alpha)}. \qquad (6)$$

While both of these models are defined via copulas, they are frailty models where α denotes the parameter of the underlying frailty. Covariates are introduced through the parameterization of the survival function and α can be estimated from the full likelihood or using a two-step approach [8, 18]. While these methods are potentially quite useful, they are still in the early stages of development with no software widely available for their implementation.

For the analysis of recurrent event data, the WLW method can be employed with k indexing the kth recurrence rather than the kth type of failure. Using this approach, all the data are used for each recurrence since an individual with two recurrences becomes a censored observation for $k > 2$. The Andersen–Gill model can be implemented by redefining the at-risk indicators for the standard partial likelihood equation. Prentice et al. [17] propose the use of a conditional model based on two different definitions of the hazard function. These definitions are based on using the time from the beginning of the study, denoted as t, or the time from the immediately preceding failure, denoted as $t - t_{n(t)}$. Thus, for this model, the hazard function is given by

$$\lambda_i(t) = \lambda_{k0}(t) \exp\{\beta_k' X_{ki}(t)\} \tag{7}$$

or

$$\lambda_i(t) = \lambda_{k0}(t - t_{n(t)}) \exp\{\beta_k' X_{ki}(Z_{ki})\}, \tag{8}$$

where the $\lambda_{k0}(\cdot)$, $k = 1, \ldots, K$, are completely arbitrary baseline hazard functions. In this case k denotes a stratification variable that may change over time for a given subject, β_k is a column vector of stratum-specific regression coefficients and $t_{n(t)}$ denotes the time of the immediately preceding recurrence. Note that these are very flexible models that can be fit using standard statistical software. The drawback of these models is that they are conditional, so that estimation of the sth recurrence is based only on the individual with $(s - 1)$ recurrences. Inferential methods are based on standard methods for the Cox proportional hazards model. All these approaches can be readily implemented using standard statistical software packages such as S-PLUS or SAS.

Multiple Endpoints, Multivariate Global Tests

The term "multiple endpoints" is often related to an investigation of a treatment effect in the setting of a **clinical trial** or biomedical research. Since there are different aspects to characterize a treatment effect, it often requires more than one **outcome measure** (or **response variable**) to characterize the efficacy of a treatment. These variables can be changes in symptoms, bodily functions, subjective assessment, or any events or phenomena that are essential to evaluate the treatment effect. We consider here the situation in which these variables are of primary importance to the process of deciding the efficacy of a treatment, and we refer here to these primary variables as *endpoints*. The following are some examples of studies that require multiple endpoints. An investigator desires to examine the effect of different dosages of an antihistamine in treating the common cold. To obtain a more complete and detailed description of the efficacy of the doses of the antihistamine, he or she measures the level of relief in various important symptoms, including runny nose, sneezing, headache, and sinus discomfort. Another example arises in a study evaluating a heartburn relief product, where a drug company compares its new product with a standard control in the relief of the heartburn episodes over a two-week period. The primary endpoints include the relief of the first episode within 30 minutes of onset of symptoms, the proportion of relief of heartburn episodes over the two weeks where relief is within 30 minutes, and the global assessment of the product at the end of the two-week trial. The process of selecting the primary endpoints is no easy task. Careful assessment, mechanism of action, clinical evidence and, sometimes, subjective judgment are required in the process. However, it is not the purpose of this article to discuss how to select the primary endpoints. Here, we assume that this step has been done and we want to discuss the different methods that can be used to analyze such multivariate data.

A variety of statistical procedures are available. In general, they can be grouped under two categories; multivariate global methods, and endpoint-specific or P level methods. Multivariate global methods are used to make an omnibus assessment of the efficacy of the treatments. They provide an overall single ***P* Value** to reflect whether there are any differences among the treatments on the several **correlated** endpoints. The endpoint specific (P level) methods are employed to evaluate how the treatments affect the individual endpoints. They involve applying individual statistical tests to each endpoint separately. In this article, we focus only on the multivariate global methods, and we leave the endpoint-specific methods to another article entitled **Multiple Endpoints, *P* Level Procedures**.

Under the category of multivariate global methods, there are two general types of test. The first type involves combining multiple endpoints into a single test statistic, so that it provides an overall (omnibus) statement to declare whether there are any significant differences among the treatments. These multivariate global tests emerged from the idea of measuring distance between multivariate populations. The notions of summing, transforming, and examining linear combinations of endpoints are fundamental to the test statistics for this first type of global test. Most of these global test methods account for the combined effect of the endpoints by incorporating their variability, intercorrelation, and often clinical relevance into the statistics. The second type of global methods arises from **Bonferroni**-type adjustments. They adjust the univariate observed P values of the individual tests to maintain the familywise type I error rate at a prescribed level, and they provide an overall probability for the trial (*see* **Level of a Test**). Familywise type I error refers to the type I error associated with rejecting at least one **null hypothesis** incorrectly over all the endpoints under consideration. Generally, any multiple testing methods can be used as a global test because, in principle, if we find rejection in any one of the multiple tests, we could reject the overall null hypothesis. For this entry, we only include P value adjustment methods which are intended specifically to be used in global testing and not as a series of tests on the individual endpoints.

Consider I treatment groups in which K correlated endpoints are measured on $n_1, n_2, \ldots, n_I$ subjects. Let Y_{ijk} represent the measurement of the kth endpoint for the jth subject in group i ($i = 1, \ldots, I$; $j = 1, \ldots, n_i$;$k = 1, \ldots, K$) and $N = n_1 + n_2 + \cdots + n_I$.

Assume that:

1. The vector $\mathbf{Y}_{ij} = (Y_{ij1}, Y_{ij2}, \ldots, Y_{ijK})'$ has a **multivariate normal distribution** and the $\mathbf{Y}_{ij}$

are independently distributed with mean $\boldsymbol{\mu}_i$ and covariance matrix $\boldsymbol{\Sigma}$.

2. $\boldsymbol{\mu}_i = (\mu_{i1}, \mu_{i2}, \ldots, \mu_{iK})'$ and $\mu_{ik} = \mathrm{E}(Y_{ijk})$ is the mean of the kth endpoint for group i.
3. $\boldsymbol{\Sigma}$ is assumed to be the same for all I populations. $\boldsymbol{\sigma}^2 = (\sigma_1^2, \sigma_2^2, \ldots, \sigma_K^2)'$ consists of the diagonal elements of $\boldsymbol{\Sigma}$ and $\sigma_k^2 = \mathrm{var}(Y_{ijk})$ is the variance of the kth endpoint. The off-diagonal elements of $\boldsymbol{\Sigma}$ are denoted by $\sigma_{kk'} = \mathrm{cov}(Y_{ijk}, Y_{ijk'})$, which is the covariance of the kth and k'th endpoints.

Unless stated otherwise, all the parametric methods that are described below were developed under these assumptions.

Classical Multivariate Global Methods for Two-Sided Alternatives

One-way **multivariate analysis of variance** (MANOVA) is a multivariate analog of the one-way **analysis of variance** (ANOVA). Traditionally, we use MANOVA to compare K endpoints simultaneously among I treatment groups, where both K and I are greater than one. To test the null hypothesis $\mathrm{H}_0 : \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2 = \cdots = \boldsymbol{\mu}_I$ vs. the alternative that at least one of the equalities does not hold, several test criteria are available. Here, we briefly describe four widely used criteria which are all functions of the **eigenvalues** of $\mathbf{E}^{-1}\mathbf{H}$, where

$$\mathbf{H} = \sum_{i=1}^{I} n_i(\overline{\mathbf{Y}}_{i\cdot} - \overline{\mathbf{Y}})(\overline{\mathbf{Y}}_{i\cdot} - \overline{\mathbf{Y}})',$$

$$\mathbf{E} = \sum_{i=1}^{I}\sum_{j=1}^{n_i}(\mathbf{Y}_{ij} - \overline{\mathbf{Y}}_{i\cdot})(\mathbf{Y}_{ij} - \overline{\mathbf{Y}}_{i\cdot})', \qquad (1)$$

where $\overline{\mathbf{Y}}_{i\cdot} = \sum_{j=1}^{n_i} \mathbf{Y}_{ij}/n_i$ and $\overline{\mathbf{Y}} = \sum_{i=1}^{I}\sum_{j=1}^{n_i} \mathbf{Y}_{ij}/N$. $\mathbf{H}$ is often called the model or hypothesis matrix, and $\mathbf{E}$ is the error matrix. They are generalizations of the between- and within-groups sums of squares in a one-way ANOVA.

Wilks [41] proposed the criterion Λ which is developed from the **likelihood ratio test** and is based on the determinant of $\mathbf{E}(\mathbf{E}+\mathbf{H})^{-1}$. The Wilks' Λ (*see* **Lambda Criterion, Wilks'**) is given as follows:

$$\Lambda = \prod_{w=1}^{s}\left(\frac{1}{1+\lambda_w}\right) = \frac{|\mathbf{E}|}{|\mathbf{E}+\mathbf{H}|}, \qquad (2)$$

where $s = \min(I-1, K)$ and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_s$ are the eigenvalues of the characteristic equation $|\mathbf{E}^{-1}\mathbf{H} - \lambda\mathbf{I}_s| = 0$ ($\mathbf{I}_s$ is the identity matrix, of dimension $s \times s$).

The exact distribution of these statistics has been derived for the special cases: (i) $I = 2$ and $K \geq 1$; (ii) $I = 3$ and $K \geq 1$; (iii) $I \geq 2$ and $K = 1$; (iv) $I \geq 2$ and $K = 2$ [18]. For other cases, there are fairly good approximations available. For large sample sizes, we can use the Bartlett chi-square approximation [2] which has approximately a **chi-square distribution** with $K(I-1)$ **degrees of freedom** (df). We reject H_0 at the α level of significance if

$$\chi_b^2 = -\left[\left(\sum_{i=1}^{I} n_i - 1\right) - \tfrac{1}{2}(K+I)\right]\ln\Lambda \geq \chi_{1-\alpha}^2[K(I-1)]. \qquad (3)$$

The other modification is due to Rao [32], and is defined as

$$F_r = \frac{\nu_2}{\nu_1}\left(\frac{1-\Lambda^{1/b}}{\Lambda^{1/b}}\right) \qquad (4)$$

where $\nu_1 = K(I-1)$ and $\nu_2 = ab - [\frac{1}{2}K(I-1)] + 1$, with

$$a = \left(\sum_{i=1}^{I} n_i - 1\right) - \tfrac{1}{2}(K+I)$$

and

$$b = \left\{\frac{[K^2(I-1)^2 - 4]}{[K^2 + (I-1)^2 - 5]}\right\}^{1/2}.$$

Rao's F_r has approximately an $\boldsymbol{F}$ **distribution** with ν_1 and ν_2 df.

The second criterion for testing H_0 is the **Lawley–Hotelling trace** criterion [15, 16, 23], which is defined as the sum of the eigenvalues of $\mathbf{E}^{-1}\mathbf{H}$:

$$U = \sum_{w=1}^{s}\lambda_w = \text{trace } (\mathbf{E}^{-1}\mathbf{H}). \qquad (5)$$

Davis [5–7] gives upper percentage points of the test statistics $[(N-I)/(I-1)]U$. We reject H_0 for large values of the statistic.

The third criterion, **Pillai's trace**, was developed by Pillai [29] and Bartlett [3]. It is defined as the sum of the eigenvalues of $\mathbf{H}(\mathbf{E}+\mathbf{H})^{-1}$:

$$V = \sum_{w=1}^{s}\frac{\lambda_w}{1+\lambda_w} = \text{trace } [\mathbf{H}(\mathbf{E}+\mathbf{H})^{-1}] \qquad (6)$$

Schuurmann et al. [35] give the upper percentage points of the test statistic V, indexed by $s = \min(K, I-1)$, $m = [|K-(I-1)|-1]/2$ and $\mathbb{N} = (N-K-I-1)/2$.

All of the criteria described so far have involved all the eigenvalues. **Roy's maximum root criterion** [34] only involves the largest eigenvalue of $\mathbf{E}^{-1}\mathbf{H}$. His statistic is defined as

$$R = \frac{\lambda_1}{1+\lambda_1}. \tag{7}$$

The statistical significance of R can be assessed by using Pearson & Hartley's table [27] or Pillai's table [30] for $s > 5$ with the three parameters (i.e. s, m, and $\mathbb{N}$).

There are no uniformly **most powerful** MANOVA tests. Based on a study of comparative **powers**, Olson [26] concluded that Roy's largest root test has greater power than the others when the differences among groups are concentrated in one canonical dimension, while the other tests have greater power than Roy's test when the standardized measure of the distance between group means is not so heavily concentrated in a single root.

A large number of **Monte Carlo** studies have also been conducted to investigate the extent to which MANOVA tests are robust to violations of multivariate normality and equality of covariance matrices [26]. For general protection against departures from normality and from homogeneity of the covariance matrices in the **fixed-effects** model, Olson recommended the Pillai–Bartlett trace criterion (i.e. V) as the most robust of the MANOVA tests, with adequate power against a variety of alternatives (*see* **Multivariate Techniques, Robustness**).

There is a special case of MANOVA under the fixed-effects model worthy of separate discussion. When $I = 2$, the MANOVA test is equivalent to the **Hotelling's T^2 test** [15, 16]. It is the classical multivariate method to compare K endpoints simultaneously between two populations. It is the only known nontrivial **unbiased** test which is invariant with respect to affine transformations [37]. To test the hypothesis $\mathrm{H}_0 : \boldsymbol{\mu}_1 - \boldsymbol{\mu}_2 = \mathbf{0}$ vs. $\mathrm{H}_\mathrm{a} : \boldsymbol{\mu}_1 - \boldsymbol{\mu}_2 \neq \mathbf{0}$, we calculate T^2:

$$T^2 = \left(\frac{n_1 n_2}{n_1+n_2}\right)(\overline{\mathbf{Y}}_{1\cdot} - \overline{\mathbf{Y}}_{2\cdot})'\mathbf{S}_p^{-1}(\overline{\mathbf{Y}}_{1\cdot} - \overline{\mathbf{Y}}_{2\cdot}), \tag{8}$$

where $\overline{\mathbf{Y}}_{i\cdot}$ is a $K \times 1$ vector of sample means with $i = 1, 2$, and $\mathbf{S}_p = \left[\sum_{i=1}^{2}\sum_{j=1}^{n_i}(\mathbf{Y}_{ij} - \overline{\mathbf{Y}}_{i\cdot})(\mathbf{Y}_{ij} - \overline{\mathbf{Y}}_{i\cdot})'\right] / (n_1+n_2-2)$ is a $K \times K$ pooled sample covariance matrix.

Under the null hypothesis,

$$F_{ht} = \frac{n_1+n_2-K-1}{K(n_1+n_2-2)}T^2 \tag{9}$$

has a central F distribution with K and n_1+n_2-K-1 df. If $F_{ht} > F_{1-\alpha}(K, n_1+n_2-K-1)$, then we reject the null hypothesis $\boldsymbol{\mu}_1 = \boldsymbol{\mu}_2$.

The Hotelling T^2 test can also be viewed as a matrix generalization of the two-sample t test (*see* **Student's *t* Statistics**). The quantity T^2 can be interpreted as the square of the maximum possible univariate t computed on any linear combination of various endpoints. This test is appropriate when we have no specific alternative of how the various endpoints differ between two treatment groups. Roy's **union–intersection principle** shows that Hotelling T^2 test is of size α, so it has an accurate control over the type I error [34]. The robustness of Hotelling's T^2 has been examined by different authors [26]. The general conclusion is that T^2 is quite robust against nonnormality and heterogeneity of variance. However, when the sample sizes are unbalanced and the variance of the group that has fewer observations is larger than the other group, the test may not be robust. This test is best used for two-sided alternatives without prior knowledge of the relative magnitude of the treatment differences. It has poor power for alternatives which correspond to an equal (even if unknown in magnitude) beneficial treatment effect on all endpoints.

O'Brien-Type Procedures for One-Sided Alternatives

O'Brien [25] discussed the inadequacy of Hotelling's T^2 and Bonferroni method in dealing with the more common clinical setting when most or all of the efficacious measures are expected to be improved. The hypotheses are $\mathrm{H}_0 : \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2 = \cdots = \boldsymbol{\mu}_I$ vs. the alternate $\mathrm{H}_\mathrm{a} : \mu_{ik} \geq \mu_{i'k}$ for $k = 1, \ldots, K$, with strict inequality for at least one k. The ith treatment is more effective than the i'th treatment. This problem received extensive attention during the 1960s. Both Kudo [21] and Perlman [28] derived the likelihood ratio tests for this one-sided multivariate problem. The computations are difficult. Instead of tackling the exact distribution for the one-sided alternatives,

O'Brien derives his tests based on a more limited model for the alternate hypothesis. He assumes that the standardized treatment differences for the K endpoints are all of equal magnitude and in the same direction. In symbols, for a generic variable if μ_{ik} and $\mu_{i'k}$ are the means of the kth endpoint for the ith and i'th group, respectively, and σ_k is the common standard deviation of the kth endpoint, then the effect (also called the standardized effect) is

$$\frac{\mu_{ik} - \mu_{i'k}}{\sigma_k}. \tag{10}$$

O'Brien basically considered the problem of generating global tests for alternate hypotheses when the effects are positive and equal for all K endpoints. He proposed three methods to handle this one-sided hypothesis testing. One of these global methods is a simple **nonparametric** rank-sum test. For this method, we first ignore the group assignment of each subject and rank the $N(= n_1 + n_2 + \cdots + n_I)$ subjects separately for each endpoint. We then add the ranks of the K endpoints for the jth subject in the ith group to obtain

$$S_{ij} = \sum_{k=1}^{K} r_{ijk}.$$

Next we apply an appropriate univariate statistical tests to these new rank-sum data $\{S_{ij}\}$.

This method reduces the K-variate observations of each subject to a sum of K ranks. According to O'Brien, these sums are uncorrelated asymptotically, so the **central limit theorem** can ensure this nonparametric procedure to maintain the size of the test in large samples. He further showed with **simulations** that this procedure is relatively **efficient**. This nonparametric test is recommended, in particular, when the variables are not normally distributed or when the sample size is small.

The other two global methods proposed by O'Brien are based on a multivariate **general linear model**. His model assumes that the standardized treatment differences [see (10)] of the K endpoints are of the same magnitude and in the same direction. Explicitly, this assumes that the endpoints are equally important. He derived his parametric statistics by applying, respectively, the ordinary **least squares** (OLS) and the generalized least squares (GLS) methods to the standardized variables, denoted by $\{Y^*_{ijk}\}$. These are obtained by subtracting from each observation (i.e. Y_{ijk}) the overall variable mean (i.e. $\overline{Y}_{\cdot\cdot k}$) and then dividing the difference by the pooled within-group sample standard deviation (i.e. $s_{\cdot\cdot k}$).

For the OLS procedure, this is equivalent to computing the mean of the K standardized observations for each subject and performing a one-way analysis of variance on the sum variables. For the GLS procedure, O'Brien utilizes the best linear unbiased estimate provided by the GLS method and proposed the following statistic:

$$F_{\mathrm{GLS}} = \frac{\sum_{i=1}^{I} n_i [\mathbf{J}'\hat{\mathbf{R}}^{-1}(\overline{\mathbf{Y}}^*_{i\cdot} - \overline{\mathbf{Y}}^*_{\cdot\cdot})]^2}{(I-1)\mathbf{J}'\hat{\mathbf{R}}^{-1}\mathbf{J}}, \tag{11}$$

where $\mathbf{J}$ is a $K \times 1$ vector of ones, $\overline{\mathbf{Y}}^*_{i\cdot} = \sum_{j=1}^{n_i} \mathbf{Y}^*_{ij}/n_i$ is a vector of sample means of the K standardized endpoints for group i, $\overline{\mathbf{Y}}^*_{\cdot\cdot} = \sum_{i=1}^{I}\sum_{j=1}^{n_i} \mathbf{Y}^*_{ij}/N$ is a vector of overall sample means for the K standardized endpoints, and $\hat{\mathbf{R}}$ is a pooled sample correlation matrix. The elements of $\hat{\mathbf{R}}$ are defined by

$$\hat{R}_{uv} = \left[\sum_{i=1}^{I}\sum_{j=1}^{n_i}(Y^*_{iju} - \overline{Y}^*_{i\cdot u})(Y^*_{ijv} - \overline{Y}^*_{i\cdot v})\right] \Big/ (N-I)$$

where $u, v = 1, \ldots, K$.

This procedure incorporates, in its statistic, the information contained in the correlation matrix. An endpoint which is highly correlated to other endpoints will receive less weight, so that the individual contribution of such an endpoint to the statistic will be smaller. As reported by O'Brien, if the underlying distributions are multivariate normal, the OLS statistic follows a standard F distribution with $I-1$ and $N-I$ df and the GLS statistic approximates a standard F distribution with $I-1$ and $N-IK$ df.

As pointed out by O'Brien, the proposed procedures are designed to detect departures in which improvement was demonstrated consistently among the endpoints. Thus, it is important to anticipate a priori the same changes in the treatment effects across all K endpoints. His procedures are inappropriate to apply in situations in which nonzero treatment effects are expected to occur in only a few endpoints, or when there is no prior knowledge as to whether the treatment is going to affect the endpoints consistently. Both Pocock et al. [31] and Lehmacher et al. [24] discussed O'Brien's GLS statistic in the two-sample

case, and presented the following statistic:

$$t_{\mathrm{GLS}} = \frac{\mathbf{J}'\mathbf{R}^{-1}(\overline{\mathbf{Y}}^{*}_{1.} - \overline{\mathbf{Y}}^{*}_{2.})}{[(1/n_1 + 1/n_2)\mathbf{J}'\mathbf{R}^{-1}\mathbf{J}]^{1/2}} = \frac{\mathbf{J}'\mathbf{R}^{-1}(\overline{\mathbf{Z}}_{1.} - \overline{\mathbf{Z}}_{2.})}{(\mathbf{J}'\mathbf{R}^{-1}\mathbf{J})^{1/2}}. \quad (12)$$

If the underlying distributions are multivariate normal and $\mathbf{R}$ is known, this two-sample GLS statistic follows a standard normal distribution under H_0. If $\mathbf{R}$ is unknown and is replaced by an estimator $\hat{\mathbf{R}}$, the statistic is asymptotically normally distributed. Pocock et al. [31] adapted the application of the two-sample GLS statistic to different set of asymptotically normal test statistics which are obtained from continuous, binary and survival data. The robustness of these asymptotic normal statistics has not been established for finite sample sizes and investigations are ongoing. Another important extension that they made to the GLS statistic is to attach unequal priorities to the endpoints. O'Brien's original GLS statistic assumes that all endpoints are equally important. This assumption is necessary for O'Brien's method to achieve optimality, but it does not necessarily coincide with the clinical relevance. For this aspect, Pocock et al.proposed a simple method to attach unequal weights to the endpoints and these weights were chosen to correspond to the relative clinical importance of the endpoints. The proposed test statistic has the following form:

$$\frac{\mathbf{J}'(\mathbf{WRW})^{-1}\mathbf{W}(\overline{\mathbf{Z}}_{1.} - \overline{\mathbf{Z}}_{2.})}{[\mathbf{J}'(\mathbf{WRW})^{-1}\mathbf{J}]^{1/2}}, \quad (13)$$

where $\mathbf{W}$ is a diagonal weighting matrix assumed to be known a priori.

For analyzing data from a group sequential clinical trial, Tang et al. [39] derived a statistic assuming that the K endpoints have unequal standardized effects, which turns out to be equivalent to the modified GLS statistic proposed by Pocock et al. [31]. O'Brien's GLS statistic can be viewed as a special case of this modified statistic. Assume that patients are entered sequentially and that an interim analysis will be undertaken on the accumulated data after each accrual of $2n$ patients (*see* **Data and Safety Monitoring**). For the first j groups of data with $2n$ patients in each group (accrued between the $(m-1)$st and mth analyses, $m = 1, \ldots, j$), we have the following statistic:

$$G = \frac{(nj/2)^{1/2}\boldsymbol{\delta}'\boldsymbol{\Sigma}^{-1}\mathbf{d}^{(j)}}{(\boldsymbol{\delta}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\delta})^{1/2}}, \quad \mathbf{d}^{(j)} = \overline{\mathbf{Y}}^{(j)}_{1.} - \overline{\mathbf{Y}}^{(j)}_{2.}, \quad (14)$$

where $\boldsymbol{\delta}$ is a $K \times 1$ vector of relative difference of interest in the K endpoints and its elements are all assumed positive, and $\mathbf{d}^{(j)}$ is the vector of differences in sample means computed from the first j groups of patients. G is normally distributed when $\mathbf{d}^{(j)}$ has a multivariate normal distribution and $\boldsymbol{\Sigma}$ is known. This statistic is intended also to be used in the power and **sample size** calculations so that a cost-effective sequential trial can be designed.

Despite the usefulness of the different extensions, there are a few problems with the O'Brien-type tests that are worth noting. First, they are based on the weighted statistics as given in (11), (12), and (14). They use $\mathbf{J}'\mathbf{R}^{-1}$ or $\boldsymbol{\delta}'\boldsymbol{\Sigma}^{-1}$ as the weights. As explained and illustrated by Pocock et al. [31] and Follman [11], it is possible for these weights to have negative components for certain correlation matrices. In practice, it does not make sense to include negative weights. To make matters worse, a negative treatment difference weighted by a negative weight may mislead the investigator to conclude efficacy in favor of a treatment, even though the treatment is worse than the control. To avoid this problem, Tang et al. [38] recommended to use O'Brien's OLS test. The second issue concerns the restricted optimality of the GLS test. The GLS test is optimal only when the treatment differences for the K endpoints have the same effect size and direction as specified in the model. As mentioned previously, the GLS test is inappropriate when the nonzero treatment effects are expected to occur only in a few endpoints, or when it is not clear whether the treatment effects are of equal magnitude or direction among the endpoints. The third issue relates to the control of type I error rates. Even though O'Brien's parametric methods are more powerful than the Bonferroni method and Hotelling's T^2 when improved treatment effects are found for all endpoints, they do not always control the prescribed or nominal level of significance when the sample size is small [22]. The actual type I error may exceed the nominal and so produce a test that is liberal. In a simulation study with repeated measures setting, O'Brien also indicated that when the variances are heterogenous, the GLS procedure may

seem to enhance power, but this is at the expense of producing a liberal test.

Likelihood Ratio Test for One-Sided Alternative

Approximate Likelihood Ratio Test

The O'Brien-type statistics are derived under a restricted model of the general one-sided alternative, and they provide an optimal test for alternatives that correspond to a half-line. A half-line is simply a specified vector projection in the positive orthant. When it corresponds to $\boldsymbol{\delta}$, which is a column vector with all positive elements, it represents the specified relative size of the treatment effects for the K endpoints. For example, $\boldsymbol{\delta} = (1, 2)'$ indicates an alternate hypothesis in which the relative size of the treatment effect for the second endpoint is twice as large as that for the first endpoint. $\mathbf{J}$ of (11) is a special case of $\boldsymbol{\delta}$ which has all the elements equal to unity and assumes the relative sizes of the treatment differences among the K endpoints are all equal. The sensitivity of the O'Brien-type tests relies on the agreement of the observed relative difference with the specified $\boldsymbol{\delta}$. In other words, they require prior knowledge of $\boldsymbol{\delta}$ in order to achieve the intended power. When the choice of $\boldsymbol{\delta}$ is not clear, they are not appropriate. In this situation, a better approach is to find a test that is powerful over all possible $\boldsymbol{\delta}$ with nonnegative components. A logical candidate is to construct a test using the maximum of the GLS statistic over all feasible $\boldsymbol{\delta}$. This coincides with constructing an optimal test for alternatives which lie in the positive orthant. Tang et al. [40] provided such a test through an approximation of the likelihood ratio test and they called it the approximate likelihood ratio (ALR) test. Tang [37] give a detailed discussion on some uniformly more powerful tests which are related to the development of the ALR test.

The ALR test involves transforming the correlated vector of mean differences, $\mathbf{d}$, to a vector of independent standardized normal variables, $\mathbf{z}$, by a transformation matrix $\mathbf{A}$:

$$\mathbf{z} = \left(\frac{n}{2}\right)^{1/2} \mathbf{A}\mathbf{d}, \tag{15}$$

where $\mathbf{A}'\mathbf{A} = \boldsymbol{\Sigma}^{-1}$. Note that the matrix $\mathbf{A}$ is not unique. Tang et al. [40] give a computational **algorithm** to obtain the appropriate $\mathbf{A}$. Once $\mathbf{A}$ is selected, we can compute the test statistic

$$g(\mathbf{z}) = \sum_{k=1}^{K} (z_k \vee 0)^2 \tag{16}$$

where z_k is the kth element of $\mathbf{z}$ and $(z_k \vee 0)$ is the maximum of 0 and z_k. The P value of $g(\mathbf{z})$ under the null hypothesis is calculated by

$$\Pr[g(\mathbf{z}) \geq c] = \frac{1}{2^K} \sum_{k=1}^{K} \binom{K}{k} \Pr[\chi^2_{1-\alpha}(k) \geq c], \tag{17}$$

which is a special case of the chi-bar-square distribution [33]. It turns out that $g(\mathbf{z})$ based on $\mathbf{A}$ may not be invariant under a different ordering of the endpoints. In order to achieve permutation invariance, Tang et al. [40] suggested applying a linear ordering algorithm to the endpoints prior to the selection of $\mathbf{A}$. Tang et al. [38] provided a simplified algorithm for the ordering.

The ALR test can be powerful when the treatment improves all the endpoints, but differences in treatment effects are larger for some endpoints than for others. Theoretically, the power of the ALR test should be more stable than that of O'Brien's GLS test because O'Brien's test approximates the image space by only a half-line, while the ALR test approximates the image space by a cone. Tang et al. [40] performed some simulation studies to compare the powers of Hotelling's T^2, O'Brien's test, and the ALR test. They confirmed that the ALR test has better power than Hotelling's T^2 and O'Brien's test when the treatment effects for the various endpoints are positive but unequal. However, the ALR test can be liberal when the sample size is small (say, 40 subjects per treatment). Follmann [11] also pointed out that, for the case of two endpoints with correlation equal to 0.75 or higher, the ALR test may reject the null hypothesis when the treatment effects are negative for both enpoints.

Other Multivariate Global Methods

Follmann's X^2_+ Test for One-Sided Alternatives

In general, the likelihood ratio tests for a one-sided alternative are quite difficult to implement in a practical situation. Tang et al. [40] have produced a simpler ALR procedure, but the computations involved

are still intensive, especially when there are a large number of endpoints. Follmann [12] proposed a relatively simple multivariate test with a one-sided alternatives. For the two-sample case, $\mathbf{X}_1, \ldots, \mathbf{X}_n$ are assumed to be the endpoint differences, which are independent and identically distributed random vectors from a K-variate normal distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. Assume that $\overline{\mathbf{X}} = (\overline{X}_1, \ldots, \overline{X}_K)$ is a vector of the sample mean differences. His test rejects $\mathrm{H}_0 : \boldsymbol{\mu} = \mathbf{0}$ at level α if the statistic

$$n\overline{\mathbf{X}}' \boldsymbol{\Sigma}^{-1} \overline{\mathbf{X}} \tag{18}$$

exceeds the 2α critical value from a chi-square distribution with K df *and* the sum of the elements of the sample mean differences vector exceeds zero (i.e. $\sum_{k=1}^{K} \overline{X}_k > 0$). This test statistic is presented symbolically as the X_+^2 test. There is no formal theoretical justification for this test, but Follmann [12] provided some formal statements and proofs that the X_+^2 test is an α-level procedure for covariance known or unknown. He also gave tight bounds on the power of the test, so that an analytic approach to calculating power for one-sided multivariate studies is possible. Simulation studies show that the X_+^2 test performs better than O'Brien's GLS test when the treatment effects are all positive but not equal in magnitude.

Läuter's Standardized Sum and Principal Component Tests

Similar to O'Brien's OLS statistic, Läuter [22] used the idea of forming a weighted sum of the K endpoints and proposed three new tests to analyze the multiple endpoints data, especially when the sample size is small or when the number of endpoints is greater than the sample size.

He proposed to combine the K observations of each subject into a weighted sum, $x_{ij} = \boldsymbol{\gamma}' \mathbf{Y}_{ij}$, where $i = 1, \ldots, I$, $j = 1, \ldots, n_i$, and $\boldsymbol{\gamma}$ is a $K \times 1$ vector of weights uniquely determined by the total covariance matrix $(\mathbf{Y} - \overline{\mathbf{Y}})(\mathbf{Y} - \overline{\mathbf{Y}})'$ where $\mathbf{Y} = (\mathbf{Y}_{11}, \ldots, \mathbf{Y}_{1n_1}, \ldots, \mathbf{Y}_{I1}, \ldots, \mathbf{Y}_{In_I})$ is a $K \times N$ matrix of observations and $\overline{\mathbf{Y}} = (1/N)\mathbf{Y}\mathbf{J}_N\mathbf{J}_N'$ is a $K \times N$ matrix of overall means for the K endpoints. For the comparison of I populations in the sense of a one-way analysis of variance, he suggested the statistic

$$F_L = \frac{h^2}{(I-1)s^2}, \tag{19}$$

where $h^2 = \mathbf{x}'\mathbf{V}\mathbf{V}'\mathbf{x}$, $s^2 = [1/(N-I)]\mathbf{x}'[\mathbf{I}_N - (1/N)\mathbf{J}_N\mathbf{J}_N' - \mathbf{V}\mathbf{V}']\mathbf{x}$, and $\mathbf{V}$ is an $N \times (I-1)$ matrix with $\mathbf{V}'\mathbf{V} = \mathbf{I}$ and $\mathbf{J}'_N\mathbf{V} = \mathbf{0}$. Based on the theory of spherical matrix distributions developed by Dawid [8, 9] and by Fang & Zhang [10], he showed that this statistic is exactly distributed as $F_{1-\alpha}(I-1, N-I)$. No explicit form of $\mathbf{V}$ is provided in his paper.

For the case of two populations, he proposed the statistic

$$t = \frac{h}{s}, \tag{20}$$

where $h = \mathbf{x}'\boldsymbol{\kappa}$, $s^2 = [1/(N-2)]\mathbf{x}'[\mathbf{I}_N - (1/N)\mathbf{J}_N\mathbf{J}_N' - \boldsymbol{\kappa}\boldsymbol{\kappa}']\mathbf{x}$, and $\boldsymbol{\kappa}$ is an N-dimensional vector with $\boldsymbol{\kappa}'\boldsymbol{\kappa} = 1$ and $\mathbf{J}_N'\boldsymbol{\kappa} = 0$. He showed that the statistic is exactly distributed as **Student's *t*** with $N-2$ df. The explicit form of

$$\boldsymbol{\kappa} = \left[\frac{n_1 n_2}{(n_1+n_2)}\right]\begin{pmatrix}(1/n_1)\mathbf{J}_{n_1}\\ -(1/n_2)\mathbf{J}_{n_2}\end{pmatrix}$$

is given. For this special case, (20) is equivalent to applying the univariate two-sample t test to the transformed variables $\{x_{ij}\}$ with $n_1 + n_2 - 2$ df. In this paper, the author proposed three explicit forms of transformations for $\mathbf{x}$. They are the standardized sum transformation and the two **principal component** transformations.

The test based on the standardized sum transformation is useful when the effects of the K endpoints are all equal. For this test, the original observations are transformed as follows:

$$z_{ij} = \sum_{k=1}^{K} \frac{Y_{ijk}}{\left[\sum_{i=1}^{2}\sum_{j=1}^{n_i}(Y_{ijk} - \overline{Y}_{\cdot\cdot k})^2\right]^{1/2}}. \tag{21}$$

Here, the original observations, Y_{ijk}, are standardized by the total variances. Recall that in O'Brien's procedure he standardized the variables by the within-sample variances.

The first principal component test is appropriate if all K variables are expected to have the same directions of treatment effects. For this test, he suggested using

$$z_{ij} = \sum_{k=1}^{K} |e_k| Y_{ijk}, \tag{22}$$

where e_k is the kth element of the first **eigenvector** obtained by solving

$$(\mathbf{Y} - \overline{\mathbf{Y}})(\mathbf{Y} - \overline{\mathbf{Y}})'\mathbf{e} = \text{diag}\,[(\mathbf{Y} - \overline{\mathbf{Y}})(\mathbf{Y} - \overline{\mathbf{Y}})']\mathbf{e}\lambda. \tag{23}$$

If we have no expectation of the direction of treatment differences, Läuter suggests using the second principal component test involving a transformation similar to (22) but with the absolute sign removed.

As stated in Läuter [22], all three proposed methods have accurate control of the type I error; but there is no discussion of the performance of these tests in terms of power and robustness.

Cureton & D'Agostino's Composite Scores

Similar to Läuter's transformed variables for the principal component test, Cureton & D'Agostino [4] presented – much earlier in time – an approach for obtaining a transformed variable through a principal component analysis. They called this transformed variable a composite score. It gives the best single measure of whatever is common to a set of at least moderately similar variables. The composite score is a weighted sum of all the variables, using the loadings on the first principal component.

The composite score of the jth subject is defined as

$$C_{ij} = a_1 Y^*_{ij1} + a_2 Y^*_{ij2} + \cdots + a_K Y^*_{ijK}, \tag{24}$$

where the $\{a_k\}$ are the loadings of the K variables on the first principal component, and the $\{Y^*_{ijk}\}$ are the standardized scores of the K variables for the jth subject in group i. The C_{ij}s are a set of deviation scores with mean 0, but they are not standard scores. To obtain the composite standard scores, we divide each C_{ij} by the standard deviation of these deviation scores, which is equal to the square root of the first eigenvalue. We can then apply the usual t statistic to these composite standard scores. It turns out that Cureton & D'Agostino's composite score is related to Läuter's principal component transformed variables, except that Cureton & D'Agostino use the standardized variables Y^*_{ijk}.

Another procedure for forming a composite score, described in Cureton & D'Agostino [4], is based on ranks. It was first presented in Kendall [19, 20]. It is a useful procedure when both the sample size and the number of endpoints are small. Ignoring the group assignment, the N subjects are first ranked on each of the K variables, using the average-rank procedure to resolve ties. The ranks of each individual are then summed, and the rank-sums are themselves ranked to obtain the composite ranks. An appropriate nonparametric rank sum test can be used on these composite ranks. This test is appropriate when the sample size is small or when normality does not hold for the data. This procedure is similar to O'Brien's rank-sum procedure.

Risk Score Test

Follmann [11] proposed a risk score statistic, which is derived on the basis of the clinical appeal rather than optimality in statistical power. Instead of using some optimal estimates as weights, he chooses weights so that the weighted sum correlates well with the occurrence of an event. For example, the risk score weights can be the estimated **logistic regression** coefficients for the endpoints from an ancillary data set. This risk score test requires the multiple endpoints to be surrogates. His derivation is based on the two treatment groups with two endpoints measured on n subjects in each group. His statistic is defined as

$$\begin{aligned} RS &= \beta_1(\overline{Y}_{1.1} - \overline{Y}_{2.1}) + \beta_2(\overline{Y}_{1.2} - \overline{Y}_{2.2}) \\ &= \beta_1 d_1 + \beta_2 d_2 \\ &= \gamma_1 d_1^* + \gamma_2 d_2^*, \end{aligned} \tag{25}$$

where $\gamma_k = \beta_k \sigma(d_k)$ and $d_k^* = d_k/\sigma(d_k)$, with $\sigma(d_k)$ the standard deviation of the mean of the group differences in the kth endpoint. Under the null hypothesis, the statistic has a normal distribution with mean zero and variance $\text{var}(\rho) = \gamma_1^2 + \gamma_2^2 + 2\rho\gamma_1\gamma_2$. For a one-sided test, we reject H_0 in favor of the treatment group at 0.05 level of significance if $\boldsymbol{\gamma}(\mathbf{d^*})' > 1.645[v(\rho)]^{1/2}$. The advantage of this risk score test is having a rejection region that corresponds to the contours of constant risk, and that the correlations of the endpoints will not affect the clinically relevant rejection region. Based on his simulation study, he concluded that the risk score test is comparable to the O'Brien GLS test in terms of power when one discounts the wrongful rejections due to the negative weights arising from the GLS test.

P Value Adjustment, Global Methods

Bonferroni-Type Methods

The Bonferroni method is often used to adjust for multiple significance tests, and it is also a popular method for testing the overall hypothesis $H_0 = \bigcap\{H_k : k = 1, \ldots, K\}$, where $H_1, \ldots, H_K$ are the hypotheses for testing the K individual endpoints. Suppose that $t_1, \ldots, t_K$ is a set of K statistics with corresponding P values $P_1, \ldots, P_K$ for testing these hypotheses. Using the Bonferroni inequality, we can perform a very simple level α test of H_0:

$$\text{reject } H_0 \text{ if } P_{(1)} \leq \frac{\alpha}{K},$$

where $P_{(1)}$ is the smallest P value.

This method is easy and convenient to apply. No distributional assumptions are required. It is particularly useful in detecting nonzero treatment effects in one or some few "unknown" and distinct endpoints. Nevertheless, the method may become very conservative, especially when the endpoints are highly correlated. Also, it puts too much emphasis on the smallest P value and does not account for the collective information that the various endpoints provide. It is inappropriate in the situation in which most or all measures of efficacy are improved.

Hommel's Adjustment Methods

Hommel [13] discussed another level α test due to Rüger's inequality. It avoids the disadvantage of overemphasis on the smallest P value. The test is to

$$\text{reject } H_0 \text{ if } P_{(k)} \leq \frac{k\alpha}{K},$$

where $P_{(k)}$ is the kth smallest P value. Using this test, the investigator has to determine k before performing the K comparison tests. There are no specific guidelines on how to select k. This mainly depends on the decision of the investigator prior to the trial. Even though k is chosen in advance, there is always room for argument. To avoid choosing k in advance, Hommel proposed another level α test which combines the Bonferroni test and all $(K - 1)$ possible Rüger tests:

$$\text{reject } H_0 \text{ if } P_{(k)} \leq \frac{k\alpha}{(KC_K)} \quad \text{for at least one } k,$$

where $k = 1, \ldots, K$ and $C_K = 1 + 1/2 + \cdots + 1/K$. Hommel [14] indicated that these level α tests of H_0 are expected to be conservative in practical applications.

Simes' Adjustment Method

Simes [36] proposed a modified Bonferroni procedure based on the ordered P values for the individual tests. It is very similar to the modified Rüger test, but is less conservative because of dropping the constant C_K. The Simes test is performed as

$$\text{reject } H_0 \text{ if } P_{(k)} \leq \frac{k\alpha}{K} \quad \text{for at least one } k.$$

As Simes pointed out, his procedure does not always lead to a level α test of H_0. His simulation study showed that the level of his procedure is less than or equal to the nominal α for a large family of multivariate distributions. He also proved that the level is exactly equal to α if the test statistics are independent. This modified procedure improves on some of the major drawbacks of the Bonferroni method. It does not rely heavily on the smallest P value, and it has better power than Bonferroni's method because it has an actual significance level much closer to the nominal level. Although Simes' procedure slightly increases the computation as compared to Bonferroni, it is still very easy and convenient to perform. However, just like Bonferroni's adjustment, Simes' method does not consider the correlations between endpoints and it becomes conservative as the correlations among the K test statistics increase.

Armitage & Parmar's Empirical Method

The P value adjustment methods discussed so far do not directly account for the correlations of the endpoints. Armitage & Parmar [1] have presented a procedure which allows for correlations in the P value adjustment. Assume that the test statistics follow a multivariate normal distribution. They suggested an adjusted correction of the following form:

$$P_{\text{adj}} = 1 - (1 - P_{\min})^{K^x} \tag{26}$$

where $0 \leq x \leq 1$. The parameters $x = 1$ if the K test statistics are independent, and $x = 0$ if the K test statistics are fully correlated. In general, the empirical

formula for computing x with an arbitrary correlation structure is given as follows:

$$x = \begin{cases} \hat{x}, & \text{if } 0 < \hat{x} < 1, \\ 0, & \text{if } \hat{x} \le 0, \\ 1, & \text{if } \hat{x} \ge 1, \end{cases}$$

where

$$\hat{x} = \{1 - [\overline{\rho} + 2V(\rho) + a(p_{\min} - 0.05)]^2\}^{1/\gamma},$$

$$\overline{\rho} = \frac{1}{n_K} \sum_k \sum_l |\rho_{kl}|, \quad \text{where } k < l,$$

$$V(\rho) = \frac{1}{n_K} \sum_k \sum_l (|\rho_{kl}| - \overline{\rho})^2, \quad \text{where } k < l,$$

$$\gamma = \begin{cases} \dfrac{n_K}{n_K - 1} + \left(3 - \dfrac{n_K}{n_K - 1}\right)(\overline{\rho} + 2V(\rho)), & \\ & k \ge 3, \\ 0.4, & k = 2, \end{cases}$$

$$a = 3.25 - 2.7(100P_{\min}) + 0.4(100P_{\min})^2,$$

$$n_K = \left(\tfrac{1}{2}\right) K(K-1).$$

They found that the adjusted P values provide good approximations to the actual P values for up to five endpoints, but further studies are required to justify the adequacy of this adjustment for higher dimensions.

James's Analytic Method

James [17] presents another P values adjustment method which allows for the presence of correlations. Her method is based on an approximation derived for multinormal probabilities with equal correlation. Unlike the Bonferroni-type methods, it assumes that the test statistics follow a multivariate normal distribution, or at least an asymptotically normal one with equal correlation ρ. The adjusted P value is defined as

$$\begin{aligned} P_{\text{adj}} &= \Pr(\text{minimum } P \le P_{\min}) \\ &= 1 - \Pr(\text{all } P > P_{\min}) \\ &= 1 - \Pr\left(\bigcap_{k=1}^{K} a \le X_k \le b\right), \end{aligned}$$

where the $\{X_k\}$ are standardized multinormal with equal correlation ρ such that

$$b = \Phi^{-1}\left(1 - \frac{P_{\min}}{2}\right), \qquad a = \Phi^{-1}\left(\frac{P_{\min}}{2}\right),$$

for the two-sided case, and

$$b = \Phi^{-1}(1 - P_{\min}), \qquad a = -\infty,$$

for the one-sided case. Φ^{-1} is the inverse of the cumulative normal distribution function.

The approximation is

$$\begin{aligned} P_{\text{adj}} = 1 &- D_1(1-\rho^2) - D_2\rho^2 - D_3\rho(1-\rho) \\ &- D_4[2 - 2(1-\rho)^{1/2} - \rho - \rho^2] \end{aligned}$$

where, for a two-sided test,

$$\begin{aligned} D_1 &= (1 - P_{\min})^K, \\ D_2 &= 1 - P_{\min}, \\ D_3 &= 0, \\ D_4 &= K(K-1)\phi(b)\int_{-\infty}^{\infty} \Phi(z)^{K-2}\phi(z)^2\,\mathrm{d}z \\ &= K(K-1)\phi(b)G(K), \\ G(K) &= \int_{-\infty}^{\infty} \Phi(z)^{K-2}\phi(z)^2\,\mathrm{d}z, \\ \phi(z) &= \frac{1}{(2\pi)^{1/2}} \exp\left(-\frac{z^2}{2}\right), \\ \phi(z) &= \int_{-\infty}^{z} \frac{1}{(2\pi)^{1/2}} \exp\left(-\frac{x^2}{2}\right)\mathrm{d}x, \\ b &= \Phi^{-1}\left(1 - \frac{P_{\min}}{2}\right), \end{aligned}$$

and, for a one-sided test,

$$\begin{aligned} D_1 &= (1 - p_{\min})^K, \\ D_2 &= 1 - p_{\min}, \\ D_3 &= \frac{K}{2}(K-1)(1-p_{\min})^{K-2}\phi(b)^2, \\ D_4 &= \frac{K}{2}(K-1)\phi(b)\int_{-\infty}^{\infty} \Phi(z)^{K-2}\phi(z)^2\,\mathrm{d}z \\ &= \frac{K}{2}(K-1)\phi(b)G(k), \\ b &= \Phi^{-1}(1 - p_{\min}). \end{aligned}$$

With this method,

$$\text{reject } H_0 \text{ if } P_{\text{adj}} \leq \alpha$$

and the probability of rejecting the overall null hypothesis can be quoted as the minimum adjusted P value.

For the unequal correlation case, James suggested: (i) replacement of ρ with the mean correlation ρ_m defined by

$$\rho_m = \sum_{k=1}^{K-1} \sum_{l=k+1}^{K} \frac{|\rho_{kl}|}{m},$$

where ρ_{kl} is the correlation between endpoint k and endpoint l, $k = 1, \ldots, K-1, l = k+1, \ldots, K$, and $m = 1/2K(K-1)$; or (ii) to replacement of ρ with ρ_{mv},

$$\rho_{mv} = \rho_m + 2 \sum_{k=1}^{K-1} \sum_{l=k+1}^{K} \frac{(|\rho_{kl}| - \rho_m)^2}{m}.$$

Estimates for the correlations, ρ_{kl}, can be obtained: (i) from a previous study or preferably a pilot trial; (ii) from the raw data if the endpoints are distributed multivariate normal; or (iii) by using the formulas provided in Pocock et al. [31] if the endpoints come from some nonnormal data.

By incorporating the correlations to the adjusted P values, James' method is definitely a solution to the problem of conservatism arising from the Bonferroni-type adjustment. She showed that the adjusted P values derived from her approximation are very close to the actual values obtained from a multivariate normal program. Furthermore, they appear to be better estimates for the true P values than the approximation proposed by Armitage & Parmar [1]. The adjustment can also be used to calculate the power of any trial with multiple testing. However, there are some trade-offs for this improvement in power. They include the increased complexity of calculations and also the requirement of the distributional assumption imposed on the test statistics. Further investigations need to be done to check the **robustness** of the method and find an error bound for the approximation. Also, it is not clear what will be the impact of various heterogeneous correlation structures on the performance of the method; particularly, when some of the correlations are negative.

Follmann's Maximum Test

Follmann [11] proposed a Bonferroni-type of method which uses the maximum of the individual test statistics. Under his model, he assumes that the statistics follow a multivariate normal distribution with equal correlation. However, instead of using a standard technique to test the maximum, he uses a critical value by the conservative Bonferroni approximation. If the maximum statistic exceeds the α/K critical value, the overall null hypothesis will be rejected at the α level of significance. This max test is equivalent to performing the Bonferroni adjustment on a one-sided P value with the assumption of normality imposed on the individual statistics. Simulations were performed to compare this max test with O'Brien's OLS test. Only two groups and two endpoints are used in his simulation. The simulation result is consistent with the known performance of the Bonferroni method, which has good power in detecting one or a few significant endpoints and performs well with a small number of endpoints. The simulations also indicate that the powers of the max test and the OLS test do not differ substantially under the alternative of equal positive treatment effects for both endpoints. However, these results may be due to the small number of endpoints used. Even though the max test is very simple, more research is needed to explore its usefulness.

Follmann [11] adapted another maximum test due to Wittes for global comparison between two groups. The method pairs the jth subjects from the two groups and reduces the data to a single paired difference for each endpoint, denoted by $d_{jk}, k = 1, \ldots, K$. $\mathbf{d}_j$ is a vector of K paired differences, which is assumed to follow a multivariate normal distribution with equal correlation, ρ. Suppose that V_j is the maximum of the K differences of the jth subjects. Follmann proposed the following statistic:

$$\overline{V}_s = \frac{\overline{V} - \mathrm{E}(V_j|\boldsymbol{\mu}, \rho)}{[\mathrm{var}(V_j|\boldsymbol{\mu}, \rho)]^{1/2}}, \tag{27}$$

where $\overline{V} = \sum_{j=1}^{n} V_j/n$ and $\mathrm{E}(V_j|\boldsymbol{\mu}, \rho)$ and $\mathrm{var}(V_j|\boldsymbol{\mu}, \rho)$ are the mean and variance of V_j, which the author suggests obtaining by **numerical integration**. Under the null hypothesis, this statistic has an asymptotic standard normal distribution by the central limit theorem. Simulations were performed to compare this maximum statistic with O'Brien's OLS test. In his simulation, two groups and two

endpoints were used. The simulation results indicate that O'Brien's method has better power than the maximum test under the alternative that both endpoints improve equally, and has poorer power than the maximum test under the alternative that only one of the two endpoints improves but that the responsive endpoint is unknown. Follmann recommended that this maximum test should be used in situations in which it is suspected that only one of the two endpoints improves and the correlation between the endpoints is large and positive. However, there are no indications as to how to justify the pairing of the subjects and how to extend this test to more than two groups.

Summary Comments

As we review each method, we can see there is no one winner for all settings. The power of each method relies on the particular setting to which it is applied. A few simulation studies [11, 12, 25, 40] have been done to compare the powers of some of the global methods. However, they basically came up with a similar conclusion, that the power of each method varies with the particular alternative assumed in the investigation. As a final note, we summarize the setting for which each global method is most appropriate.

Hotelling's T^2 and MANOVA are still the appropriate methods to be used in any trials when the investigator does not have any prior knowledge on how the treatments may affect the endpoints; for example, in a pilot study. They perform quite well even when the assumptions on multivariate normality and homogeneity of covariance are violated. However, if we have prior information about an equal improvement in the expected differences of the K endpoints, we may want to consider the one-sided global methods or the P value adjustment.

O'Brien-type parametric tests are good candidates for the situation in which we expect that most or all of the endpoints will demonstrate consistent improvement in the treatment effect. For clinical relevance, the O'Brien GLS statistic as modified by Pocock et al. [31] has the flexibility of incorporating the clinical importance of the endpoints as part of the weights, and at the same time preserving the optimality of statistical power. However, we have to be aware that the power of the GLS test may be enhanced at the expense of an increased type I error rate.

Under the expectation of equal improvement for all endpoints, the GLS test is appropriate if we can be sure that there are no negative components in the weights of the statistic [i.e. $\mathbf{J}\mathbf{R}^{-1}$ and $\boldsymbol{\delta}\boldsymbol{\Sigma}^{-1}$ in (11) and (14) respectively] and the sample sizes are large. When we are not sure about the composition of the weights, it is reasonable to use the O'Brien OLS test if we have a large sample size and the rank sum test if the sample size is small. Also, Läuter's standardized sum test seems to be appropriate here, due to its similar transformations as compared with the O'Brien OLS test. A definite advantage of using Läuter's standardized sum test is protection against an erroneously liberal type I error.

In situations in which most or all of the endpoints are expected to be improved, but it is not clear if the relative treatment differences (effects) are going to be equal, we may consider the approximate likelihood test. Again, we have to keep in mind that this gain in power may be misleading because of the inflated actual type I error rate, and also the problem with the negative weights. To solve the problem of the inflated type I error rate, some authors have suggested using the permutation distribution of the ALR test statistic instead of the chi-bar-square distribution. However, this approach is very **computer-intensive** and the level of complexity increases with the number of endpoints. If there are concerns about the complexity of computations and inflated type I error rates, we may consider using the classical tests (MANOVA tests), as long as the changes in treatment effects are not all of the same magnitude. Other candidates are the composite score tests. They can protect the type I error rates and they should perform reasonably well if the endpoints behave similarly. Of course, they will not be as powerful as the ALR test.

The next setting arises when the treatment is effective in only one or a few "unknown" and distinct endpoints. The method proposed by Simes appears to be a good candidate when the correlations among the endpoints are low or moderate (say, $\rho \leq 0.5$). This method is more powerful than the Bonferroni adjustment and the methods proposed by Hommel. The calculation is relatively easy. Also, it works quite well for multivariate distributions other than the normal. When the endpoint correlations are large, Simes' adjustment tends to be conservative. In this case, the

method proposed by James may be a better choice due to its ability to account for correlations. Unfortunately, she only provided a simple example that illustrates a power comparable to O'Brien's test when the treatment effects are almost equal and a power better than O'Brien's when the treatment effects are all positive but not equal. There are no formal power comparisons performed to support this claim in general. Further investigations on this method seem worthwhile.

By design, the composite score methods, such as the standardized sum test, the various versions of principal component composite score tests, and the risk score test, are not optimal with respect to their statistical power in detecting mean differences among groups. Therefore, under the different settings described above, there is always a better test than these composite score methods. However, as pointed by Follmann [11], statistical power should not be the only concern in evaluating treatment efficacy. Clinical considerations are also important in the evaluation process. We should not underestimate the usefulness of these methods, because they put more emphasis on a certain optimal structure of the endpoints, which may be clinically more appealing. However, more research is definitely needed in order to understand better the properties of these methods.

Multiple Endpoints, *P* Level Procedures

In **clinical trials** or biomedical research, multiple endpoints are often used to investigate a treatment effect. Diseases usually affect patients in more than one way, and in order to characterize completely the efficacy of a treatment, various endpoints are required. There has been substantial debate and controversy in determining the appropriate approach to analyze these multiple endpoints. The main difficulty is how to account for the multiplicity of inferences. Sometimes this problem comes in two parts owing to the presence of multiple groups as well as multiple endpoints. The problem of multiple groups comparisons has received substantial attention, and there is an extensive literature on procedures of multiple groups comparison (*see* **Multiple Comparisons**; **Paired Comparisons**; **Simultaneous Inference**). In this article we focus on the problem of multiplicity due to the presence of multiple endpoints and describe some methods that can be used to analyze these multidimensional data.

There are researchers who advocate the simple no-adjustment approach. They apply a univariate t test (*see* **Student's *t* Statistics**) or one-way **analysis of variance** (ANOVA) to each endpoint separately and claim a significant effect for a specific endpoint if the observed ***P* value** obtained from the corresponding test is at, or less than, the prescribed level of significance, say α. This approach is legitimate if the objective of the researchers is exploratory or simply to present the comparisons examined and draw no conclusions about the treatments. However, most researchers are not satisfied with this. It is usually desired to reach conclusions about the efficacy of the treatments. The no-adjustment approach is too liberal for this, for it inflates the familywise error rate as the multiple tests are performed. The familywise error rate is the probability of making at least one type I error in the given family of inferences [9], and the type I error is the error of making a false rejection of a **null hypothesis** when it is true (*see* **Hypothesis Testing**). This inflation of the familywise error rate is undesirable, especially in clinical trials, because it may increase the chance of providing an ineffective treatment to patients. The no-adjustment approach is not recommended.

To substantiate the presence of a treatment effect, some researchers take the approach of combining the various endpoints into a single statistic. This supplies an overall probability statement about the effectiveness of a treatment. The procedures that provide a single statistic obtained by combining the multiple endpoints in some optimal way are generally called *global procedures* or *omnibus tests*. Some common omnibus tests for multiple endpoints have been reviewed (*see* **Multiple Endpoints, Multivariate Global Tests**). These global methods provide an objective and reasonable solution to a problem with multidimensional features. They consider various endpoints simultaneously and attempt to answer the question of whether the treatments in the comparison are different in an overall sense, or whether any treatments show a more significant overall improvement than the others. However, the answer to this question is usually not the end of the investigation. Rather it leads to the next question of how the treatments affect each endpoint individually. For this case we need to test the significance of each endpoint to determine treatment effects. There are two common approaches to deal with this. Some researchers employ the approach of first using a global test as a preliminary criterion. If significance is achieved, then they apply endpoint-specific analyses to the individual endpoints. This approach is used in the hope that the global test will control the familywise type I error rate, will account for the **correlations** among the endpoints, and will increase the accuracy of identifying the effect on the individual endpoint when the endpoint-specific tests are performed. However, there is disagreement on whether this joint use of global and endpoint-specific tests can actually achieve the desired protection and power. Some researchers believe that it is redundant to perform a global test because most of the endpoint-specific procedures can control the familywise error rate and they have reasonable power to detect treatment differences among various endpoints. Their approach to the analyses is simply to use only the endpoint-specific procedures. There is no clear answer which approach is better. Since both approaches need to use the endpoint-specific procedures, it is our purpose in this article to review some of the popular endpoint-specific methods as well as the recent developments in this area of research.

Endpoint-specific procedures are intended to be used to identify the significance of the individual

endpoints. These procedures are also called P level procedures because they usually involve making statistical decisions on the basis of the P levels, resulting from examining the endpoints separately. The P level is the observed level of significance. As previously stated, these P level procedures can be used in the primary analyses or as second-step analyses in conjunction with multivariate global tests. To facilitate the presentation we adopt the same grouping scheme as described by Troendle [21, 22] and classify the endpoint-specific methods into three categories: (i) Bonferroni-type tests, (ii) normal-based tests, and (iii) resampling procedures. Within each category the methods can be further classified as single-step, step-down, or step-up tests. For the single-step tests, each comparison is based on the observed values of that particular endpoint. Both step-down and step-up tests involve comparing the ordered observed P values (or test statistics) with a set of critical constants, $c_1 \leq \cdots \leq c_K$. The testing is carried out sequentially one null hypothesis at a time. If the testing is *step-down*, then it starts with the null hypothesis corresponding to the most significant (i.e. smallest) P value (or largest test statistics) and proceeds towards the least significant null hypothesis. The testing stops when an acceptance occurs the first time. Then the remaining null hypotheses are accepted also. All null hypotheses before the first accepted null hypothesis are rejected. If the testing is *step-up*, then it starts with the null hypothesis corresponding to the least significant (i.e. largest) P value (or smallest test statistics) and proceeds towards the most significant null hypothesis. The testing stops when a rejection occurs the first time and the remaining null hypotheses are rejected also. The complexity in the computations of the critical constants usually increases in the order of single-step, step-down, and step-up analyses.

Bonferroni-Type Methods

Let $P_1, P_2, \ldots, P_K$ be the observed P values for testing the hypotheses ${H_0}^1, {H_0}^2, \ldots, {H_0}^K$. The **Bonferroni inequality** [15] sets an upper bound on the overall significance level α and produces the simplest endpoint-specific procedure that controls the familywise error rate, α. Here, the familywise error rate means the probability of rejecting incorrectly at least one true null hypothesis. For testing K endpoints, the Bonferroni procedure is performed by dividing α by the number of endpoints (i.e. K). This division of α by K is often called the *Bonferroni adjustment*. Suppose the single hypothesis on the kth endpoint is denoted by

$$ {H_0}^k : \mu_{1k} = \mu_{2k} = \cdots = \mu_{Ik}, \qquad (1) $$

where I is the number of treatments in comparison and $k = 1, \ldots, K$. The test for the kth endpoint is carried out by rejecting ${H_0}^k$ at level α if $P_k \leq \alpha/K$. This is done separately for all K endpoints. Because the test for each endpoint has an α/K probability of making a type I error, the familywise type I error is at most α. The Bonferroni method is classified as a single-step test [9].

Example

Suppose we have eight endpoints and the observed P values from the univariate tests are

$$ \begin{aligned} P_1 &= 0.061, & P_2 &= 0.255, \\ P_3 &= 0.143, & P_4 &= 0.003, \\ P_5 &= 0.048, & P_6 &= 0.001, \\ P_7 &= 0.008, & P_8 &= 0.004. \end{aligned} $$

Using Bonferroni's method, we reject ${H_0}^k$ at level $\alpha = 0.05$ if $P_k \leq 0.05/8 (= 0.0063)$ for $k = 1, \ldots, 8$. So, here we reject ${H_0}^4$, ${H_0}^6$, and ${H_0}^8$ with a 0.05 level of significance. These hypotheses correspond to the fourth, sixth, and eighth endpoints.

The advantage of the classical Bonferroni test is its computational simplicity. In addition it can also be used to construct **confidence** sets. Furthermore, it has good power in detecting real treatment effects in one or a few distinct endpoints. However, it is conservative when the alternative hypothesis for most or all measures of efficacy are uniformly improved and there are no marked differences among endpoints. In 1987, Pocock et al. [17] did a **simulation** study on the performance of the Bonferroni correction in comparing K endpoints between two treatment groups, where K ranges from two to 10 endpoints. The simulated data were based on K-variate normally distributed endpoints, each with known variance, and all K endpoints equicorrelated with correlation ρ. The results showed that the Bonferroni method works well when endpoints are independent. For each number of endpoints, the Bonferroni adjustment displayed

an elevated degree of conservatism as the correlation increases. It works reasonably well provided the pairwise correlation is less than 0.5. The authors concluded that this method works well when the endpoints are at least asymptotically normally distributed with moderate to low correlations. There is no noticeable deterioration in the Bonferroni correction as the number of correlated endpoints increases from two to 10. While this study did not consider K large, it is quite clear that the Bonferroni adjustment procedure will diminish in power if K is large [8].

The classical Bonferroni method uses a factor $1/K$ to account for the possibility of the presence of K true null hypotheses and the rejection of any one of these may cause a type I error. To improve on the power of the classical Bonferroni adjustment, Holm [10] proposes a stepwise rejection Bonferroni test. This procedure is based on the fact that if one null hypothesis is rejected, then there are only $K - 1$ possible true null hypotheses that need protection from type I error. Thus, the factor $1/K$ can be changed to $1/(K - 1)$. Owing to the sequential reduction of the denominator of the factor, Holm's procedure is conventionally known as a step-down improvement of the classical Bonferroni method. In his procedure, the univariate P values are ordered such that $P_{(1)} \leq P_{(2)} \leq \cdots \leq P_{(K)}$, where $H_0{}^{(1)}, H_0{}^{(2)}, \ldots, H_0{}^{(K)}$ are the corresponding null hypotheses. The procedure starts with the smallest P value and rejects $H_0{}^{(1)}$ if the smallest P value, $P_{(1)}$, is less than α/K. Given that $H_0{}^{(1)}$ is rejected, $H_0{}^{(2)}$ will be rejected if $P_{(2)} \leq \alpha/(K - 1)$. Given that $H_0{}^{(2)}$ is rejected, $H_0{}^{(3)}$ will be rejected if $P_{(3)} \leq \alpha/(K - 2)$. Given that $H_0{}^{(j-1)}$ is rejected, $H_0{}^{(j)}$ will be rejected if $P_{(j)} \leq \alpha/(K - j + 1)$, and so forth. One proceeds in this manner until the first time a null hypothesis is accepted, then the procedure stops and the remaining null hypotheses are accepted also. Of course, acceptance of a null hypothesis here means that the null hypothesis is not rejected.

To illustrate Holm's method, we use the observed P values presented in the above example and arrange them in descending order as follows:

Unordered observed P values:

$P_1 = 0.061$, $P_2 = 0.255$,
$P_3 = 0.143$, $P_4 = 0.003$,
$P_5 = 0.048$, $P_6 = 0.001$,
$P_7 = 0.008$, $P_8 = 0.004$.

Ordered observed P values:

$P_{(1)} = 0.001$, $P_{(2)} = 0.003$,
$P_{(3)} = 0.004$, $P_{(4)} = 0.008$,
$P_{(5)} = 0.048$, $P_{(6)} = 0.061$,
$P_{(7)} = 0.143$, $P_{(8)} = 0.255$.

Using Holm's method, we start with $P_{(1)}$:

$P_{(1)} = 0.001 \leq 0.05/8$
$= 0.0063 \longrightarrow$ reject $H_0{}^{(1)}$ and continue,
$P_{(2)} = 0.003 \leq 0.05/7$
$= 0.0071 \longrightarrow$ reject $H_0{}^{(2)}$ and continue,
$P_{(3)} = 0.004 \leq 0.05/6$
$= 0.0083 \longrightarrow$ reject $H_0{}^{(3)}$ and continue,
$P_{(4)} = 0.008 \not\leq 0.05/5$
$= 0.0100 \longrightarrow$ do not reject $H_0{}^{(4)}$ and the remaining hypotheses.

So, we reject $H_0{}^{(1)}$, $H_0{}^{(2)}$, and $H_0{}^{(3)}$ at level $\alpha = 0.05$. These hypotheses correspond to the fourth, sixth, and eighth endpoints.

Although Holm's test involves a slightly more complicated computations than the classical Bonferroni test, it is strictly more powerful than the Bonferroni test, except in some trivial cases. The gain in power depends on the **alternative hypotheses**. This is small if most of the null hypotheses are true. But it may become substantial when there exist many false null hypotheses. Similar to Bonferroni adjustment, Holm's test controls the familywise error rate and it can be applied to any parametric or nonparametric model and always has good power. There are no restrictions on the type of individual tests used, the only requirement being that it is possible to calculate the observed P level for each separate test.

Holm [10] also suggested an interesting extension of his test to the case of applying different weights to different hypotheses. This is useful when there is a known hierarchy of importance among the hypotheses. As before, $P_1, P_2, \ldots, P_K$ are the observed P values for testing the null hypotheses $H_0{}^1, H_0{}^2, \ldots, H_0{}^K$. Suppose $w_1, w_2, \ldots, w_K$ are positive weights indicating the importance of the hypotheses. Greater weights indicate greater importance of the hypotheses. Let $S_k = P_k/w_k$, with $S_{(1)} \leq S_{(2)} \leq \cdots \leq S_{(K)}$. $H_0{}^{(1)}, H_0{}^{(2)}, \ldots, H_0{}^{(K)}$ are the corresponding null hypotheses and $w_{(1)}, w_{(2)}, \ldots, w_{(K)}$ are the corresponding constants. This algorithm starts with the smallest $S_{(1)}$. We reject $H_0{}^{(1)}$ if $S_{(1)} \leq$

$\alpha/(w_{(1)} + w_{(2)} + \cdots + w_{(K)})$. Then, $H_0{}^{(2)}$ is rejected if $S_{(2)} \leq \alpha/(w_{(2)} + w_{(3)} + \cdots + w_{(K)})$, and so on. If we fail to reject the null hypothesis at any step, then the procedure will be stopped and the remaining null hypotheses will not be rejected. This generalized sequential rejective test increases the power for null hypotheses with high values of w_k at the cost of decreasing the power for hypotheses with small values of w_k.

Two important step-up procedures were proposed by Hommel [11] and Hochberg [7]. Both were developed by applying the closure principle [14] to the modified Bonferroni method of Simes [20]. In 1986 Simes provided a level α test under the overall null hypothesis $H_0 = \cap\{H_0{}^k : k = 1, \ldots, K\}$ with the assumption that the endpoints are independent. In the case of investigating mean difference among I treatment groups with K endpoints, H_0 can be written as $\boldsymbol{\mu}_1 = \boldsymbol{\mu}_2 = \cdots = \boldsymbol{\mu}_I$, where $\boldsymbol{\mu}_i = (\mu_{i1}, \mu_{i2}, \ldots, \mu_{iK})$ is a $K \times 1$ vector consisting of the means of the K endpoints for treatment group $i = 1, 2, \ldots, I$. With Simes' procedure, H_0 is rejected if $P_{(j)} \leq j\alpha/K$ for any $j = 1, 2, \ldots, K$. He then showed by simulation that under H_0, the level does not exceed α for a variety of **multivariate normal** and **gamma** test statistics even when the statistics are correlated. In 1988, Hommel [11] extended Simes' procedure to test the significance of K individual endpoints. Hommel's procedure is performed by starting in succession with $m = 1, 2, \ldots, K$ until we find the maximum m that has $P_{(K-m+j)} \geq j\alpha/m$ for $j = 1, \ldots, m$. Suppose we find the maximum m equal to t. Then we reject all $H_0{}^k, k = 1, \ldots, K$, for which $P_k \leq \alpha/t$.

The following example is a demonstration of how to perform Hommel's method.

Unordered observed P values:

$P_1 = 0.061, \quad P_2 = 0.255,$
$P_3 = 0.143, \quad P_4 = 0.003,$
$P_5 = 0.048, \quad P_6 = 0.001,$
$P_7 = 0.008, \quad P_8 = 0.004.$

Ordered observed P values:

$P_{(1)} = 0.001, \quad P_{(2)} = 0.003,$
$P_{(3)} = 0.004, \quad P_{(4)} = 0.008,$
$P_{(5)} = 0.048, \quad P_{(6)} = 0.061,$
$P_{(7)} = 0.143, \quad P_{(8)} = 0.255,$

$m = 1$:
$j = 1\ P_{(8)} = 0.255 > 0.05 \longrightarrow$ continue,

$m = 2$:
$j = 1\ P_{(8)} = 0.255 > 0.05,$
$j = 2\ P_{(7)} = 0.143 > 0.05/2$
$= 0.0250 \longrightarrow$ continue,

$m = 3$:
$j = 1\ P_{(8)} = 0.255 > 0.05,$
$j = 2\ P_{(7)} = 0.143 > 2(0.05)/3 = 0.0333,$
$j = 3\ P_{(6)} = 0.061 > 1(0.05)/3$
$= 0.0167 \longrightarrow$ continue,

$m = 4$:
$j = 1\ P_{(8)} = 0.255 > 0.05,$
$j = 2\ P_{(7)} = 0.143 > 3(0.05)/4 = 0.0375,$
$j = 3\ P_{(6)} = 0.061 > 2(0.05)/4 = 0.0250,$
$j = 4\ P_{(5)} = 0.048 > 1(0.05)/4$
$= 0.0125 \longrightarrow$ continue,

$m = 5$:
$j = 1\ P_{(8)} = 0.255 > 0.05,$
$j = 2\ P_{(7)} = 0.143 > 4(0.05)/5 = 0.040,$
$j = 3\ P_{(6)} = 0.061 > 3(0.05)/5 = 0.030,$
$j = 4\ P_{(5)} = 0.048 > 2(0.05)/5 = 0.020,$
$j = 5\ P_{(4)} = 0.008 \not> 1(0.05)/5 = 0.010 \longrightarrow$ stop.

So, the maximum $m = 4$ and the critical level is $0.05/4 (= 0.0125)$. Comparing all the P values with this critical level, we find P_4, P_6, P_7, and P_8 less than 0.0125. Therefore, we conclude that $H_0{}^4$, $H_0{}^6$, $H_0{}^7$, and $H_0{}^8$ should be rejected at the 0.05 level of significance.

Hochberg [7] also extended Simes' procedure for making inferences on individual hypotheses. His procedure is a step-up sequential rejection procedure. It uses the same adjustment factor as Holm's procedure but Hochberg starts with the largest P value and progressively reduces the factor from 1 to $1/K$. Owing to the sequential increase of the denominator of the factor, Hochberg's approach is conventionally known as a step-up procedure. This procedure rejects the hypothesis $H_0{}^{(k)}$ and all other null hypotheses corresponding to the smaller P values (i.e. $H_0{}^{(k-1)}, H_0{}^{(k-2)}, \ldots, H_0{}^{(1)}$) if $P_{(k)} \leq \alpha/(K - k + 1)$ for $k = 1, 2, \ldots, K$. To perform this procedure we start by looking at $P_{(K)}$, the largest P value; we reject $H_0{}^{(K)}, H_0{}^{(k-1)}, \ldots, H_0{}^{(1)}$ and stop further testing if $P_{(K)} \leq \alpha$. If $P_{(K)} > \alpha$, then we do not reject $H_0{}^{(K)}$ and we consider the second largest P value and reject $H_0{}^{(K-1)}, H_0{}^{(K-2)}, \ldots, H_0{}^{(1)}$ if $P_{(K-1)} \leq \alpha/2$. The procedure continues in this manner until the

first time a hypothesis $H_0^{(k)}$ is rejected. Then we stop the testing and conclude that the hypotheses $H_0^{(k-1)}, H_0^{(k-2)}, \ldots, H_0^{(1)}$ are also rejected. Recall that $P_{(1)} \leq P_{(2)} \leq \cdots \leq P_{(K)}$ so we are rejecting for the $k-1$ null hypotheses with smallest P values.

To illustrate Hochberg's method, we again use the observed P values presented in the above example.

Unordered observed P values:

$P_1 = 0.061, \quad P_2 = 0.255,$
$P_3 = 0.143, \quad P_4 = 0.003,$
$P_5 = 0.048, \quad P_6 = 0.001,$
$P_7 = 0.008, \quad P_8 = 0.004.$

Ordered observed P values:

$P_{(1)} = 0.001, \quad P_{(2)} = 0.003,$
$P_{(3)} = 0.004, \quad P_{(4)} = 0.008,$
$P_{(5)} = 0.048, \quad P_{(6)} = 0.061,$
$P_{(7)} = 0.143, \quad P_{(8)} = 0.255.$

Using Hochberg's method, we start with $P_{(8)}$.

$P_{(8)} = 0.255 > 0.05$
$\longrightarrow$ continue,
$P_{(7)} = 0.143 > 0.05/2 = 0.0250$
$\longrightarrow$ continue,
$P_{(6)} = 0.061 > 0.05/3 = 0.0167$
$\longrightarrow$ continue,
$P_{(5)} = 0.048 > 0.05/4 = 0.0125$
$\longrightarrow$ continue,
$P_{(4)} = 0.008 \leq 0.05/5 = 0.0100$
$\longrightarrow$ reject $H_0^{(4)}$ and the remaining hypotheses.

So, $H_0^{(1)}, H_0^{(2)}, H_0^{(3)}$, and $H_0^{(4)}$ are rejected at the $\alpha = 0.05$ level. These hypotheses correspond to the fourth, sixth, seventh and eighth endpoints in the original unordered hypotheses.

Both of these step-up methods can be used with different types of statistics. Hochberg's procedure is easier to apply than Hommel's. In terms of power, they are both uniformly better than Holm's step-down method and Hommel's procedure is slightly more powerful than Hochberg's procedure [12].

Both Hommel's and Hochberg's methods are able to control the familywise error rate if, under the overall null hypothesis H_0, the original Simes' test can maintain the overall type I error rate close to the nominal significance level, α [12]. It is not clear if they can control the familywise error rates when the original Simes' test does not have the α-level control under H_0.

Rom [18] proposed a method to improve on Hochberg's method. He modifies the critical points of Hochberg's procedure by integrating the joint density functions of the ordered P values and finds the new critical points by solving a recursive equation through iterations. However, the power gained from performing Rom's method is small and probably not worth the increased complexity of computations.

Hochberg & Benjamini [8] took a graphic approach to improve the power of the stepwise procedures due to Holm and Hochberg. It involves plotting the complements of the individual P values (i.e. $q_{(j)} = 1 - P_{(K-j+1)}$) vs. their order (i.e. j). Let $Q_{(j)}$ be the random variable with the observed value equal to $q_{(j)}$. The authors suggested that the set of $Q_{(j)}$s will behave as an ordered sample from a **uniform distribution** over [0, 1] if all null hypotheses are true. Assume m_0 is the number of true null hypotheses. The plot of the observed value $q_{(j)}$ is approximately linear along the line with the slope $1/(m_0+1)$ passing through the origin. The P values corresponding to the false null hypotheses are smaller than the P values corresponding to the true null hypotheses, so the $q_{(j)}$s corresponding to the false null hypotheses will be located on the right-hand side of the plot. The relationship over the left-hand side of the plot should remain approximately linear with the slope $1/(m_0+1)$. On the basis of this relationship, the authors suggested estimating m_0 by fitting an ordinary **least squares** regression line through the smallest $q_{(j)}$s located on the left-hand side of the plot. See [8] for implementation of this procedure.

Normal-Based Methods

A second group of endpoint-specific procedures focus on incorporating the covariance structure of the data into the analysis. This group of procedures requires the test statistics to be multivariate normal distributed with equal variances and a known common correlation coefficient.

Assume the test statistics are K-variate normally distributed with equal correlation ρ. Armitage & Parmar [1] presented a procedure that allows for correlations in the P value adjustment. They suggested an adjusted correction for the minimum P of the

following form:

$$P_{\text{adj}} = 1 - (1 - P_{\min})^{K^x}, \tag{2}$$

where $0 \leq x \leq 1$ and $P_{\min}$ is the minimum P value. $x = 1$ if the K test statistics are independent and $x = 0$ if the K test statistics are fully correlated. The empirical formula for computing x with an arbitrary correlation structure is given in [1]. In application, we find the adjusted P value for each endpoint by replacing $P_{\min}$ with the unadjusted P value and reject $H_0{}^k$ if the adjusted P value of the kth endpoint is less than or equal to the nominal level, α.

James [13] presents another P value adjustment method that allows for the presence of correlations. Her method is based on an approximation derived for multinormal probabilities with equal correlation. Her procedure assumes that the test statistics follow a multivariate normal distribution, or at least are asymptotically normal with equal correlation ρ. The adjusted P value for the minimum per-experiment error rate is defined as

$$\begin{aligned} P_{\text{adj}} &= \Pr(\text{minimum } P \leq p_{\min}) \\ &= 1 - \Pr(\text{all } P_k > p_{\min}) \\ &= 1 - \Pr\left(\bigcap_{k=1}^{K} a \leq Z_k \leq b\right), \end{aligned} \tag{3}$$

where $p_{\min}$ is the smallest of the per-experiment error rates and $(Z_1, Z_2, \ldots, Z_K)$ are standardized multinormal random variables with equal correlation ρ, such that

$$b = \Phi^{-1}\left(1 - \frac{P_{\min}}{2}\right), \qquad a = \Phi^{-1}\left(\frac{P_{\min}}{2}\right)$$

for the two-sided case, and

$$b = \Phi^{-1}(1 - P_{\min}), \qquad a = -\infty$$

for the one-sided case.

The approximation is given in James [13]. Using her approach, we calculate the adjusted correction for each P value and declare significance to the hypothesis corresponding to the P value if the adjusted P value is less than or equal to the nominal level of significance.

James' method improved the Bonferroni-type adjustment in the sense that it can account for the correlation structure of the data. She showed that the adjusted P values derived from her approximation are very close to the actual values obtained from a multivariate normal program [19]. They appear to be better estimates for the true P values than the approximation in [1]. The adjustment can also be used to calculate the **power** of any trial with multiple testing. However, there are some tradeoffs for this improvement in power. They include the increased complexity of calculations and also the requirement of the distributional assumption imposed on the test statistics. Further investigations need to be done to find an error bound for the approximation. Also, it is not clear what is the impact of various heterogeneous correlation structures on the performance of the method, particularly when some of the correlations are negative.

In addition to the P value adjustment methods, normal theory-based hypothesis testing procedures have also been developed. They were originally derived for the purpose of comparing multiple groups, but they can also be used to test multiple endpoints when there are only two treatment groups. Let t_k be the usual t statistic for testing $H_0{}^k$, where $k = 1, \ldots, K$. If $H_0{}^1, \ldots, H_0{}^m$ are true, then the corresponding random variables $T_1, \ldots, T_m$ have Student's m-variate central t distribution with ν df and the associated common correlation ρ (*see* **Multivariate *t* Distribution**). Let $c_m{}' = t_{1-\alpha}(m, \nu, \rho)$ be the upper α point of $\max_{1 \leq k \leq m} T_k$ for $m = 1, \ldots, K$. Bechhofer & Dunnett [2] have compiled extensive tables for the distribution of the maximum of m student t variables under various correlation structures. These tables provide the critical constants $c_k{}'$. In the usual single-step test procedure, $H_0{}^k$ is rejected if $t_k \geq c_k{}'$.

Miller [15] proposed a normal-based step-down procedure in 1966 which was further studied by Naik [16] in 1975 and Marcus et al. [14] in 1976. In 1991, Dunnett & Tamhane [4] presented step-down multiple tests in the unbalanced one-way layouts. In general, one can implement the step-down procedure by ordering the statistics as $t_{(1)} \leq t_{(2)} \leq \cdots \leq t_{(K)}$ and the corresponding hypotheses as $H_0{}^{(1)}, H_0{}^{(2)}, \ldots, H_0{}^{(K)}$. $H_0{}^{(k)}$ is rejected if $H_0{}^{(j)}$ is rejected for $j = k + 1, \ldots, K$ and $t_{(k)} \geq c_k{}'$. In most cases $c_k{}'$ is easy to obtain. They are extensively tabulated for the case of equal correlations [2]. Since $c_k{}' < c_K{}'$ for $k < K$, it is obvious that the step-down procedure is uniformly more powerful than the single-step procedure.

Dunnett & Tamhane [5] introduced a normal-based step-up procedure. The step-up procedure relies

on a different set of critical constants $c_1^*, \ldots, c_K^*$. It will accept $H_0^{(k)}$ if $H_0^{(j)}$ is accepted for $j = 1, \ldots, k-1$ and $t_{(k)} < c_k^*$. The step-up procedure begins by testing the smallest t statistic and working upwards, accepting one hypothesis at a time and stopping by rejecting $H_0^{(k)}, H_0^{(k+1)}, \ldots, H_0^{(K)}$ when $t_{(k)} \geq c_k^*$. The critical constants, c_k^*, are computed recursively based on the analytic approximation of the joint distribution of the ordered P values. The computational algorithm can be found in Dunnett & Tamhane [5]. With a nonnegative correlation coefficient the authors have shown that their step-up method is empirically more powerful than Hochberg's method, and in a numerical study they also achieve higher power than Hommel's method. Although this procedure is quite powerful and also it can control the familywise error rate, it requires that the parameter estimates to be normally distributed with a common variance, which is a known multiple of an unknown σ^2, and known correlations which are equal. The computations of the critical constants turn out to be rather complicated. Also, because of the equal correlation restriction it is not suitable to be used in unbalanced data situations. To resolve this problem, Dunnett & Tamhane [6] extended the step-up procedure in [5] to include unequally correlated estimates. It has been shown by simulations that the familywise error rate of applying this procedure is at most α, and the procedure enjoys a power advantage over the step-down procedure presented in [4]. However, the computations of the critical constants for this step-up method become progressively more difficult for $m > 2$.

Resampling Procedures

Westfall & Young [23] proposed determining the multiplicity adjustments through bootstrap or permutational resampling (*see* **Bootstrap Method**) for dichotomous outcomes data (*see* **Binary Data**). The adjustments through resampling offer improvements over the Bonferroni-type adjustments by incorporating the dependence structures and other distributional characteristics into the analysis. Their distributional setup assumes that there are I treatment groups with n_i subjects per group and the data are represented by $\{\mathbf{X}_{ij}\}$, where $\mathbf{X}_{ij}$ is a vector consisting of the measurements of the K endpoints ($i = 1, \ldots, I$ and $j = 1, \ldots, n_i$). The $\mathbf{X}_{ij}$ are independently and identically distributed as multivariate Bernoulli vectors $\mathrm{MVB}_k(p_i, 1, D_i)$, where D_i denotes a particular probability distribution subject to the constraint that $E(\mathbf{X}_{ij}) = p_i$. They are motivated by the belief that false significances are most likely to occur when the overall null hypothesis H_0 is true (i.e. $p_1 = \cdots = p_I = p$ and $D_1 = \cdots = D_I = D$). Therefore, they suggested computing the adjusted P values of the original tests according to this worst-case scenario.

If one wishes an unconditional analysis, then the adjusted P values will depend on the unknown population parameters p and D. These quantities and the adjusted P values may be estimated using the data and by bootstrap resampling. To implement the procedure, the authors provided the following algorithm. The first step is to compute the unadjusted P values using the test statistics of choice. Then, generate a with-replacement sample from the data. Using only the bootstrap sample, one computes the P values with the same choice of test statistics for calculating the unadjusted P values and notes whether the minimum of the P values from the bootstrap sample is less than or equal to each of the unadjusted P values. The same algorithm will be repeated for a specified number of times and the adjusted P value for the kth endpoint is defined as the proportion of samples for which the minimum of the P values is less than or equal to the unadjusted P value for the kth endpoint.

Suppose M is denoted as the number of bootstrap samples, $P_k^{(i)}$ as the P value for the kth endpoint from the ith bootstrap sample, and $P_{k,\mathrm{unadj}}$ as the unadjusted P value for the kth endpoint observed from the original data. The formula for the adjusted P value for the kth endpoint using the bootstrap approach is given by

$$P_{k,\mathrm{adj}} = \frac{1}{M} \sum_{i=1}^{M} I\left[\min\left(P_1^{(i)}, P_2^{(i)}, \ldots, P_K^{(i)}\right) \leq P_{k,\mathrm{unadj}}\right] \tag{4}$$

where $I[A] = 1$ if event A is true and $I[A] = 0$ if event A is false.

If one is interested in a conditional analysis, then one may obtain the adjusted P values exactly using the technique of Brown & Fears [3]. They suggest reporting the permutational probability of having a P value less than or equal to a given threshold, conditional on the observed marginal frequencies. Using this method, one may obtain the adjusted

P values as the proportion of permutations of the observed vectors $\{\mathbf{X}_{ij}\}$ for which the minimum of the observed P values in a permutation sample is less than or equal to the unadjusted P values. One can calculate the adjusted P values by using the same algorithm described for the bootstrap resampling with the exception that here one generates the random permutations of the observed data and the resampling requires a without-replacement sample.

These resampling techniques are improvements over the Bonferroni-type adjustments in the sense that they are able to account for the dependence structure and discreteness of the data. They are recommended if the goal of the analysis is to isolate particular comparisons from a very large set of comparisons, particularly when many true null hypotheses are expected. The permutation approach tends to be more conservative than the bootstrap approach because the bootstrap analysis approximates the nominal significance levels more closely. As expected, the bootstrap method is more powerful than the permutation method. However, the permutation method is preferred when we cannot assert that the data are multivariate binomial distributed. In this situation the permutation method is valid provided that the subjects have been properly randomized before allocation to treatment groups. In general, the resampling techniques have reasonable power when there are marked departures from the null hypothesis at only a few endpoints. But they become conservative in the case when there are many false null hypotheses.

Westfall & Young [23] show how resampling can be used to compute adjusted P values for multivariate binomial data in a single-step manner. Both Westfall & Young [24] and Troendle [21] give a step-down improvement which does not require any distributional assumptions on the data. Westfall & Young [24] consider a more general hypothesis testing setup such that the hypotheses could come from any set of hypotheses under consideration and P values are used to perform the adjustments. Troendle's step-down resampling procedure focuses more on the hypotheses for testing multiple endpoints between two treatment groups. He argues that in the case when we decided to reject $H_0^{(K)}$ which corresponds to the largest test statistic. If $H_0^{(K)}$ is true, then we have already committed a type I error. Therefore, to control the familywise type I error rate, we should assume $H_0^{(K)}$ is false and delete the component corresponding to $t_{(K)}$ before the evaluation of the next hypothesis $H_0^{(K-1)}$. $t_{(K)}$ is the largest observed test statistic. On the basis of this principle, the following stepwise resampling algorithm is derived for testing the hypotheses. The first step of the algorithm is to order the observed test statistics and hypotheses so that $t_{(1)} \leq \cdots \leq t_{(K)}$ corresponding to $H_0^{(1)}, \ldots, H_0^{(K)}$. Suppose that M resamples, each of size $2N_0$, are used to estimate α_k, which is the significance level for $H_0^{(K-k+1)}$. Using the estimated distribution of $T_{(K-k+1)}^{(K-k+1)}$ from resampling, one can estimate

$$\alpha_k = \Pr_{H_0^{(K-k+1)}} \left[T_{(K-k+1)}^{(K-k+1)} \geq t_{(K-k+1)} \right] \tag{5}$$

where $T_{(K-k+1)}^{(K-k+1)}$ is the largest of the $(K-k+1)$ test statistics corresponding to $t_{(1)}, \ldots, t_{(K-k+1)}$. However, often there are errors in estimating α_k by an estimate based on a finite number of resamples of the data. Therefore, the following estimate is proposed:

$$\alpha_j^* = \frac{1}{M} \sum_{i=1}^{M} I \left[\max_k T_{ki}^* \geq t_{(K-j+1)} \right], \tag{6}$$

where T_{ki}^* is the test statistic of the kth endpoint corresponding to the ith resampled data and $I[A]$ is the indicator function of the event A. The maximum extends over all k corresponding to $t_{(1)}, \ldots, t_{(K-j+1)}$. We generate the kth test statistic in the ith resample where $k = 1, \ldots, K$ and $i = 1, \ldots, M$ and then calculate α_j^* as defined in (6). If $\alpha_j^* \geq \alpha$, then we stop the algorithm and accept the remaining hypotheses $H_0^{(1)}, \ldots, H_0^{(K-j+1)}$. If $\alpha_j^* < \alpha$, then we reject $H_0^{(K-j+1)}$, increment j, and repeat the resampling with the component corresponding to $t_{(K-j+1)}$ deleted.

Troendle [21] has shown in general that his step-down resampling method is asymptotically conservative (i.e. the probability that any type I error is committed is asymptotically bounded above by α). In the case when the univariate tests violate the parametric assumptions, the asymptotic conservative property of this resampling method remains. The adjusted P values obtained by the resampling method are distribution-free no matter what kind of parametric tests are used to obtain the unadjusted P values or test statistics. In other words, it is not necessary to make any parametric assumption on the distributions of the data. From the simulations, the familywise type I error rate of the method has been shown to be very close to the nominal level and the precision improves

with an increasing number of resamples. It provides increased power to reject individual hypotheses when compared with the method of Hochberg [7] except when there are many false null hypotheses. It has also been shown by simulations that this step-down resampling method provides a good approximation to the step-up method of Dunnett & Tamhane [5] when the assumptions of the step-up method are satisfied. But in the case of the presence of unequal correlations, the step-down resampling method performs better than the step-up method described in [5]. It appears that Troendle's step-down resampling method is a relatively better method, especially when the distribution or correlation structure of the data is unknown.

However, the step-down resampling method has been shown to be conservative when there are many false null hypotheses. For this aspect, a step-up permutation method was proposed by Troendle [22], since step-up methods generally have higher power than step-down methods when there are many false null hypotheses. To pursue this issue, Troendle further explored a step-up alternative to handle the multiplicity of inferences for the case of comparing two treatment groups. He introduced a step-up procedure that uses permutational resampling to estimate conditional probabilities so that one can find the critical constants for which the familywise error rate is controlled asymptotically. The form of this step-up resampling procedure takes after the step-up method for normal data proposed by Dunnett & Tamhane [5]. Suppose, for some $1 \le m \le K$, that $H_0{}^{(1)}, \ldots, H_0{}^{(m)}$ are true and $H_0{}^{(m+1)}, \ldots, H_0{}^{(K)}$ are false. The method proceeds by first testing the smallest test statistic, $t_{(1)}$. It sequentially accepts the hypotheses $H_0{}^{(1)}, H_0{}^{(2)}, \ldots$ until $t_{(k)} > c_k^{**}$ for some $k = 1, \ldots, K$. Then the procedure will be stopped and the remaining hypotheses $H_0{}^{(k)}, \ldots, H_0{}^{(K)}$ will be rejected. $\{c_k^{**}\}$ is the set of critical constants that are determined recursively such that

$$\frac{1}{M}\sum_{j=1}^{M} I\left[\left(T_{(1)}^{j(m)} > q_1\right) \cup \left(T_{(2)}^{j(m)} > q_2\right) \cup \cdots \cup \left(T_{(m)}^{j(m)} > q_m\right)\right] \le \alpha, \tag{7}$$

where M is the number of distinct permutations, $m = 1, \ldots, K$, $T_{(l)}^{j(m)}$ is defined as the lth order statistics from the components of the m smallest test statistics $T_{(1)}, \ldots, T_{(m)}$ in the jth permutation, and $I[A]$ is the indicator function for event A. The exact algorithm used to determine the critical constants is quite complex and a detailed explanation is given in [22].

This step-up method enjoys all the benefits as reflected in the step-down resampling. It requires no specific distributional assumptions of the data and it is applicable to any correlation structure. It has been shown by simulations that when the correlation is equal among the endpoints, Troendle's step-up method [22] and Dunnett et al.'s step-up method [5] have a very similar familywise type I error rate as well as power. When the correlation is unequal or unknown, Troendle's step-up permutation method is shown to be slightly more powerful than the other competing procedures through simulation. As expected, the step-up permutation method provides better power than the step-down resampling method when many false null hypotheses exist. The obvious shortcoming of this procedure is the computational complexity in the determination of the critical constants as well as the adjusted P values.

Conclusion

The advantages of the Bonferroni-type methods are simplicity in computations and applicability to data of any distribution, provided the observed P values are available. In general they can control the familywise error rate. However, they do not account for the correlation structure of the endpoints. They may become overly conservative if the tests are highly correlated. The normal-based tests incorporate the correlation structure of the endpoints. Simulations have shown some of them to be slightly more powerful than the Bonferroni-type methods, but the gain in power is quite small. They are also able to control the familywise error rate.

However, despite these advantages, they require a specific distribution of the data, the calculations of the critical constants are rather cumbersome and, so far, for the purpose of testing multiple endpoints, the normal-based tests are only applicable for the case of comparing two groups. Resampling procedures use the resampling techniques to incorporate the correlation structure of the endpoints. They require no specific distributional assumptions of the data and they are applicable to any correlation structure. These methods are shown to be able to have the probability of committing any type I error bounded above by α asymptotically. Through simulation studies, the

resampling methods achieve comparable power to the normal-based methods when the data follow the specified structure as defined in the normal-based methods. But when the distribution of the data is unknown, the resampling methods are slightly more powerful than the normal-based methods. The shortcomings of these methods are the heavy dependence on the computer and that the algorithms to determine the critical constants are quite complicated. For both the normal-based and resampling methods, the step-up procedures generally appear to have more power in detecting the alternative when all or most of hypotheses are false. The step-down procedures are more sensitive to the scenario when only one or a few hypotheses are false.

There does not seem to be an all-round winner among all the methods discussed above. It appears that power of a method is often gained at the expense of increased complexity in computations. Also, the gain in power given the added complexity seems to be very small. On the basis of the consideration of a reasonable balance between computational complexity and power, we recommend Hochberg's method, which is easy to perform and, at the same time, has comparatively good power among the Bonferroni-type methods and in comparison to the normal-based and resampling methods [5, 21, 22].

Multiple Imputation Methods

Missing data occur frequently in biomedical studies. For example, they occur in a survey on people's health (*see* **Surveys, Health and Morbidity**) when some people do not respond to all of the survey questions. Another example is a medical experiment (*see* **Clinical Trials, Overview**) in which some follow-up visits are skipped or some measurements are accidentally not taken.

A common technique for handling missing data is to impute, i.e. fill in, a value for each missing datum. This results in a completed data set, so that standard methods that have been developed for analyzing complete data can be applied immediately. Thus, imputing for missing values followed by using a standard complete-data method of analysis is typically easier than creating specialized techniques to analyze the incomplete data directly. Simplicity of subsequent analyses is an important practical advantage of imputation.

Imputation has other advantages in the context of the production of a data set for general use, such as a public-use file from a health survey. One such additional advantage is that the data producer can use specialized knowledge about the reasons for missing data, including confidential information that cannot be released to the public, to create the imputations. In addition, imputation by the data producer fixes the missing data problem in the same way for all users, so that consistency of analyses across users is ensured. When imputation is not carried out by the data producer, so that each user implements some method for handling missing data, the knowledge of the data producer can fail to be incorporated, analyses are not typically consistent across users, and all users expend resources addressing the missing-data problem.

Although imputation satisfies critical data-processing objectives and can incorporate knowledge from the data producer, single imputation, i.e. imputing one value for each missing datum, fails to satisfy statistical objectives concerning the validity of the resulting **inferences** based on the completed data. Specifically, for validity, the resulting estimates based on the data completed by imputation should be approximately **unbiased** for their population estimates, **confidence intervals** should attain at least their nominal coverages, and tests of **null hypotheses** should not reject true null hypotheses more frequently than their nominal levels. Because a single imputed value cannot reflect any of the uncertainty about the true underlying value, analyses that treat imputed values just like observed values systematically underestimate uncertainty. Thus, imputing a single value for each missing datum and then analyzing the completed data using standard techniques designed for complete data will result in **standard error** estimates that are too small, confidence intervals that fail to attain their nominal coverages, and ***P* values** that are too significant (*see* **Hypothesis Testing**); this is true even if the modeling for imputation is carried out carefully. For example, **large-sample** results in [24] show that for simple situations with 30% of the data missing, single imputation under the correct model followed by the standard complete-data analysis results in nominal 90% confidence intervals having actual coverages below 80%. The inaccuracy of nominal levels is even more extreme in multiparameter problems [22, Chapter 4], where nominal 5% tests can easily have rejection rates of 50% or more when the null hypothesis is true.

For particular estimates in certain situations, techniques have been developed that enable the data analyst to obtain correct estimates of variability from singly-imputed data [17, 31]. These techniques, however, require the data analyst to use nonstandard procedures that must be specially developed for each combination of imputation method and analysis, and they sometimes require the data producer to provide extra information to the data analyst. Thus, in solving one problem associated with single imputation, they lose the critical advantages inherent to imputation.

Multiple imputation [19, 22] is an approach that retains the advantages of single imputation while allowing the data analyst to obtain valid assessments of uncertainty. The basic idea is to impute two or more times for the missing data using independent draws of the missing values from a distribution that is appropriate under the posited assumptions about the data and the mechanism creating missing data. This results in two or more completed data sets, each of which is analyzed using the same standard complete-data method. The analyses are then combined in a simple way that reflects the extra uncertainty due to having imputed rather than actual

data. Multiple imputations can also be created under several different models to display sensitivity to the choice of missing-data model. Recent reviews of work on multiple imputation are given in [23] and [26].

Theoretical Motivation for Multiple Imputation

The theoretical motivation for multiple imputation is **Bayesian**, although the procedure has excellent properties from a frequentist perspective. Examples of publications containing information on the properties of multiple imputation are [5], [9], [11–13], [22, Chapter 4], [24], and [25]. More extensive references can be found in [23] and [30].

Formally, let Q be the population quantity of interest, and suppose the data can be partitioned into observed values, $\mathbf{X}_{\text{obs}}$, and missing values, $\mathbf{X}_{\text{mis}}$. If $\mathbf{X}_{\text{mis}}$ had been observed, then inferences for Q would have been based on the complete-data posterior density $p(Q|\mathbf{X}_{\text{obs}}, \mathbf{X}_{\text{mis}})$. Because $\mathbf{X}_{\text{mis}}$ is not observed, inferences are based on the actual posterior density $p(Q|\mathbf{X}_{\text{obs}})$, which can be expressed as

$$p(Q|\mathbf{X}_{\text{obs}}) = \int p(Q|\mathbf{X}_{\text{obs}}, \mathbf{X}_{\text{mis}}) p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}})\, \mathrm{d}\mathbf{X}_{\text{mis}}. \tag{1}$$

Eq. (1) shows that the actual posterior density of Q can be obtained by averaging the complete-data posterior density over the posterior predictive distribution of $\mathbf{X}_{\text{mis}}$. In principle, multiple imputations are repeated independent draws from $p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}})$. Thus, multiple imputation allows the data analyst to approximate (1) by separately analyzing each data set completed by imputation and then combining the results of the separate analyses.

Analyzing a Multiply Imputed Data Set

The exact computation of the posterior distribution (1) by simulation would require that an infinite number of values of $\mathbf{X}_{\text{mis}}$ be drawn from $p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}})$. This section summarizes simple approximations to (1) that can be used when only a small number of imputations of $\mathbf{X}_{\text{mis}}$ have been drawn. Fortunately, as indicated earlier, these approximations work very well in most practical situations.

Inferences for Scalar Q

Suppose that if the data were complete, inferences for Q would be based on a point estimate $\hat{Q}$, an associated variance estimate $\hat{U}$, and a **normal** reference distribution. When data are missing and there are M sets of imputations for the missing data, the result is M sets of complete-data statistics, say $\hat{Q}_m$ and $\hat{U}_m, m = 1, \ldots, M$.

Rubin & Schenker [24] suggested the following procedure for drawing inferences about Q from the multiply imputed data. The point estimate of Q is the average of the M completed-data estimates,

$$\overline{Q} = \sum_{m=1}^{M} \frac{\hat{Q}_m}{M},$$

and the associated **variance** estimate is

$$T = \overline{U} + (1 + M^{-1})B,$$

where $\overline{U} = \sum_{m=1}^{M} \hat{U}_m/M$ is the average within-imputation variance, and $B = \sum_{m=1}^{M} (\hat{Q}_m - \overline{Q})^2/(M-1)$ is the between-imputation variance. The approximate reference distribution for interval estimates and significance tests is a t distribution (*see* **Student's *t* Distribution**) with degrees of freedom

$$\nu = (M-1)(1 + r^{-1})^2,$$

where $r = (1 + M^{-1})B/\overline{U}$ is the estimated ratio of the between-imputation component of variance to the within-imputation component of variance.

Significance Tests for Multicomponent Q

Consider an estimand $\mathbf{Q}$ with $k > 1$ components, and suppose the goal is to obtain a significance level for a null value of $\mathbf{Q}$, say $\mathbf{Q}_0$. **Multivariate** analogs of the expressions given in the previous section for scalar Q have been derived by Rubin [22, Section 3.4] and Li et al. [13] for the situation in which the complete-data analysis that is applied to each completed data set produces both a point estimate for $\mathbf{Q}$ and an associated variance estimate. Meng & Rubin [16] developed methods for **likelihood-ratio testing** when the available information consists of point estimates and evaluations of the complete-data log likelihood ratio statistic as a function of these estimates and the completed data. Asymptotically, the procedures of Li

et al. [13] and the procedures of Meng & Rubin [16] are equally accurate.

With large data sets and large models, such as in the situation of a multiway **contingency table**, the complete-data analysis might produce only a test statistic and no estimates, unlike the situations considered by Rubin [22, Section 3.4], Li et al. [13], and Meng & Rubin [16]. With such limited information, Rubin [22, Section 3.5] provided initial methods and Li et al. [12] developed improved methods that require only the M complete-data **chi-square** statistics (or equivalently the M complete-data P values) that result from testing a null hypothesis about Q using each of the M completed data sets. These methods are less accurate than methods that use the completed-data estimates.

Creating Multiple Imputations

Ideally, multiple imputations are M independent random draws from the posterior predictive distribution of $\mathbf{X}_{\text{mis}}$ under appropriate Bayesian modeling assumptions. Such imputations are called *repeated imputations* in Rubin [22, Chapter 3]. In practice, approximations are often used and work well.

Modeling Issues

Several important issues arise in the creation of imputation models. These include the criticality of predictive models, explicit vs. implicit models, and ignorable vs. nonignorable models.

An initial modeling issue in creating imputations (see, for example, Little's discussion [14] of single and multiple imputation) is that the predictive distribution for the missing values should be conditional on all observed values. This consideration is particularly important in the context of a public-use data base. Omitting a variable from the imputation model is equivalent to assuming that the variable is not associated with the variables being imputed, at least conditionally given all other variables in the model; imputing under this assumption can result in **biases** in subsequent analyses, with estimated parameters representing conditional association pulled toward zero. Because it is not known which analyses will be carried out by subsequent users of a public-use data base, ideally it is best not to omit any variables from the imputation model. It is usually infeasible, of course, to incorporate every available variable, including **interactions**, into an imputation model, but it is desirable to condition imputations on as many variables as possible and to use subject-matter knowledge to help select those variables that are likely to be used together in subsequent complete-data analyses.

Imputation procedures can be based on explicit models or implicit models, or even combinations (see, for example, [22, Chapter 5] and [26]). An example of a procedure based on an explicit model is stochastic normal **regression** imputation, where imputations for missing values are created by adding normally distributed errors to predicted values obtained from a **least-squares** regression fit. A common type of procedure based on implicit models is hot deck imputation, which replaces the missing values for an incomplete case by the values from a matching complete case, where the matching is carried out with respect to variables that are observed for both the incomplete case and complete cases (*see* **Missing Data Estimation, "Hot Deck" and "Cold Deck"**).

Rather than attempting to match cases exactly in hot deck imputation, sometimes it is useful to define a distance function on the basis of variables that are observed for both complete and incomplete cases and then to impute values for each incomplete case from a complete case that is close with respect to this distance. In practice, the function may not be a mathematical "distance" (i.e. it can be zero without all components exactly matching). When the distance function is the absolute value of the difference between the nonrespondent's and respondent's predicted values of the variables to be imputed, the matching procedure is termed *predictive mean matching* [9, 14, 21, 33]. Hot deck imputation using predictive mean matching on the basis of an explicit prediction model (e.g. normal linear regression) is an example of an imputation procedure that combines aspects of both an implicit method and an explicit method.

The model underlying an imputation procedure, whether explicit or implicit, can be based on the assumption that the reasons for missing data are either ignorable or nonignorable [18]. The distinction between an ignorable and a nonignorable model can be illustrated by a simple example with two variables, X and Y, where X is observed for all cases, whereas Y is sometimes missing. Ignorable models assert that a case with Y missing is only

randomly different from a complete case having the same value of X. Nonignorable models assert that there are systematic differences between an incomplete case and a complete case even if they have identical X values. An important issue with nonignorable models is that because the missing values cannot be observed, there is no direct evidence in the data to address the assumption of nonignorability. It can be important, therefore, to consider several alternative models and to explore a **sensitivity analysis** of resulting inferences to the choice of model. In current practice, almost all imputation models are ignorable; limited experience suggests that in major surveys with limited amounts of missing data and careful design, ignorable models are satisfactory for most analyses (see, for example, [28]).

Incorporating Proper Variability

Multiple imputation procedures that incorporate appropriate variability across the M sets of imputations within a model are called *proper* in [22, Chapter 4], where precise conditions for a method to be proper are also given. Rubin [23] provides more intuitive statements of the conditions, and Meng [15] discusses closely related issues. Because, by definition, proper methods reflect sampling variability correctly, inferences based on the multiply-imputed data are valid from the standard repeated-sampling (i.e. design-based) frequentist perspective.

One important principle related to incorporating appropriate variability is that imputations should be random draws rather than best predictions. Imputing best predictions can lead to distorted estimates of quantities that are not linear in the data, such as measures of variability and **correlation**, and it generally results in severe underestimation of uncertainty and therefore invalid inferences.

For imputations to be proper, the variability due to estimating the model must be reflected along with the variability of data values given the estimated model. For this purpose, a two-stage procedure is often useful, as we now explain. Suppose that a Bayesian predictive distribution for $\mathbf{X}_{\text{mis}}$ has been formulated using a parameter β. Then the posterior predictive density, which appears on the right-hand side of (1), can be expressed as

$$p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}}) = \int p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}}, \beta)\, p(\beta|\mathbf{X}_{\text{obs}})\, \mathrm{d}\beta, \tag{2}$$

where $p(\beta|\mathbf{X}_{\text{obs}})$ is the posterior distribution of β, and $p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}}, \beta)$ is derived from a parametric model for the data (e.g. normal linear regression, **loglinear**). It can be seen from (2) that a draw of a value of $\mathbf{X}_{\text{mis}}$ from its posterior predictive distribution can be obtained by first drawing a value of β from its posterior distribution and then drawing a value of $\mathbf{X}_{\text{mis}}$ conditional on the drawn value of β. Fixing β at a point estimate (e.g. the **maximum likelihood** estimate), say $\hat{\beta}$, across the M imputations and drawing $\mathbf{X}_{\text{mis}}$ from $p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}}, \hat{\beta})$, generally leads to inferences based on the multiply imputed data that are too sharp, as shown, for example, in [22, Chapter 4], [24], and [25].

The two-stage paradigm can be followed in the context of **nonparametric methods** such as hot deck imputation as well as in the context of parametric models with formal posterior distributions for β. The simple hot deck procedure that randomly draws imputations for incomplete cases from matching-complete cases is not proper because it ignores sampling variability owing to the fact that the population distribution of complete cases is not known but rather is estimated from the complete cases in the sample. Rubin & Schenker [24, 26] discuss the use of the **bootstrap** [4] to make the hot deck procedure proper, and call the resulting procedure the *approximate Bayesian bootstrap*, since it approximates the Bayesian bootstrap [20]. The two-stage procedure first draws a bootstrap sample from the complete cases and then draws imputations randomly from the bootstrap sample. Thus, bootstrap sampling from the complete cases before drawing imputations is a nonparametric analog of drawing values of the parameters of the imputation model from their posterior distribution before imputing conditionally upon the drawn parameter values. The bootstrap has also been used in conjunction with parametric models in multiple imputation in an effort to produce imputations that reflect the variability due to estimating the parametric models [3, 9].

Choice of M

Another issue to be discussed when multiple imputations are to be created is the choice of M. This choice involves a trade-off between **simulating** more accurately the posterior distribution (2), as is possible with larger values of M, vs. using a smaller

amount of computing and storage, as occurs with smaller values of M. The effect of the value of M on accuracy depends on the fraction of information about the estimand Q that is missing, a quantity defined in [22, Chapters 3 and 4]. With ignorable missing data and just one variable, the fraction of missing information is simply the fraction of data values that are missing. When there are several variables, however, the fraction of missing information is often smaller than the fraction of cases that are incomplete because of the ability to predict missing values from observed values.

For the moderate fractions of missing information (<30%) that occur with most analyses of data from most large surveys, Rubin [22, Chapter 4] showed that a small number of imputations (say, $M = 3$ or 4) results in nearly fully **efficient estimates** of Q. In addition, Rubin & Schenker [24], Rubin [22, Chapter 4], and Li et al. [13] have shown that if proper multiple imputations are created, then the resulting inferences generally have close to their nominal coverages or significance levels, even when the number of imputations is moderate. A substantial body of work [2, 9, 24, 34], and additional publications cited in [23], supports these claims in practical cases.

Use of Iterative Simulation Techniques

Recent developments in iterative simulation, such as data augmentation [35] and Gibbs sampling [6, 7] (*see* **Markov Chain Monte Carlo**), can facilitate the creation of multiple imputations in complicated parametric models. Consider a joint model for $\mathbf{X}_{\text{obs}}$ and $\mathbf{X}_{\text{mis}}$ governed by a parameter, say θ. The data augmentation (Gibbs sampling) procedure that results in draws from the posterior distribution of θ produces multiple imputations as well. Let $\theta^{(t)}$ and $\mathbf{X}_{\text{mis}}^{(t)}$ denote the draws of θ and $\mathbf{X}_{\text{mis}}$ at iteration t in the Gibbs sample. At iteration $t+1$, a value $\theta^{(t+1)}$ is drawn from $p(\theta|\mathbf{X}_{\text{obs}}, \mathbf{X}_{\text{mis}}^{(t)})$ and then a value $\mathbf{X}_{\text{mis}}^{(t+1)}$ is drawn from $p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}}, \theta^{(t+1)})$. As t approaches infinity, $(\theta^{(t)}, \mathbf{X}_{\text{mis}}^{(t)})$ converges to a draw from $p(\theta, \mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}})$. Thus, for large t, $\mathbf{X}_{\text{mis}}^{(t)}$ is close to a draw from $p(\mathbf{X}_{\text{mis}}|\mathbf{X}_{\text{obs}})$ and can be used as an imputation of $\mathbf{X}_{\text{mis}}$ in a multiple-imputation scheme. Schafer [30] developed **algorithms** that use iterative simulation techniques to multiply imputed data when there are arbitrary patterns of missing data and the missing-data mechanism is ignorable. Such techniques are being considered for use in the 2000 **census** [29] and have been used in other contexts, such as in **National Center for Health Statistics** surveys [32].

Some Recent Applications of Multiple Imputation in Health Care Research

To illustrate settings in which multiple imputation can be useful, brief descriptions of several recent applications of multiple imputation to **health services research** are now given. References to many other examples are given in [23].

Research on Health and Nutrition

Schafer et al. [32] used multiple imputation to handle incomplete observations in the National Health and Nutrition Examination Survey (NHANES) III. Each NHANES is a national survey conducted by the National Center for Health Statistics (NCHS) to assess the health and nutritional status of the US population and important subgroups. The data from NHANES were obtained through household interviews and through standardized physical examinations. The NHANES imputation project is significant because it demonstrates the feasibility of generating proper multiple imputations for a public-use sample survey with many observations and variables, high rates of missingness on several key variables of interest, and various patterns of **nonresponse**.

NHANES III and other NHANES were used in a simulation study conducted by Ezzati-Rice et al. [5] to evaluate the frequentist performance of model-based multiple imputations in NCHS health examination surveys. The simulations were based on a hypothetical population constructed from previous data sets to resemble populations surveyed by NHANES. The hypothetical population contained 17 variables, with both categorical and continuous variables.

From the hypothetical population, 1000 samples, each with missing values and five imputations of the missing values, were generated by a three-step process: (i) **stratified samples** were drawn to mimic some of the characteristics of NHANES sampling designs; (ii) for each generated sample, missing data

patterns were imposed on the sample using an ignorable missing data mechanism that utilized missing data patterns observed in NHANES III; (iii) for each incomplete sample, five imputations of the missing data were generated under a general location model for the complete data, which is popular when there are both categorical and continuous variables.

Ezzati-Rice et al. [5] studied the validity of multiple-imputation interval estimates for population and subdomain means and proportions. Their results indicated that the imputation model was successful in creating valid design-based repeated-sampling inferences. In other words, the interval estimates had at least nominal coverage for a wide range of estimands.

Research on AIDS

Taylor et al. [36] applied multiple imputation in a project whose goal was to estimate the distribution of times from human immunodeficiency virus (HIV) seroconversion to the onset of acquired immune deficiency syndrome (**AIDS**) from a four-year, multicentered **cohort study** of homosexual and bisexual men in the US. The subjects in the study were divided into two cohorts: (i) those men who were already infected with HIV when enrolled in the study (the "seropositives"); and (ii) those men who became infected during the follow-up period (the "seroconverters"). The seropositive cohort presents the difficulty that the times of seroconversion are unknown for its members, whereas the seroconverter cohort presents the difficulty that the dates of diagnosis with AIDS are unknown for most of its members owing to the 4-year follow-up time.

To alleviate these difficulties, Taylor et al. [36] multiply imputed the date of diagnosis with AIDS for the seroconverters who were AIDS-free during the follow-up period, using a failure time regression model (*see* **Survival Analysis, Overview**) that was estimated from the data for the seropositive cohort. The **covariates** in the regression model were chosen so that the time to AIDS diagnosis, given the covariates, could be considered nearly independent of the time since HIV infection. Each data set for the seroconverters that was completed by imputation was analyzed using **Kaplan–Meier estimation** and Greenwood's formula. The completed-data estimates were then combined to obtain an estimate of the distribution of times from HIV seroconversion to AIDS diagnosis. In this example, multiple imputation helped to "extend" the study period, so that estimates and assessments of variability were possible for longer follow-up times.

Research on Malnutrition

In studies of malnutrition, it is of interest to estimate the percentage of children who are short for their ages ("stunted") as well as the percentage of children who are light for their heights ("wasted"), where the comparison is made with a sample of normal, healthy children. Such estimation is difficult when the ages of the children in a study are reported with accuracy only to the nearest year or half-year; this inaccurate age reporting is called *age heaping*.

Heitjan & Rubin [10] considered a data set for a sample of children under 6 years of age from the Dodoma region of Tanzania. To deal with the apparently large amount of age heaping in this data set, Heitjan & Rubin [10] multiply imputed the true ages of the children. Two methods were explored for purposes of sensitivity analysis: (i) a simple procedure in which a child's age was imputed uniformly from an interval determined from the reported age; and (ii) a complex procedure in which the age-heaping process and the true age were modeled simultaneously using the sex, body measurements, and reported age of the child. The resulting estimates displayed some sensitivity to assumptions about whether the ages were rounded or truncated as well as assumptions about the width of the interval within which the ages were heaped to one reported age. The multiple-imputation inferences were, however, more similar to each other than to the inferences obtained using any method based on single imputation, which cannot reflect the proper uncertainty about the missing true ages.

Research on Hip Replacement

Dorey et al. [3] considered data on patients at UCLA Medical Center who had received a total hip arthroplasty. The routine follow-up of each such patient includes evaluations of radiographs to determine whether the prosthesis is loosening. When certain measurements from the radiographs pass a prespecified threshold, the prosthesis is considered to be at increased risk of loosening. A patient who is past this threshold at a follow-up visit frequently did not reach

this threshold by the previous visit. Thus, the time at which the threshold has been crossed is known only to be between two time points, a phenomenon known as *interval censoring*.

A standard practice for dealing with interval censoring has been to set each unknown value of the threshold-crossing time equal to the right endpoint of the known interval that contains it. Dorey et al. [3] compared this practice with approaches that multiply impute the threshold-crossing time within the interval, including a method that uses the radiographic measurements at the endpoints of the interval to predict when during the interval the threshold had been crossed. It was found that subsequent analyses were sensitive to whether imputations were created by the standard practice, or from a distribution over the interval.

Research on Drinking Behavior

Glynn et al. [8] examined data from the Normative Aging Study, a longitudinal study of community-dwelling men conducted by the US Department of Veterans affairs in Boston. Part of the study was a survey on drinking behavior. A large fraction of the men surveyed provided essentially complete information, whereas for a smaller fraction there was background information available but no information on drinking behavior. Because drinking behavior is a sensitive subject, there was concern that such nonresponse might be nonignorable.

A subsequent survey collected information on drinking behavior from about one-third of the prior nonrespondents. Glynn et al. [8] used this information to multiply impute data on drinking for the remaining nonrespondents, under the assumption that given this new information as well as the background information that had been collected previously, nonresponse was now ignorable. It was found that inferences about the effect of retirement status on drinking behavior (adjusting for age) were very sensitive to whether the multiply-imputed data were used, or, rather, only the data for the initial respondents to the survey were used.

Available Software for Multiple Imputation

There is currently only a limited amount of software for generating multiple imputations under multivariate complete-data models and for analyzing multiply imputed data sets (i.e. completing the data sets, running the complete-data analyses, and combining the complete-data outputs), but the situation appears to be improving rapidly. For generating imputations, software to implement the methodology developed in [30] has been written for the **S-PLUS** statistical package and is freely available on the **internet**. This software, which will also be expanded and incorporated into S-PLUS as a commercial add-on module to the base S-PLUS software, includes programs for multiple imputation in the contexts of incomplete **multivariate normal** data, incomplete categorical data, and incomplete data under the general location model allowing both categorical and multivariate normal variables. These programs have been used to generate imputations for NHANES III [32] and for several other multiple imputation projects. For analyzing multiply imputed data sets, a suite of programs for the Stata statistical package has been developed by J. Barnard and will be freely available on the Internet.

More software for generating multiple imputations and for analyzing multiply imputed data sets should be shortly available. Several packages, both commercial and freeware, are currently under development for generating imputations, e.g. M by J. Barnard, C. Liu, and D.B. Rubin and software within HERMES [1]. A project is also under way to develop multiple-imputation analysis software for SAS (*see* **Software, Biostatistical**).

Multiple Linear Regression

Multiple linear regression represents a generalization, to more than one explanatory variable, of the method of analysis known as **simple linear regression**. The term **"regression"** was first introduced by **Galton** [5, p. 246], who used it to characterize a tendency towards mediocrity (i.e. more average) observed in the offspring of parent seeds. Pearson & Lee [7] also described the relationship between the heights of father–son pairs as a regression, concluding that the estimated slope of 0.516 provided confirmation of Galton's "law of universal regression".

Today, Galton's meaning of the term regression is largely forgotten. In current usage, regression refers to the body of statistical methods used to characterize, quantitatively, the relationship between a **response** (dependent, outcome) variable, Y, which varies randomly, and one or more **explanatory** (independent, predictor) variables, $X_1, \ldots, X_k$. The adjective "multiple" indicates that, initially, at least two explanatory variables are involved in the modeling exercise. The values of the explanatory variables are assumed to be known, or under the control of an investigator. However, in many applications the observed values of $X_1, \ldots, X_k$ are also unknown, and may be observed concurrently with Y. We assume that any inherent variation in the measurement of a particular X_j, $j = 1, \ldots, k$, can be ignored. If this is not the case, we recommend the use of methods that are appropriate when there is measurement error in one or more explanatory variables (*see* **Errors in Variables**). The individual explanatory variables may be nominal (e.g. gender), categorical (e.g. different types of disease), ordered categorical (e.g. tumor grade), or interval or continuous (e.g. forced expiratory volumes) (*see* **Measurement Scale**). Multiple linear regression involves finding the best-fitting surface that relates $\mathrm{E}(Y|X_1, \ldots, X_k)$, the mean value of Y given values of $X_1, \ldots, X_k$, and $X_1, \ldots, X_k$, using an equation with a suitable functional form, such as

$$\mathrm{E}(Y|X_1, \ldots, X_k) = \beta_0 + \beta_1 X_1 + \cdots + \beta_k X_k. \quad (1)$$

As written, (1) characterizes the mean value, $\mathrm{E}(Y|X_1, \ldots, X_k)$, as a linear (planar) function of $X_1, \ldots, X_k$. In a sense, this may be an artifice of notation, since X_1 could represent the square root of weight in kg, i.e. $X_1 = \sqrt{W}$. Likewise, Y could be the logarithm of systolic blood pressure (SBP) in mm Hg, i.e. $Y = \log(\mathrm{SBP})$, where SBP is the outcome variable originally measured. Thus, the *linear* aspect of regression does not indicate that the model linking $\mathrm{E}(Y|X_1, \ldots, X_k)$ and $X_1, \ldots, X_k$ is necessarily a straight-line (linear) function of the explanatory variables. Rather, the average response, $\mathrm{E}(Y|X_1, \ldots, X_k)$, is a linear function of the $k + 1$ unknown parameters $\beta_0, \beta_1, \ldots, \beta_k$. The model equation $\mathrm{E}(Y|Z) = \beta_0 + \beta_1 Z + \beta_2 Z^2$ is a special case of (1) with $X_1 = Z$ and $X_2 = Z^2$, and represents the multiple linear regression of Y on Z involving a quadratic dependence between the average response, $\mathrm{E}(Y|Z)$, and the explanatory variable, Z.

Whatever the functional form of the regression model, the objectives of linear regression are:

1. to determine whether Y and one or more of the explanatory variables are associated in some systematic way, and/or
2. to estimate or predict the value of Y, or its mean, corresponding to known values of a selected subset of $X_1, \ldots, X_k$.

The analysis is based on estimates of the $k + 1$ unknown parameters, $\beta_0, \beta_1, \ldots, \beta_k$, and their statistical properties when certain assumptions concerning the randomly varying responses, Y, are thought to be valid. The estimates of these parameters, which are known as regression coefficients, are derived from data – $n(k + 1)$-tuples $(X_{1i}, \ldots, X_{ki}, Y_i)$, $i = 1, \ldots, n$ – using the classical method of **least squares**. However, before fitting a linear regression model to data, it is wise to examine individual scatterplots of Y vs. $X_1, \ldots, X_k$ to ensure that the functional form of the proposed relationship is sensible (*see* **Graphical Displays**).

Figure 1 shows six such scatterplots for measurements of oxygen uptake, Y, in milliliters per kilogram of body weight per minute vs. age, X_1, in years, weight, X_2, in kilograms, time, X_3, in minutes required to run 1.5 miles, resting pulse, X_4, in beats per minute, running pulse, X_5, in beats per minute, and maximum pulse, X_6, recorded while running, in beats per minute. The measurements were obtained from 31 subjects – 21 men ($X_7 = 1$) and 10 women ($X_7 = 0$) – who participated in a physical fitness workshop. For these data the notion that

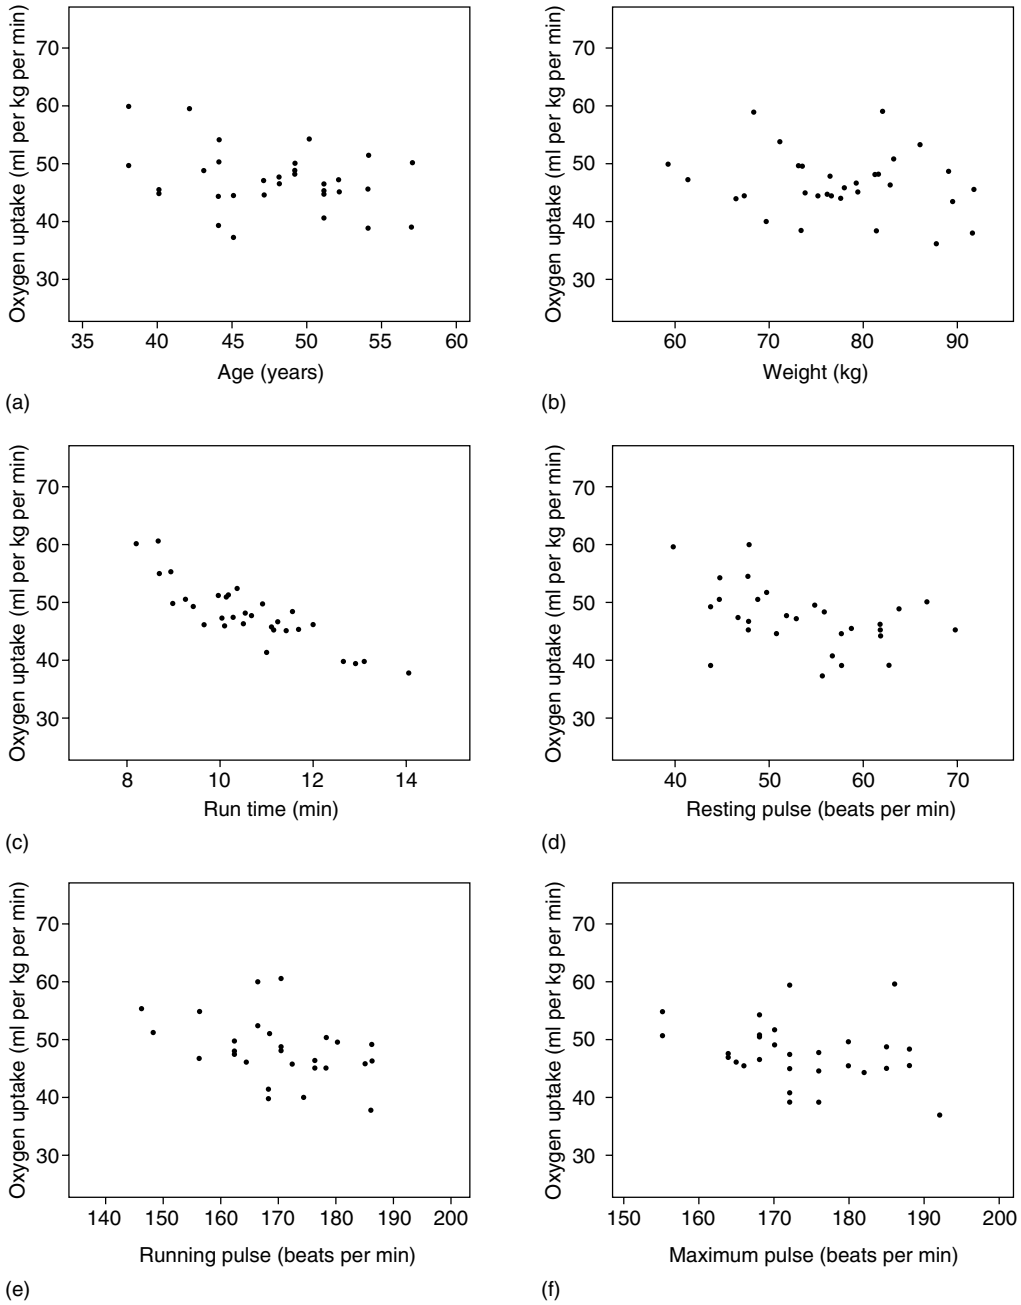

Figure 1 Scatterplots of oxygen uptake measurements, Y, vs. six explanatory measurements for a sample of 31 subjects: (a) Y vs. age; (b) Y vs. weight; (c) Y vs. running time; (d) Y vs. resting pulse; (e) Y vs. running pulse; (f) Y vs. maximum pulse

average oxygen uptake depends, systematically, in a roughly linear fashion on one or more of these potential explanatory variables seems plausible.

Least Squares Estimation

Every linear regression model consists of a systematic component – the model equation, such as that specified in (1) – and a **residual** (random, error) component, ε. Equating the sum, $\beta_0 + \beta_1 X_1 + \cdots + \beta_k X_k + \varepsilon$, to Y defines the regression equation for the response. The residual, $\varepsilon = Y - \beta_0 - \beta_1 X_1 - \cdots - \beta_k X_k$, represents the amount that an observed value of Y deviates from the predicted mean, $\beta_0 + \beta_1 X_1 + \cdots + \beta_k X_k$. Few $(k+1)$-tuples $(X_{1i}, \ldots, X_{ki}, Y_i), i = 1, \ldots, n$, in a given set of data are likely to lie on the predicted plane. The method of least squares identifies the unique values of $\beta_0, \ldots, \beta_k$ that minimize the average of the squared residuals. The details of the calculations, which are readily handled by almost any software package that includes statistical procedures, are best summarized in terms of matrix notation. Let $\mathbf{X}$ denote the data matrix, sometimes called the design matrix:

$$\begin{pmatrix} 1 & X_{11} & X_{21} & \ldots & X_{k1} \\ 1 & X_{12} & X_{22} & \ldots & X_{k2} \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ 1 & X_{1n} & X_{2n} & \ldots & X_{kn} \end{pmatrix}$$

Each row in $\boldsymbol{X}$ represents the data obtained from a case (study unit or subject), and each column corresponds to an explanatory variable; the column of 1s is usually inserted automatically by the statistical software, and corresponds to the constant or intercept term, β_0, unless the user specifically chooses to omit it from the assumed model. If $\boldsymbol{Y}$ denotes a column vector consisting of the corresponding response measurements, $Y_1, \ldots, Y_n$, then the least squares estimator of the column vector, $\boldsymbol{\beta}$, with entries $\beta_0, \beta_1, \ldots, \beta_k$ is

$$\hat{\boldsymbol{\beta}} = (\boldsymbol{X}'\boldsymbol{X})^{-1}\boldsymbol{X}'\boldsymbol{Y}. \qquad (2)$$

This formula presupposes that the matrix $\mathbf{X}'\mathbf{X}$ is nonsingular, i.e. that the $k+1$ simultaneous equations summarized in the single, least squares vector equation $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta}$ have a unique solution in the $k+1$ unknowns, $\beta_0, \ldots, \beta_k$. When this is not the case, most software packages provide the user with a suitable warning of problems encountered in evaluating $\hat{\boldsymbol{\beta}}$. The equation of the estimated regression of Y on $X_1, \ldots, X_k$ is

$$\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 X_1 + \cdots + \hat{\beta}_k X_k.$$

To obtain estimates of $\hat{\beta}_0, \ldots, \hat{\beta}_k$, we need to make the minimal least squares assumptions that the residuals, $\varepsilon_1, \ldots, \varepsilon_n$, are uncorrelated and have a mean value of 0 and constant variance, σ^2. We use the estimated residuals,

$$\hat{\varepsilon}_i = Y_i - \hat{Y}_i = Y_i - \hat{\beta}_0 - \hat{\beta}_1 X_{1i} - \cdots - \hat{\beta}_k X_{ki}, \quad i = 1, \ldots, n,$$

to estimate σ^2. The formula

$$s^2 = \hat{\sigma}^2 = \frac{1}{n-k-1}\sum_{i=1}^{n} \hat{\varepsilon}_i^2,$$

which involves $\sum_{i=1}^{n} \hat{\varepsilon}_i^2$, the estimated residual sum of squares, emphasizes that $k+1$ parameters, $\beta_0, \ldots, \beta_k$, are estimated; the divisor, $n - (k+1) = n - k - 1$, is known as the residual **degrees of freedom** (df). Adoption of the additional assumption that the residuals are normally distributed leads to various statistical procedures that we discuss subsequently. First, however, we examine linear regression as an explanation for the observed variability in the response, Y.

Partitioning the Variability in Y

In simple linear regression, the use of a single explanatory variable to model $\mathrm{E}(Y|X)$ provides two sources for the observed variability in Y – variation due to changes in X and hence in $\mathrm{E}(Y|X)$, and residual variation in values of Y that have the same X value and hence the same mean. In multiple linear regression, each additional explanatory variable incorporated into the model for $\mathrm{E}(Y|X_1, \ldots, X_k)$ represents an additional, potential source for the observed variability in the response. Since the total variation in Y is fixed, and equal to $\sum_{i=1}^{n}(Y_i - \overline{Y})^2$, the inclusion of additional explanatory variables in the model for the mean value of Y necessarily means that the magnitude of the estimated residual variation – the estimated residual sum of squares, $\sum_{i=1}^{n} \hat{\varepsilon}_i^2$ – will decrease. Consequently, the

estimated value of σ^2 tends to decrease also, as additional explanatory variables are added to the model for the mean response. For example, in the regression of oxygen uptake on the explanatory variables $X_1, \ldots, X_7$, Table 1 shows that adding age, running pulse, maximum pulse, gender, and weight to successively more complex models involving running time and all the previously used explanatory variables results in monotonically smaller estimates of σ.

However, when resting pulse is added to the previous model, the value of s increases, even though the model sum of squares increases (and hence the residual sum of squares decreases) by 0.3. The change in the model sum of squares associated with adding resting pulse to the previous model is marginal at best. Clearly, knowing a subject's age, for example, in addition to knowing the time he or she takes to run 1.5 miles, is informative in predicting that subject's oxygen uptake. However, the same subject's resting pulse does not provide important information about what his or her oxygen uptake is likely to be when the values of running time, age, running pulse, maximum pulse, gender, and weight have already been used to predict oxygen uptake.

It can be shown that the partitioning of the variability in Y is represented in the equation

$$\sum_{i=1}^{n}(Y_i - \overline{Y})^2 = \sum_{i=1}^{n}(\hat{Y}_i - \overline{Y})^2 + \sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2,$$

which is alternately described by the relationship

$$\text{total sum of squares} = \text{model sum of squares} + \text{residual sum of squares.}$$

The partitioning that corresponds to any particular model equation is usually summarized in an **analysis of variance** (ANOVA) table, such as the one corresponding to the example shown in Table 2.

Table 2 ANOVA table corresponding to the regression of oxygen uptake on the explanatory variables running time, age, running pulse, maximum pulse, gender, and weight for a sample of 31 subjects

Source	SS	df	MS	F ratio
Model	729.1	6	121.52	23.8
Residual	122.3	24	5.10	
Total	851.4	30		

The ratio of the model sum of squares to the total sum of squares is called R^2, and represents the proportion of the observed variability in Y that is accounted for by modeling the mean response for Y as the assumed function of the explanatory variables in the model equation for $\mathrm{E}(Y|X_1, \ldots, X_k)$.

Interpreting the Estimated Regression Coefficients

If two values of one of the explanatory variables, say X_j, differ by one unit, then the corresponding values of the model equation differ by β_j, provided the values of all the other explanatory variables in a model equation remain the same. Therefore, $\hat{\beta}_j$ represents the estimated change in the mean response associated with a unit increase in the corresponding explanatory variable, provided the values of $X_1, \ldots, X_{j-1}, X_{j+1}, \ldots, X_k$ do not change. Similar interpretations apply to each of the regression coefficients, $\beta_i, i = 1, \ldots, k$, in any postulated regression model similar to (1). Of course, each estimated coefficient and its interpretation are only applicable within the range of values of the corresponding explanatory variable that was used in fitting the linear regression model.

The value β_0 represents the mean response when all the explanatory variables in the regression model are equal to 0. In most cases, this mean response will

Table 1 Successive partitions of the observed variability in oxygen uptake measurements into the systematic (model) and residual components, as a result of incorporating additional explanatory variables in the model equation

	Subscripts of explanatory variables in the model equation for $\mathrm{E}(Y)$						
	3	1,3	1,3,5	1,3,5,6	1,3,5,6,7	1,2,3,5,6,7	1,2,3,4,5,6,7
Model	632.9	650.7	690.6	712.5	723.1	729.2	729.5
Residual	218.5	200.7	160.8	138.9	128.3	122.2	121.9
Residual df	29	28	27	26	25	24	23
s	2.74	2.68	2.44	2.31	2.27	2.26	2.30

be of no interest to the investigator, or may not belong to the range of values of $X_1, \ldots, X_k$ used in fitting the model to data. Armitage & Berry [1, pp. 313–314] show that $\hat{\beta}_0$ is equal to $\overline{y} - \hat{\beta}_1\overline{x}_1 + \cdots + \hat{\beta}_k\overline{x}_k$. This result leads to an alternative form for the fitted model, namely

$$\hat{Y} = \overline{y} + \hat{\beta}_1(X_1 - \overline{x}_1) + \cdots + \hat{\beta}_k(X_k - \overline{x}_k),$$

which reveals that the estimated mean response when $X_j = \overline{x}_j$, $j = 1, \ldots, k$, is simply the sample mean of Y. More than likely, this estimate will have a scientific meaning that an investigator can interpret sensibly.

If a regression model containing X_1, X_3, and X_5 is fitted to the oxygen uptake data discussed previously, the estimates of β_1, β_3, and β_5 are -0.26, -2.83, and -0.13, respectively. From these data we conclude that 2.83 ml per kg of body weight per min is the estimated decrease in mean oxygen uptake associated with a 1 min increase in the time that a subject takes to run 1.5 miles, provided age and running pulse are unchanged. Likewise, 0.26 ml per kg of body weight per min is the estimated decrease in mean oxygen uptake associated with a one-year increase in age, provided running time and running pulse do not change. At an age of $\overline{x}_1 = 27.7$ years, a running time for 1.5 miles of $\overline{x}_3 = 10.6$ min, and a running pulse of $\overline{x}_5 = 170$ beats per min, the estimated mean oxygen uptake among these subjects is $\overline{y} = 47.4$ ml per kg of body weight per min.

Of course, with seven potential explanatory variables, we require some systematic way of determining which of the $2^7 = 128$ possible models involving $X_1, \ldots, X_7$ represents the most satisfactory summary of the observed data. Various model or explanatory **variable selection** strategies have been developed. Some strategies depend only on the minimal, least squares assumptions, while others rely on the more powerful, and therefore more restrictive, additional premise that $Y_1, \ldots, Y_n$ are normally distributed. In the following section we describe a method of winnowing the set of all possible regression models involving the explanatory variables $X_1, \ldots, X_k$ into a shortlist of two or three, based solely on the least squares requirements of uncorrelated residuals with a common mean of 0 and constant variance represented by σ^2. Thereafter, we introduce the normal theory assumptions, and consequent methods of statistical inference, that provide a basis for differentiating among alternatives on the shortlist of candidate models for the data.

Identifying Good Candidate Models Based on all Possible Subsets

Only the advent of modern, high-speed computing, and the widespread availability of carefully written statistical software, has made the use of this approach to model selection feasible for many users. We do not intend to provide any details concerning the actual calculations involved, assuming that the interest of readers is focused elsewhere. It suffices to state that the result of the calculations is a table of all possible models, or perhaps a subset of all possible models, in which each candidate for the shortlist is identified by the list of explanatory variables it contains and the values of one or more criteria to use in comparing various candidates. Such a table is usually organized according to the number of explanatory variables used. For the oxygen uptake example, there is one model containing none of $X_1, \ldots, X_7$, seven possible models consisting of just one explanatory variable, 21 involving a pair of variables, 35 that employ three variables, a further 35 using a total of four of the k Xs, another 21 that depend on five explanatory variables, an additional seven that omit exactly one of X_1 through X_7, and one so-called full model that consists of all seven explanatory variables.

Three distinct but related numerical criteria are generally used to rank candidate models involving the same number of explanatory variables, and also to distinguish among the best models involving different numbers of explanatory variables. These are: (i) $R^2(p)$, (ii) $s^2(p)$, and (iii) **Mallow's C_p statistic** [6]. The dependence of each of these quantities on the variable p emphasizes that the value obtained changes according to p, the number of explanatory variables in the candidate model, as well as the choice of the particular subset of p explanatory variables from the full set of k Xs.

We noted previously that each time an additional explanatory variable is added to a model previously fitted, the model sum of squares increases, and hence the residual sum of squares decreases. Since R^2 is the ratio of the model sum of squares to the total

sum of squares, $R^2(p)$ will increase as p increases. In general, $s^2(p)$ decreases, although, as we have already seen in the example, the value may achieve a minimum for some value of $p < k$. Like $s^2(p)$, the C_p statistic usually decreases initially as p increases, although it is common that the value of C_p is minimized for some $p < k$. Models that are candidates for the shortlist typically have values of C_p that approach p. For the example discussed in this article, Table 3 provides a shortlist of two candidate models for each value of p, and summarizes the values of $R^2(p)$, $s^2(p)$, and C_p that were used to select these candidate models for further consideration.

To distinguish further among the various possibilities, we require statistical procedures that allow us to determine whether or not the contributions that particular explanatory variables make to a given model are important when compared with $\hat{\sigma}$, the estimated residual variability for observations.

Statistical Inference in Multiple Linear Regression

We assume that the goal in multiple linear regression modeling is to identify a fitted model that provides reasonably precise estimates of the mean response using a parsimonious set of explanatory variables. If we also assume that the residuals, $\varepsilon_1, \ldots, \varepsilon_n$, are normally distributed, the estimators of $\beta_0, \ldots, \beta_k$ have normal **sampling distributions**. Estimated **standard errors** (est se) for $\hat{\beta}_0, \ldots, \hat{\beta}_k$ are routinely produced by most computing packages. For each explanatory variable included in the model equation, the ratio of the difference, $\hat{\beta}_j - \beta_j$, to its corresponding estimated standard error follows a **Student's *t* distribution** with $n - (k + 1) = n - k - 1$ df, where k corresponds to the number of explanatory variables in the fitted model under consideration. From these results, **hypothesis tests** and/or **confidence intervals** for $\beta_0, \ldots, \beta_k$ can be evaluated. These tools will allow us to determine whether or not the association between Y and a particular explanatory variable, X_j, in a given fitted model is real ($\beta_j \neq 0$).

The same assumptions also lead to the result that the sampling distribution of $\overline{Y}$ is normal, and the corresponding estimated standard error is $s/\sqrt{n}$, where $s^2 = \hat{\sigma}^2$.

A test of the null hypothesis, $H_0 : \beta_j = 0$, is routinely used to assess the significance of the regression with respect to the explanatory variable X_j, i.e. to determine whether the data constitute statistical evidence of an association between Y and X_j. This test can be based either on the ratio $\hat{\beta}_j$/est se $(\hat{\beta}_j)$, which has a Student's t distribution with $n - k - 1$ df, or on $[\hat{\beta}_j/\text{est se } (\hat{\beta}_j)]^2$, which has an ***F* distribution** with 1 and $n - k - 1$ df.

Table 3 Shortlists of candidate models involving p explanatory variables for the regression of 31 oxygen uptake measurements on age, X_1, weight, X_2, running time, X_3, resting pulse, X_4, running pulse, X_5, maximum pulse, X_6, and gender, X_7

p	Explanatory variables included in the model equation	Corresponding values of $R^2(p)$	$s^2(p)$	C_p
1	X_3	0.743	7.53	14.1
	X_5	0.159	24.71	108.0
2	X_1, X_3	0.764	7.17	12.8
	X_3, X_5	0.761	7.25	13.3
3	X_1, X_3, X_5	0.811	5.96	7.3
	X_3, X_5, X_6	0.810	5.99	7.5

With respect to the example, Table 3 indicates that good models involving three, four, or five explanatory variables all include running time, X_3, running pulse, X_5, age, X_1, and one or both of maximum pulse, X_6, and gender, X_7. Table 4, part (a), summarizes the results of fitting a model that contains all five explanatory variables. Neither the regression coefficient for maximum pulse nor that for gender is significantly different from 0; however, the significance levels (*see* ***P*** **Value**) corresponding to coefficients associated with the remaining three explanatory variables are all less than 0.05. These results suggest that, for the oxygen uptake data, we probably want to consider a model that involves running time, running pulse, and age, but perhaps only one of the variables gender or maximum pulse. Table 4, part (b), summarizes the results of fitting the two models that involve running time, running pulse, age, and either maximum pulse or gender. Based on these tabulated results, we conclude that the contribution of either

Table 4 Results of fitting various multiple linear regression models to the measurements on oxygen uptake (Y)

(a) Model involving age, X_1, running time, X_3, running pulse, X_5, maximum pulse, X_6, and gender, X_7

Explanatory variable	Estimated regression coefficient	Estimated standard error	Student's t statistic	Significance level
X_1	−0.200	0.094	−2.137	0.04
X_3	−2.872	0.342	−8.406	$<10^{-4}$
X_5	−0.354	0.115	−3.071	0.01
X_6	0.206	0.139	1.485	0.15
X_7	1.919	1.338	1.434	0.16

(b) Two models involving only four explanatory variables

Explanatory variable	Estimated regression coefficient	Estimated standard error	Student's t statistic	Significance level

maximum pulse or gender in predicting the mean oxygen uptake is marginal, once we have used the information provided by a subject's running time, running pulse, and age. If, for the sake of model **parsimony**, we decide to select as a final model one involving just the three common explanatory variables running time, running pulse, and age, then we obtain the estimated regression coefficients and corresponding estimated standard errors given in Table 4, part (c). The values of R^2 and s^2 for this model (see Table 3) are 0.811 and 5.96, respectively, and the equation of the fitted model is

$$\hat{Y} = 111.72 - 0.256X_1 - 2.825X_3 - 0.131X_5. \quad (3)$$

The individual 95% confidence intervals for β_1, β_3, and β_5 are $(-0.45, -0.06)$, $(-3.56, -2.09)$, and $(-0.23, -0.03)$, respectively. For $\overline{Y}$, the corresponding interval estimate is (46.5, 48.3) ml of oxygen per kg of body weight per min.

Automatic Model Selection

Software packages frequently offer automatic methods of selecting variables for a final regression model from a list of candidate variables. There are three typical approaches, usually known as forward selection, backward elimination, and stepwise regression. These methods rely on significance tests known as partial F tests (*see* **Analysis of Variance**) to select an explanatory variable for inclusion in or deletion from the regression model. The forward selection approach begins with an initial model that contains only a constant term, i.e. $\mathrm{E}(Y|X_1, \ldots, X_k) = \beta_0$, and successively adds explanatory variables to the model from the set $X_1, \ldots, X_k$ until the pool of candidate variables remaining contains no variables that, if added to the current model, would contribute information that is statistically important concerning the mean value of the response. The backward elimination method begins with an initial model that contains all explanatory variables in the list, and then identifies the single variable that contributes the least information concerning the mean value of the response, i.e. results in the smallest decrease in the model sum of squares. If a partial F test identifies that this contribution is not statistically significant, then the variable is eliminated from the current model. Successive iterations of the method result in a "final" model from which no variable can be eliminated without adversely affecting, in a statistical sense, the predicted value of the mean response.

The stepwise regression method of variable/model selection combines elements of both forward selection and backward elimination. The initial model for stepwise regression is one that contains only a constant term. Subsequent cycles of the approach involve first the possible addition of an explanatory variable to the current model, followed by the possible elimination of one of the variables included in the newly augmented model. Both steps in the cycle rely on suitable partial F statistics. Succeeding cycles follow the same pattern until the set of variables in the model stabilizes, at which time a "final" model is declared.

The results produced by any of these, or most other, methods of automatic selection depend crucially on various user-selected adjustments for each procedure. For example, in forward selection the user has to specify (or use the default value of) a significance level to enter (SLE). This adjustment represents a threshold value that determines whether or not a candidate explanatory variable is eligible to be added to the current model. For backward elimination, there is a corresponding significance level to stay (SLS) – a threshold value that determines whether or not an explanatory variable is a candidate for removal from the current model. In stepwise regression, the user needs to specify both an SLE and an SLS. For example, if forward selection is used for the oxygen uptake data with a value of 0.05 for SLE, the final model involves age X_1, running time, X_3, and running pulse, X_5. When $\mathrm{SLE} = 0.10$, the final model selected by forward selection also includes maximum pulse, X_6. The use of forward selection with the default value of SLE (0.50) built into one widely used software package results in a final model consisting of all the explanatory variables except resting pulse X_4.

A separate factor that influences the results of all automatic methods of model selection in an unpredictable fashion is the underlying **correlation** structure of the data. If two explanatory variables are strongly correlated with one another, it is highly unlikely that any of the usual automatic methods of model selection will produce a final model that includes both variables. This outcome is appropriate, since curious statistical pathologies are likely to occur if two highly correlated, and therefore nearly

collinear, variables are simultaneously included in a regression model. However, the final model that automatic selection produces hides the fact that another line of modeling exists based on the second of the two highly correlated variables, and the end result of pursuing that direction might be equally satisfactory, statistically or scientifically, or perhaps even better.

In summary, automatic methods of model or variable selection provide no guarantee of identifying a "best" model in any overall scientific sense. Consequently, we recommend that investigators treat the results of an automatic approach to model selection with a healthy measure of skepticism. In particular, if there is no indication that the final model, no matter how it was arrived at, has been subjected to the diagnostic scrutiny outlined in the next section, then there are sound statistical grounds for questioning any conclusions based on the results of the model-fitting process.

Model Diagnostics

For simplicity, we assume that the result of a thoughtful, comprehensive model-fitting strategy depends on explanatory variables labeled $X_1, \ldots, X_p$. A fitted regression model and associated statistical inferences are based on various assumptions concerning the functional form of the model for $\mathrm{E}(Y|X_1, \ldots, X_p)$ and distributional properties of the residuals. Violations of these assumptions may invalidate conclusions based on the regression analysis. Therefore, it is essential to check these assumptions, using various types of diagnostic plots.

The estimated residuals,

$$\hat{\varepsilon}_i = Y_i - \hat{Y}_i = Y_i - \hat{\beta}_0 - \hat{\beta}_1 X_{1i} - \cdots - \hat{\beta}_p X_{pi},$$
$$i = 1, \ldots, n,$$

play an essential role in model **diagnostics**. Many computer packages offer the option of using these ordinary residuals or the corresponding standardized or studentized (*see* **Studentization**) residuals, which have a common variance. Use of either of the latter two is preferable, since the $\hat{\varepsilon}_i$s do not all have the same variance.

The following diagnostic plots furnish graphical evidence that one or more of the model assumptions may be contradicted by the data:

1. Residuals vs. the fitted values, $\hat{Y}_i$. An unsuitable functional form is usually revealed by the systematic appearance of this plot, as is nonconstant variance.
2. Residuals vs. the explanatory variables, $X_i, i = 1, \ldots, p$. Systematic patterns in these plots can indicate violations of the mean 0, constant variance assumptions, or an inappropriate model form.
3. Normal probability plot of the residuals. This plot checks the normal distribution assumption on which all the statistical inference procedures are based.
4. Residuals vs. the temporal/spatial order of data collection. Unexpected regularity in this plot suggests that the Y_is may be correlated. To prepare this diagnostic check, it is essential to record the temporal/spatial ordering when data are first collected.
5. Index plots (plot against case number) of the leverages and Cook's distance. The former are a measure of the amount of influence exerted on $\hat{Y}_i$ by the corresponding observed response, Y_i. Cook's distance is a summary measure of the influence that each case exerts on the estimated regression coefficients. These two diagnostic plots can reveal **outliers** (values of Y that are anomalous with respect to the rest of the data) or influential points (values of $(X_{1j}, \ldots, X_{pj}, Y_j)$ that strongly influence the estimated values of $\hat{\beta}_0, \ldots, \hat{\beta}_p$ and s^2).

Deviations from the expected (null) pattern in any of these plots may indicate problems that require further investigation or remedial action.

Various diagnostic plots for the oxygen uptake example are displayed in Figure 2. These reveal that two, or possibly three, of the observations are somewhat unusual relative to the rest of the data set. Omitting the two most prominent points identified in these plots from the data set results in a fitted model that is little different from (3). In particular, only the regression coefficient for run time, X_3, changes noticeably, increasing from -2.83 to -2.62; the corresponding change in the estimated standard error is a reduction from 0.358 to 0.313. The stability of the fitted model, despite the omission of possible influential points, is reassuring.

Computer packages with good facilities for multiple linear regression modeling routinely incorporate

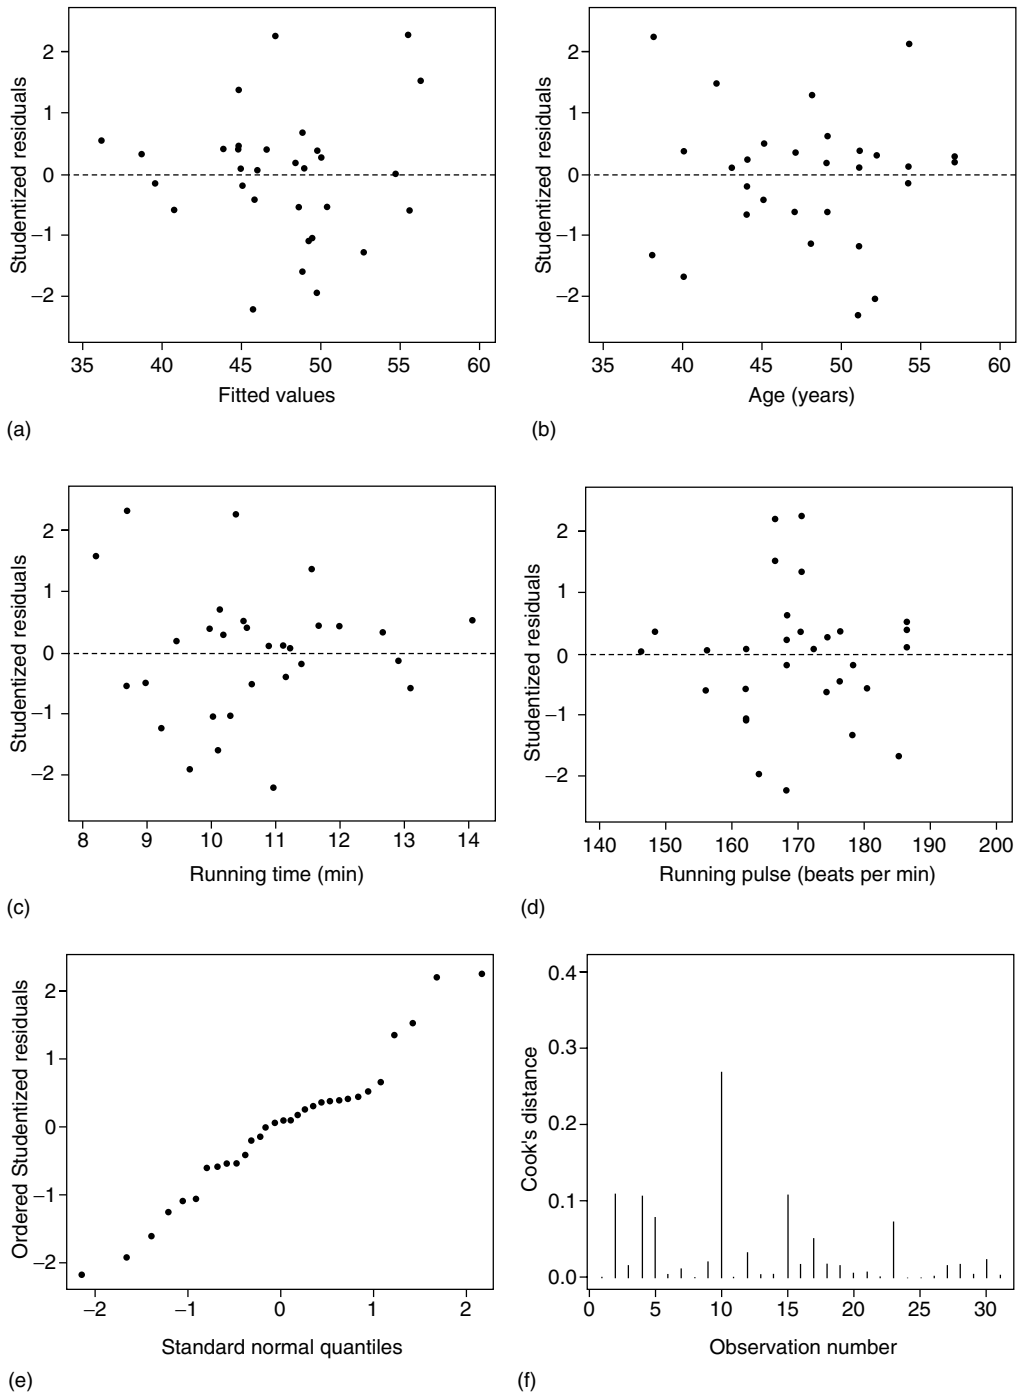

Figure 2 Diagnostic plots for the regression model $\hat{Y} = 111.72 - 0.256X_1 - 2.825X_3 - 0.131X_5$ fitted to the oxygen uptake measurements displayed in Figure 1: (a) estimated Studentized residuals ($\hat{\varepsilon}^*$) vs. $\hat{Y}$; (b) $\hat{\varepsilon}^*$ vs. age; (c) $\hat{\varepsilon}^*$ vs. running time; (d) $\hat{\varepsilon}^*$ vs. running pulse; (e) normal probability plot for $\hat{\varepsilon}^*$; (f) index plot of Cook's distance

simple methods of preparing all the diagnostic plots mentioned in the preceding list. For additional details concerning model diagnostics, see [2] or [3]. Further details concerning examination of the adequacy of a fitted regression model are found in the article, **Goodness of Fit**.

Prediction

The problem of **prediction** using a fitted regression model can be posed in two distinct ways. For example, a researcher may be interested in predicting the mean value of the response, $E(Y|X_1, \ldots, X_p)$, in the subgroup of the study population defined by the values $X_1 = x_1, \ldots, X_p = x_p$ of the explanatory variables. Under the assumption that the residuals in the model are uncorrelated and normally distributed with mean 0 and common standard deviation σ, this mean value is a parameter of the resulting normal distribution of responses in the subgroup. Hence, we can obtain both point and interval estimates of $\mu' = E(Y|X_1 = x_1, \ldots, X_p = x_p)$. The former, which is equal to

$$\hat{\mu}' = \hat{\beta}_0 + \hat{\beta}_1 x_1 + \cdots + \hat{\beta}_p x_p,$$

is the least squares (and **maximum likelihood**) estimate of the mean response, μ', when $X_1 = x_1, \ldots, X_p = x_p$, whereas the latter represents the range of plausible values for μ' that are consistent with the observed data on which the fitted model is based. Narrow interval estimates indicate that the data and fitted model permit us to estimate μ' rather precisely; wider intervals reflect a greater degree of uncertainty concerning the mean value of response in this particular subgroup. It is possible to show, mathematically, that *interval estimates* for μ' are always narrowest in the observed center of the space defined by $X_1, \ldots, X_p$, i.e. at $X_1 = \overline{x}_1 \ldots, X_p = \overline{x}_p$. At the boundaries of the explanatory space, the estimated standard error of $\hat{\mu}'$ is frequently substantially larger than the corresponding estimated standard error at $X_1 = \overline{x}_1, \ldots, X_p = \overline{x}_p$. For example, in the case of the oxygen uptake data, the median values of age, running time, and running pulse are 48, 10.47, and 170, respectively, and all three values are very close to the corresponding observed means, 47.6, 10.58, and 169.6. The estimated mean oxygen uptake for runners in the study population whose age, running time, and running pulse are equal to the median values is

$$\hat{\mu}' = 111.72 - 0.256(48) - 2.825(10.47) - 0.131(170) = 47.6$$

ml per kg per min, and the corresponding estimated standard error is 0.444. Thus, a 95% confidence interval for the mean response among such individuals is (46.7, 48.5) ml per kg per min. However, among older, slower runners who are less fit, e.g. $X_1 = 55$, $X_3 = 13.63$, $X_5 = 185$, the estimated mean oxygen uptake is only 34.9 ml per kg per min and the corresponding estimated standard error is 1.322, resulting in the much wider 95% confidence interval (32.2, 37.6). This threefold increase in the estimated standard error of $\hat{\mu}'$ reflects the increased uncertainty that is a natural consequence of trying to predict the mean oxygen uptake in a region of the space of explanatory variables that is sparsely covered by the observed data.

The second aspect of the prediction problem concerns individual response measurements in the subgroup of the study population defined by the values $X_1 = x_1, \ldots, X_p = x_p$. Some authors recommend that the predicted mean value for the subgroup is a suitable point estimate for an individual response as well; however, the estimated standard error for a predicted response is greater than the corresponding estimated standard error for the predicted mean value, for reasons that we will subsequently explain. We prefer to suggest that point estimates of individual responses, i.e. of Y for a subject with values $X_1 = x_1, \ldots, X_p = x_p$ of the explanatory variables in the fitted regression model, cannot be determined, since these would be observations from a normal distribution rather than characteristics (parameters) of the distribution. However, interval estimates for individual responses in the same subpopulation defined by the values $X_1 = x_1, \ldots, X_p = x_p$ can be evaluated. Of necessity, these interval estimates will be even wider than interval estimates for the corresponding mean response. This is because, according to the multiple linear regression model, an individual response is the sum of a particular mean response and a residual. Thus, to the uncertainty about the location of the mean response in the subgroup we need to add the uncertainty due to the residual associated with an individual response, i.e. est se $(Y) =$

$\{[\text{est se}(\hat{\mu})]^2 + [\text{est se}(\varepsilon)]^2\}^{1/2} > \text{est se}(\hat{\mu})$. To illustrate, consider runners in the example of those running pulses that have the median values 48, 10.47, and 170, respectively. A 95% prediction interval for an oxygen uptake measurement on a new runner belonging to this particular subgroup is (42.5, 52.7) – roughly five times wider than the corresponding 95% confidence interval of (46.7, 48.5) ml per kg per min for the mean response among such individuals. Also, attempting to predict individual responses in regions of the space of explanatory variables that are sparsely covered by the observed data inevitably results in interval estimates that are wider still. For example, a 95% prediction interval for oxygen uptake among young, faster runners who are quite fit, e.g. $X_1 = 40$, $X_3 = 8.62$, $X_5 = 154$, is (51.3, 62.6), whereas the corresponding interval estimate for the mean response in the same subgroup is (54.4, 59.5) ml per kg per min.

Most computer packages with well-designed routines for multiple linear regression modeling offer users the option of computing suitable confidence intervals for both aspects of the problem of prediction, as well as point estimates of the mean response for any set of values of the explanatory variables in a fitted model.

Weighted Regression

A diagnostic plot may exhibit a systematic pattern, suggesting that the variability of the estimated residuals is not constant from one observation to another. Alternatively, it may be known that some of the observations in a set of data are less reliable, i.e. more variable than the remaining observations collected.

Whatever the reason, if the residuals, $\varepsilon_1, \ldots, \varepsilon_n$, and hence the corresponding response measurements, $Y_1, \ldots, Y_n$, are correlated and/or do not all have roughly the same standard deviation, σ, the least squares estimator specified in (2) is no longer appropriate, since the minimal assumptions for least squares estimation are not satisfied.

To illustrate the general solution to such problems, we consider the simple but artificial problem of fitting a simple linear regression model, $Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i, i = 1, \ldots, n$, when the residuals, ε_i, are uncorrelated but have different, known standard deviations, $\sigma_i, i = 1, \ldots, n$. If the standard deviations were all the same, i.e. if $\sigma_i = \sigma, i = 1, \ldots, n$, then the ordinary (unweighted) least squares estimates of β_0 and β_1 in this simple linear regression context would be $\hat{\beta}_1 = S_{xy}/S_{xx}$ and $\hat{\beta}_0 = \overline{y} - \hat{\beta}_1 \overline{x}$, where $\overline{x} = \sum_{i=1}^n x_i/n$, $\overline{y} = \sum_{i=1}^n y_i/n$,

$$S_{xy} = \sum_{i=1}^n x_i y_i - n^{-1} \left(\sum_{i=1}^n x_i \right) \left(\sum_{i=1}^n y_i \right)$$

and

$$S_{xx} = \sum_{i=1}^n x_i^2 - n^{-1} \left(\sum_{i=1}^n x_i \right)^2 .$$

However, as we outline subsequently, when the standard deviations of the residuals are different, the correct (weighted) least squares estimates of β_1 and β_0 are

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n w_i x_i y_i - \left(\sum_{i=1}^n w_i x_i \right) \left(\sum_{i=1}^n w_i y_i \right)}{\sum_{i=1}^n w_i x_i^2 - \left(\sum_{i=1}^n w_i x_i \right)^2} \quad (4)$$

and

$$\hat{\beta}_0 = \sum_{i=1}^n w_i y_i - \hat{\beta}_1 \sum_{i=1}^n w_i x_i, \quad (5)$$

where $w_i = \sigma_i^{-2} / \sum_{i=1}^n \sigma_i^{-2}$. Weighted least squares estimation associates a weight, w_i, $0 \le w_i \le 1$, $\sum_{i=1}^n w_i = 1$, with observation $i, i = 1, \ldots, n$, and these weights are inversely proportional to the variances of the corresponding residuals. Thus, the inherent reliability of each observation, which is reflected in the variance of the corresponding residual, directly determines the weight, and hence the contribution, of that observation to the estimation of the regression coefficients, β_0 and β_1, in the assumed model. Incidentally, if the standard deviations of the residuals, ε_i, are all the same, i.e. if $\sigma_i = \sigma, i = 1, \ldots, n$, then $w_i = 1/n, i = 1, \ldots, n$, and the formulas for the weighted least squares estimates of β_0 and β_1 specified in (4) and (5) simplify to the ordinary (unweighted) least squares expressions.

The preceding example shows that the solution to the problem of nonconstant residual standard deviations involves suitably weighting (transforming) the measurements associated with each observation. According to the simple linear regression

model, the residual is the difference between the observed response and the systematic component of the assumed model, i.e. $\varepsilon_i = Y_i - \beta_0 - \beta_1 X_i, i = 1, \ldots, n$. Thus, transforming the response and explanatory measurements for observation i automatically modifies the residuals in an identical manner, thereby producing transformed residuals that do satisfy the minimal assumptions for least squares estimation. The estimates of the regression coefficients that are derived using the weighted or transformed measurements are known as weighted least squares estimates.

The method of resolving the general problem represented by residuals that are correlated and/or do not all have roughly the same standard deviation, σ, involves identifying a unique, nonsingular, symmetric matrix, **T**, i.e. a matrix of suitable weights for each observed response and corresponding values of the explanatory variables, $(X_{1i}, \ldots, X_{ki}, Y_i), i = 1, \ldots, n$, such that $\mathbf{Z} = \mathbf{TY}$ and the effect of the same matrix, **T**, on the vector of residuals, $\boldsymbol{\varepsilon} = (\varepsilon_1, \ldots, \varepsilon_n)'$, produces transformed residuals, $\mathbf{T}\boldsymbol{\varepsilon}$, that are uncorrelated and do have a constant standard deviation.

Once the transformation matrix, **T**, has been identified, (2) can be used on the transformed response measurements; the vector **Y** is replaced by **Z** and the matrix, **X**, by **TX**, its corresponding equivalent in the transformed problem. Although it is possible to restate the solution for $\hat{\beta}$ in terms of the matrices **T**, **X** and the vector, **Y**, it is simpler to carry out any necessary calculations directly using **Z**, the vector of transformed response measurements, and **TX**, the matrix of transformed explanatory variable values for each observation. Once a suitable parsimonious model for $Z_1, \ldots, Z_n$ has been identified, appropriate statistical inferences concerning the estimated regression coefficients can be formulated provided that the assumption that the residuals for the estimation problem follow a normal distribution is not contradicted by the transformed data. To check all these least squares and normal theory assumptions, it is essential to examine the estimated residuals for the transformed data, i.e. $Z_i - \hat{Z}_i, i = 1, \ldots, n$, where $\hat{Z}_i$ denotes the predicted value of the transformed response for observation i and is obtained using $\hat{\boldsymbol{\beta}}$ and the vector of transformed explanatory variable values for observation i.

In the preceding discussion we did not indicate precisely how to identify the key matrix **T** by which all that previously was wrong is set right. This is because there is no universal antidote to cover all situations when one or more of the least squares assumptions fail to hold for a given set of data. Often, a simple **transformation** such as $Z_i = \sqrt{Y_i}$ or perhaps $Z_i = \log Y_i, i = 1, \ldots, n$, can put things right, particularly if the original difficulty with least squares was due to a failure of the constant variance assumption. If not, then much more effort will probably be required, as will a certain degree of data-analytic artistry which cannot be summarized in the small amount of space available here. Draper & Smith [4, pp. 112–115] discuss a numerical example in which the entries in the transformation matrix, **T**, are estimated from response measurements that are exact repeats taken at the same value of X, the only explanatory variable in the problem, or approximate repeated response measurements collected at values of X that are in close proximity to each other.

Multiple Time Series

Multiple time series, also known as multivariate time series, and sometimes vector time series, refers to the analysis of observations taken simultaneously on two or more time series. Biomedical data examples include monthly recordings of death attributed to bronchitis, emphysema and asthma for males and females, and temperature, blood pressure and weight for a regularly monitored patient. Environmental examples include readings of lead concentrations at several sites at five minute intervals, air temperature readings taken at hourly intervals at a fixed height above sea level at several locations and monthly ozone levels at several recording stations. Univariate time series models are very useful for individual time series, but multiple time series models have the potential for helping to understand the *system* that gives rise to the data.

Parzen [21] gives a concise background to the theory of multiple time series and the references provide an excellent source to track its history. In this article I complement Parzen by updating many of the references and report some of the progress that has been made possible by the increased computing power that is now generally available. Most of the theoretical developments in multiple time series before and since 1985 have been driven by problems in economics, business and econometrics. Theoretical and practical contributions may be found in [2, 7, 9–11, 16, 17, 24, 26, 27, 30, 31], and [33].

Statistical Concepts

Let $\mathbf{Y_t} = (Y_{1,t}, Y_{2,t}, \ldots, Y_{m,t})'$ be a vector of m time series for $t = 1, 2, \ldots, n$. It is second-order stationary if (i) $\mathrm{E}(\mathbf{Y}_t) = \boldsymbol{\mu}$, independent of time, and (ii) the set of m series is jointly covariance stationary (*see* **Coherence Between Time Series**). Point (ii) means that the cross-covariance function $\gamma_{ij}(k) = \mathrm{cov}(Y_{i,t}, Y_{j,t-k})$ is independent of t for all i, j and k and the variance of each series, $\gamma_{ii}(0)$, is finite. The function $\gamma_{ii}(k)$ is a covariance function and is not necessarily symmetric. The function $\rho_{ij}(k) = \gamma_{ij}(k)/[\gamma_{ii}(0)\gamma_{jj}(0)]^{1/2}$ is the cross-correlation function, and the autocorrelation function is $\rho_{ii}(k) = \gamma_{ii}(k)/\gamma_{ii}(0)$. The matrix $\boldsymbol{\rho}(k)$ with the ijth entry equal to $\rho_{ij}(k)$ is the correlation matrix. The Fourier transform of $\boldsymbol{\rho}(k)$ (*see* **Fast Fourier Transform (FFT)**) is the *spectral density* matrix $\mathbf{f}(\omega) = \sum_{v=-\infty}^{\infty} \exp(-2\pi i \omega v)\boldsymbol{\rho}(k)$, $(-0.5 \le \omega \le 0.5)$, and is nonnegative definite. The complex-valued function, which is the ijth entry in this matrix, is the cross-spectral density. The real and imaginary parts of this matrix define the *cospectrum* and *quadrature spectrum*. The *amplitude*, $a_{ij}(\omega)$, and *phase*, $\phi_{ij}(\omega)$, of $\mathbf{f}(\omega)$ are obtained by considering the polar representation of the cross spectrum in the form $f_{ij}(\omega) = a_{ij}(\omega)\exp\{i\phi_{ij}(\omega)\}$. The quantity $a_{ij}(\omega)/\sqrt{[f_{ii}(\omega)f_{jj}(\omega)]}$ is called the coherency, represents the correlation between the frequency components of $Y_{i,t}$ and $Y_{j,t}$ and lies between zero and one [6, p. 212].

For m observed series the main task is to obtain sample estimates of the matrices of population quantities and use them to identify an appropriate model that will best describe $\mathbf{Y}_t$. The time domain approach involves working with estimates of $\rho_{ij}(k)$, while the frequency domain approach uses estimates of $\mathbf{f}(\omega)$. Practical progress can only be made by entertaining classes of time series models that can then be estimated. The multivariate generalization of Wold's decomposition theorem states that $\mathbf{Y}_t$ can always be represented by an infinite matrix linear combination of a vector white noise process [8, p. 158]. This leads one to consider the multivariate generalization of univariate autoregressive moving average (ARMA) processes (*see* **ARMA and ARIMA Models**) in the form $\boldsymbol{\Phi}(B)\mathbf{Y}_t = \mathbf{C} + \boldsymbol{\Theta}(B)\boldsymbol{\varepsilon}_t$, where $\boldsymbol{\Phi}(B) = \mathbf{I} - \boldsymbol{\Phi}_1 B - \ldots - \boldsymbol{\Phi}_p B^p$ and $\boldsymbol{\Theta}(B) = \mathbf{I} - \boldsymbol{\Theta}_1 B - \ldots - \boldsymbol{\Theta}_q B^q$ are matrix polynomials of orders p and q, respectively, B is the backward shift operator such that $B\mathbf{Y}_t = \mathbf{Y}_{t-1}$, all the zeros of the determinantal polynomials $|\boldsymbol{\Phi}(B)|$ and $|\boldsymbol{\Theta}(B)|$ are on or outside the unit circle and $\boldsymbol{\varepsilon}_t$ is a vector *white noise* process with $\boldsymbol{\varepsilon}_t = (\varepsilon_{1,t}, \varepsilon_{2,t}, \ldots, \varepsilon_{m,t})'$, having the properties $\mathrm{E}(\varepsilon_{i,t}) = 0$, for all i, $\mathrm{E}(\varepsilon_{i,t}\varepsilon_{j,t-k}) = 0$, for all k, $i \ne j$ and $k \ne 0$, $i \ne j$. These processes are usually termed vector ARMA (VARMA) models.

Identification

There are some major and difficult problems with VARMA modeling and many are discussed in [26], [7, pp. 244–259] and [16, p. 241]. First, if m is much larger than two or three, a rather large number of autocorrelations, cross-correlations and partial

correlations have to be interpreted. This makes the selection of the order of each polynomial somewhat difficult. In any case, these tools do not yield totally unambiguous messages about the models that should be estimated. Secondly, unique identification of a VARMA structure is not guaranteed by specifying a minimum order for the autoregressive and moving average operators. Thirdly, misspecification of multiple time series models can have more serious consequences than for univariate models. For these reasons, often the preference of applied researchers is to specify, estimate and analyze pure vector autoregressive (VAR) models. This assumes that a sufficiently long VAR model can capture the structure of $\mathbf{Y}_t$. A different approach is needed to solve the nonuniqueness problem for the general VARMA case. Lutkepohl & Poskitt [17] provide a strategy that results in a parsimonious and uniquely identifiable structure based on the echelon form of a VARMA model.

Estimation

The Gaussian likelihood of $(\mathbf{Y}_1, \mathbf{Y}_2, \ldots, \mathbf{Y}_n)$ for the VARMA process is derived by Brockwell & Davis [2, p. 431]. Unlike in the univariate case, it is not possible to compute maximum likelihood estimators of $\mathbf{\Phi}(B)$ and $\mathbf{\Theta}(B)$ independently of the variance–covariance matrix of the noise series [2, p. 427] and so the maximization of the likelihood has to be done simultaneously. Efficient nonlinear optimization algorithms have to be used and it is particularly important to have good initial estimates of the parameters. This is because the likelihood function can have many local maxima that are smaller than the global maximum. Poskitt & Salau [22] show that generalized least squares estimates of VARMA models and corresponding Gaussian estimators are asymptotically convergent. In the case of estimating a pure VAR, the multivariate Durbin–Levinson algorithm for fitting autoregressions of increasing order is often used [2, p. 432]. An efficient algorithm for evaluating the exact likelihood function for VARMA models is given by Mauricio [18].

Model Checking

Univariate theory is easily extendable to yield Lagrange multiplier-type tests for vectors of estimated parameters and portmanteau-type tests for vectors of residual autocorrelations [16, pp. 298–301]. The latter procedure is, however, unlikely to be very powerful under a broad range of alternative VARMA models, since, even in the univariate case, portmanteau tests lack power [5].

Forecasting

Optimal h-step forecasts for VARMA models are straightforward to obtain [16, p. 228]. However, since a potentially large number of parameters may have been estimated in the identified multivariate model, prediction intervals for forecasts can be wider than expected. Both short- and long-term forecasting are important. For example, forecasts of wind speed and direction at several locations may be needed for 15-minute horizons, whereas environmentalists may need predictions of next year's rainfall over a wide and geographically spread region. Modeling long-range dependence by fractionally differenced VARMA models is in its infancy, but may prove to be a productive area for predicting environmental-type time series [23].

Data and Worked Examples

The World Wide Web is a useful source of information and data on biomedical and other time series (*see* **Internet**). A home page is available at the url `http://hachiman.mscs.mu.edu/research/biomedts` and there are some useful links from there. A bivariate worked example using monthly numbers of male and female deaths from bronchitis, emphysema and asthma is given by Diggle [6, p. 202]. Those data are also considered by Venables & Ripley [32, p. 373]. Both analyses concentrate on time and frequency domain statistics, and some useful plots are presented. No VARMA models are estimated. Using a state–space representation, Jones [12, p. 158] gives examples of estimating bivariate and trivariate multiple time series models for medical time series that are irregularly spaced.

Software

Sources of software (*see* **Software, Biostatistical**) for both univariate and multivariate time series analysis are provided by Aghadazeh & Romal [1] and

Rycroft [25]. The number of packages that specifically handle multiple time series is small and, to date, a comparative review of them has not been done. Ord & Lowe [20] compare five *automatic* forecasting systems for univariate analysis, only one of which provides for multiple time series analysis.

Finding innovative and useful ways to present m multiple time series, the joint behavior of all subsets of them and the statistics needed to identify VARMA models is challenging and not yet complete. Newton [19, p. 803] argues that essential features for good time series graphics are that the plots should be interactive, dynamic and linked. Few packages possess all these properties, but the statistical system in S [4] and LISP-STAT [28] have the greatest potential for the creation of useful plots for multiple time series modeling. Newton [19, p. 817] used the S system to present data on monthly ozone levels at nine recording stations with instantaneous scatter plots for all 36 pairs of series and the 45 plots of autocorrelations and cross-correlations. Other quantities, such as coherency, gain and phase need to be examined: currently, there is no readily available off-the-shelf program that presents these statistics in innovative ways.

The excellent book by Venables & Ripley [32, pp. 349–382] gives examples of graphical displays of time and frequency domain statistics for multiple time series analysis that can be produced using the S-PLUS system. VAR estimation (but not VARMA) is implemented in the system with appropriate model checking and diagnostic tools. A library of S functions for multivariate state–space and ARMA time series models is available from statlib in the S archive under the title time·series. These S functions allow for inclusion of exogenous variables and treat VAR models as a special case. They include methods for simulating, estimating and converting among different model representations. They are implemented using classes and methods so that it is easy to add new estimation methods and not difficult to add other model representations.

Scientific Computing Associates (SCA, PO Box 625, DeKalb, Illinois, USA) market a PC-based statistical system that includes a product dedicated to multivariate time series analysis and forecasting using VARMA models [15]. Box & Tiao have helped with the development of the system, and so it has a very good pedigree.

An easy-to-use and highly graphical package has been developed at the London School of Economics and is described by Koopman et al. [14] with case studies given in [13]. The software assumes that structural multivariate time series models are appropriate, with time-varying unobservable components that are themselves assumed stochastic. A full range of high quality graphical output is available to assist the modeler. The software is PC-based and a Windows version will be available shortly.

The software of Brockwell & Davis [3] allows VAR models to be estimated and forecast in a PC environment. In that software, model selection can be made simpler using the AIC criterion. The estimation routines for multivariate conditional heteroscedastic models used by Wong & Li [35] are written using the MATLAB software and may be obtained from the authors.

Extensions and Generalizations

Biomedical investigations usually involve experimental designs with deliberate replication of experiments. When these are conducted over time, relatively short and nonstationary time series arise in which trends and other features are the main interest. These kinds of data are generally known as *repeated measures* and the modeler can use time series techniques to accommodate serial dependence within the individual time series. In this way, repeated measurements can be regarded as multiple time series. A worked example using the body weight of rats is given by Diggle [6, p. 136].

State–space generalizations of multiple time series are given by Lutkepohl [16, p. 415] and Harvey [11, p. 423] (*see* **Structural Time Series Models**) and the multivariate dynamic linear model for time series is described by West & Harrison [34, p. 597]. A general methodology for the Bayesian analysis of short- and long-memory multiple integrated models is given by Ravishankar & Ray [23]. These authors illustrate their techniques by applying them to sea surface temperature series. Extensions to multivariate conditional heteroscedastic time series models, including their links to multivariate random coefficient autoregressive models, is given by Wong & Li [35]. In that paper the problems of identification, estimation and diagnostic checking are addressed. Univariate nonlinear time series modeling is itself in its infancy,

but Tong [29, p. 429] tentatively suggests the possibility of using multiple nonlinear time series models and gives an example that features threshold autoregressive series. The extra generality provided by these new developments should prove very useful for modeling biomedical- and environmental-type multivariate time series, since long-range dependence and changing conditional variance are commonly observable phenomena in biostatistical data.

Multiplicative Model

In epidemiology and biostatistics, **relative risk models** are often called *multiplicative models*. In a relative risk model the effect of an exposure or other factors is described as

$$R = R_0 \times RR(z),$$

where R_0 is the background (or baseline) risk and $RR(z)$ is the **relative risk** associated with a **covariate** vector z.

The most commonly used relative risk model is the **loglinear model** $RR(z) = \exp\left(\sum_i \beta_i z_i\right)$. This is a multiplicative function since the effect of each covariate is to multiply the **risk** by a factor proportional to the covariate value. However, additive functions are also useful in describing relative risks. For example, in the assessment of **dose–response** it is often reasonable to describe the relative risk of an exposure in terms of an **additive model** for the **excess relative risk**, i.e. $ERR = RR - 1 = \beta_1 z_1$. If there is an additional exposure of interest, then it is useful to consider additive relative risk models of the form:

$$RR = 1 + \beta_1 z_1 + \beta_2 z_2$$

or

$$RR = 1 + \beta_1 z_1 + \beta_2 z_2 + \beta_3 z_1 z_2.$$

The second of these models is a generalization of the multiplicative excess relative risk model

$$RR = (1 + \boldsymbol{\beta}_1 z_1) \times (1 + \boldsymbol{\beta}_2 z_2).$$

Thomas [2] and Breslow & Storer [1] describe general relative risk functions that include both additive and multiplicative models. The articles on **Relative Risk Modeling** and the **Cox Regression Model** contain additional discussion of relative risk models. The articles on **Parametric Models in Survival Analysis** and **Poisson Regression in Epidemiology** present general classes of additive and multiplicative models that are useful in describing excess and relative risks. These articles also discuss methods for parameter **estimation** and **inference** with such models.

Multiplicity in Clinical Trials

The simplest randomized **clinical trial** involves the comparison of two treatments with respect to just one outcome measure. Usually, the **null hypothesis** of interest is that there is no true difference in outcome (*see* **Outcome Measures in Clinical Trials**) between the two treatment groups. In this case, the observed difference in outcome between the two treatment groups is evaluated in a statistical test (*see* **Hypothesis Testing**) to generate a ***P* value** that describes the chance of seeing the observed difference, or one more extreme, under the assumption that the null hypothesis is true. Thus, obtaining a P value of 0.01 from the test implies that the difference in outcome observed, or one more extreme, would occur by chance in one out of every 100 clinical trials involving no true difference in the effects of the two treatments. The problem of multiplicity arises whenever the clinical trial departs from this simple design and analysis of two treatments and a single outcome measure. It primarily concerns the interpretation of the multitude of hypothesis tests, often referred to as **multiple comparisons**, that might then be undertaken (*see* **Simultaneous Inference**).

The statistical problem that arises when considering multiple comparisons centers on the error rate that should be controlled. For example, if there are two outcome measures being compared between two treatments, then the conclusion that one treatment is superior to the other might be made if the P value obtained from the comparison of at least one of the outcomes is less than some level, α. The level α is the *marginal* type I error rate, and implies that the probability of concluding that one treatment is superior to the other with respect to that particular outcome measure is no more than α, irrespective of the result for the other outcome measure. In contrast, the **experiment-wise error rate** quantifies the probability of concluding that one treatment is judged superior to the other when the decision is based on data for both outcomes, despite there being no true difference between treatments with respect to either measure. In practice, the decision of superiority is often made when either or both of the marginal P values for the comparisons between the two treatments is less than α. The experiment-wise error rate is then at least α (being equal to α if the outcome measures are perfectly correlated) but may be as high as $2\alpha - \alpha^2$ if the outcome measures are independent. More generally, if K comparisons are made, each at a marginal significance level of α, then the experiment-wise error rate may be as high as $1 - (1 - \alpha)^K$, which is approximately equal to $K\alpha$ if α is small, although the exact value depends on the **correlations** between the outcome measures. The statistical problem is, therefore, aimed at controlling the experiment-wise error rate in the face of multiple comparisons. However, the appropriateness of doing this rather than controlling the marginal error rate specific to each comparison is dependent on the application being considered, and, specifically, the source of the multiplicity, and, even then, there are different methods for controlling the experiment-wise error rate. Cook & Farewell [2] give an excellent overview of the issues.

Controlling Experiment-Wise Error Rates

Global Tests

Consider the situation in which there are K comparisons of interest, each of which can be summarized by one parameter, β_k for $k = 1, \ldots, K$. Then, the global comparison involves a test of the null hypothesis that $\beta_1 = \beta_2 = \cdots = \beta_k$ vs. the **alternative hypothesis** that at least one of the β_ks differs from the remaining ones. This reduces the multiple comparisons problem to a single test and so preserves the experiment-wise error rate. However, the difficulty usually encountered is that a significant test result does not identify the source of the difference. Thus, further testing of specific comparisons is usually of interest. Furthermore, as the global test seeks any departure from the null hypothesis, it lacks **power** to detect specific patterns of differences that might be of interest. For example, a global test gives equal emphasis to the situation in which β_1 and β_2 differ from the remaining β_ks, regardless of whether they do so in the same or opposite directions, whereas, in some applications, it might be anticipated that the directions of the true departures would be the same. Thus, power is lost in the comparisons. This criticism can be overcome to some extent by using tests that are sensitive to departures from the null hypothesis in the same direction, particularly if they are also of a similar magnitude [9, 14] (*see* **Multiple Endpoints, Multivariate Global Tests**).

Adjusted Marginal Tests

There are a large number of procedures that are based on the marginal tests of each β_k, but that provide criteria for determining significance so as to control the experiment-wise error rate. The most well known of these is the **Bonferroni** adjustment procedure. From each marginal test, a marginal P value is obtained and the null hypothesis is then rejected if this P value is less than α/K, where α is the desired maximum experiment-wise error rate. This procedure is conservative in that the actual experiment-wise error rate may be somewhat less than α, particularly if the quantities being compared are highly correlated. Simes [13] and Hochberg [6] have developed modified Bonferroni procedures that aim to be less conservative (*see* **Multiple Endpoints, *P* Level Procedures**). Other general procedures for marginal testing are available, some of which are described below in the context of specific multiple comparisons problems.

Summary Measures

Rather than working with K comparisons, an alternative approach involves reducing the dimension of the problem by summarizing the data involved in the K comparisons to give just one comparison. Control of the error rate for this one comparison then results directly from the reduction in the dimension of the problem.

Sources of Multiplicity

There are five major sources of multiple comparisons in clinical trials: (i) multiple treatments; (ii) multiple outcome measures; (iii) repeated measurements over time of a specific outcome measure; (iv) comparisons of outcome over subpopulations (subgroups) of subjects; and (v) interim analyses while a trial is ongoing.

Multiple Treatments

The decision to evaluate multiple treatments within a single clinical trial almost always implies some form of structure among the treatments, and so a greater interest in some comparisons than others. For example, it is very rare to design a clinical trial in which one of the treatment arms is not a standard of care, even if that one arm involves a placebo or no treatment. Thus, global tests are rarely appropriate, as they give equal weight to all comparisons and do not exploit the greater interest in particular comparisons.

In the rare circumstances in which there is no such standard, it seems natural that the main objective of the trial should be to define an ordering of treatments from worst to best in terms of some outcome. This procedure, a form of adjusted marginal test procedure, aims to identify groups of treatments such that treatments within each group are not significantly different from each other. Miller [8] gives an example in which the mean response for each of five treatments, A to E, was 16.1, 17.0, 20.7, 21.1, 26.5, respectively. Application of the Newman–Keuls procedure involves comparison of the best and worst treatments, A and E, first; this establishes a significant difference among treatments within the group of five treatments. This is followed by evaluation for differences within the two groups of four treatments, {A, B, C, D} and {B, C, D, E}, then the groups of three treatments, etc. until no further significant differences are found. The result in this example was that there was no significant difference within the group {A, B} nor within the group {B, C, D}. Thus, treatment E differed significantly from all other treatments, and treatment A differed significantly from treatments C and D. The lack of a significant difference between treatments A and B, and between treatments B and C, despite a significant difference between treatments A and C, seems somewhat confusing, but may simply reflect low **power** to detect smaller differences among treatments. This approach is appropriate when there are equal amounts of information for each treatment; the situation is more complex when this is not the case, as the power for detecting differences will vary between different pairs of treatments.

In the more general situation in which there is some structure among treatments, a sequence of tests can usually be defined in order of their importance, and, in some circumstances, marginal tests applied with no adjustment for multiple comparisons are appropriate. Some examples will illustrate the issues. A common use of clinical trials is the simultaneous evaluation of $K-1$ new treatments vs. a standard treatment, as this is considered more efficient than doing the $K-1$ separate clinical trials comparing each new treatment with the standard (though this might also depend on the practicalities of undertaking

a large trial vs. a small one). Dunnett [4] provided a procedure for adjusting each of the $(K-1)$ marginal tests to control the experiment-wise error rate. However, it is debatable whether the error rate for the comparison of treatment A vs. the standard should be affected by the fact that treatment B has also been compared with the standard. Indeed, if two separate trials had been undertaken, then each would be reported separately, with no adjustment to significance levels to reflect the existence of the other trial. Proschan & Follmann [11] discuss this issue and show that there is little difference in the proportion of marginal tests giving type I errors, whether the new treatments are compared with the standard in a single trial or in different trials. This supports the idea of not adjusting marginal test results in this situation. However, having established that some of the new treatments are superior to the standard, it might then be of interest to investigate the evidence for differences among these treatments. In this case, there might be more of a rationale for controlling the experiment-wise error rate among the comparisons in that subset, using an adjusted marginal test approach such as the Newman–Keuls procedure discussed above.

Related to this first example is a second example, in which the $K-1$ new treatments being compared to a standard treatment are different doses of the same drug. In this case, the problem can often be considered as a sequence of two questions: first, is there evidence that the drug is superior to the standard treatment (often, in this context, a placebo) and, secondly, is there a difference in effect between doses? Rather than test each dose against the placebo, it is usually better to compare a summary measure of the response obtained across all $K-1$ doses to the response in the placebo arm. Then, if this establishes an effect of the new treatment, one would test for an association between magnitude of response and dose.

In general, the latter test would also be undertaken using a summary measure, usually defined by some prior knowledge of a model that is likely to describe the association between response and dose. Although there are two hypotheses being assessed, there is little rationale for adjusting for multiple comparisons, as the hypothesis about a **dose–response** is likely to be secondary in nature, dependent on an effect of the new treatment being first established.

A third example concerns the evaluation of a combination of treatments. A trial of the combination of two antiretroviral drugs that target the human immunodeficiency virus infection, ZDV + ddI, was undertaken to compare that combination with each of ZDV and ddI separately. The doses of ZDV and ddI used in the combination arm were the same as in the two monotherapy arms, and so it was anticipated that greater toxicities would be seen in the combination arm, which was also more expensive. Thus, the combination treatment might only be recommended if it was shown to be superior to each of the two monotherapies. In this case, the error rate of interest is the probability of recommending ZDV + ddI when there is no difference between it and either ZDV or ddI alone. This probability is less than α if the marginal pairwise comparison of ZDV + ddI vs. ZDV and that of ZDV + ddI vs. ddI is undertaken using a level of α, and so no adjustment for multiple comparisons is required.

These examples help to illustrate the fact that control of the experiment-wise error rate is rarely of interest in clinical trials involving multiple treatments. Instead, more specific sequencing of hypotheses is often possible with little, if any, control of error rates necessary. Indeed, the **sample size** and power considerations of most well-designed clinical trials are dictated by some prioritization of hypotheses, which should then determine whether any error rate control is necessary.

Multiple Outcome Measures

For many diseases, there may not be a single obvious measure of outcome (*see* **Outcome Measures in Clinical Trials**). This is particularly common in trials of symptomatic diseases such as arthritis or neuropathy in which pain or other measures at different joints or in different muscles are of interest. However, it also arises in studies of diseases that have major morbidity outcome measures, such as the occurrence of both strokes and myocardial infarctions, as well as death, in cardiovascular trials. The important consideration in determining how to address the multiple comparisons problem in this context concerns how similar the various outcome measures are to one another. In the case of joint or muscular pain, the impact on a patient's **quality of life** may be similar regardless of the joint or muscle affected. In contrast, a nondebilitating stroke or myocardial infarction is clearly less important than death.

Consider a clinical trial that is designed to compare two treatments with respect to K outcome measures. Denote the true difference between treatments by β_k for $k = 1, \ldots, K$. Then the null hypothesis of interest might be $H_0 : \beta_1 = \beta_2 = \cdots = \beta_k = 0$. Global tests might be considered if the outcome measures are similar in their clinical significance and the magnitude of the treatment effect is likely to be similar for each measure, so that the alternative hypothesis is $H_1 : \beta_1 = \beta_2 = \cdots = \beta_k = \beta$ for some β. O'Brien [9], Pocock et al. [10] and Wei et al. [15] present tests for this situation. These tests effectively involve a weighted average of the outcome measures, where the weights are chosen to optimize the power of the test to detect a treatment difference. If it is likely that the treatment differences vary among outcome measures, particularly if the directions of the differences might differ, then comparisons between treatments with respect to each outcome measure are likely to be more important. In this case, Follmann [5] has shown that the Bonferroni procedure applied to the K outcome measures is to be preferred, particularly when it is unknown which outcome measure is likely to have the largest treatment difference. Note that more generic global tests such as **Hotelling's T^2** test (a multivariate extension of the two-sample t test) or **chi-square tests** for $2 \times K$ **contingency tables** are rarely useful in clinical trials, as they focus on any departure from the null hypothesis, including those in which the directions of the differences (i.e. the signs of the β_ks) might differ.

Cook & Farewell [2] give a very nice critique of a colorectal cancer trial in which there were two outcome measures, tumor response and survival, of different clinical significance. In this case, the rationale for any adjustment for multiple comparisons, whether using global tests or an adjusted marginal testing approach, is weak. Specifically, global tests are of little interest because one wishes to understand how the treatments affect each of the two measures separately. Thus, marginal tests are more appropriate. However, Cook & Farewell argue against adjustment to marginal tests, on the basis that the implications for clinical practice from finding, for example, very strong evidence in favor of a tumor response and weak evidence in favor of survival, are very different from finding weak evidence in favor of a tumor response but very strong evidence in favor of survival. Thus, the relevance of an experiment-wise error rate is questionable. Indeed, in this type of situation, it might be more useful to consider a hierarchy of hypotheses that focus on the outcomes in a decreasing order defined by their clinical importance. In addition, composite outcome measures might be useful. For example, in anti-HIV trials, the first hypothesis of interest might be whether the treatments differ with respect to mortality. If they do, then other differences might be of lesser interest. If they do not, then it is natural to investigate treatment differences with respect to the composite endpoint of death or progression to AIDS, as this reflects a clinically serious outcome (AIDS) or a worse outcome (death), rather than investigate progression to AIDS separately from death.

An alternative approach for handling multiple outcome measures involves the use of summary measures. As an example, Salsburg [12] describes a clinical trial of treatment for acute painful diabetic neuropathy. In this trial, each patient was asked to score pain, numbness and weakness in each of their left and right feet, calfs, thighs, hands and arms giving 30 outcome measures in all. Instead of analyzing these 30 outcomes in a global test, or using adjusted marginal tests, two summary measures were identified for analysis. The first, the "maximum distress" score, was the maximum score across all 30 measures. The second, the "dominant symptom" score, was the score for the symptom with the worst score prior to starting study treatment. These two measures were considered clinically relevant, reflecting the most significant aspects of the disease to each patient. They also provided a more powerful analysis than that obtained by looking at all 30 measures separately, because many patients showed no distress throughout the study for certain measures.

Repeated Measurements over Time

It is very common to follow patients over time with repeated measurements of outcome (*see* **Longitudinal Data Analysis, Overview**). For example, clinical trials of antihypertensive agents often collect blood pressure measurements over time. Global tests are rarely of interest in this context. Adjusted marginal tests are also of limited value as they ignore the explicit structure of the data, and tend to be conservative because of the correlation between successive measurements. As with multiple outcome measures, this is a situation where summary measures

are often particularly valuable. For example, in antihypertensive trials, there might be interest in whether the trend in blood pressure over the duration of the study differs between treatments. In this case, the trend might be calculated for each patient using standard methods for **linear regression**, and then the average of the trends across patients compared between treatments using, for example, a two-sample t test (*see* **Student's *t* Statistics**). This is, therefore, a two-step process. Alternatively, the analysis can be done in one step, using methods for mixed effects models [7]. For example, such a model might involve a linear trend for each subject, with a further level of the model describing how these trends vary among subjects and their dependence on treatment assignment. In other applications; for example, anti-HIV trials, there might be interest in the maximal extent of viral suppression achieved and also in the durability of effect, often expressed as the change from baseline to the level at about one year after treatment started. Thus, an important advantage of the summary measure approach is that it focuses the analysis on aspects of the data that are considered most clinically relevant. However, summary measures are sometimes used in order to gain statistical power, without adequate care being given to their interpretation. For example, in anti-HIV trials, the area under the curve, formed by joining the results of successive measurements over the duration of the trial and bounded by the pretreatment level, is sometimes recommended (*see* **Bioequivalence**). However, this measure is effectively a time-weighted average and does not distinguish short-term effects from long-term effects, so that statistical significance might be obtained at the expense of clinical relevance.

An alternative approach to the analysis is to calculate a test statistic at each measurement time, and then to combine the test statistics into one value (taking into account the fact that they are correlated), as suggested by Wei & Johnson [14]. This reduces the analysis to a single test. However, this method also has the disadvantage that it does not distinguish short-term effects from long-term effects or other patterns of change that might be of clinical interest.

Subgroup Analyses

Common secondary analyses involve the investigation of whether differences between treatments vary between different subgroups of the population studied, where the subgroups are defined by the values of some covariate. From a multiple comparisons perspective, there are two problems. First, there may be many possible subpopulations defined by a particular covariate for which differences might be evaluated. Collins et al. [1] showed the hazards of this very nicely in an example in which they used the zodiac birth sign as a means of defining subpopulations and showed that the relative effect of treatment was "significant" for patients born under Scorpio, but was not for the other birth signs combined, almost undoubtedly a chance finding reflecting a type I error. This type of analysis is inappropriate. Instead, a single test of **interaction** should be undertaken to assess whether the relative effect of treatment does vary across subgroups defined by the covariate (*see* **Treatment-covariate Interaction**).

The second problem is that there may be many **covariates** used in defining different divisions of the study population. Adjusted marginal tests (applied to the tests of interaction defined by each covariate) should be considered, particularly if there is no prior reason for anticipating a difference between subpopulations. In the latter case, prespecification of the subpopulations for subgroup analyses might help as a means of identifying potential subgroups of interest. However, it is important to appreciate that prespecification is only desirable for a very limited number of subpopulations (one or two), and that prespecification of an extensive list of subpopulations does not avoid the multiple comparisons problem.

Interim Analyses

Interim analyses are sometimes undertaken during the conduct of the trial for ethical (*see* **Ethics of Randomized Trials**) and cost reasons, with the idea that a trial might be modified or terminated early if significant treatment differences are found. The successive analyses will lead to an increase in the error rate. In extreme, with continuous monitoring, the error rate can be inflated to a very high level so that a "significant" difference will be obtained with very high probability, even if there is no true difference; what Cornfield [3] termed "sampling to a foregone conclusion". Thus, control of the error rate in the face of the multiple comparisons is desirable. Methods specific to this application have been developed and are

discussed in detail elsewhere (*see* **Data and Safety Monitoring**).

Closing Remarks

The multiple comparisons problem is a major issue in the interpretation of results from clinical trials. The discussion above shows that, in many instances, the issue is better addressed by defining the specific questions of greatest clinical interest. In this way, the dimension of the multiple comparisons problem can often be reduced, and a study better designed to address these questions. When multiple comparisons are still required, then prespecification of a limited number of comparisons of primary interest is wise. In many circumstances, the analysis can proceed without further adjustment for multiple comparisons by determining that it is the marginal error rates that are of prime interest rather than the experiment-wise error rates. This requires that thought be given to the decisions that might follow from the results of the trial, and to whether these decisions are to be made on the basis of marginal hypotheses or upon the collection of hypotheses, respectively.

Although the focus has been on **hypothesis testing** and error rates, the problem of multiple comparisons is also relevant to interval estimation (*see* **Estimation, Interval**). Specifically, whenever it is considered that some control of error rates across comparisons is desirable, then similar arguments apply in the construction of **confidence intervals**.

MICHAEL D. HUGHES

Multistage Carcinogenesis Models

Cancer is a disorder of cells whereby a visible tumor is the end result of a whole series of changes which may have taken many years to develop. Cancers generally derive from the clonal expansion of a single cell (monoclonal) that is dramatically altered by the series of events.

To understand the process of carcinogenesis, the story must start at the beginning – normal cells. A normal cell has a well-defined shape and is organized within its environment of other normal cells. Growth (cell division or replication) is dictated by the stimulatory and inhibitory signals of the environment, which are normally in balance until a growth stimulus is required. In normal development and growth, growth control allows individual organs (e.g. heart, liver, lungs) to reach a specific size which is homeostatically maintained.

The process of replication brings with it the risk of mutations. Mutations may be thought of as permanent alterations in DNA (occurring within all or part of the DNA of a cell) that can impair the regulatory communication between the cell and its environment. The most generally accepted mechanism is as follows. A single mutation alters the physical nature of the cell, making it less responsive to external stimuli, resulting in frequent cell division. As genetic damage accumulates, the damaged cell becomes deaf to external stimuli. Lack of external influence eventually results in uncontrolled replication, characteristic of malignancy, and the resulting tumor (clonal mass of mutated cells) damages healthy tissue in its neighborhood or metastasizes where it may establish new colonies at distant sites. Other mechanisms exist including loss of genetic material, alterations in cellular death, alterations in cellular communication not related to mutations, and alteration in mitochondrial DNA. The net effect in all cases is general loss of homeostatic control of cellular division, growth of a tumor, and resulting damage to surrounding tissue (*see* **Cell Cycle Models**).

One hundred and forty years ago, Johannes Mueller, a German microscopist, demonstrated that cancers were made up of cells. This discovery initiated a search for the specific differences between normal and cancer cells. By 1914, the German cytologist, Theodor Boveri, concluded that malignant cells had atypical chromosomes and that any event leading to such abnormality would cause cancer. Advances in biological technology, especially in the fields of cellular and molecular biology, have identified many genes that take part in the progression from normalcy to cancer.

The process of carcinogenesis is inherently probabilistic, at least as long as it is unknown why certain individuals are afflicted with cancer under certain conditions and others are unaffected. Attention will be focused on stochastic models of carcinogenesis at the cellular level since one of the least understood aspects of tumor development is the **latent period** between cancer initiation and the appearance of tumors. Mathematical models of carcinogenesis strive to investigate the number and types of events in the progression from normalcy to malignancy and allow examination of hypothetical schemes that may be tested objectively.

There are two basic concepts that have been used in describing the events leading to carcinogenesis: hit theory and multistage theory. The biological hypothesis behind the hit theory of carcinogenesis is that a cell must be damaged a certain number of times before it loses growth control and becomes tumorigenic. The damage to the cell is thought to be caused by particles of the carcinogen hitting the nucleus of the cell. The damage incurred is dependent on the number of hits the cell receives and the dose of the carcinogenic agent. A majority of the literature on hit theory modeling comes from the area of biophysics where interest has centered on the interaction between **radiation** and target cells with respect to mutagenicity. Hit theory directly related to modeling the process of carcinogenesis does not have a pronounced history. Figure 1 displays a three-hit model of carcinogenesis.

The first mathematical model of carcinogenesis was that of Iversen & Arley [5]. Their model postulated that carcinogenic "hits" are independently and randomly distributed among all normal cells of a tissue. Each normal cell hit by the carcinogen undergoes an irreparable change which marks the onset of the cancer process. This model is frequently referred to as the "one-hit" model of carcinogenesis because only a single hit is necessary for a cell to undergo a mutation which will eventually lead to malignancy. Once the cell becomes mutated, it is assumed to lose growth control and proliferates

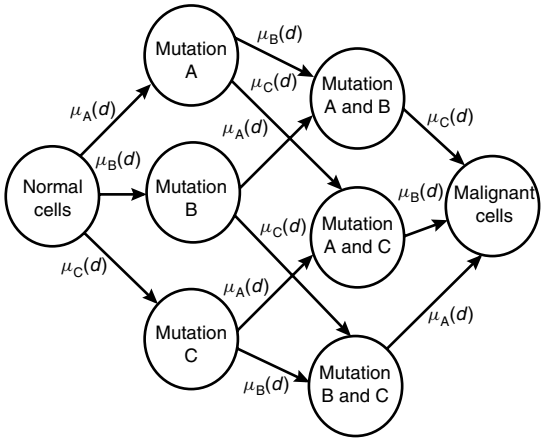

Figure 1 Three-hit model of carcinogenesis [16]. In this model, mutation rates are denoted by μ_i, ($\mu_A = \mu_B = \mu_C = \mu$). All rates are expressed as number of mutations per unit dose of carcinogen (denoted by d) for a fixed period of time

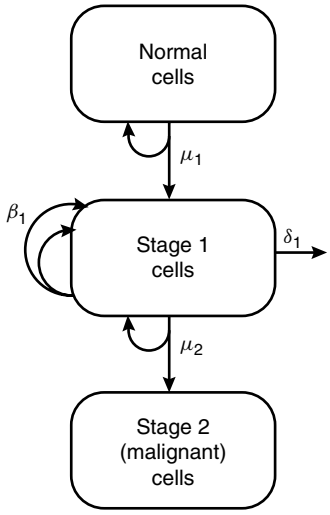

Figure 2 Two-stage model of carcinogenesis. In this model, mutation rates are denoted by μ_i, birth rates are denoted by β_i, and death/differentiation rates are denoted by δ_i. All rates are expressed as number of events per cell per unit of time

via replication. An observable tumor results when enough replicated cells have amassed to be clinically detectable.

Stochastic Models of Carcinogenesis

Many years after the development of Iversen & Arley's stochastic cancer model, Rai & Van Ryzin [16] resurrected the underlying theme of the one-hit model and adapted it to include more than a single hit, i.e. a multihit model. The biological hypothesis behind the multihit model is that a normal cell must be damaged a multiple number of times before it results in a malignant cell. The amount of damage that is incurred is dependent on the number of hits the cell receives and the dose of the carcinogenic agent. Rai & Van Ryzin further assumed that, once a cell has been subjected to at least j hits, it becomes malignant and will eventually result in a tumor. Unlike Iversen & Arley [5], they did not model the growth process of malignant cells. Mathematically, it was assumed that once a cell received j hits it instantaneously became an observable tumor.

The multihit model has been used to model the occurrence of cancer in a variety of tissues; however, it is not clear from Rai & Van Ryzin's mathematical derivation that their theory applies to entire tissues as it does to an individual cell. Disregarding this caveat, the "hit" theory of carcinogenesis was still not well received even after Rai & Van Ryzin's development of a generalized theory, and was generally abandoned at this point. This was most likely due to the perceived simplistic nature of the "hit" theory model and a lack of plausibility relative to the multistage theory of carcinogenesis.

The multistage theory of carcinogenesis also assumes several events leading to DNA damage; however, it is hypothesized that these events must occur in a particular sequence. In essence, the multistage model is an order-restricted multihit model. This theory was initially conceptualized by Muller [10] and Nordling [12] from the observation that for some carcinomas the cancer incidence rate rapidly increased with increasing age. Multistage theory continues to be a popular concept since current biological evidence suggests that genetic changes usually occur in a specific order. Figure 2 displays a two-stage model of carcinogenesis.

The two-stage model shown in Figure 2 assumes that a normal cell must pass through two unique, sequential stages before becoming malignant. This model has three types of cells: normal cells, stage-one cells, and stage-two (malignant) cells. In the small time interval $[t, t + \Delta t)$, the following events may occur:

1. A normal cell may acquire a mutation resulting in damage to a single strand of the DNA which results in one normal cell and one stage-one cell with probability $\mu_1 \Delta t + o(\Delta t)$.
2. A stage-one cell may replicate, resulting in two stage-one cells with probability $\beta_1 \Delta t + o(\Delta t)$.
3. A stage-one cell may differentiate or die, i.e. leave the system, with probability $\delta_1 \Delta t + o(\Delta t)$.
4. A stage-one cell may acquire a mutation, resulting in damage to a single strand of the DNA which results in one stage-one cell and one stage-two (malignant) cell with probability $\mu_2 \Delta t + o(\Delta t)$.

The probability of more than one event occurring in this small time interval is $o(\Delta t)$.

For the model shown in Figure 2 (and most classes of multistage models used to date) the growth of normal cells is assumed to be constant or deterministic. In the context of the model, it is assumed that the number of normal cells at any time t is constant. All intermediate cell types (in this case, stage-one cells) are assumed to undergo growth kinetics via a linear birth–death process (*see* **Stochastic Processes**). A linear birth–death process implies that the rate of growth of a cell population is proportional to the number of cells in the tissue. Further modeling assumptions are that the birth–death processes and mutation processes are stochastic and independent of one another. In addition, each cell acts independently of other cells, the transformation process is irreversible, i.e. damage to the genome is "fixed", and once a malignant cell is produced it loses growth control and will eventually result in a tumor. Mathematically, these assumptions imply that the model portrays the process of carcinogenesis as a **Markov process**. A Markov process describes the fate of any cell at time t as depending only on the present state of the cell at time t and not on the past history of that cell. More precisely, this model may be described as a continuous-time multiple **branching process** since all cell types (with the exception of malignant cells) implement growth kinetics that spawn birth–death processes from which the progeny form branching processes.

Mathematically, the main outcome studied in the context of these mathematical models of carcinogenesis is the time-to-first-entry into the malignant state, generally referred to as the **tumor incidence** rate. Let T be the associated random variable, in which case tumor incidence is defined as

$$\lambda(t) = \lim_{\Delta t \to 0} \frac{\Pr[T \in [t, t + \Delta t) | (T \geq t)]}{\Delta t}. \qquad (1)$$

This is generally converted into a cumulative distribution function (CDF) for tumor onset by the formula

$$\Pr(T < t) = 1 - \exp\left[- \int_0^t \lambda(s)\, \mathrm{d}s \right]. \qquad (2)$$

For the simple two-stage model of carcinogenesis in Figure 2, several authors have derived a closed-form solution for the tumor incidence rate for time-constant rate parameters (Kopp–Schneider et al. [6] and Zheng [21]). The solution is given as

$$\Pr(T \leq t) = 1 - \exp[-\Lambda(t)], \qquad (3)$$

where

$$\Lambda(t) = \left(\frac{X_0 \mu_1}{\beta} \right) \left[\frac{t}{2} (\beta - \delta - \mu_2 + R) + \log \left(\frac{(\delta - \beta + \mu_2 + R) + (\beta - \delta - \mu_2 + R) \exp(-Rt)}{2R} \right) \right], \qquad (4)$$

where

$$R = [(\beta + \delta + \mu_2)^2 - 4\beta\delta]^{1/2} \qquad (5)$$

The most general formulation for the CDF is derived by Portier et al. [15]. They use the Kolmogorov backwards equations to develop a system of ordinary differential equations (ODEs) which, through a simple algebraic manipulation, can be used to derive (2) for any nonhomogeneous multistage model of carcinogenesis. The model is still required to be stochastically linear (the rate constants cannot depend upon the numbers of cells in each stage of the process). If we expand the two-stage model in Figure 2 to include a birth–death process on the normal cells (rates $\beta_0(t)$ and $\delta_0(t)$ for birth and death of normal cells, and rates $\beta_1(t)$ and $\delta_1(t)$ for stage-one cells), then the ODEs derived by Portier et al. [15] are

$$\frac{\mathrm{d}}{\mathrm{d}s} \Psi_0(s) = \beta_0(t - s)[\Psi_0(s)]^2 + \delta_0(t - s) + \mu_1(t - s)\Psi_0(s)\Psi_1(s) - [\beta_0(t - s) + \delta_0(t - s) + \mu_1(t - s)]\Psi_0(s)$$

and

$$\frac{\mathrm{d}}{\mathrm{d}s}\Psi_1(s) = \beta_1(t-s)[\Psi_1(s)]^2 + \delta_1(t-s) - [\beta_1(t-s) + \delta_1(t-s) + \mu_2(t-s)]\Psi_1(s), \quad (6)$$

where the initial conditions are $\Psi_0(0) = 1$ and $\Psi_1(0) = 1$. The CDF for tumor incidence is calculated by solving this system from $s = 0$ to $s = T$ and plugging the solutions into the calculation

$$\Pr(T \leq t) = [\Psi_0(t)]^{m_0}[\Psi_1(t)]^{m_1}, \quad (7)$$

where m_i is the initial number of cells in stage i of the process at time $t = 0$. A detailed derivation of these ODEs would be inappropriate in this context; interested readers should refer to the manuscript by Portier et al. [15] for the details.

Even without the details, it is possible to develop systems of ODEs intuitively for more complex multistage models. Examining the form of system (7) relative to the form of the model in Figure 2, it is possible to illustrate the pattern of these equations. Starting with the end of (6) first, it is clear that in the equations pertaining to $\Psi_i(s)$, the rates of the process by which cells move out of state $i[\beta_i(t-s), \delta_i(t-s)$, and $\mu_{i+1}(t-s)]$ are summed, multiplied by $\Psi_i(s)$ and subtracted from the differential equation. The remaining terms in the differential equation for $\Psi_i(s)$ are the product of each rate for cells leaving the state i times the $\Psi.(s)$ for the eventual location of the resulting cell(s). These terms are all added to the differential equation. For example, a birth results in two cells returning to the state in which the birth occurs. For state i, the resulting product to be added to the differential equation for $\Psi_i(s)$ is $\beta_i(t-s)\Psi_i(s)\Psi_i(s)$; that is the rate for the event of birth for the proper time, $\beta_i(t-s)$, times the **generating functions** for the states of the two resulting cells, $\Psi_i(s)$ and $\Psi_i(s)$. A mutation from state i results in one cell returning to state i and the next cell going on to state $(i+1)$ so the resulting product to be added to the differential equation for $\Psi_i(s)$ is $\mu_i(t-s)\Psi_i(s)\Psi_{i+1}(s)$. Note that, for the state just prior to the malignant state (state 1 in the two-stage model), since the function for the final state [$\Psi_2(s)$ in the two-stage model] is identically zero at all times, this term drops out of the system. Finally, since death/differentiation simply removes a cell and does not place it into any state being followed by the system, the proper term to add to $\Psi_i(s)$ for a death is simply $\delta_i(t-s)$. The calculation of the CDF is a direct extension of (7) to include all stages in the more complicated model.

The most important aspect of this modification to the determination of the CDF for tumor onset is the ability to consider much more complicated and realistic models (see below) and to incorporate biochemical and pharmacological events into the determination of rate constants for the model (see Portier et al. [15]).

Towards More Realistic Models

The hit theory and multistage theory have played dominant roles in the mathematical modeling of carcinogenesis. The history of carcinogenic modeling can be described as a hierarchy of models within a respective framework, i.e. hits or stages. Generally, each newly developed model encompasses the previously developed models. Thus, mathematical models attempt to include the evolution of biological evidence in cancer biology. A natural extension in the mathematical modeling of carcinogenesis is the development of a single model which incorporates concepts from both hit theory and multistage theory. This class of models still embodies all of the mathematical models constructed under the multihit and multistage paradigms, and thus the history of carcinogenesis modeling is preserved, while simultaneously current experimental evidence is being incorporated into this class of models. In essence, a natural extension in the continuum of the mathematical modeling of carcinogenesis is being implemented. This class of models is referred to as the multipath/multistage models of carcinogenesis.

In fusing the hit theory and multistage theory of carcinogenesis, it is important to understand the notions of stages and hits in the context of the multipath/multistage model. Stages will be defined as necessary events for carcinogenesis that must occur in a specific order. Conversely, hits are defined as events that have no specific ordering and no direct bearing on carcinogenesis; however, they may augment the rate at which a stage occurs. Consequently, by definition, hits yield alternative pathways to cancer. Figure 3 displays a two-path/three-stage model of carcinogenesis. There are two possible scenarios

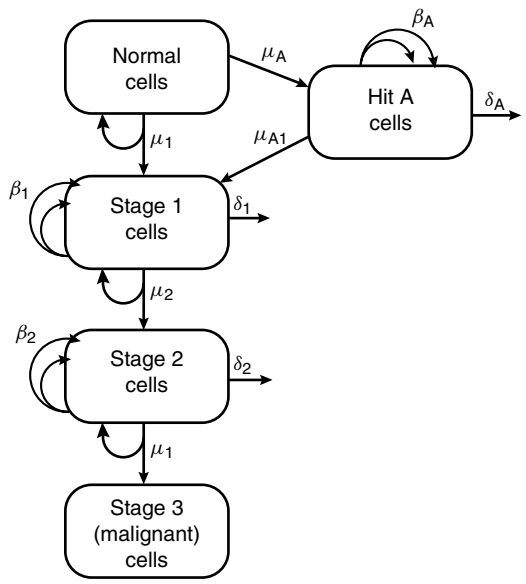

Figure 3 Two-path/three-stage model of carcinogenesis. In this model, mutation rates are denoted by μ_i, birth rates are denoted by β_i, and death/differentiation rates are denoted by δ_i. All rates are expressed as number of events per cell per unit of time

for a normal cell to be transformed into a malignant cell:

1. A normal cell may undergo three mutational events: transformation from the normal state to stage one (rate μ_1), transformation from stage one to stage two (rate μ_2), and then transformation from stage two to the malignant state (rate μ_3). This is the most direct path to carcinogenesis where three stages are traversed.
2. A normal cell may undergo four mutational events: transformation from the normal cells to hit A cells (rate μ_A), transformation to stage one (rate μ_{A1}), transformation from stage one to stage two (rate μ_2), and then transformation to the malignant state (rate μ_3).

In a modeling context, Figure 3 is a four-stage model added to a three-stage model since hits and stages are mathematically indistinguishable. However, biologically this is not simply a fourth stage added to a simple three-stage model, but a construct based on some observations regarding certain carcinogenic mechanisms. Because the hit A cells still lead to stage-one cells, this state does not really constitute a stage by the definition given. It is more closely related to a hit since passage through this stage in moving to stage one is not required, but does alter the overall mutation rate.

Experimental evidence for the multipath/multistage model is supported by current cancer research in the area of oncogenes and tumor suppressor genes. Oncogenes are thought to be genes whose activation accelerates replication. Tumor suppressor genes are thought to act in the opposite manner; they are genes whose deactivation removes some restrictions on the mechanism that regulates cell proliferation. Thus, if oncogenes are activated and tumor suppressor genes deactivated, the net result is believed to be a cell, and eventually a colony of cells, with little or no growth control (malignancy) (*see* **Tumor Growth**).

Current biological theory in the area of molecular carcinogenesis suggests that a malignant cell results from the accumulation of genetic damage to a single cell. The multipath/multistage model may possibly explain the underlying mechanisms involved in the transformation of the mechanisms by which the oncogenes and suppressor genes control replication. Three equally likely possibilities exist:

1. Oncogene activation and suppressor gene deactivation must occur in a sequential manner and induce carcinogenesis. This situation would fit the multistage theory of carcinogenesis. This theory includes models such as those by Armitage & Doll [1, 2], Neyman & Scott [11], Moolgavkar & Venzon [9], and Portier & Kopp-Schneider [14].
2. Oncogene activation and suppressor gene deactivation are not restricted to a particular order of occurrence. Thus, carcinogenesis is induced once both these events occur, regardless of order. This would directly relate to the multihit theory hypothesis. Models in this class have been proposed by Iversen & Arley [5] and Rai & Van Ryzin [16].
3. One of the events in the process, say oncogene activation, could have no direct bearing on carcinogenesis such that it is unnecessary for tumor formation. However, it may still alter the rate at which one of the other events, say suppressor gene deactivation, occurs. Thus, oncogene activation could be considered as a potential hit which augments suppressor gene deactivation.

Because suppressor gene deactivation is necessary for carcinogenesis, it is a stage in the process. Models in this class have been proposed by Portier [13] and Tan [20], and developed by Sherman & Portier [17].

Estimation Considerations

Historically, mathematical models related to the cancer process have relied on tumor response data, i.e. the presence or absence of a tumor, for parameterization. However, tumor response data are not sufficient to uniquely parameterize the simplest of mathematical cancer models. Mathematical and statistical techniques have been derived over the past several years to take advantage of some of the intermediate cancer biomarker data currently being collected [3, 4, 6, 19]. Premalignant lesion data from rodent skin papilloma studies (number of skin papillomas) and hepatocarcinogenicity studies (number and size of enzyme-altered hepatic lesions) have been used to elucidate the underlying cancer mechanisms of a variety of chemical carcinogens.

Mathematical models have also been developed to focus strictly on the growth properties of premalignant lesions. From cell labeling studies carried out over a period of time (incidence labeling data), Moolgavkar & Luebeck [8] have developed methods to estimate the birth rate of premalignant cells. Lyles [7] incorporates incidence and prevalence cell labeling data (BrdU cell labeling data and PCNA cell labeling data, respectively) to estimate the rate parameters of the cell cycle. From these methods, one may test a variety of hypotheses which may elucidate aberrant cell growth typically characterized by premalignant cell populations.

Mathematical models of carcinogenesis are not limited to using a single type of data (i.e. tumor response data alone or labeling index data alone) in the modeling process. Several pieces of information may be incorporated into a single model to more fully describe the cancer process or fill in the gaps created by previous models. Important aspects of this approach are its close ties to the underlying biology of the cancer process and the enhancement of statistical **power** in **hypothesis testing** (due to the use of additional data). Once a model and data are chosen, one may use **maximum likelihood** techniques to arrive at parameter **estimates** and **likelihood ratio tests** to examine a broad range of hypotheses.

Multistage Sampling

Multistage sampling is an extension of **cluster sampling**. The sampling units are hierarchically arranged: primary, secondary, tertiary, etc. units are established in accordance with the number of stages in the multistage sampling design. For simplicity of illustration, we consider a population that has been divided into primary sampling units (PSUs), where the PSUs are initially unstratified. A frame of M PSUs is assumed (*see* **Sampling Frames**). A first-stage sample of m PSUs is randomly selected from this frame. The population within the ith sampled PSU is itself divided into N_i secondary units, and a sample cluster of n_i units is randomly selected from this frame. In multistage sampling $n_i < N_i$ as opposed to cluster sampling where $n_i = N_i$. The sampling within each PSU is independent of the sampling in other PSUs and may be carried to any number of stages. One may use any **probability sampling** method (such as **stratified sampling** or cluster sampling) at any stage, and these methods may differ between PSUs. The enumeration or listing units on which surveys are conducted are the units selected at the last sampling stage.

Other names used for multistage sampling are *nested sampling* and *k-stage sampling* where k is the number of sampling stages in the survey design. The term *subsampling* is also used to describe the use of sample clusters as the population for the subsequent sampling stage.

Multistage sampling should not be confused with multiphase sampling. The sampling units in a multistage sample are nested. By contrast, multiphase sampling uses the same set of units at all phases included in its design. However, it is possible to use both multistage and multiphase techniques in a complex survey design (see Kish [4, Section 12.1] and Foreman [2, Section 7.4]).

The primary reason for using multistage sampling is to reduce the costs of data collection. For example, in a single-stage sample of households in a city one would have to list the households in the whole city, whereas in a multistage sample with city blocks used as PSUs, one could restrict listing activities to a sample of city blocks. One also uses multistage sampling when an exhaustive listing of the target population cannot be compiled. For instance, a list of hospital patients does not exist, but a list of hospitals does. Kish [4, Chapters 6, 9–11] and Sudman [6, Chapter 7] give detailed procedures for listing units in multistage area surveys.

The operational advantages of multistage sampling are offset by a loss in sampling efficiency. A multistage sample usually results in larger sampling error than does a **simple random sample** of the same size for the corresponding sample estimates. However, multistage sampling usually yields smaller **variances** for a unit of cost.

To facilitate discussion, we consider two-stage samples. Extensions to more sampling stages are intuitive. A sample of m PSUs is selected from the population total of M PSUs. A sample cluster of n_i secondary units is selected from the population of N_i secondary units in the ith sample PSU. The total number of listing units in the population and sample are $N = \sum_I^M N_I$ and $n = \sum_i^m n_i$, respectively.

The overall selection probability, P_{ij}, for the jth secondary unit in the ith PSU is the product $P_{ij} = P_{1i} \times P_{2ij}$, where P_{1i} and P_{2ij} are sampling fractions at the first and second sampling stages, respectively. The P_{2ij} is the **conditional probability** of selecting the jth unit provided the ith PSU is selected. One usually uses equal selection probabilities, $P_{2ij} = f_{2i}$, within PSUs, especially at the last stage. This article assumes equal selection probabilities within PSUs.

When sampling fractions within PSUs are uniform across PSUs, i.e. $f_{2i} = f_2$, N_i is frequently not a multiple of the expected sample cluster size $\mathrm{E}(n_i) = f_{2i} \times N_i$ and the expected size includes a fraction. The actual size is then variable with possible values n_i or $n_i + 1$. To minimize the effort of determining the actual sample cluster sizes in such situations, one usually uses **systematic random sampling** to select secondary units, thus allowing the random start to determine the sample cluster size from each PSU.

Estimation

In multistage sampling, **estimation** is also done in stages, starting with the last units. In two-stage samples one first estimates PSU aggregates with data from secondary units. Here, we consider samples in which simple random sampling is used at both stages without replacement. For equal probability samples of secondary units,

$$x_i' = \frac{N_i}{n_i} \sum_j^{n_i} x_{ij} \tag{1}$$

is an **unbiased** estimate of the PSU aggregate X_i. These estimates are used in place of X_i in the unbiased estimate,

$$x' = \frac{M}{m}\sum_{i}^{m} x_i', \tag{2}$$

of the aggregate X for the entire population. The variance of x' is

$$\sigma_{x'}^2 = \frac{M^2}{m}\frac{M-m}{M}S_{1X}^2 + \frac{M}{m}\sum_{I}^{M}\frac{N_I^2}{n_I}\frac{N_I - n_I}{N_I}S_{2IX}^2$$
$$= B_{x'}^2 + W_{x'}^2 \tag{3}$$

where

$$S_{1X}^2 = \frac{\sum_{I}^{M}(X_I - \overline{X})^2}{M-1}, \tag{4}$$

$$S_{2IX}^2 = \frac{\sum_{J}^{N_I}(X_{IJ} - \overline{\overline{X}}_I)^2}{N_I - 1}, \tag{5}$$

$$X_I = \sum_{J}^{N_I} X_{IJ}, \quad \overline{X} = \frac{\sum_{I}^{M} X_I}{M} = \frac{X}{M} \quad \text{and}$$

$$\overline{\overline{X}}_I = \frac{\sum_{J}^{N_I} X_{IJ}}{N_I} = \frac{X_I}{N_I} \tag{6}$$

[3, Volume I, Section 6.6, Volume II, Section 6.1]. The S_{1X}^2 is the population variance between PSU totals. The S_{2IX}^2 is the population variance between secondary units within the Ith PSU.

The variance of x' in (3) is expressed in terms of the contributions at each sampling stage. The first term is the between-PSU component of variance; it represents the contribution due to sampling PSUs. The second term is the within-PSU component of variance; it is the contribution due to sampling secondary units. The between-PSU component is the variance one gets if there were no subsampling within PSUs ($n_i = N_i$) i.e. if the sample were a one-stage cluster sample. The within-PSU component is the variance one gets if one takes all PSUs into the sample ($m = M$), i.e. if the sample were a stratified sample with M strata (*see* **Variance Components**).

In multistage sampling the estimates of means and proportions are usually ratios of estimated aggregates because the denominator, as well as the numerators, are unknown and, hence, must also be estimated. For a ratio $R = X/Y$ of aggregate variates X and Y, one may use the estimate $r = x'/y'$, where x' and y' are defined in (2). Expressions for σ_r^2 are similar in form to those for $\sigma_{x'}^2$. The variance of r for samples selected with equal probability without replacement at both stages is approximately

$$\sigma_r^2 = \frac{M^2}{m}\frac{M-m}{M}S_{1R}^2 + \frac{M}{m}\sum_{I}^{M}\frac{N_I^2}{n_I}\frac{N_I - n_I}{N_I}S_{2IR}^2$$
$$= B_r^2 + W_r^2, \tag{7}$$

where

$$S_{1R}^2 \doteq \left(\frac{1}{Y^2}\right)(S_{1X}^2 + R^2 S_{1Y}^2 - 2RS_{1XY}) \tag{8}$$

with S_{1X}^2 and S_{1Y}^2 defined in (4) and population covariance defined as

$$S_{1XY} = \frac{\sum_{I}^{M}(X_I - \overline{X})(Y_I - \overline{Y})}{M-1}, \tag{9}$$

and where

$$S_{2IR}^2 \doteq \left(\frac{1}{Y}\right)^2 (S_{2IX}^2 + R^2 S_{2IY}^2 - 2RS_{2IXY}), \tag{10}$$

with S_{2IX}^2 and S_{2IY}^2 defined in (5) and the population covariance defined as

$$S_{2IXY} = \frac{\sum_{J}^{N_I}(X_{IJ} - \overline{\overline{X}}_I)(Y_{IJ} - \overline{\overline{Y}}_I)}{N_I - 1}. \tag{11}$$

The variance approximation in (7) is good if the sample size is large enough that the coefficient of variation $V_{y'} = \sigma_{y'}/Y$ for the denominator is less than 0.05 [3, Volume I, Section 6.6], or if the sample is large enough that both $V_{x'} = \sigma_{x'}/X$ and $V_{y'}$ are less than 0.10 [1, Section 6.3] (*see* **Ratio and Regression Estimates**).

Two estimates of variance are useful in multistage estimates. When not designing samples, one may approximate the combined contribution of the first and second stages of variance simply with ultimate cluster variance estimates. An ultimate cluster is the entire sample of listing units selected from a PSU,

regardless of how many sampling stages are used. For example, in a three-stage sample where city blocks, households, and persons are selected at the first, second, and third sampling stages, persons are the listing units and blocks are the PSUs; an ultimate cluster then consists of all persons selected to the sample from one block. When two or more PSUs are selected to the sample, the ultimate cluster estimate of σ_z^2 for generic statistic z (z is the aggregate estimate x' or ratio estimate r) is

$$\hat{\sigma}_z^2 = \frac{M^2}{m} s_{cZ}^2. \tag{12}$$

If z is the aggregate estimate x' defined in (3), then

$$s_{cX}^2 = \frac{\sum_i^m (x_i' - \overline{x})^2}{(m-1)}, \tag{13}$$

where x_i' is an unbiased estimate of PSU aggregate X_i, and $\overline{x} = x'/M$. Similarly, if z is a ratio estimate r, then

$$s_{cR}^2 \doteq \left(\frac{1}{y'}\right)^2 (s_{cX}^2 + r^2 s_{cY}^2 - 2r s_{cXY}), \tag{14}$$

with

$$s_{cXY} = \frac{\sum_i^m (x_i' - \overline{x})(y_i' - \overline{y})}{m-1}. \tag{15}$$

Expressions (13) and (14) are variances between ultimate clusters.

The estimate in (12) is **consistent**. One may use it with any multistage sample, regardless of the number of stages or probability subsampling methods, provided the sampling is independent between PSUs. When the PSUs are selected with replacement, $\hat{\sigma}_{x'}^2$ for the aggregate estimate x' is unbiased. When PSUs are selected without replacement (*see* **Sampling With and Without Replacement**), $\hat{\sigma}_z^2$ overstates σ_z^2, but it may still be a useful approximation, especially when m/M is small and the between-PSU variance component is not a large portion of the total variance (see Hansen [3, Volume I, Sections 6.7 and 9.15] and Foreman [2, Section 8.5]).

When one designs samples and needs approximations for the separate variance components, one may use the following consistent estimates. An estimate of the within-PSU component in (3) or (7) is

$$w_z^2 = \frac{M^2}{m} \hat{s}_{2z}^2, \tag{16}$$

where

$$\hat{s}_{2Z}^2 = \frac{1}{m} \sum_i^m \frac{N_i^2}{n_i} \frac{N_i - n_i}{N_i} s_{2iZ}^2. \tag{17}$$

When z is the aggregate estimate x',

$$s_{2iX}^2 = \frac{\sum_j^{n_i} (x_{ij} - \overline{\overline{x}}_i)^2}{n_i - 1}, \tag{18}$$

and, when z is the ratio estimate r,

$$s_{2iR}^2 \doteq \left(\frac{1}{y'}\right)^2 (s_{2iX}^2 + r^2 s_{2iY}^2 - 2r s_{2iXY}), \tag{19}$$

with

$$s_{2iXY} = \frac{\sum_j^{n_i} (x_{ij}' - \overline{\overline{x}}_i)(y_{ij}' - \overline{\overline{y}}_i)}{n_i - 1}. \tag{20}$$

A consistent estimate of the between-PSU component B^2 in (3) or (7) is

$$b_z^2 = \frac{M^2}{m} \frac{M-m}{M} (s_{cZ}^2 - \hat{s}_{2Z}^2), \tag{21}$$

where s_c^2 is defined in (13) or (14) and $\hat{s}_2^2$ is defined in (17) [3, Volume I, Section 6.7, Volume II, Section 6.4].

Sample Size and Allocation

For guidance in selecting among alternative sampling designs, it is frequently helpful to compare them with simple random samples. If one's multistage sample is self-weighting ($f_{2i} = f_2$ so $f_{ij} = f_1 \times f_2 = f$) in addition to being selected with equal probabilities at both stages, the comparison is conveniently made by approximating the variance of estimate z with

$$\sigma_z^2 \doteq \frac{\sigma_Z^2}{m\overline{n}}[1 + \delta_Z(\overline{n} - 1)] = \frac{\sigma_Z^2}{m\overline{n}} \text{ DEFF } (z), \tag{22}$$

where σ_Z^2 is the population variance between listing units for variate Z, $\overline{n} = f\overline{N}$ is the expected sample size per PSU, $\overline{N} = N/M$, and δ_Z is a measure of the homogeneity for variate Z between listing units within PSUs. The factor $\sigma_Z^2/m\overline{n}$ in (22) is the variance that would result if a simple random sample of $n = m\overline{n}$ listing units were used to estimate Z. The remaining factor is the **design effect**, DEFF, which reflects the precision lost due to use of a multistage sample instead of a simple random sample of listing

units. The DEFF and δ differ with sampling design and with the variate being estimated.

For self-weighting samples with both stages selected with equal probabilities without replacement, the appropriate value of δ is expressed by

$$\delta_Z = \frac{\frac{M-1}{M} S_{1Z}^2 - \overline{N} S_{2Z}^2}{\frac{M-1}{M} S_{1Z}^2 + \overline{N}(\overline{N}-1) S_{2Z}^2}, \tag{23}$$

where S_{1Z}^2 is defined in (4) for aggregates and in (8) for ratios, and where

$$S_{2Z}^2 = \sum_I^M \frac{N_I}{N} S_{2IZ}^2, \tag{24}$$

with S_{2IZ}^2 defined in (5) or (10). The measure of homogeneity for a multistage sample is approximately the same as that for the population. Thus, a simple estimate for the δ in (23) is

$$\delta_z' = \frac{s_{cz}^2 - \overline{n} s_{2z}^2}{s_{cz}^2 + \overline{n}(\overline{n}-1) s_{2z}^2}, \tag{25}$$

where s_{cz}^2 is defined in (13) or (14), and

$$s_{2z}^2 = \sum_i^m \frac{n_i}{n} s_{2iz}^2, \tag{26}$$

with s_{2iz}^2 defined in (18) or (19) (see Hansen et al. [3, Volume I, Section 6.8] and Foreman [2, Sections 8.2–8.3]).

Expression (22) shows that for a fixed sample size $n = m\overline{n}$, σ_z^2 varies with the factor $1 + \delta_Z(\overline{n} - 1)$ and, thus with δ_Z and $\overline{n}$. For many populations the natural clusters consist of units that are homogeneous relative to the units in the population as a whole, i.e. $\delta_Z > 0$. For example, persons residing in a city block tend to be more similar to one another than to persons in the city as a whole. Hence, as a general rule one wants to maximize the number of PSUs while minimizing the sample size within each PSU.

Increasing the number or size of sample PSUs may adversely affect survey costs. For example, the costs of listing households increases with the number of city blocks sampled when blocks are the PSUs in a multistage sample of households. To determine the most efficient sample allocation between PSUs and secondary units, one must consider both the costs and internal homogeneity of PSUs. For a two-stage sample, a simple cost function is

$$C = C_1 m + C_2 m\overline{n}, \tag{27}$$

which includes one term for each sample stage. The term for the kth sampling stage is the total cost for that stage of sampling. That term is the product of the number of units selected at the kth stage times C_k, where C_k is the average cost that is incurred when the kth-stage sample is increased by one unit. Among other costs, C_1 includes the cost for a list of all secondary units within a PSU; it also includes the costs of travel to reach PSUs if PSUs are geographically spread out. For example, in a sample of hospital discharges, C_1 includes the cost of gaining the hospital's cooperation and the cost of constructing a sampling frame of all of that hospital's eligible discharges. The second-stage cost, C_2, includes costs for collecting and processing data about the listing unit. Hansen et al. [3, Volume I, Sections 6.10–6.15] has a good discussion on constructing cost functions for multistage samples, but the costs need updating.

For two-stage samples selected with equal probabilities at both stages and the cost model in (27), the optimum sample size per PSU is

$$\text{opt. } \overline{n}_z = \left(\frac{C_1}{C_2}\frac{1-\delta_Z}{\delta_Z}\right)^{1/2} = \overline{N}\left(\frac{C_1}{C_2}\frac{S_{2Z}^2}{S_{1Z}^2 - \overline{N} S_{2Z}^2}\right)^{1/2}, \tag{28}$$

where δ is defined in (23). The optimum in (28) is independent of total survey costs. It requires only the ratio of unit costs. The optimum increases with $(1-\delta)/\delta = [(1/\delta) - 1]$; it increases as δ decreases. It also increases as the PSU costs increase relative to the secondary unit costs. The optimum number of sample PSUs depends on which of two objectives one wants satisfied by the optimized sample. When that objective is to produce estimates for a fixed value C_0 for the survey cost C defined in (27), then

$$\text{opt. } m_z = \frac{C_0}{C_1 + C_2 \text{ opt. } \overline{n}_z}, \tag{29}$$

where opt. $\overline{n}_z$ is given in (28). If, instead of a fixed survey cost, one wants to produce an estimate z with

a specified value σ_0^2 for σ_z^2 defined in (3) or (7), then

$$\text{opt. } m_z = \frac{MS_{1Z}^2 + \dfrac{N^2}{\text{opt.}\overline{n}}\dfrac{\overline{N} - \text{opt. } \overline{n}}{\overline{N}}S_{2Z}^2}{\sigma_0^2 + MS_{1Z}^2}, \quad (30)$$

where opt.$\overline{n}$ is defined in (28), the S_1^2 is defined in either (4) or (8), and S_2^2 is defined in (24) [5, Sections 10.4–10.5]. Values for C_1 and C_2, as well as estimates for S_{1Z}^2 and S_{2Z}^2, can be derived from experience in similar surveys for similar variates. For more on optimizing multistage samples, see Hansen et al. [3, Volume I, Sections 6.16–6.26, 9.7] and Foreman [2, Section 8.4].

Variable PSU Sizes

When PSUs vary in size, sampling them with equal probability is frequently not efficient. Simple random samples of varying sized PSUs will likely yield large between-PSU variance components for estimates of totals for the entire population if the PSU totals are correlated with the PSU size. Such samples will also yield sample clusters of varying sizes if the second-stage sampling fractions are uniform ($f_{2i} = f_2$). Variation in sample cluster sizes usually means increased survey costs owing to variation in work load between PSUs. Efforts to reduce variation in PSU size (by splitting large PSUs, combining small PSUs, or otherwise reconstructing PSUs) are usually too difficult or costly to be worthwhile.

There are three basic methods generally used for controlling the effects of variation in PSU sizes. Each requires some information on PSU size for every PSU. However, one usually uses approximations because the actual sizes are rarely known. One may use a stratified sample of PSUs with strata defined by PSU size. The largest PSUs or unusual PSUs can then be placed in a certainty stratum, where the estimate has no between-PSU variance component. The estimate for an aggregate X for the entire population is then the sum of estimates for stratum aggregates and the variance of that estimate is the sum of the variances for stratum estimates. If one uses simple random sampling at each stage within strata, the estimate of aggregate X_h for the hth stratum is given in (2) with variance given in (3).

Another method of controlling for varying PSU sizes is to select PSUs by **sampling with probability proportional to size** (pps). Under pps, one selects the ith PSU with probability $\pi_i = m(A_i/A) = mP_i$, provided $A_i < A/m$. The A_I is the approximation to size of the Ith PSU and $A = \sum_I^M A_I$. When $A_I > A/m$, one typically places the Ith PSU in a certainty stratum and then uses pps to select a sample of $m - 1$ PSUs from the remaining population. For sample PSUs with $A_i < A/m$, one almost always uses the probability $f_{2i} = f \times (1/p_i)$ to select the ijth secondary unit. That makes the sample self-weighting and the sample clusters approximately equal in size. Some variation in n_i is likely because of imperfect PSU size measures. When PSUs are selected with varying probabilities, an unbiased estimator of the population aggregate X is the **Horvitz–Thompson estimator**

$$x' = \sum_i^m \frac{x_i'}{\pi_i} = \frac{1}{m}\sum_i^m \frac{x_i'}{P_i}, \quad (31)$$

where x_i' is given in (1). When the P_i are uniform ($P_i = 1/M$), (31) becomes identical to (2). For a self-weighting sample with PSUs selected with pps without replacement, the variance of x' in (31) is approximately

$$\sigma_{x'}^2 = \frac{1}{m}\sum_I^M P_I \frac{1 - nP_I}{1 - P_I}\left(\frac{X_I}{P_I} - X\right)^2 + \frac{1}{m}\sum_I^M \frac{N_I^2}{P_I}\frac{(N_I - n_I)}{N_I n_I}S_{2IX}^2, \quad (32)$$

with S_{2IX}^2 defined in (5) (see Foreman [2, Section 7.5] and Hansen et al. [3, Volume I, Section 8.14, Volume II, Section 8.11]). The variance of ratio r is

$$\sigma_r^2 \doteq \left(\frac{1}{Y}\right)^2 (\sigma_{x'}^2 + R^2\sigma_{y'}^2 - 2R\sigma_{x'y'}), \quad (33)$$

where

$$\sigma_{x'y'} = \frac{1}{m}\frac{\sum_I^M P_I \dfrac{1 - nP_I}{1 - P_I}\left(\dfrac{X_I}{P_I} - X\right)\left(\dfrac{Y_I}{P_I} - Y\right)}{m - 1} + \frac{1}{m}\sum_I^M \frac{N_I^2}{P_I}\frac{(N_I - n_I)}{N_I n_I}S_{2IXY} \quad (34)$$

with S_{2IXY} defined in (11).

When two or more PSUs are selected with pps, the ultimate cluster estimate for $\sigma_{x'}^2$ is

$$\hat{\sigma}_{x'}^2 \doteq \frac{1}{m} \frac{\sum_i^m \left(\frac{x_i'}{P_i} - x' \right)^2}{m-1}, \tag{35}$$

where x_i' is an unbiased estimate of the PSU population aggregate X_i and x' is defined in (31).

Probability proportional to size and a fixed overall sampling fraction usually decrease variances compared with samples in which first-and second-stage probabilities are uniform. However, pps increases the portion of large PSUs selected to the sample. This may increase survey costs, especially if the cost of listing secondary units within PSUs is related to the number of them within the PSU. However, the work load at the second stage will be approximately the same from PSU to PSU, because the within-PSU samples are about equal. Generally, when it is economic to use pps, pps is preferred to stratification.

A third method of controlling for variations in PSU sizes depends on a ratio estimate. When one has supplementary information (from a census, administrative records, or source other than the survey) on the population total for an independent characteristic Y, one may estimate the total X by

$$x'' = \frac{x'}{y'} Y = rY, \tag{36}$$

where x' and y' are defined in (31). The variance of x'' is $\sigma_{x''} = Y^2 \sigma_r^2$, where σ_r^2 is defined in (33). When Y_I is the PSU population total N_I for listing units or some other measure of PSU size that is highly correlated with X_I, the variance of x'' may be substantially less than that of x'. The estimate x'' is biased, but the bias becomes trivial with large numbers of sample PSUs. If one uses actual PSU totals Y_i in place of estimates y_i' in (31), then y' has no sampling at the second stage. The term involving the within-PSU variance component is dropped from $\sigma_{y'}^2$ in (32).

For more on controlling for variation in PSU sizes see Hansen et al. [3, Volume I, Chapter 8] and Foreman [2, Sections 7.4–7.6].

Multivariate Adaptive Splines for Analyzing Longitudinal Data

Longitudinal data represent one of the most commonly encountered data structures in health-related studies as well as in other fields including economics and finance. For every subject in a study, the outcome variable is measured repeatedly over time, and some (p) **covariates** are also collected, which may or may not vary over time. The classic method for analyzing longitudinal data is the **mixed-effects** linear model [4]. The purpose of this article is to describe MASAL [7] – **nonparametric**, method for analyzing and exploring longitudinal and **growth** curve data.

As an illustration, Figure 1 displays a subset of the data analyzed by Zhang [8]. In this data set, weights (kg) in the first one and half years were collected from 298 infants in an effort to examine the potential impact of the mother's cocaine use during pregnancy on the infant's growth after birth. In addition, information on gestational age, sex, and race is also available. The objective is to characterize the growth pattern and identify the variables that affect the growth pattern.

For the notation, suppose that data are observed for n subjects. For subject i, let $\mathbf{y}_i = (y_{i1}, \ldots, y_{iT_i})'$ be the response vector (e.g. an infant's weights) measured at T_i time points $\mathbf{t}_i = (t_{i1}, \ldots, t_{iT_i})'$ and X_i a $T_i \times p$ design matrix (e.g. a mother's cocaine use and the infant's sex). Laird and Ware [4] introduced the following mixed-effects model:

$$\mathbf{y}_i = X_i\beta + Z_i\mathbf{b}_i + \mathbf{e}_i, \qquad (1)$$

where β is the $p \times 1$ fixed effect parameter vector, Z_i a random effect design matrix, $\mathbf{b}_i$ the random effects, and $\mathbf{e}_i$ the measurement error. In general, $\mathbf{e}_i$ and $\mathbf{b}_i$ are assumed independent each other and among different subjects, and follow **multivariate normal distributions** with mean 0.

Some nonparametric or **semiparametric** methods have emerged to extend the mixed-effects model. Here, the term "nonparametric" or "semiparametric" is with respect to the fixed effect. In most extensions, the time is isolated from the other covariates, and the fixed effect is decomposed as $X_i\beta + \mu(\mathbf{t}_i)$ or $X_i\beta(t)$, where X_i excludes the measurement time, but may contain other **time-dependent covariates**. In other words, the time trend is either additive or multiplicative to the covariate effects. The major advantage of such an extension is that one-dimensional smoothing (*see* **Spline Smoothing**) has been extensively studied and well implemented in the statistical literature (*see also* **Spline Function**), and the interpretation is relatively easy.

In contrast, MASAL is the unique model that is based on a multivariate nonparametric smoothing. As we know, there are usually no *a priori* reasons to believe that $X_i\beta + \mu(\mathbf{t}_i)$ or $X_i\beta(t)$ is necessarily appropriate. As we will see later, a fitted MASAL model can help us decide whether $X_i\beta + \mu(\mathbf{t}_i)$ or $X_i\beta(t)$ is appropriate.

Specifically, Zhang [7] considered a general nonparametric model

$$y_{ij} = f(x_{1,ij}, \ldots, x_{p,ij}, t_{ij}) + e_{ij}(t_{ij}), \qquad (2)$$

where f is an unknown smooth function and $e_{ij}(t_{ij})$ is an element of $\mathbf{e}_i$. Because t_{ij} can be viewed as one of the time-varying covariates, for notational convenience, we include the time as one of the covariates and write $f(X_i) = f(x_{1,ij}, \ldots, x_{p,ij}, t_{ij})$. The estimation of a MASAL model proceeds in two steps: one deals with the **covariance matrix**, and the other fits the f function for a given covariance matrix.

First, suppose that the covariance matrix, $\Sigma_i (i = 1, \ldots, n)$, is given. The f function is estimated by finding a member in the following class of functions:

$$\left\{ \sum_{k=0}^{M} \beta_k B_k(X),\, M = 0, 1, \ldots \right\},$$

where $B_k(X)$ is a basis function to be defined shortly and β_k the regression coefficient ($k = 0, 1, \ldots, M$), to minimize the weighted **least squares** (WLS).

$$\sum_{i=1}^{n} (\mathbf{y}_i - f(X_i))' \sum_{i}^{-1} (\mathbf{y}_i - f(X_i)).$$

Unlike parametric **regression**, the number of terms, M, and the individual basis, $B_k(X)$, need to be estimated from the data. Particularly, $B_k(X)$ is made of these two basis functions: $(x_l - \tau)^+$ and $x_l, l = 1, \ldots, p$, where τ is called knot and needs to be estimated, and for any number a, $a^+ = \max(a, 0)$. $B_k(X)$ is either one of the forgoing two bases, for example, $(x_1 - 2)^+$, or the product of those functions involving distinct covariates such as $(x_1 - 2)^+ x_2 (x_3 - 5)^+$.

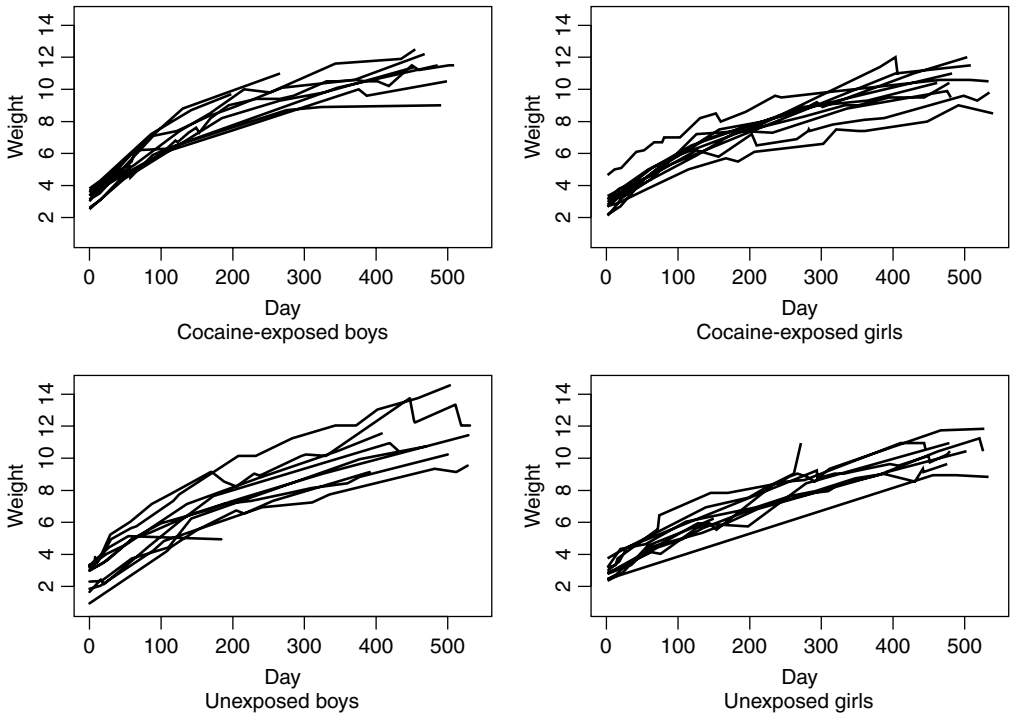

Figure 1 Growth curves of prenatally cocaine exposed and unexposed boys and girls. Ten infants are arbitrarily chosen in each group

The global minimization of the WLS is intractable. Instead, forward and backward procedures are used in practice [2, 6–8, 10] (*see* **Variable Selection**). In terms of computation, the most challenging step is to find the best τ during the forward stepwise. The fastest and exact **algorithm** is described by Zhang [7].

Next, we turn to the practical situation where Σ_i's are unknown. There are two main strategies. First, as discussed in Zhang [7], we can assume a general structure for Σ_i, for example, compound symmetry, auto-regressive correlation (*see* **ARMA and ARIMA Models**), or unstructured. Second, we decompose e_{ij} into an independent random measurement error and a systematic random variation. For example, in the analysis of growth curve data (sometimes referred to as *functional data analysis*), we may assume

$$e_{ij}(t_{ij}) = \sum_{l=1}^{L} \varphi_l(t_{ij}) b_{il} + \varepsilon_{ij}, \tag{3}$$

where similar distributions can be assumed for ε_{ij}'s and b_{il}'s to those in the linear mixed-effects model, and $\varphi_l(t)(l = 1, \ldots, L)$ is a prespecified function of t such as$\varphi(t) = t$ or $\sqrt{t}$ [5].

Once the general covariance structure, Σ_i, is chosen, the entire estimation procedure for MASAL proceeds as follows. We begin the process with initializing the parameters in Σ_i, for example, by assuming the independence of all observations. Then, the function, f, can be estimated as described above. Next, the **residuals** between $\mathbf{y}_i$ and its predicted value $\hat{f}(X_i)$ are computed and used to estimate the parameters in Σ_i. Then, the function f can be reestimated, and so on. While a theory has not been established, in nearly all applications that I have encountered, this process settles after the second iteration in the sense that there are few changes in the estimated f function and the WLS is hardly different in the subsequent iterations.

Assuming that (usually it is useful to examine a few choices)

$$e_{ij}(t_{ij}) = b_{i1} + \sqrt{t_{ij}} b_{i2} + \varepsilon_{ij}, \tag{4}$$

and applying MASAL to the infant growth data introduced earlier, the initial estimate of the f function under the independence assumption is

$$0.11 + \{0.5 - 0.28x_3 - 0.37(x_2 - 3)^+\}x_4 + (0.028 + 0.00028x_2 - 0.0008x_3)t, - \{0.016 + 0.00036(x_5 - 35)^+ - 0.0015x_1\}(t - 153)^+ \equiv \tilde{X}\beta(t) \quad (5)$$

where x_1 denotes race (white or black), x_2 the number of previous pregnancies, x_3 gender, x_4 cocaine exposure, x_5 gestational age, $\beta(t) = (0.11, 0.1, 0.01t, 0.01(t - 153)^+)'$ and $\tilde{X} = (1, \{5 - 2.8x_3 - 3.7(x_2 - 3)^+\}x_4, (28 + 0.028x_2 - 0.08x_3), 16 + 0.036(x_5 - 35)^+ - 0.15x_1)$.

Thus, this initial model requires time-varying coefficients $\beta(t)$[3] (*see* **Time-dependent Covariate**) although the design matrix is adaptively determined from the data. Using the residual estimates from this initial model, the covariance parameters are estimated, which in turn leads to the updated estimate for the f function:

$$0.12 + 0.014x_4 + 0.035t - 0.012(t - 60)^+ - 0.01(t - 150)^+ - 0.003(t - 300)^+.$$

Whereas the change from the initial model to the second one is notable, it is not so after the second iteration. As initially suggested, time-varying coefficients are not warranted in the final model. This model indicates an interesting growth pattern of the infants. First, the presence of x_4 is indicative of the importance of cocaine exposure. Second, the overall growth is increasing in time thanks to the term, $0.35t$, the growth becomes slower and slower after 2 months, 5 months, and 10 months.

Basic diagnostic procedures have been proposed [9] to assess the assumption of the covariance structure, although further investigation is clearly warranted. Owing to the highly adaptive nature of MASAL, a formal theory for statistical inference is difficult. However, **bootstrap** method [1] can be used to resample the data and consider **confidence intervals** and bands for the parameters of interest. For instance, we can test the contribution of a variable by removing it from our consideration and assess the magnitude of the degraded **goodness of fit**. Likewise, we can also test the linearity of a variable by excluding the nonlinear part of a variable. It is noteworthy, however, that these strategies need careful scrutiny.

In summary, MASAL is the only available model that is based on a high-dimensional smoothing technique and does not impose functional restrictions on time and covariates *a priori*. Not only does it accommodate time-varying covariates, but it also allows unrestricted interactions among covariates and between time and covariates. In addition, the fitted models are easy to calculate and readily interpretable. Thus, the mixed-effects multivariate adaptive splines model is handy for exploring longitudinal data. However, before the related procedures for statistical inference is thoroughly examined, MASAL should be primarily used as a way to explore the data structure in longitudinal and growth curve data, rather than a method of **hypothesis testing**. Executable MASAL programs (both stand-alone and **S-PLUS** compatible versions) are available from Heping Zhang's web site at `http://peace.med.yale.edu`.

HEPING ZHANG

Multivariate Analysis of Variance

The multivariate analysis of variance, or MANOVA, is an extension of the univariate **analysis of variance** to multidimensional, or vector-valued, observations. The same **experimental design** or treatment layout applies to each of the observed response variables. The univariate assumption of a normal distribution is replaced by the **multivariate normal distribution** for the data vectors and the random error components in the mathematical model of the design.

The One-Way Analysis of Variance Layout

We begin with the univariate one-way layout. Random samples of observations on some variable X have been obtained under k treatments or other experimental conditions. The data are arranged as shown in Table 1. The datum x_{ij} is an observation on a normally distributed random variable with mean μ_j and a constant variance σ^2 for all $N = N_1 + \cdots + N_k$ experimental units. More generally, the observations may be represented by the linear model

$$x_{ij} = \mu + \tau_j + e_{ij},$$

where μ is an effect common to all units, τ_j is the effect of the jth treatment, and e_{ij} is a normally distributed random variable with mean $\mathrm{E}(e_{ij}) = 0$ and variance $\mathrm{var}(e_{ij}) = \sigma^2$. The purpose of the one-way analysis of variance is to test the hypothesis that the k treatment means, $\mu_1, \ldots, \mu_k$, are equal, or equivalently that the **null hypothesis** of no treatment effects,

$$\mathrm{H}_0 : \tau_j = 0, \quad j = 1, \ldots, k,$$

Table 1

	Treatment			
	1	.	.	.	k
	x_{11}	.	.	.	x_{1k}
	.	.	.	.	.
	.	.	.	.	.
	.	.	.	.	.
	$x_{N_1 1}$	.	.	.	$x_{N_k k}$
Mean	$\overline{x}_1$	.	.	.	$\overline{x}_k$
Sample size	N_1	.	.	.	N_k

is true. To test the hypothesis we compute the within-treatments sum of squares

$$E = \sum_{j=1}^{k} \sum_{i=1}^{N_j} (x_{ij} - \overline{x}_j)^2$$

and the between-treatments sum of squares

$$H = \sum_{j=1}^{k} N_j (\overline{x}_j - \overline{x})^2,$$

where $\overline{x}$ is the grand mean of all observations. The mean square $E/(N-k)$ is an **unbiased** estimate of the variance σ^2, and $H/(k-1)$ is such an unbiased estimate only if the hypothesis of equal treatment effects is true. E and H are independently distributed, so that

$$F = \frac{[H/(k-1)]}{[E/(N-k)]}$$

has the ***F* distribution** with $k-1$ and $N-k$ degrees of freedom when the null hypothesis is true. When the alternative of unequal treatment effects holds, the expected value of F will be large, and the null hypothesis should be rejected for F in excess of an appropriate critical value.

The one-way multivariate analysis of variance has the same experimental design, but the observations x_{ij} are replaced by $p \times 1$ observation vectors $\mathbf{x}_{ij}$. The p components, x_{ijh}, are measurements or other data on p response variables describing characteristics or dimensions of the experimental unit. The linear model for the vector elements is

$$x_{ijh} = \mu_h + \tau_{jh} + e_{ijh},$$

where μ_h is a general effect for the hth response variable, τ_{jh} is the effect of the jth treatment on the hth response, and e_{ijh} is a random disturbance. The vector $\mathbf{e}'_{ij} = [e_{ij1}, \ldots, e_{ijp}]$ has the multivariate normal distribution with null mean vector and **covariance matrix** $E(\mathbf{e}_{ij}\mathbf{e}'_{ij}) = \mathbf{\Sigma}$. As in the univariate model, a common covariance matrix holds for all pairs (i, j), and the $\mathbf{e}_{ij}$ of different experimental units are independently distributed. The hypothesis of equal treatment effects can be expressed as

$$\mathrm{H}_0 : \tau_{jh} = 0, \quad j = 1, \ldots, k, h = 1, \ldots, p,$$

or, in terms of the treatment mean vectors,

$$\boldsymbol{\mu}'_j = [\mu_1 + \tau_{j1}, \ldots, \mu_p + \tau_{jp}],$$

Table 2

	Treatment		
	1	. . .	k
Mean vector	$[\overline{x}_{11}, \ldots, \overline{x}_{1p}]$	. . .	$[\overline{x}_{k1}, \ldots, \overline{x}_{kp}]$
Grand mean vector	$[\overline{x}_1, \ldots, \overline{x}_p]$		

as

$$\mathrm{H}_0 : \boldsymbol{\mu}_1 = \cdots = \boldsymbol{\mu}_k.$$

The alternative is that of unequal mean vectors.

For the multivariate analysis of variance we begin by replacing the treatment means by mean vectors (Table 2). The treatment sum of squares, H, becomes the $p \times p$ matrix

$$\mathbf{H} = \begin{bmatrix} h_{11} & . & . & . & h_{1p} \\ . & . & . & . & . \\ . & . & . & . & . \\ . & . & . & . & . \\ h_{1p} & . & . & . & h_{pp} \end{bmatrix},$$

in which

$$h_{rs} = \sum_{j=1}^{k} N_j(\overline{x}_{jr} - \overline{x}_r)(\overline{x}_{js} - \overline{x}_s), \quad r, s = 1, \ldots, p.$$

The diagonal terms, h_{rr}, are the treatment sums of squares for the individual response variables, while the off-diagonal values, h_{rs}, are the sums of cross-products for all pairs of the variables. The within-treatments sum of squares, E, is extended to the $p \times p$ matrix

$$\mathbf{E} = \begin{bmatrix} e_{11} & . & . & . & e_{1p} \\ . & . & . & . & . \\ . & . & . & . & . \\ . & . & . & . & . \\ e_{1p} & . & . & . & e_{pp} \end{bmatrix},$$

with general element

$$e_{rs} = \sum_{j=1}^{k} \sum_{i=1}^{N_j} (x_{ijr} - \overline{x}_{jr})(x_{ijs} - \overline{x}_{js}).$$

The rth diagonal element of $\mathbf{E}$ is merely the one-way analysis of variance within-groups sum of squares for the rth response variable. The off-diagonal term, e_{rs}, is a corresponding sum of products of the observations on the rth and sth responses. From those univariate definitions of the h_{rs} and e_{rs} terms we can easily construct the matrices $\mathbf{H}$ and $\mathbf{E}$ for the one-way layout or, for that matter, those for any layout for which an analysis of variance is available.

The relative closeness of the elements of $\mathbf{H}$ to those of $\mathbf{E}$ is a measure of the validity of the hypothesis of equal mean vectors. We measure "closeness" by various functions of the roots of the determinantal equation $|\mathbf{H} - \lambda\mathbf{E}| = 0$ or, equivalently, the characteristic roots of the matrix $\mathbf{E}^{-1}\mathbf{H}$ (*see* **Eigenvalue**). The following are the principal test statistics for the multivariate analysis of variance:

Wilks' determinantal ratio:

$$\begin{aligned} \Lambda &= \frac{|\mathbf{E}|}{|\mathbf{H} + \mathbf{E}|} \\ &= \frac{1}{|\mathbf{E}^{-1}\mathbf{H} + \mathbf{I}|} \\ &= \frac{1}{\text{product of the characteristic roots of } \mathbf{E}^{-1}\mathbf{H}+\mathbf{I}} \end{aligned}$$

(*see* **Lambda Criterion, Wilks'**).

Roy's greatest root:

$$c_s = \text{largest characteristic root of } \mathbf{E}^{-1}\mathbf{H},$$

or

$$\theta_s = \frac{c_s}{(1 + c_s)}$$

(*see* **Roy's Maximum Root Criteria**).

Lawley–Hotelling trace:

$$\begin{aligned} T_0^2 &= \operatorname{tr} \mathbf{E}^{-1}\mathbf{H} \\ &= \text{sum of the characteristic roots of } \mathbf{E}^{-1}\mathbf{H} \end{aligned}$$

(*see* **Lawley–Hotelling Trace**).

Pillai trace:

$$V = \operatorname{tr} \mathbf{H}(\mathbf{H} + \mathbf{E})^{-1}$$

(*see* **Pillai's Trace Test**).

We give the distributional properties of the statistics in a later section.

An Example

As an illustration of the one-way multivariate analysis of variance we use $p = 3$ dimensions of the skulls of four variants of the wolf *Canis lupus L.* The data were discussed by Jolicoeur [4, 5] and given

as an example by Morrison [7]. The measurements are given in **Multivariate Analysis, Overview**. The response variables are these dimensions:

$$X_1 = \text{palatal length},$$
$$X_2 = \text{postpalatal length},$$
$$X_3 = \text{zygomatic width}.$$

The four groups consisted of male and female wolves from the Rocky Mountain and Arctic Archipelago regions of Canada. The mean vectors and covariance matrices for the four data sets are as follows:

1. *Rocky Mountain males* $(N_1 = 6)$:

$$\bar{\mathbf{x}}_1' = [126.50, 108.17, 145.17],$$
$$\mathbf{S}_1 = \begin{bmatrix} 1.5000 & 1.7000 & 2.3000 \\ 1.7000 & 6.1667 & 5.6667 \\ 2.3000 & 5.5667 & 24.9667 \end{bmatrix}.$$

2. *Rocky Mountain females* $(N_2 = 3)$:

$$\bar{\mathbf{x}}_2' = [117.33, 102.67, 128.67],$$
$$\mathbf{S}_2 = \begin{bmatrix} 5.3333 & 0.6667 & 2.6667 \\ 0.6667 & 0.3333 & -1.1667 \\ 2.6667 & -1.1667 & 10.3333 \end{bmatrix}.$$

3. *Arctic males* $(N_3 = 10)$:

$$\bar{\mathbf{x}}_3' = [115.80, 100.80, 142.40],$$
$$\mathbf{S}_3 = \begin{bmatrix} 6.1778 & 4.8444 & 6.4222 \\ 4.8444 & 9.5111 & 10.5333 \\ 6.4222 & 10.5333 & 31.8222 \end{bmatrix}.$$

4. *Arctic females* $(N_4 = 6)$:

$$\bar{\mathbf{x}}_4' = [110.83, 96.17, 137.00],$$
$$\mathbf{S}_4 = \begin{bmatrix} 5.3667 & 2.4333 & 4.2000 \\ 2.4333 & 9.7667 & 5.8000 \\ 4.2000 & 5.8000 & 25.2000 \end{bmatrix}.$$

From these we compute the between-groups sums of squares and products matrix:

$$\mathbf{H} = \begin{bmatrix} 781.16 & 585.28 & 364.29 \\ 585.28 & 445.51 & 245.66 \\ 364.29 & 245.66 & 656.74 \end{bmatrix};$$

the within-groups sums of squares and products matrix:

$$\mathbf{E} = \begin{bmatrix} 100.60 & 65.60 & 95.63 \\ 65.60 & 165.93 & 149.30 \\ 95.65 & 149.30 & 557.90 \end{bmatrix};$$

and

$$\mathbf{E}^{-1}\mathbf{H} = \begin{bmatrix} 7.88522 & 5.90989 & 3.20985 \\ 1.36789 & 1.13769 & -0.46443 \\ -1.06476 & -0.87718 & 0.75123 \end{bmatrix}.$$

The characteristic roots of $\mathbf{E}^{-1}\mathbf{H}$ are 8.5280, 1.20595, and 0.04018. The values of the four test statistics and their approximate p values are shown in Table 3. The hypothesis of equal mean vectors should be rejected at any reasonable significance level.

The Multivariate General Linear Model

The Model

We now consider the multivariate analysis of variance for the multidimensional general linear model. The model is

$$\mathbf{X} = \mathbf{A}\boldsymbol{\xi} + \boldsymbol{\varepsilon}$$
$$= [\mathbf{A}_1\ \mathbf{A}_2]\begin{bmatrix} \boldsymbol{\xi}_1 \\ \boldsymbol{\xi}_2 \end{bmatrix} + \boldsymbol{\varepsilon},$$

in which

$\mathbf{X}$ = the $N \times p$ observation matrix,
$\mathbf{A}$ = the $N \times q$ design matrix of rank r for the given experimental design,
$\mathbf{A}_1$ = the $N \times r$ basis matrix for $\mathbf{A}$,
$\mathbf{A}_2$ = the $N \times (q - r)$ completion of $\mathbf{A}_1$ into $\mathbf{A}$,
$\boldsymbol{\xi}$ = the $q \times p$ parameter matrix,
$\boldsymbol{\xi}_1$ = the $r \times p$ parameter matrix corresponding to the basis of $\mathbf{A}$,

Table 3

Criterion	Statistic	p value
Roy's greatest root	8.5280	$\ll 0.01$
Wilks' Λ	0.04574	3.17×10^{-10}[a]
Lawley–Hotelling T_0^2	9.7741	1.55×10^{-47}[a]
Pillai trace V	1.4804	0.00029[a]

[a]Based on **large-sample** limiting distributions.

$\boldsymbol{\xi}_2$ = the $(q-r)\times p$ matrix of parameters for the completion $\mathbf{A}_2$ of $\mathbf{A}$, and
$\boldsymbol{\varepsilon}$ = the $N\times p$ matrix of random disturbances.

Each row of $\boldsymbol{\varepsilon}$ is independently distributed as a p-dimensional multinormal random variable with null mean vector and common covariance matrix $\boldsymbol{\Sigma}$.

The set of linear parametric functions, $\mathbf{a}'\boldsymbol{\xi} = \mathbf{a}_1'\boldsymbol{\xi}_1 + \mathbf{a}_2'\boldsymbol{\xi}_2$, is said to be *estimable* if $\mathbf{a}_1$ and $\mathbf{a}_2$ satisfy the following relation:

$$\mathbf{a}_2' = \mathbf{a}_1'(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1'\mathbf{A}_2$$

(Roy [20]). Then the **minimum variance unbiased estimator** of $\mathbf{a}'\boldsymbol{\xi}$ is

$$\widehat{\mathbf{a}'\boldsymbol{\xi}} = \mathbf{a}_1'(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1'\mathbf{X}.$$

General Linear Hypothesis

The multivariate general linear null hypothesis is

$$\mathrm{H}_0 : \mathbf{C}\boldsymbol{\xi}\mathbf{M} = \mathbf{0},$$

as opposed to its alternative, $\mathrm{H}_1 : \mathbf{C}\boldsymbol{\xi}\mathbf{M} \neq 0$. The $g\times q$ matrix $\mathbf{C}$ has rank $g \le r$, and is specified by the analyst. $\mathbf{C}$ is partitioned as $[\mathbf{C}_1 \quad \mathbf{C}_2]$, where its submatrices have respective dimensions $g\times r$ and $g\times(q-r)$ to conform with the partitioning of $\mathbf{A}$ and $\boldsymbol{\xi}\cdot\mathbf{M}$ is a $p\times u$ matrix that will generate linear functions of the responses or their parameters. Of necessity, $u \le p$. If the original response variables are to be used, then $\mathbf{M} = \mathbf{I}$. The null hypothesis can be written in terms of the submatrices as

$$\mathrm{H}_0 : \mathbf{C}_1\boldsymbol{\xi}_1\mathbf{M} + \mathbf{C}_2\boldsymbol{\xi}_2\mathbf{M} = \mathbf{0}.$$

The hypothesis is said to be *testable* if the rows of $\mathbf{C}_1$ and $\mathbf{C}_2$ satisfy the estimability conditions, or if

$$\mathbf{C}_2 = \mathbf{C}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1'\mathbf{A}_2.$$

We test the null hypothesis through the $\mathbf{H}$ and $\mathbf{E}$ matrices defined by

$$\mathbf{H} = \mathbf{M}'\mathbf{X}'\mathbf{A}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{C}_1'[\mathbf{C}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{C}_1']^{-1} \times \mathbf{C}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1'\mathbf{X}\mathbf{M},$$

$$\mathbf{E} = \mathbf{M}'\mathbf{X}'[\mathbf{I} - \mathbf{A}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1']\mathbf{X}\mathbf{M}.$$

$\mathbf{H}$ and $\mathbf{E}$ are independently distributed square symmetric matrices. $\mathbf{E}/(N-r)$ is an unbiased estimator of the population covariance matrix $\boldsymbol{\Sigma}$ as long as the linear model holds. $\mathbf{H}/g$ is only an unbiased estimator of $\boldsymbol{\Sigma}$ if H_0 is true. Examples of design and hypothesis matrices and the resulting matrices $\mathbf{H}$ and $\mathbf{E}$ have been given for some common experimental design layouts by Morrison [7].

We may compute the elements of the general $\mathbf{H}$ and $\mathbf{E}$ matrices from the univariate analysis of variance in the same manner as for the one-way MANOVA. The diagonal elements $h_{11},\ldots,h_{uu}$ of $\mathbf{H}$ are the univariate hypothesis sums of squares for the u linear functions of the multivariate response variables (or the p response variables themselves if $\mathbf{M} = \mathbf{I}$). The off-diagonal elements h_{ij} of $\mathbf{H}$ are sums of products, or bilinear forms, whose matrices are identical to the sums of squares quadratic forms on the diagonal of $\mathbf{H}$. Similarly, the diagonal elements $e_{11},\ldots,e_{uu}$ of $\mathbf{E}$ can be obtained from the corresponding univariate ANOVA. Each e_{ii} is the univariate error sum of squares for the successive u linear compounds. The off-diagonal terms e_{ij} are sums of products of all $u(u-1)/2$ pairs of the linear compounds of the observations, with the same bilinear form matrix as the quadratic forms e_{ii}. By those definitions one may avoid the matrix expressions for $\mathbf{H}$ and $\mathbf{E}$.

Test Statistics for the General Hypothesis

We now describe four common statistics for testing the general hypothesis $\mathrm{H}_0 : \mathbf{C}\boldsymbol{\xi}\mathbf{M} = \mathbf{0}$. The first is due to Roy [19, 20], and arises from his **union–intersection method** of test construction. The statistic is the greatest characteristic root c_s of $\mathbf{E}^{-1}\mathbf{H}$, or the greatest root $\theta_s = c_s/(1+c_s)$ of $(\mathbf{H}+\mathbf{E})^{-1}\mathbf{H}$. Upper critical values of the distribution of θ_s have been computed and tabulated by Heck [1], Pillai & Bantegui [15], and Pillai [12–14]. Charts and tables of those critical values are available in current texts, e.g. Morrison [7]. The parameters of the distribution of the greatest root statistic θ_s when H_0 is true are

$$s = \min(g, u),$$
$$m = \frac{(|g-u|-1)}{2},$$
$$n = \frac{(N-r-u-1)}{2}.$$

The hypothesis $\mathrm{H}_0 : \mathbf{C}\boldsymbol{\xi}\mathbf{M} = \mathbf{0}$ is rejected if $\theta_s > x_{\alpha;s,m,n}$. When $s = 1$ the single nonzero characteristic

root θ has the **beta distribution**, so that

$$F = \left[\frac{(n+1)}{(m+1)}\right]\frac{\theta}{(1-\theta)}$$
$$= \left[\frac{(n+1)}{(m+1)}\right]\operatorname{tr}\mathbf{E}^{-1}\mathbf{H}$$

has the F distribution with $2m+2$ and $2n+2$ degrees of freedom when H_0 is true. The Wilks' [22] determinantal ratio statistic $\Lambda = |\mathbf{E}|/|\mathbf{H}+\mathbf{E}|$ follows from the generalized **likelihood ratio test** construction. For large N,

$$\chi^2 = -\left[\frac{N-r-(u-g+1)}{2}\right]\ln\Lambda$$

has the **chi-square distribution** with gu degrees of freedom when H_0 is true, and H_0 would be rejected for large values of χ^2. Rao [17, 18] has given a transformation of Λ whose distribution can be closely approximated by that of an F variate. Exact null hypothesis distributions are also available in certain special cases. If $s = 1$, then

$$F = \left[\frac{(1-\Lambda)}{\Lambda}\right]\left[\frac{(n+1)}{(m+1)}\right]$$

has the F distribution with $2m+2$ and $2n+2$ degrees of freedom. When $s = 2$,

$$F = \left[\frac{(1-\Lambda^{1/2})}{\Lambda^{1/2}}\right]\left[\frac{(2n+2)}{(2m+3)}\right]$$

is distributed as an F variate with $4m+6$ and $4(n+1)$ degrees of freedom. The Lawley [6] and Hotelling [2, 3] statistic, $NT_0^2 = N\operatorname{tr}\mathbf{H}\mathbf{E}^{-1}$ tends to have a chi-square distribution with gu degrees of freedom when N is large and H_0 is true. Similarly, the Pillai [11] statistic, $(N-r)V = (N-r)\operatorname{tr}\mathbf{H}(\mathbf{H}+\mathbf{E})^{-1}$, has a large-sample chi-square distribution with gu degrees of freedom under the null hypothesis. None of these criteria appears to be **most powerful** against all **alternative hypotheses**. Most statistical **software** systems for MANOVA give values for all of the major statistics.

Power and Robustness Properties

A number of studies have shown that the power probabilities of the four MANOVA test statistics differ only slightly for selected alternate hypotheses. Pillai & Jayachandran [16] found only small second-decimal-place differences. The Roy greatest-root test had lowest power against those alternatives, but other studies showed it surpassed the competing tests in the case of an alternative with a single large characteristic root. Olson [8–10] concluded that the Pillai trace statistic appeared to be the most robust in terms of preserving its α level (*see* **Level of a Test**) and power probabilities under nonnormality and unequal covariance matrices. The greatest-root test seemed to be affected the most by those departures from the usual model assumptions. Some further aspects of the sensitivity of MANOVA to nonnormality and heterogeneous covariance structures have been described in the article **Multivariate Techniques, Robustness**.

Simultaneous Tests and Confidence Intervals

As in the univariate case, MANOVA only indicates whether the overall hypothesis H_0 should be rejected, and not which response variables and treatment effects may have contributed to that decision. The union–intersection test based on the greatest root statistic leads directly to a **multiple comparisons** method due to Roy & Bose [21]. One may test all possible hypotheses of the sort $H_0 : \mathbf{b}'\mathbf{C}\boldsymbol{\xi}\mathbf{M}\mathbf{a} = \mathbf{0}$ for any treatment comparisons defined by $\mathbf{b}'\mathbf{C}$ and any linear functions of the response variables specified by $\mathbf{M}\mathbf{a}$ with an overall error rate not in excess of some given level α. Alternately, confidence intervals can be found for all parametric functions $\mathbf{b}'\mathbf{C}\boldsymbol{\xi}\mathbf{M}\mathbf{a}$ with a simultaneous confidence coefficient not less than $1-\alpha$. Explicit expressions for the test statistics and intervals are available in many sources on multivariate methods, e.g. Morrison [7].

DONALD F. MORRISON

Multivariate Analysis, Bayesian

Multivariate **Bayesian** analysis is that branch of statistics that uses **Bayes' theorem** to make inferences about several, generally **correlated**, unknown quantities. The unknown quantities may index probability distributions, or they may be hypotheses or propositions, or they may be **probabilities** themselves. Such procedures have widespread biostatistical applications. Some of the basic concepts of the subject include the likelihood principle (*see* **Foundations of Probability**), multivariate **prior** and posterior distributions, **Markov chain Monte Carlo** numerical methods, and the use of Bayesian computer programs to implement the multivariate Bayesian procedures. These concepts, methods, and applications are discussed below.

Bayes' Theorem, Posterior Distributions, and Inference

In Bayesian analysis an unknown quantity is assigned a probability distribution, to represent one's degree of belief about the unknown quantity. This degree of belief is then updated via Bayes' theorem, as new information becomes available through observational data, experience, or new insights.

Multivariate Bayesian inference is based on Bayes' theorem for correlated **random variables**. The theorem asserts that the joint density of several correlated, jointly continuous, but unobservable random variables, given observations on one or more observable random variables, is proportional to the product of the **likelihood** function for the observable random variables and the probability density function of the probability distribution for the unknown variables. (If the unobservable random variables are jointly discrete, then we use the joint probability mass function instead of the joint density in Bayes' theorem; the analogous statement holds for unobservable, correlated random variables with mixed distributions.) The proportionality constant does not depend upon the unobservable quantities of interest; it is just that constant that makes the probability density function for the random variables of interest integrate to unity.

Bayes' Theorem

Symbolically, let $\boldsymbol{\Theta}$ denote a collection (vector) of k unobservable random variables, and $\mathbf{X}$ a collection (vector) of p observable random variables. Let $f(\cdot)$, $g(\cdot)$, and $h(\cdot)$ represent densities (probability mass functions) of their arguments. (Lower case letters will be used to represent observed values of the random variables designated by upper case letters.) Bayes' theorem asserts that

$$h(\boldsymbol{\theta}|\mathbf{x}) = \frac{1}{c} f(\mathbf{x}|\boldsymbol{\theta}) g(\boldsymbol{\theta}),$$

where $\boldsymbol{\theta}$ and $\mathbf{x}$ denote fixed values of $\boldsymbol{\Theta}$ and $\mathbf{X}$, respectively, and c denotes a constant (depending on $\mathbf{x}$, but not on $\boldsymbol{\Theta}$), which is given by

$$c = \int f(\mathbf{x}|\boldsymbol{\theta}) g(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}.$$

The integration is taken over all possible values in k-dimensional space, and the notation $f(\mathbf{x}|\boldsymbol{\theta})$ should be understood to mean the density of the conditional distribution of $\mathbf{X}$ given $\boldsymbol{\Theta} = \boldsymbol{\theta}$.

$f(\mathbf{x}|\boldsymbol{\theta})$ is the joint sampling density for $\mathbf{x}|\boldsymbol{\theta}$. When it is viewed as a function of $\boldsymbol{\theta}$, it is called the *likelihood function* (see section on "Likelihood Principle" below).

$g(\boldsymbol{\theta})$ is the *prior density* of $\boldsymbol{\Theta}$, since it is the density of $\boldsymbol{\Theta}$ prior to having observed $\mathbf{X}$ (it is a density if the variables in the $\boldsymbol{\Theta}$ array are continuous, and it is a probability mass function if they are discrete). Note that the prior density should not depend in any way on the current data set, although it certainly could and often does depend upon earlier-obtained data sets. If the prior were permitted to depend upon the current data set, then the use of Bayes' theorem in this inappropriate way would violate the laws of probability.

$h(\boldsymbol{\theta}|\mathbf{x})$ is the *posterior density* (probability mass function) of $\boldsymbol{\Theta}$, since it is the distribution of $\boldsymbol{\Theta}$ "subsequent" to having observed $\mathbf{X}$.

Bayesian inference in multivariate distributions is based on the posterior distribution of the unobservable random variables, say $\boldsymbol{\Theta}$, given the observable data (the unobservable random variable may be a vector or a matrix).

A Bayesian estimator (or posterior summary) of $\boldsymbol{\Theta}$ is generally taken to be a measure of location of the marginal posterior distribution of $\boldsymbol{\Theta}$, such as its mean, median, or mode.

For example, if there tends to be an underlying "quadratic **loss**" penalty function in an estimation problem, then the **mean** of the posterior distribution is optimal as an estimator, since it minimizes the expected loss (penalty). (For the same reason, **medians** are used with absolute error loss functions, and **modes** with binary types of decision rules.)

To obtain the marginal posterior density of $\boldsymbol{\Theta}$ given the data, it is often necessary to integrate the joint posterior density over spaces of other unobservable random variables that are jointly distributed with $\boldsymbol{\Theta}$.

For example, if the sampling distribution of $\mathbf{X}$ given $(\boldsymbol{\theta}, \boldsymbol{\Sigma})$ is $N(\boldsymbol{\theta}, \boldsymbol{\Sigma})$ (*see* **Multivariate Normal Distribution**), the marginal posterior density of $\boldsymbol{\Theta}$ is obtainable by integrating the joint posterior density of $(\boldsymbol{\theta}, \boldsymbol{\Sigma})$ over all elements of $\boldsymbol{\Sigma}$ that make it positive definite.

Credibility Regions (Credible Regions)

Bayesian confidence regions (called *credibility regions or credible regions*) are obtainable for any preassigned level of credibility directly from the cumulative distribution function of the posterior distribution. We make a distinction here between "credibility" and "confidence" that is fundamental, and not just a simple choice of alternate words.

The *credibility region* is a probability region for the unknown, unobservable vector or matrix, conditional on the specific value of the observables that happened to have been observed in this instance, regardless of what values of the observables might be observed in other instances (the region is based upon $P\{\boldsymbol{\Theta}|\mathbf{X}\}$). For example, $\boldsymbol{\Omega}$ denotes a 95% credibility region for $\boldsymbol{\Theta}|\mathbf{X}$ if

$$\Pr\{\boldsymbol{\Theta} \in \Omega|\mathbf{X}\} = 95\%.$$

The *confidence region*, by contrast, is obtained from a probability statement about the observable variables, conditional on the unobservable ones, so it really represents a region based upon the distribution of where the observables are likely to be, rather than where the unobservables are likely to be (the region is based upon $P\{\mathbf{X}|\boldsymbol{\Theta}\}$). When non uniform, proper prior distributions are used, the resulting credibility and confidence regions will generally be quite different from one another.

Prediction

Predictions about a data vector(s) or matrix not yet observed are carried out by averaging the likelihood for the future observation vector(s) or matrix over the best information we have about the indexing parameters of its distribution, namely the posterior distribution of the indexing parameters given the data already observed.

Hypothesis Testing

Hypothesis testing may be carried out by comparing the posterior probabilities of all competing hypotheses, given all data observed, and selecting the hypothesis with the largest posterior probability. These notions are identical to those in univariate Bayesian analysis. In multivariate Bayesian analysis, however, in order to make posterior inferences about a given hypothesis, conditional upon the observable data, it is generally necessary to integrate out over all the components of $\boldsymbol{\Theta}$.

Likelihood Principle

The *likelihood function* is uniquely defined only up to a multiplicative constant. The likelihood function may be taken to be any constant multiple of the ordinary sampling, or frequency, function (probability mass function) of the joint distribution of all of the observable random variables given the unobservable ones.

The *likelihood principle* asserts that all relevant information about $\boldsymbol{\Theta}$ obtainable from the observable data is found in the likelihood function. The implication is that in terms of the observable data, to make inferences about $\boldsymbol{\Theta}$ we merely require the likelihood of the data, and nothing else. So if there are stopping rules (*see* **Sequential Analysis**), or other additional information about the sampling process, then such information is irrelevant for Bayesian inference. Nor should values of the observables that might have been taken, but were not, be relevant. For example, the expected value of the observables, a quantity required for invoking an **unbiasedness** principle, is not relevant for inference.

(Multivariate) Prior Distributions

The process of developing a prior distribution to express the beliefs of the analyst about the likely values of a collection of unobservables is called multivariate **subjective probability** assessment. None of the variables in a collection of unobservables, $\boldsymbol{\Theta}$, is ever known. The multivariate prior probability density function, $g(\boldsymbol{\theta})$, for continuous $\boldsymbol{\Theta}$ (or its counterpart, the prior probability mass function for discrete $\boldsymbol{\Theta}$), is used to denote the degrees of belief the analyst holds about $\boldsymbol{\Theta}$. The parameters that index the prior distribution are called *hyperparameters*.

For example, suppose $\boldsymbol{\Theta}$ is **bivariate** ($k = 2$), so that there are two unobservable, one-dimensional random variables Θ_1 and Θ_2. Suppose, furthermore (for simplicity), that Θ_1 and Θ_2 are discrete random variables, and let $g(\theta_1, \theta_2)$ denote the joint probability mass function for $\boldsymbol{\Theta} = (\Theta_1, \Theta_2)$.

Suppose Θ_1 and Θ_2 can each assume only two values, 0 and 1, and the analyst believes the probable values to be given by those in Table 1. Thus, for example, the analyst believes that the chances that Θ_1 and Θ_2 are both 1 is 0.4, i.e.

$$\Pr\{\Theta_1 = 1, \Theta_2 = 1\} = g(1, 1) = 0.4.$$

Note that this bivariate prior distribution represents the beliefs of the analyst, and need not correspond to the beliefs of any other individual or group. Other individuals may feel quite differently about $\boldsymbol{\Theta}$.

Multivariate prior distributions are sometimes difficult to assess owing to the complexities of thinking in many dimensions simultaneously. It is easier to assess one-dimensional marginal prior distributions than it is to assess the distribution of a person's joint beliefs about several random variables simultaneously. The higher the dimension of the problem, the more this difficulty is exacerbated. We next describe several methods that have been proposed for reducing the difficulties of assessing multivariate prior distributions:

Table 1 Prior distribution: $g(\theta_1, \theta_2)$

$\theta_1 \downarrow \mid \theta_2 \rightarrow$	0	1
0	0.2	0.1
1	0.3	0.4

1. One procedure that has been proposed for assessing multivariate prior distributions involves predicting future values of observables, and then imputing backwards to an implied distribution for the unobservable, unknown indexing parameters (see Kadane et al. [22]).
2. Another proposal for assessing a multivariate prior distribution involves using the assessments of a homogeneous, informed group of experts (see Press [29; 30, Chapter 5]), and combining their assessments into a composite multivariate distribution by means of multivariate **density estimation**.
3. In another approach, Arnold et al. [2] proposed using bivariate normal and bivariate **Pareto** *natural conjugate* families for (Θ_1, Θ_2), (see discussion of natural conjugate families of prior distributions below). The natural conjugate families are conditionally specified distributions of $(\Theta_1|\Theta_2)$ and $(\Theta_2|\Theta_1)$; the appropriate family has eight hyperparameters in the case of the normal, and six hyperparameters in the case of the Pareto. It is suggested that the hyperparameters be assessed using elicitation of many values of conditional **moments** of Θ_1 fixed at various values of Θ_2, followed by elicitation of many values of conditional moments of Θ_2 fixed at various values of Θ_1. By regressing the one set of conditional assessments on the other set, we can estimate the hyperparameters of the joint prior distribution by least squares estimation. It was suggested that the same approach could be applied to more general **exponential families**.

The ability of individuals to assess correlation coefficients was studied by Gokhale & Press [19].

For an outline of numerous methods for assessing prior distributions that have been proposed, see Kass & Raftery [23] and Press [30], Chapter 5.

(Multivariate) Vague Priors

In some situations the analyst does not feel at all knowledgeable about the likely values of unknown, unobservable variables. In such cases he will probably resort to use of a "vague" (sometimes called "diffuse" or "noninformative") prior distribution.

Let $\boldsymbol{\Theta}$ denote a collection of k continuous, unknown variables, each defined on $(-\infty, +\infty)$. $g(\boldsymbol{\theta})$ is a *vague* prior density for $\boldsymbol{\Theta}$ if the elements of

$\boldsymbol{\Theta}$ are mutually independent, and if the probability mass of each variable is diffused evenly over all possible values. We write the (improper) prior density for $\boldsymbol{\Theta}$ as

$$g(\boldsymbol{\theta}) \propto \text{constant},$$

where $\propto$ denotes proportionality. Note that while this density characterization corresponds in form to the density of a **uniform distribution**, the fact that this uniform distribution must be defined over the entire real line means that the distribution is improper except in the case where the components of $\boldsymbol{\theta}$ are defined on a finite interval.

If an unobservable variable were strictly positive, such as an unknown variance, σ^2, then we could adopt a vague prior for σ^2 by considering $\log \sigma^2$ as a new variable defined on $(-\infty, +\infty)$, and taking a vague prior on the variable $\log \sigma^2$, as above. Thus

$$g(\log \sigma^2) \propto \text{constant}.$$

But by a change of variable this implies an (improper) prior for σ^2, i.e.

$$g(\sigma^2) \propto \frac{1}{\sigma^2}.$$

We next extend this idea to multidimensional variables.

The notion of "positive", one-dimensional random variables, extends, in a multivariate context, to "positive definite", when we consider an array (a matrix) of variables. Thus, if $\boldsymbol{\Sigma}$ denotes a k-dimensional square and symmetric **covariance matrix**, and if $\boldsymbol{\Sigma}$ is a positive definite matrix, a vague prior on $\boldsymbol{\Sigma}$ is given by

$$g(\boldsymbol{\Sigma}) \propto |\boldsymbol{\Sigma}|^{-(k+1)/2},$$

where $|\boldsymbol{\Sigma}|$ denotes the determinant of the matrix $\boldsymbol{\Sigma}$.

This prior density was proposed by Jeffreys [21]. He suggested that to obtain a prior distribution for an unknown $\boldsymbol{\Theta}$, the inferences of which will be invariant under changes in the parameterization of the problem, it is necessary to adopt a prior distribution whose density is expressible as

$$p(\boldsymbol{\theta}) \propto [J(\boldsymbol{\theta})]^{1/2},$$

where $J(\boldsymbol{\theta})$ denotes the Fisher **information matrix**. (For an elaboration of such priors, see, for example, Press [28, Sections 3.6 and 3.8; 41, Sections 2.7.2–2.7.4].) For additional invariance arguments relating to these priors see Hartigan [20], Jeffreys [21], and Villegas [36]. The exponent of $|\boldsymbol{\Sigma}|$ in the Jeffreys invariant prior density presented here was first given by Geisser & Cornfield [13].

For discussions of controversial issues relating to multivariate vague prior distributions, see Press [30], Chapter 5; Stein [33], and Dawid et al. [6]

(Multivariate) Natural Conjugate Priors

It is sometimes convenient for an analyst to confine his description of his prior information about some unobservable $\boldsymbol{\Theta}$ to some preassigned family of distributions. The family most often used is called the *natural conjugate family* of prior distributions (the term and concept is attributable to Raiffa & Schlaifer [31]). The appropriate family is obtained by interchanging the roles of the observable and unobservable random variables in the likelihood function, and then "enriching" the parameters so that they have arbitrary, assignable values. A property of natural conjugate families of prior distributions is that the posterior density belongs to the same family as the prior density. So if the prior density family is **normal**, then the posterior density family will also be normal; if the prior density family is **beta**, then the posterior density family will also be beta, etc.

For example, if $L(\mathbf{x}|\boldsymbol{\theta}) = \mathrm{N}(\mathbf{0}, \mathbf{I}_p)$, where $\mathbf{I}_p$ denotes the p-dimensional identity matrix, and $\mathrm{N}(\mathbf{0}, \mathbf{I}_p)$, denotes the normal distribution with mean vector $\mathbf{0}$, and covariance matrix $\mathbf{I}_p$, then $L(\boldsymbol{\theta}|\boldsymbol{\varphi}, \mathbf{A}) = \mathrm{N}(\boldsymbol{\varphi}, \mathbf{A})$ is a natural conjugate prior distribution for $\boldsymbol{\Theta}$. This result is obtained by writing out the density of $(\mathbf{X}|\boldsymbol{\Theta})$ and noting that if the same density is viewed as a density of $(\boldsymbol{\Theta}|\mathbf{X})$, then the resulting density is proportional to that of a normal distribution. So we adopt a normal distribution as a prior for $\boldsymbol{\Theta}$. We then "enrich" the parameters by adopting completely general parameters for this prior, namely $(\boldsymbol{\varphi}, \mathbf{A})$ (in this way the hyperparameters do not depend upon the sample data). Next, we use our prior beliefs about $\boldsymbol{\Theta}$ to assess the hyperparameters $(\boldsymbol{\varphi},\ \mathbf{A})$.

(Multivariate) Mixture Priors

It sometimes happens that the family of prior distributions being considered for adoption to represent the analyst's prior information about a multivariate probability distribution is not sufficiently rich to capture the nuances of his information. For such situations it

has been proposed [7] that the analyst adopt a prior distribution that is a mixture (a convex combination, in particular) of natural conjugate distributions. Such a class of prior distributions is richer in hyperparameters than a single natural conjugate family, and therefore can better accommodate to the richer information the analyst has about the sampling distribution parameters.

For example, consider the very simple case in which a sample of size n has been taken from a multivariate normal distribution with unknown mean vector $\boldsymbol{\Theta}$, but known covariance matrix $\boldsymbol{\Sigma}_0$, and we have found the sample mean $\bar{\mathbf{x}}$. We can formulate the likelihood function from the fact that $(\bar{\mathbf{x}}|\boldsymbol{\theta}, \boldsymbol{\Sigma}_0) \sim \mathrm{N}(\boldsymbol{\theta}, \boldsymbol{\Sigma}_0/n)$. We must next adopt a prior distribution for the unknown $\boldsymbol{\Theta}$. For this purpose we decide to use the mixture density of the normal distribution natural conjugate densities,

$$p_1(\boldsymbol{\theta}) \propto \sum \delta_i \{\mathrm{N}(\boldsymbol{\varphi}_i, \mathbf{A}_i)\}, \quad i = 1, \ldots, m,$$

with $\delta_i \geq 0, \sum \delta_i = 1$.

Note that the hyperparameters $(\delta_i, \varphi_i, A_i, i = 1, \ldots, m)$ must all be preassigned by assessment. Then, the posterior density for $\boldsymbol{\theta}$ becomes

$$p(\boldsymbol{\theta}|\bar{\mathbf{x}}, \boldsymbol{\Sigma}_0) \propto p_1(\boldsymbol{\theta}) p_2(\bar{\mathbf{x}}|\boldsymbol{\theta}, \boldsymbol{\Sigma}_0),$$

or

$$p(\boldsymbol{\theta}|\bar{\mathbf{x}}, \boldsymbol{\Sigma}_0, \boldsymbol{\varphi}_1, \ldots, \boldsymbol{\varphi}_m, \mathbf{A}_1, \ldots, \mathbf{A}_m, \delta_1, \ldots, \delta_m) \propto \sum \delta_i \left[\exp\left(\frac{-1}{2}\right)(\boldsymbol{\theta} - \boldsymbol{\varphi}_i)' \mathbf{A}_i^{-1} (\boldsymbol{\theta} - \boldsymbol{\varphi}_i)\right] \left[\exp\left(\frac{-n}{2}\right)(\bar{\mathbf{x}} - \boldsymbol{\theta})' \boldsymbol{\Sigma}_0^{-1} (\bar{\mathbf{x}} - \boldsymbol{\theta})\right],$$

or

$$p(\boldsymbol{\theta}|\bar{\mathbf{x}}, \boldsymbol{\Sigma}_0, \boldsymbol{\varphi}_1, \ldots, \boldsymbol{\varphi}_m, \mathbf{A}_1, \ldots, \mathbf{A}_m, \delta_1, \ldots, \delta_m) \propto \sum \delta_i \left\{\exp\left(\frac{-1}{2}\right)\left[(\boldsymbol{\theta} - \boldsymbol{\varphi}_i)' \mathbf{A}_i^{-1} (\boldsymbol{\theta} - \boldsymbol{\varphi}_i) + n(\bar{\mathbf{x}} - \boldsymbol{\theta})' \boldsymbol{\Sigma}_0^{-1} (\bar{\mathbf{x}} - \boldsymbol{\theta})\right]\right\}.$$

After the two quadratic forms in $\boldsymbol{\theta}$ in the last equation are combined by completing the square on θ, each term in the summation becomes a normal density in $\boldsymbol{\theta}$, but the weights must be modified. We finally obtain the posterior density as the mixture

$$p(\boldsymbol{\theta}|\bar{\mathbf{x}}, \boldsymbol{\Sigma}_0, \boldsymbol{\varphi}_1, \ldots, \boldsymbol{\varphi}_m, \mathbf{A}_1, \ldots, \mathbf{A}_m, \delta_1, \ldots, \delta_m) \propto \sum \delta_i^* \mathrm{N}(\boldsymbol{\varphi}_i^*, \mathbf{A}_i^*),$$

where

$$(\mathbf{A}_i^*)^{-1} = (\mathbf{A}_i)^{-1} + n\boldsymbol{\Sigma}_0^{-1},$$
$$\boldsymbol{\varphi}_i^* = \mathbf{A}_i^*[(\mathbf{A}_i)^{-1}\boldsymbol{\varphi}_i + n\boldsymbol{\Sigma}_0^{-1}(\bar{\mathbf{x}})]$$

and

$$\delta_i^* = \frac{\left[\delta_i |(\mathbf{A}_i^*)|^{1/2} \exp(-c_i/2)\right]}{\sum [\delta_j |(\mathbf{A}_j^*)|^{1/2} \exp(-c_j/2)]},$$

with

$$\delta_i^* \geq 0, \qquad \sum(\delta_i^*) = 1,$$

and

$$c_i = \boldsymbol{\varphi}_i' \mathbf{A}_i^{-1} \boldsymbol{\varphi}_i + n(\bar{\mathbf{x}}' \boldsymbol{\Sigma}_0^{-1} \bar{\mathbf{x}}) - (\boldsymbol{\varphi}_i^*)' \times (\mathbf{A}_i^*)^{-1} (\boldsymbol{\varphi}_i^*).$$

We note that the posterior density is in the same class as the prior, namely a mixture of normal densities. If the sampling covariance matrix were unknown as well, then the mixture would become more complicated, but could be managed completely analogously.

Exchangeability

A multivariate cumulative distribution function (cdf) that does not depend on the order in which the random variables appear is sometimes referred to as **exchangeable**. The corresponding populations are also said to be exchangeable. Suppose, for example, that $(\Theta_1 \ldots \Theta_k, \ldots)$ are one-dimensional random variables any k of which follow the joint distribution $\mathrm{N}(a\mathbf{e}, \mathbf{H})$, where $\mathbf{e}$ denotes a k-dimensional vector of ones, a denotes any scalar, and $\mathbf{H}$ denotes a covariance matrix with equal diagonal elements, and equal off-diagonal elements. If the Θ_is are permuted, the joint cdf, or joint density, does not change, or any Θ_i could be exchanged for any other, so the distribution is called exchangeable. The original concept was applied to Bernoulli sequences of trials (infinite sequences) (*see* **Binary Data**) and has now been extended to more general sequences.

In some situations in Bayesian multivariate analysis it is useful to adopt an exchangeable prior distribution to express ignorance. For instance, suppose we have observations from three multivariate normal populations with equal covariance matrices, and we wish to carry out Bayesian inference on the mean vectors to compare the closeness of the three populations (**multivariate analysis of variance**). In many situations like this it would not be unreasonable to take the prior distributions for each of the mean vectors to be the same, i.e. to assume, a priori, that the populations are exchangeable (in the absence of any information to the contrary). Thus, if $(\boldsymbol{\Theta}, \boldsymbol{\Phi}, \boldsymbol{\eta})$ denote the mean vectors for the three normal populations, we could adopt the joint prior distribution for their mean vectors,

$$g(\boldsymbol{\Theta}, \boldsymbol{\Phi}, \boldsymbol{\eta}) = g^*(\boldsymbol{\Theta})g^*(\boldsymbol{\Phi})g^*(\boldsymbol{\eta}),$$

where the distribution of $\boldsymbol{\Theta}$ (or of $\boldsymbol{\Phi}$, or of $\boldsymbol{\eta}$) is perhaps $N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, and the hyperparameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ must be assessed. Note that such an approach to multivariate prior distribution assessment not only simplifies the analysis, but it greatly reduces the number of hyperparameters that must be assessed.

Numerical Methods of Bayesian Multivariate Analysis

Numerical methods are of fundamental importance in Bayesian multivariate analysis. They are used for evaluating and approximating the normalizing constants of multivariate posterior densities, for finding marginal densities, for calculating moments and other functions of marginal densities, and for sampling from multivariate posterior densities, and for many other needs associated with multivariate Bayesian statistical inference (*see* **Numerical Integration**).

Methods for evaluating and approximating multidimensional integrals associated with multivariate posterior distributions are nicely summarized in Evans & Swartz [11]. They include discussions of the Laplace method, importance sampling and variance reduction techniques, multiple quadrature rules, and Markov chain Monte Carlo (MCMC) methods, including the Metropolis Algorithm.

MCMC, data augmentation, and related methods have been studied and explicated by Metropolis et al. [25], Geman & Geman [17], Tanner & Wong [35], Gelfand & Smith [14], Casella & George [4], Gelman & Rubin [15], Tanner [34, Chapter 6], O'Hagen [26], Chib & Greenberg [5], Gelman et al. [16, Part III], Carlin & Louis [3], and by many other authors who have made a wide variety of contributions to this rapidly expanding field.

Computer-Assisted Bayesian Multivariate Statistical Inference

It was pointed out in the previous section that it is often the case in Bayesian multivariate analysis that posterior distributions are sometimes sufficiently complicated that numerical procedures and computers are required to effect posterior inferences. Fortunately, computer programs have already been written for many of the known multivariate Bayesian inference procedures: see, for example, Spiegelhalter et al. [32], for a general computer program for Gibbs sampling (called BUGS); O'Hagen [26] for a program (based upon the APL language) which introduces Bayes' theorem graphically in one dimension (called "First Bayes"); Albert [1] for a text that introduces the use of Bayesian inference by means of MINITAB 10; Press [27; 30, Chapter 6 and its complements A & B], and Goel [18], for compilations and accompanying descriptions of many Bayesian programs. Most of such computer programs became obsolete shortly after they were written, but they are still useful (*see* **Software, Biostatistical**).

Applications

Multivariate Bayesian analysis abounds with applications in biostatistics. One important area of biostatistical application in multivariate Bayesian analysis involves Bayesian **meta-analysis** (see, for example, DuMouchel [8, 9], DuMouchel & Harris [10], and Lindley & Press [24]).

Some case studies of other applications have been collected as conference proceedings and are detailed in Gatsonis et al. [12]. There are atleast six such volumes now available under the same title (with different authors). Some biostatistical multivariate Bayesian applications presented in the first volume deal with nonignorable nonresponse (*see* **Bias from Nonresponse**); estimation of costs in a sewerage operation; the Ames salmonella/microsome assay (*see* **Mutagenicity Study**); and a cost-utility analysis of breast cancer screening (*see* **Screening Benefit, Evaluation of**).

Multivariate Analysis, Overview

Multivariate analysis is concerned with mathematical models for representing multidimensional observations, and methods for analyzing those data. A common example of multivariate data might be the lengths of a particular bone measured at six-month intervals in young children, or the set of subtest scores made by a subject on a cognitive intelligence test. The measurements or scores obtained from each person constitute a *vector-valued* observation. We assume that the vector $\mathbf{x}_i$ obtained on the ith individual, or sampling unit, is an observation on the $p \times 1$ vector random variable $\mathbf{X}$ with some p-dimensional multivariate distribution described by the density function $f(\mathbf{x})$. Traditionally, most of the multivariate methods for continuous variables assume that the population distribution is **multivariate normal**, with the density function

$$f(\mathbf{x}) = (2\pi)^{-p/2}|\boldsymbol{\Sigma}|^{-1/2} \times \exp\left[-\left(\tfrac{1}{2}\right)(\mathbf{x}-\boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu})\right].$$

The elements of $\mathbf{x}$ each have the range $-\infty < x_i < \infty$, so the admissible values of $\mathbf{x}$ constitute p-dimensional Euclidean space. The parameters of the multivariate normal distribution are the mean vector $\mathrm{E}(\mathbf{X}) = \boldsymbol{\mu}$ and the **covariance matrix** $\mathrm{E}\{[\mathbf{X} - \mathrm{E}(\mathbf{X})][\mathbf{X} - \mathrm{E}(\mathbf{X})]'\} = \boldsymbol{\Sigma}$. $\boldsymbol{\Sigma}$ is always symmetric, and must be positive definite for the density function to exist. Otherwise, the distribution is said to be *singular*, and must be described by its cumulative distribution function. A multivariate normal random vector with parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ is denoted by the Wilks symbol, $\mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$.

The justification for the multivariate normal distribution follows from the **central limit theorem** [3, pp. 81–82], which essentially says that sequences of properly standardized sums of independently distributed random vectors with a common well-defined distribution tend to the multivariate normal form as the number of terms in the sums increases without limit. Often the central limit theorem model of random variables as the sum of many independent underlying random components does not hold, and the multivariate distributions are not even approximately normal. In such cases appropriate **transformations** of the individual variables may give random vectors with distributions closer to that of the multivariate normal.

Some Methods for the Multivariate Normal Distribution

This review of multivariate analysis for continuous variables will be restricted to those methods that arise from the multivariate normal population model. First we extend the common univariate **hypothesis tests** and **confidence** statements on means to the mean vector $\boldsymbol{\mu}$. Next, we generalize the **analysis of variance** for one variable to the case of vector-valued observations. We then describe methods for classifying an observation vector to one of two or more unknown populations by the linear or quadratic discriminant function (*see* **Discriminant Analysis, Linear**). **Principal components analysis** and **factor analysis** will be described as means for dissecting covariance and correlation structures and their matrices.

Inferences About the Multivariate Normal Distribution

Estimation of the Mean Vector and Covariance Matrix

Assume that a random sample of N p-component observation vectors $\mathbf{x}_1, \ldots, \mathbf{x}_N$ has been drawn from the $\mathrm{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ multinormal population. The usual estimates of the mean vector and covariance matrix are the sample mean vector and the sample covariance matrix,

$$\hat{\boldsymbol{\mu}} = \left(\frac{1}{N}\right)\sum_{\mathrm{i}=1}^{N}\mathbf{x}_{\mathrm{i}} = \overline{\mathbf{x}},$$

$$\hat{\boldsymbol{\Sigma}} = \left[\frac{1}{(N-1)}\right]\sum_{\mathrm{i}=1}^{N}(\mathbf{x}_{\mathrm{i}} - \overline{\mathbf{x}})(\mathbf{x}_{\mathrm{i}} - \overline{\mathbf{x}})' = \mathbf{S}.$$

$\overline{\mathbf{x}}$ and $\mathbf{S}$ are unbiased estimates of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. $\overline{\mathbf{x}}$ is also the **maximum likelihood** estimator, and $\mathbf{S}$ can be obtained by maximum likelihood followed by the replacement of the divisor N by $N-1$ to achieve **unbiasedness**. $\overline{\mathbf{x}}$ has the multivariate normal distribution with the obvious mean vector $\boldsymbol{\mu}$ and covariance matrix $(1/N)\boldsymbol{\Sigma}$. The distribution of $\mathbf{S}$ is more complicated. The sums of squares and products matrix

$\mathbf{A} = (N-1)\mathbf{S}$ has the **Wishart distribution** [41] with parameters degrees of freedom $n = N-1$ and covariance matrix $\boldsymbol{\Sigma}$. The density function of the Wishart distribution is

$$f(\mathbf{A}) = \begin{cases} \dfrac{|\mathbf{A}|^{1/2(n-p-1)} \exp\left(\dfrac{-1}{2}\operatorname{tr}\mathbf{A}\boldsymbol{\Sigma}^{-1}\right)}{2^{np/2}\pi^{p(p-1)/4}|\boldsymbol{\Sigma}|^{n/2}\displaystyle\prod_{i=1}^{p}\Gamma\left[\frac{1}{2}(n+1-i)\right]}, \\ \qquad \mathbf{A} \text{ positive definite}, \\ 0, \qquad \text{elsewhere.} \end{cases}$$

When $p = 1$ the Wishart density is equivalent to that of a $\chi^2\sigma^2$ random variable, or to a chi-square density if $\boldsymbol{\Sigma} = 1$. The Wishart distribution also has many of the properties of the **chi-square distribution**, e.g. the sum of independent Wishart matrices with a common covariance matrix parameter is also Wishart with degrees of freedom equal to the sum of the degrees of freedom of the individual matrices. The Wishart density is useful as a starting point for deriving estimates, hypothesis tests, and distributions based on the normal distribution covariance matrix.

Another parameterization of the multivariate normal distribution is composed of the mean vector, the p standard deviations or variances, and the matrix of correlations. When the population covariance matrix is a general positive definite matrix the joint distributions of the sample sums of squares and sample correlations are rather complicated, and are not in forms that lend themselves to useful applications.

Inferences About Mean Vectors

Hypothesis tests and confidence intervals for means based on normal distribution theory can be extended to mean vectors. Since the mean vector $\bar{\mathbf{x}}$ of N independently and multinormally distributed p-component vectors is also multivariate normal with covariance matrix $(1/N)\boldsymbol{\Sigma}$, the quadratic form,

$$\chi^2 = N(\bar{\mathbf{x}} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}),$$

has the chi-square distribution with p degrees of freedom. If $\boldsymbol{\Sigma}$ is known, then we can test the hypothesis $\mathrm{H}_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$ against the general alternative that the mean vector is not $\boldsymbol{\mu}_0$ by rejecting H_0 when χ^2 exceeds some right-hand critical value of the chi-square distribution. The test statistic is the **Mahalanobis distance** of $\bar{\mathbf{x}}$ from the hypothesized population mean vector $\boldsymbol{\mu}_0$. The statistic has an important property: it is invariant under affine transformations $\mathbf{Y} = \mathbf{A}\mathbf{X} + \mathbf{h}$ on the sample and population mean vectors. $\mathbf{A}$ is a nonsingular (i.e. $|\mathbf{A}| \neq 0$) $p \times p$ matrix of constants, and $\mathbf{h}$ is a $p \times 1$ nonrandom vector.

If the covariance matrix is unknown and estimated by the sample matrix $\mathbf{S}$, then the hypothesis on the mean vector can be tested by the **Hotelling T^2** statistic [12]:

$$T^2 = N(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)'\mathbf{S}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}_0).$$

When the null hypothesis is true, $F = [(N-p)/p(N-1)]T^2$ has the ***F* distribution** with degrees of freedom p and $N-p$, and $\mathrm{H}_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$ would be rejected at the α level if F exceeds the critical value $F_{\alpha;p,N-p}$. When the alternative hypothesis, $\mathrm{H}_1 : \boldsymbol{\mu} = \boldsymbol{\mu}_1$, is true, the F statistic has the noncentral F distribution with degrees of freedom $p, N-p$, and noncentrality parameter

$$\delta^2 = N(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0)'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0).$$

We can use the noncentral F distribution to compute the **power** of the T^2 test for different alternatives, or to determine the sample size N which will provide some minimal power for a given α level.

The single-sample T^2 statistic can also be used to test the equal-means hypothesis for repeated-measures data (*see* **Analysis of Variance for Longitudinal Data**). The p repeated observations on each of the N sampling units are first transformed to $p-1$ successive differences, or $p-1$ differences from the first, last, or other repeated measure response. The null hypothesis of zero means for the $p-1$ new variables is then tested by T^2. An alternative approach to the analysis of repeated measurements or longitudinal data through **generalized estimating equations** has been given by Liang & Zeger [24] and Zeger et al. [42, 43].

The two-sample hypothesis, $\mathrm{H}_0 : \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2$, of equal mean vectors in two multivariate normal populations with a common covariance matrix $\boldsymbol{\Sigma}$ can also be tested by the T^2 statistic. From the independent random samples of N and M p-component observation vectors, $\mathbf{x}_{i1}$ and $\mathbf{x}_{i2}$, we compute the respective mean vectors, $\bar{\mathbf{x}}_1$ and $\bar{\mathbf{x}}_2$, and

the within-samples covariance matrix, $\mathbf{S}$, defined by

$$\mathbf{S} = \left[\frac{1}{(N+M-2)}\right]\left[\sum_{i=1}^{N}(\mathbf{x}_{i1}-\bar{\mathbf{x}}_1)(\mathbf{x}_{i1}-\bar{\mathbf{x}}_1)' + \sum_{i=1}^{M}(\mathbf{x}_{i2}-\bar{\mathbf{x}}_2)(\mathbf{x}_{i2}-\bar{\mathbf{x}}_2)'\right].$$

($\mathbf{S}$ is an unbiased estimate of $\boldsymbol{\Sigma}$). The two-sample T^2 statistic is

$$T^2 = \left[\frac{NM}{(N+M)}\right](\mathbf{x}_1-\mathbf{x}_2)'\mathbf{S}^{-1}(\mathbf{x}_1-\mathbf{x}_2).$$

When the null hypothesis of a common mean vector is true, $F = [(N+M-p-1)/(N+M-2)p]T^2$ has the F distribution with p and $N+M-p-1$ degrees of freedom, and the null hypothesis would be rejected at the α level if $F > F_{\alpha;p,N+M-p-1}$. When the alternative hypothesis of unequal mean vectors holds, F has the noncentral F distribution with degrees of freedom $p, N+M-p-1$, and noncentrality parameter $[NM/(N+M)](\boldsymbol{\mu}_1-\boldsymbol{\mu}_2)'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1-\boldsymbol{\mu}_2)$. As in the single-sample test, charts or tables of the noncentral F distribution can be used to find the power of the T^2 test, or to determine the sample sizes N and M that will satisfy specified power and α probabilities. Details and examples have been given by Morrison [26, Section 2.8].

Simultaneous Inferences for Mean Vectors

The previous T^2 tests only tell us whether or not hypotheses on mean vectors should be rejected. If the hypothesis has been rejected, then the test does not tell us which of the p response variables may have contributed to that decision. It is possible to test hypotheses on the individual responses or linear combinations of them with an overall, or "family", error rate α using a method due to Roy & Bose [35] (*see* **Multiple Comparisons**). The Roy–Bose simultaneous tests and confidence intervals are described under the **Hotelling T^2** entry, and in most texts on multivariate analysis, e.g. Morrison [26, Section 2.3].

Multivariate Analysis of Variance

Generalization of Univariate Analysis of Variance

The univariate **analysis of variance** (ANOVA) begins with the partition of a total sum of squares into two independent components. The error component, E, when divided by an appropriate degrees of freedom parameter, always gives an unbiased estimate of the error variance for the underlying linear model. The other component, H, only has an expected value proportional to the error variance if some hypothesis on the model's parameters is true. Under the hypothesis, H/E is proportional to an F random variable, and the hypothesis would be rejected for large values of H/E.

The **multivariate analysis of variance** (MANOVA) for p-dimensional observation vectors is a generalization of ANOVA to hypotheses on mean vectors and matrices. We assume the same mathematical model holds for each of the p response variables, and those variables are jointly distributed according to a p-dimensional multivariate normal distribution with the same covariance matrix for all N sampling units in the experimental design or other investigation. The mean vector of the distribution will depend on the hypothesis being tested, and whether or not it is true. The error sum of squares E is generalized to the $p \times p$ symmetric matrix

$$\mathbf{E} = \begin{bmatrix} e_{11} & \dots & e_{1p} \\ \vdots & \dots & \vdots \\ e_{1p} & \dots & e_{pp} \end{bmatrix},$$

in which e_{jj} = error sum of squares for the ANOVA on the jth response variable, and e_{ij} = sum of products for the ith and jth response variables, obtained by rewriting the sum of squares expression e in one variable as a sum of products in two variables. The generalization of the hypothesis sum of squares is the $p \times p$ symmetric matrix

$$\mathbf{H} = \begin{bmatrix} h_{11} & \dots & h_{1p} \\ \vdots & \dots & \vdots \\ h_{1p} & \dots & h_{pp} \end{bmatrix},$$

where h_{jj} = univariate ANOVA hypothesis sum of squares for the jth response variable, and h_{ij} = sum of products for the ith and jth response variables, obtained by rewriting the sum of squares expression in one variable for h as a sum of products in two variables.

The test statistic for the multivariate analysis of variance null hypothesis that each of the hypotheses for the individual responses is true is some function of the roots of the determinantal equation

$$|\mathbf{H} - \lambda\mathbf{E}| = 0,$$

or equivalently, the characteristic roots (*see* **Eigenvalue**) of the matrix product $\mathbf{E}^{-1}\mathbf{H}$. These include the Wilks [39] determinantal ratio $\Lambda = |\mathbf{E}|/|\mathbf{H} + \mathbf{E}|$ (*see* **Lambda Criterion, Wilks'**), the **Lawley–Hotelling** [16] statistic

$$T_0^2 = \operatorname{tr} \mathbf{H}\mathbf{E}^{-1}$$
$$= \text{the sum of the characteristic roots of } \mathbf{E}^{-1}\mathbf{H},$$

the Roy [33] greatest root statistic c_s = maximum characteristic root of $\mathbf{E}^{-1}\mathbf{H}$ (*see* **Roy's Maximum Root Criteria**), and the **Pillai** [29] **trace statistic** $V = \operatorname{tr} \mathbf{H}(\mathbf{H} + \mathbf{E})^{-1}$.

The distributions of the test statistics under the appropriate null hypotheses have been obtained for large sample sizes (*see* **Large-sample Theory**), and in some cases for small samples and special values of the experimental design parameters. The asymptotic theory of generalized **likelihood ratio test** statistics implies that the transformed Wilks Λ,

$$\chi^2 = -\left[N - r - \left(\tfrac{1}{2}\right)(p - g + 1)\right] \ln \Lambda,$$

is distributed as a χ^2 random variable with pg degrees of freedom where

N = the total number of independent observations in the experimental design,
r = the rank of the design matrix, or
$N - r$ = error degrees of freedom for the design,
g = the rank of the hypothesis matrix, $= k - 1$ for the one-way layout,
p = the number of response variables.

Similarly, NT_0^2 has the large-sample χ^2 distribution with pg degrees of freedom when the null hypothesis is true. Heck [11] computed critical values for a transformation of the Roy greatest characteristic root statistic. Charts of those percentage points and tables of additional values computed by K.C.S. Pillai may be found in Morrison [26] and other texts on multivariate analysis. The Pillai trace statistic, $(N - r)V$, has the chi-square distribution with pg degrees of freedom when N is large and the null hypothesis is true.

No statistic appears to be **uniformly most powerful** against all **alternative hypotheses**. Instead, some of the tests have highest **power** against certain types of alternatives. One advantage of the Roy criterion is that its **union–intersection** development leads directly to simultaneous tests and confidence intervals to determine which responses and treatment comparisons may have led to rejection of the overall multivariate hypothesis.

Olson [27] studied the robustness of six multivariate analysis of variance test criteria through extensive sampling studies. He concluded that the Roy greatest characteristic root statistic was least robust under nonnormality or unequal covariance matrices, while the Pillai trace measure seemed most robust.

An Example

We illustrate the one-way multivariate analysis of variance with some measurements on the skulls of the wolf *Canis lupus L.* discussed by Jolicoeur [18, 19] and given as an example by Morrison [26]. These three skull dimensions were chosen:

X_1 = palatal length,
X_2 = postpalatal length,
X_3 = zygomatic width.

The four groups consist of male and female wolves from the Rocky Mountain and Arctic Archipelago areas of northwestern Canada. The measurements, in millimeters, are reprinted in Table 1 with the kind permission of Pierre Jolicoeur.

The data form an unbalanced two-way layout, but we shall treat them as a one-way design for simplicity. The matrices for the multivariate analysis of variance are as follows.

Between-groups sums of squares and products matrix:

$$\mathbf{H} = \begin{bmatrix} 781.16 & 585.28 & 364.29 \\ 585.28 & 445.51 & 245.66 \\ 364.29 & 245.66 & 656.74 \end{bmatrix}.$$

Within-groups (error) sums of squares and products matrix:

$$\mathbf{E} = \begin{bmatrix} 100.60 & 65.60 & 95.63 \\ 65.60 & 165.93 & 149.30 \\ 95.63 & 149.30 & 557.90 \end{bmatrix},$$

$$\mathbf{E}^{-1}\mathbf{H} = \begin{bmatrix} 7.88522 & 5.90989 & 3.20985 \\ 1.36789 & 1.13769 & -0.46443 \\ -1.06476 & -0.87718 & 0.75123 \end{bmatrix}$$

Characteristic roots of $\mathbf{E}^{-1}\mathbf{H}$: 8.5280, 1.20595, 0.04018.

Values of the major multivariate analysis of variance test statistics are given in Table 2. The null

Table 1

hypothesis of equal mean vectors for the three skull dimensions in each of the four region and gender groups would be rejected by each of the test statistics.

Multivariate General Linear Model and Hypothesis

The **H** and **E** matrices also follow from a general linear model for a multivariate data matrix and hypothesis tests on the model's parameters. We represent the $N \times p$ data matrix by the following linear model:

$$\mathbf{X} = \mathbf{A}\boldsymbol{\mu} + \mathbf{e} = \mathbf{A}_1\boldsymbol{\mu}_1 + \mathbf{A}_2\boldsymbol{\mu}_2 + \mathbf{e},$$

in which $\mathbf{A}$ is the $N \times q$ design matrix describing the experimental design, $\boldsymbol{\mu}$ is the $q \times p$ matrix of model parameters, $\mathbf{A}_1$ is the $N \times r$ basis of $\mathbf{A}$, $\mathbf{A}_2$ is the $N \times (q - r)$ completion of $\mathbf{A}_1$, $\boldsymbol{\mu}_1$ is the $r \times p$ submatrix of $\boldsymbol{\mu}$ corresponding to the basis of $\mathbf{A}$, and $\boldsymbol{\mu}_2$ is the $(q - r) \times p$ submatrix of the parameters corresponding to the completion of $\mathbf{A}_1$. Note that each of the p columns of $\mathbf{X}$ has the same experimental design matrix. Then the multivariate general linear hypothesis is

$$\mathrm{H}_0 : \mathbf{C}\boldsymbol{\mu}\mathbf{M} = \mathbf{C}_1\boldsymbol{\mu}_1\mathbf{M} + \mathbf{C}_2\boldsymbol{\mu}_2\mathbf{M} = \mathbf{0},$$

and its alternative is simply that $\mathbf{C}\boldsymbol{\mu}\mathbf{M} \neq \mathbf{0}$. $\mathbf{C}$ is a $g \times q$ matrix specifying the hypothesis; $\mathbf{C}_1$ and $\mathbf{C}_2$ are its $g \times r$ and $g \times (q - r)$ submatrices corresponding to the parameter matrices $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, respectively, and $\mathbf{M}$ is a $p \times u$ matrix of constants that allows for hypotheses on linear compounds of the multivariate response parameters. The **H** and **E** matrices for the general model and hypothesis can be shown to be

$$\mathbf{H} = \mathbf{M}'\mathbf{X}'\mathbf{A}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{C}_1'[\mathbf{C}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{C}_1']^{-1} \times \mathbf{C}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1'\mathbf{X}\mathbf{M},$$

$$\mathbf{E} = \mathbf{M}'\mathbf{X}'[\mathbf{I} - \mathbf{A}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1']\mathbf{X}\mathbf{M}.$$

The matrices $\mathbf{C}_2$ and $\mathbf{C}_1$ must satisfy a *testability* condition [34]:

$$\mathbf{C}_2 = \mathbf{C}_1(\mathbf{A}_1'\mathbf{A}_1)^{-1}\mathbf{A}_1'\mathbf{A}_2.$$

Classification and Discrimination

The Linear Discriminant Function

Suppose two multivariate normal populations can be used to describe a p-component random variable. From respective random samples of N and M observations we have estimates $\bar{\mathbf{x}}_1$ and $\bar{\mathbf{x}}_2$ of their mean vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, and the within-sample estimate $\mathbf{S}$ of their common covariance matrix $\boldsymbol{\Sigma}$. Now consider a new $(N + M + 1)$th observation vector $\mathbf{x}$ from one of the two populations. We wish to assign $\mathbf{x}$ to population 1 or 2 on the basis of the values of the linear function $\mathbf{a}'\mathbf{x}$, where the vector $\mathbf{a}$ has been chosen to maximize the squared univariate t statistic,

$$t^2(\mathbf{a}) = \frac{[\mathbf{a}'(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)]^2}{\left\{\mathbf{a}'\mathbf{S}\mathbf{a}\left[\left(\frac{1}{N}\right) + \left(\frac{1}{M}\right)\right]\right\}},$$

subject to the condition that $\mathbf{a}'\mathbf{S}\mathbf{a} = 1$. The coefficient vector $\mathbf{a}$ maximizes the absolute distance between the means $\mathbf{a}'\bar{\mathbf{x}}_1$ and $\mathbf{a}'\bar{\mathbf{x}}_2$ given the constraint $\mathbf{a}'\mathbf{S}\mathbf{a} = 1$ on the elements of $\mathbf{a}$. The maximizing vector is given by

$$\mathbf{a} = \mathbf{S}^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2),$$

and the maximum squared t^2 $(\mathbf{a})$ is the Hotelling two-sample statistic:

$$T^2 = \left[\frac{NM}{(N+M)}\right](\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2).$$

If each population is equally likely, then we adopt the classification rule:
Assign x to population 1 if $\mathbf{a}'\mathbf{x}$ *is closer to the mean* $\mathbf{a}'\bar{\mathbf{x}}_1$, *and to population 2 if* $\mathbf{a}'\mathbf{x}$ *is closer to the other mean* $\mathbf{a}'\bar{\mathbf{x}}_2$.
Equivalently,
Assign $\mathbf{x}$ *to population 1 if* $\mathbf{a}'\mathbf{x} > \mathbf{a}'(\bar{\mathbf{x}}_1 + \bar{\mathbf{x}}_2)/2$, *and to population 2 otherwise*.
The new variable, $y = \mathbf{a}'\mathbf{x} = (\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}^{-1}\mathbf{x}$, is called the *sample linear discriminant function*. The midpoint, $\mathbf{a}'(\bar{\mathbf{x}}_1 + \bar{\mathbf{x}}_2)/2 = (\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}^{-1}(\bar{\mathbf{x}}_1 + \bar{\mathbf{x}}_2)/2$, between the means of the linear discriminant function for the two samples is also subject to sampling variation, and the discriminant function is sometimes expressed as the Wald–Anderson statistic:

$$W = \frac{\mathbf{x}'\mathbf{S}^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2) - (\bar{\mathbf{x}}_1 + \bar{\mathbf{x}}_2)'\mathbf{S}^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)}{2}$$

(Wald [38] and Anderson [1]). Then the classification rule in terms of W is:
Assign $\mathbf{x}$ *to population 1 if* $W > 0$, *and to population 2 otherwise*.
The distribution of W is complex for small samples, and the calculation of misclassification probabilities is difficult. A large literature exists on the estimation of different kinds of misclassification rates; some references have been given by Morrison [26].

In the rather artificial case of known parameters the linear discriminant function becomes

$$y = \mathbf{x}'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2),$$

and the classification rule is:
Assign $\mathbf{x}$ *to population 1 if* $\mathbf{x}'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2) - (\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)'\boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2)/2 > 0$, *and to population 2 otherwise*.
The linear discriminant function y has the univariate normal distribution, and misclassification probabilities are easily calculated. The classification method can be extended to the **Bayesian** case of **prior** probabilities p and $1 - p$ for the respective populations, and misclassification costs $C(1|2)$ and $C(2|1)$ [1, 3].

For classification with k independent populations we compute the Wald–Anderson statistics,

$$W_{ij} = \frac{\mathbf{x}'\mathbf{S}^{-1}(\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_j) - (\bar{\mathbf{x}}_i + \bar{\mathbf{x}}_j)'\mathbf{S}^{-1}(\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_j)}{2},$$

for all $k(k-1)$ pairs of the k sample mean vectors, and use the rule:
Assign $\mathbf{x}$ *to the ith population if* $W_{ij} > 0$ *for all* $j \neq i$.
We note that $W_{ji} = -W_{ij}$, and of course $W_{ii} = 0$. Alternatively, we can compute the sample **Mahalanobis distances**,

$$D_i^2 = (\mathbf{x} - \bar{\mathbf{x}}_i)'\mathbf{S}^{-1}(\mathbf{x} - \bar{\mathbf{x}}_i), \quad i = 1, \ldots, k,$$

and assign $\mathbf{x}$ to the population with the minimum D_i^2. The two rules are algebraically identical.

When the populations have unequal covariance matrices $\boldsymbol{\Sigma}_1$ and $\boldsymbol{\Sigma}_2$ the likelihood ratio classification rule leads to a quadratic discriminant function the form of which, with sample mean vectors and covariance matrices $\mathbf{S}_1$ and $\mathbf{S}_2$, is

$$h(\mathbf{x}) = (\mathbf{x} - \bar{\mathbf{x}}_2)'\mathbf{S}_2^{-1}(\mathbf{x} - \bar{\mathbf{x}}_2) - (\mathbf{x} - \bar{\mathbf{x}}_1)'\mathbf{S}_i^{-1}(\mathbf{x} - \bar{\mathbf{x}}_1) - \ln\left(\frac{|\mathbf{S}_1|}{|\mathbf{S}_2|}\right).$$

The vector $\mathbf{x}$ is assigned to population 1 if $h(\mathbf{x}) > 0$, and to population 2 otherwise. An alternative classification rule with multivariate normal populations with unequal covariance matrices $\mathbf{\Sigma}_1$ and $\mathbf{\Sigma}_2$ has been proposed by Anderson & Bahadur [4]. When the parameters of the distributions are known, the vector $\mathbf{x}$ would be assigned by the linear discriminant function

$$y = \mathbf{x}'(t_1\mathbf{\Sigma}_1 + t_2\mathbf{\Sigma}_2)^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)$$

to population 1 if y is greater than some constant c, and to Population 2 otherwise. A number of methods have been proposed for determining t_1, t_2, and c. When the parameters are unknown and estimated from the sample data, the linear discriminant function might be written as

$$y = \mathbf{x}'[t\mathbf{S}_1 + (1-t)\mathbf{S}_2]^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2),$$

and the constant chosen as the midpoint

$$c = \frac{(\bar{\mathbf{x}}_1 + \bar{\mathbf{x}}_2)'[t\mathbf{S}_1 + (1-t)\mathbf{S}_2]^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)}{2}$$

between the mean values of y for the two samples. The quantity t might be chosen in some pragmatic manner, as, for example, to minimize the number of misclassified individuals.

Inferences About Covariance Matrices

Generalized likelihood ratio tests are available for hypotheses on covariance matrices of multivariate normal distributions. From a single sample we may test that a covariance matrix has a specified form or particular pattern, or that all of its correlations are zero. The generalized likelihood ratio test of zero correlations is particularly simple. We compute the determinant $|\mathbf{R}|$ of the $p \times p$ correlation matrix $\mathbf{R}$, and from it the statistic

$$\chi^2 = -\left[\frac{N - 1 - (2p+5)}{6}\right] \ln |\mathbf{R}|.$$

If the null hypothesis that all $p(p-1)/2$ population correlations are zero is true, then χ^2 has the chi-square distribution with $p(p-1)/2$ degrees of freedom for large N, and the hypothesis is rejected if $\chi^2 > \chi_{\alpha;p(p-1)/2}$.

We may test that k populations have a common covariance matrix, although the usual determinantal form of that test appears to be affected seriously by departures from normality. The hypothesis that two subsets $\mathbf{X}_1$ and $\mathbf{X}_2$ of multivariate normal random variables are independent, or that

$$\mathrm{H}_0 : \mathrm{cov}(\mathbf{X}_1, \mathbf{X}_2') = \mathbf{\Sigma}_{12} = \mathbf{0}$$

is tenable, can be tested by a generalized likelihood ratio test due to Wilks [40], and sharpened in its chi-square approximation by Box [5]. Developments of the likelihood ratio tests can be found in Anderson [3], Morrison [26], and other sources for multivariate analysis.

Roy [33] found a union–intersection test of $\mathrm{H}_0 : \mathbf{\Sigma}_{12} = \mathbf{0}$. If the sample covariance matrix is partitioned as

$$\mathbf{S} = \begin{bmatrix} \mathbf{S}_{11} & \mathbf{S}_{12} \\ \mathbf{S}_{12}' & \mathbf{S}_{22} \end{bmatrix},$$

then the Roy union–intersection test statistic is the greatest characteristic root of the matrix product $\mathbf{S}_{11}^{-1}\mathbf{S}_{12}\,\mathbf{S}_{22}^{-1}\mathbf{S}_{12}'$ or any cyclic permutation of it, or the corresponding product in the correlation submatrices $\mathbf{R}_{ij}$. Details of the test and critical values have been given by Morrison [26]. The union–intersection test is based on the *largest squared* **canonical correlation** *coefficient*, or the greatest squared sample **correlation** between the linear compounds $U = \mathbf{a}'\mathbf{X}_1$ and $V = \mathbf{b}'\mathbf{X}_2$ of the variables in the first and second subsets. U and V were called the *canonical variates* by Hotelling [14, 15], who proposed their use for determining the nature of the correlation structure between the two subsets. Further pairs of canonical variates can be found from the second greatest, third greatest, etc. characteristic roots of the matrix product.

The Latent Structures of Covariance and Correlation Matrices

The dependence structures of multivariate normal random variables can be analyzed by various representations of the covariance or correlation matrices. The first method, principal components analysis, consists of rotating the coordinate axes of the original p variables to conform with the directions of successively smaller variation. The methodology is due to Hotelling [13], although it had been proposed much earlier by Pearson [28]. The second, factor analysis, is based on the assumption that the correlations among the p observed variables are generated by

a smaller number, m, of uncorrelated latent factor variables.

Principal Components

From the sample of N p-component observation vectors we compute the mean vector $\overline{\mathbf{x}}$ and the covariance matrix $\mathbf{S}$. The first principal component of the sample data, or of $\mathbf{S}$, is the new variable $Y_1 = \mathbf{a}_1'\mathbf{x}$, where the vector of constants $\mathbf{a}_1$ has been chosen to maximize the sample variance of Y_1, or $\mathbf{a}_1'\mathbf{S}\mathbf{a}_1$, subject to the constraint $\mathbf{a}_1'\mathbf{a}_1 = 1$. $\mathbf{a}_1$ is the characteristic vector (*see* **Eigenvector**) of $\mathbf{S}$ corresponding to the greatest characteristic root c_1, or the vector satisfying the equations $[\mathbf{S} - c_1\mathbf{I}]\mathbf{a}_1 = \mathbf{0}$, where c_1 is the largest root of the determinantal equation $|\mathbf{S} - c_1\mathbf{I}| = \mathbf{0}$. The remaining principal components are found by extracting the other $p - 1$ characteristic roots and vectors of $\mathbf{S}$: The ith principal component is the variate $Y_i = \mathbf{a}_i'\mathbf{x}$ with variance $c_i = \mathbf{a}_i'\mathbf{S}\mathbf{a}_i$. If the p characteristic roots are distinct then the characteristic vectors are mutually **orthogonal**, and the principal components are uncorrelated. The total variance of the principal components is

$$c_1 + \cdots + c_p = \operatorname{tr}\mathbf{S} = s_1^2 + \cdots + s_p^2,$$

and the proportion of the total variance due to the ith component is $c_i/tr\ \mathbf{S}$. In practice we prefer to consider the first few components that account for as much of the total variance as possible. If, for example, components 1, 2, and 3 explain 86% of the total variance, then we might consider the true dimensionality of the sample to be three rather than p.

Geometrically, $\mathbf{a}_i$ is interpretable as the vector of direction cosines of the line from the mean $\overline{x}$ through the direction of the ith greatest variation in the p-dimensional scatter plot of the data. When the c_i are distinct, the successive axes are orthogonal, or perpendicular, to one another. Each axis has an orientation that minimizes the sum of squared perpendicular distances to the data points, so that principal components analysis amounts to an "orthogonal least squares fit" of the component axes.

Certain patterned covariance matrices have distinctive principal components. If $\mathbf{S}$ is a diagonal matrix with successive diagonal elements $c_1 > c_2 > \ldots > c_p$, then the principal component axes are identical to those of the original variables. If the $p \times p$ matrix $\mathbf{S}$ has the equal-variance, equal-covariance pattern

$$\mathbf{S} = \begin{bmatrix} a & b & \ldots & b \\ b & a & \ldots & b \\ \vdots & \vdots & \cdots & \vdots \\ b & b & \ldots & a \end{bmatrix},$$

then the first principal component is $Y_1 = (x_1 + \ldots x_p)/\sqrt{p}$, and its variance is $c_1 = a + (p-1)b$. The second through pth components each have the same variance, $a - b$, and coefficient vectors that are mutually orthogonal with elements that sum to zero so that they are also orthogonal to the first component. Such a covariance matrix is called *semi-isotropic*, because it describes an ellipsoid in p-dimensional space with a single long axis (if $b > 0$), and $p - 1$ axes of equal lengths around it.

When the original variables are incommensurable or have very different variances, it may be more meaningful to extract principal components from the correlation matrix. This is equivalent to a component analysis on the standard scores $z_{ij} = (x_{ij} - \overline{x}_j)/s_j$ computed from the original observations x_{ij} obtained from the ith sampling unit's jth variable. Then the total variance for the p components will always be p.

A large-sample distribution theory for principal components has been developed by Girshick [7, 8], Anderson [2], and others. This includes tests and confidence intervals for component variances, and tests for component vectors. Asymptotic results for inferences on components extracted from correlation matrices are limited in scope, and depend on very complicated distributions. **Jackknife** and **bootstrap** methods show some promise for simpler inferences in this area.

Factor Analysis

Just as principal components were invented to explain portions of the total variance, factor analysis is designed to explain the correlation structure of multivariate data. We postulate that the observable $p \times 1$ multivariate normal random vector $\mathbf{X}$ with parameters $\mathrm{E}(\mathbf{X}) = \boldsymbol{\mu}$ and $\mathrm{cov}(\mathbf{X}, \mathbf{X}') = \boldsymbol{\Sigma}$ is related to the $m \times 1$ latent vector $\mathbf{Y}$ by the linear model

$$\mathbf{X} = \boldsymbol{\mu} + \boldsymbol{\Lambda}\mathbf{Y} + \mathbf{e},$$

where $\mathbf{e}$ is another $p \times 1$ random vector distributed independently of $\mathbf{Y}$. The number of latent variables m is much smaller than p. $\mathbf{Y}$ has expectation $\mathrm{E}(\mathbf{Y}) = \mathbf{0}$

and covariance matrix $\text{cov}(\mathbf{Y}, \mathbf{Y}') = \mathbf{I}$. $\text{E}(\mathbf{e}) = \mathbf{0}$ and $\text{cov}(\mathbf{e}, \mathbf{e}') = \boldsymbol{\Psi}$, a diagonal matrix with ith diagonal element ψ_i. Hence, $\text{E}(\mathbf{X}) = \boldsymbol{\mu}$, and

$$\begin{aligned}\text{cov}(\mathbf{X}, \mathbf{X}') &= \boldsymbol{\Sigma} \\ &= \boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}.\end{aligned}$$

The factor model representation of $\mathbf{X}$ has led to the decomposition $\boldsymbol{\Sigma} = \boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}$ of the original covariance matrix. For our purposes factor analysis will consist of the estimation of $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$, the expression of $\boldsymbol{\Lambda}$ in an "optimal" form, and the test of the fit of the observed covariance matrix to that reproduced by the factor model.

The matrix $\boldsymbol{\Lambda}$ of **factor loading** *parameters* is not unique. If $\mathbf{T}$ is an $m \times m$ orthogonal matrix, or one such that $\mathbf{T}\mathbf{T}' = \mathbf{T}'\mathbf{T} = \mathbf{I}$, then the new matrix $\boldsymbol{\Gamma} = \boldsymbol{\Lambda}\mathbf{T}$ is equally suited for reproducing the covariance matrix, for

$$\boldsymbol{\Sigma} = \boldsymbol{\Psi} + \boldsymbol{\Gamma}\boldsymbol{\Gamma}' = \boldsymbol{\Psi} + (\boldsymbol{\Lambda}\mathbf{T})(\boldsymbol{\Lambda}\mathbf{T})' = \boldsymbol{\Psi} + \boldsymbol{\Lambda}\boldsymbol{\Lambda}'.$$

The selection of the matrix $\mathbf{T}$ is known *as factor* **rotation**, for multiplication by the orthogonal matrix $\mathbf{T}$ is equivalent to a rigid rotation of the m factor axes. In practice, $\mathbf{T}$ is often found by using such algorithms as the Kaiser varimax method [20–22] (*see* **Varimax Rotation**), or occasionally, when m is small, by successively graphically rotating pairs of the factor axes to obtain as many large and as many nearly-zero loadings as possible. Sometimes, to achieve this **oblique rotations** are employed. This makes the factors correlated.

The elements of $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$ can be estimated by maximum likelihood under the assumption that the N independent observations on $\mathbf{X}$ are from the nonsingular multivariate normal distribution. This approach is due to Lawley [23], although it has been recast by Rao [31] and others in the context of characteristic roots and vectors. Allowance has also been made by most current statistical programs for global maxima on the boundary of the parameter space. For the determination of stationary maxima the Wishart density of the sample covariance matrix $\mathbf{S}$ can be substituted for the likelihood of the original data, and then maximized with respect to $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$. Lawley obtained the following nonlinear equations for the estimates:

$$\begin{aligned}\mathbf{S}\boldsymbol{\Psi}^{-1}\boldsymbol{\Lambda} &= \boldsymbol{\Lambda}(\mathbf{I} + \boldsymbol{\Lambda}'\boldsymbol{\Psi}^{-1}\boldsymbol{\Lambda}), \\ \text{diag}\,(\boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}) &= \text{diag}\,(\mathbf{S}),\end{aligned}$$

where the second equation merely requires that the diagonal elements of the covariance matrix $\hat{\boldsymbol{\Sigma}} = \hat{\boldsymbol{\Lambda}}\hat{\boldsymbol{\Lambda}}' + \hat{\boldsymbol{\Psi}}$ reproduced by the factor model are the same as those in the original matrix $\mathbf{S}$. Unlike principal components scale transformations on the original p variables simply transform the rows of the loading matrix $\boldsymbol{\Lambda}$ by the same amounts. Hence, the factor loadings obtained from the correlation matrix of the original variables differ from those of the covariance matrix only by scale factors.

The maximum likelihood estimation process leads to a test of the fit of the m-factor model to the observed covariance structure. The generalized likelihood ratio principle leads to the following goodness-of-fit test statistic:

$$\chi^2 = \left[\frac{N - 1 - (2p + 5)}{6} - \frac{2m}{3}\right] \times \ln\left(\frac{|\hat{\boldsymbol{\Psi}} + \hat{\boldsymbol{\Lambda}}\hat{\boldsymbol{\Lambda}}'|}{|\mathbf{S}|}\right),$$

which is distributed as a chi-square variate with $[(p - m)^2 - p - m]/2$ degrees of freedom when N is large. An approximation to the test statistic is

$$\chi^2 = \left[\frac{N - 1 - (2p + 5)}{6} - \frac{2m}{3}\right] \times \sum\sum_{i<j} \frac{(s_{ij} - \hat{\sigma}_{ij})^2}{\hat{\psi}_i \hat{\psi}_j},$$

or a measure of the closeness of the observed and reproduced covariances. In either case the hypothesis of an m-factor model is rejected for large values of the statistic.

Several other methods are available for data reduction and latent structure analysis. Multidimensional scaling was originally introduced by Richardson [32] and developed by Torgerson [36, 37] as a means of approximately representing multivariate data in lower-dimensional spaces. Gabriel [6] proposed the biplot for describing both the relationships among multivariate observations and the dependence structure of the variables (*see* **Graphical Displays**). Guttman [9, 10] proposed his simplex and circumflex models for responses ordered on a line or circle.

Nonnormal Multivariate Methods

Although in this review of multivariate methods we have largely assumed multivariate normal populations, in some cases alternative approaches not based on normality are available. **Logistic regression** may be substituted for discriminant analysis; Press & Wilson [30] have compared the two approaches with multivariate data sets, and prefer logistic regression in the case of nonnormality. Howe [17] showed that the normal-theory maximum likelihood estimation equations in factor analysis also follow from a minimum partial correlation argument independent of the multivariate normality assumption. Mooijart [25] has developed estimation methods for factor analysis models that do not assume multinormality, but do require the computation of higher-order crossproduct matrices of the variables. Some of the effects of nonnormality are described in the article **Multivariate Techniques, Robustness**.

Multivariate Bartlett Test

In multivariate analysis we often employ **Hotelling's T^2 test** and **multivariate analysis of variance** (MANOVA) to compare two or more mean vectors. One of the underlying assumptions for the T^2 and MANOVA tests is that the corresponding population **covariance matrices** are equal. It has shown that the T^2 and MANOVA tests are fairly robust to heterogeneity of covariance matrices as long as the sample sizes are large and equal [7]. For other cases we may use the multivariate Bartlett test to test the homogeneity of covariance matrices.

The univariate **Bartlett test** was proposed in 1937 to test the homogeneity of variances [2]. It was later extended to the multivariate case [3]. Assume independent samples of size $n_1, n_2, \ldots, n_k$ are randomly drawn from k multivariate normally distributed populations. The **null hypothesis** of equality of covariance matrices is given by

$$\mathrm{H}_0 : \mathbf{\Sigma}_1 = \mathbf{\Sigma}_2 = \cdots = \mathbf{\Sigma}_k.$$

Suppose p is the number of variables involved, so $\mathbf{\Sigma}_i$ is of size $p \times p$. To perform the test, we calculate

$$M = \frac{|\mathbf{S}_1|^{\nu_1/2}|\mathbf{S}_2|^{\nu_2/2}\ldots|\mathbf{S}_k|^{\nu_k/2}}{|\mathbf{S}_{\mathrm{pl}}|^{\nu_{\mathrm{E}}}},$$

where $\nu_i = n_i - 1$, $\nu_{\mathrm{E}} = \sum_{i=1}^{k} \nu_i = \sum_{i=1}^{k} n_i - k$, $\mathbf{S}_i$ is the covariance matrix of the ith sample, and $\mathbf{S}_{\mathrm{pl}}$ is the pooled sample covariance matrix

$$\mathbf{S}_{\mathrm{pl}} = \frac{\sum_{i=1}^{k} \nu_i \mathbf{S}_i}{\sum_{i=1}^{k} \nu_i}.$$

A tractable expression for the exact null distribution of M exists only for the case $k = 2$ [1, 6]. For $k > 2$ populations, Box [4, 5] provided **chi-square** and ***F* distribution** approximations for the distribution of M. They are both referred to as Box's M test. For the χ^2 approximation, we use the statistic u which is given as

$$u = -2(1 - c_1) \ln M,$$

where

$$c_1 = \left[\sum_{i=1}^{k} \frac{1}{\nu_i} - \left(\frac{1}{\sum_{i=1}^{k} \nu_i} \right) \right] \left[\frac{2p^2 + 3p - 1}{6(p+1)(k-1)} \right].$$

For computational purposes, we may use the following form of $\ln M$:

$$\ln M = \frac{1}{2} \sum_{i=1}^{k} \nu_i \ln |\mathbf{S}_i| - \frac{1}{2} \left(\sum_{i=1}^{k} \nu_i \right) \ln |\mathbf{S}_{\mathrm{pl}}|.$$

u is approximately distributed as $\chi^2_{1-\alpha}\left[\frac{1}{2}(k-1)\ p(p+1)\right]$. We reject H_0 if $u > \chi^2_{1-\alpha}$.

For the F approximation, the statistic depends on two quantities, c_1 and c_2, where c_1 is defined as above and c_2 is defined as follows:

$$c_2 = \frac{(p-1)(p+2)}{6(k-1)} \left[\sum_{i=1}^{k} \frac{1}{\nu_i^2} - \left(\frac{1}{\left(\sum_{i=1}^{k} \nu_i \right)^2} \right) \right].$$

If $c_2 > c_1^2$, then

$$F = -2b_1 \ln M.$$

If $c_2 < c_1^2$, then

$$F = -\frac{a_2 b_2 \ln M}{a_1(1 + 2b_2 \ln M)},$$

where

$$a_1 = \tfrac{1}{2}(k-1)p(p+1), \qquad a_2 = \frac{a_1 + 2}{|c_2 - c_1^2|},$$

$$b_1 = \frac{1 - c_1 - a_1/a_2}{a_1}, \qquad b_2 = \frac{1 - c_1 - 2/a_2}{a_2}.$$

Both F_{s} are approximately distributed as $F_{1-\alpha}(a_1, a_2)$.

Olsen [7] showed that the Box M test is very sensitive to some forms of nonnormality for which the MANOVA tests are rather robust. Therefore, in some cases the M test may indicate types of covariance heterogeneity that have only inconsequential effects on the MANOVA tests. Hence, the test is not recommended as a routine diagnostic for MANOVA tests.

Multivariate Classification Rules: Calibration and Discrimination

This article emphasizes multivariate classification rules, or models, where the classification is into one of two possible states, but also discusses extensions to multistate classifications. The accuracy of fit of a model is the degree to which the predicted values, $\hat{p}_i$, coincide with the observed outcomes, y_i, when these form a sample of size N drawn from a **random variable** Y. When the outcome is binary, being either a positive ($y_i = 1$) or a negative ($y_i = 0$) outcome the predicted values are often expressed as probabilities. Because the outcome takes only two values, predicted and observed values will not match closely for each observation as they might for a continuous outcome. Instead, models can be checked for good *discrimination* (also called *resolution* or *refinement*) and *calibration* (or *reliability*). Discrimination (*see* **Discriminant Analysis, Linear**) refers to the ability of the model to correctly distinguish the two classes of outcomes with distinct predicted values. **Calibration** of a probabilistic model describes how closely the predicted probabilities agree numerically with the actual outcomes. For example, events with a predicted outcome probability of 60% should occur about six times in 10. Generally, a model is well calibrated only when predicted and observed values agree for any reasonable grouping of the observations, whether ordered by increasing predicted values or selected according to some external characteristic like a risk factor.

Although a model with good calibration will tend to have good discrimination, and vice versa, a given model may be strong in one measure and weak in another. A model that predicts all negative outcomes to occur with probability 0.49 and all positive outcomes to occur with probability 0.51 has perfect discrimination but bad calibration, whereas a model that predicts all events to occur with probability equal to the prevalence of the outcome has perfect calibration but no discrimination. However, given the choice, some have recommended that good discrimination be preferred to good calibration if prediction is the goal, because a model with good discrimination can always be recalibrated, but the rank orderings of the probabilities cannot be changed to improve discrimination [7, 21]. A model with good discrimination can distinguish when events will occur for an individual and not just on average. Diamond [4] shows that a model with predictions **uniformly distributed** over [0, 1] and perfect calibration, in which the observed event rate is the same as the predicted rate for any subset of observations, cannot have perfect discrimination (as defined by the area under the **receiver-operating characteristic (ROC) curve**).

Brier Score

Mean squared error is a standard measure of the fit of a model. For binary data, the mean squared error, $\Sigma(y_i - \hat{p}_i)^2/N$, is called the *Brier score (BS)*. Here $\hat{p}_i$ is the predicted probability of a positive outcome or event for individual i and N is the total sample size. The Brier score can be considered a weighted **loss function** in which increasing distance between observed and predicted is penalized by a quadratic measure. Other scoring rules which have been suggested are the logarithmic rule [18] and the spherical rule [20]. These three rules are called *proper scoring rules* because they cannot be improved by giving any predictions other than those consistent with the long-run frequency probabilities of the system. In other words, if the modeler knew the true event rate in each prediction category, then he could do no better than predicting that true rate.

The numerical value of the Brier score has no direct meaning, but some weak standards of comparison are available. The simplest is obtained by noting that a prediction of 0.5 for each individual results in a Brier score of 0.25. Another reference value is the Brier score calculated assuming that all individuals are given a predicted probability equal to the prevalence, $\overline{y}$. Writing this as $B_0 = \Sigma(y_i - \overline{y})^2/N = \overline{y}(1 - \overline{y})$, we see that this is simply the variance of the y_i. This suggests that we can form a statistic like the multiple **correlation** coefficient R^2 by normalizing the Brier score B_1 as $R^2 = (B_0 - B_1)/B_0$, thus allowing a comparison of Brier scores across models fit to data with different prevalences [13]. This is important because the Brier score can be changed simply by changing the prevalence. A number of decompositions of the Brier score into components of calibration and discrimination have been suggested [12, 15, 21].

Sanders' decomposition [15] is

$$BS = \frac{\sum_j n_j(\overline{y}_j - \hat{p}_j)^2}{N} + \frac{\sum_j n_j \overline{y}_j(1-\overline{y}_j)}{N},$$

where the summation is over all groups with distinct predicted probabilities $\hat{p}_j$ having an observed event proportion of $\overline{y}_j$ on a sample of size n_j. (In this article, the subscript j refers to a group of individuals while the subscript i refers to single individuals.) The first component describes calibration. It is minimized when the observed event rate is the same as the predicted rate for each unique prediction. The second component describes resolution and is minimized if each $\overline{y}_j$ equals 0 or 1. It therefore measures how well the predictions divide the outcomes into homogeneous collections. As the observed group event rates approach 0.5, the resolution decreases because the predictions are not able to differentiate between outcome categories. Geometrically, the Sanders decomposition is similar to an **analysis of variance** decomposition of the distance between observed and predicted expressed as the sum of the distance between the value of an observation and the mean of the group in which the observation is placed plus the distance between the group mean and the predicted value.

Murphy [12] noted that the Sanders resolution may be inflated by the overall prevalence of the outcome. He therefore separated the resolution component into two pieces in order to describe the resolution adjusted for prevalence. In the Murphy decomposition,

$$BS = \overline{y}(1-\overline{y}) + \frac{\sum_j n_j(\overline{y}_j - \hat{p}_j)^2}{N} - \frac{\sum_j n_j(\overline{y}_j - \overline{y})^2}{N},$$

because the first term is the baseline Brier score, B_0, the sum of the second and third terms must be the negative of the numerator of the normalized Brier score represented by R^2. This representation shows explicitly how the Brier score is affected by changing prevalence. The second term of the Murphy decomposition is just the Sanders calibration. The third term is then the part of the Sanders resolution that does not depend on the overall prevalence and can be controlled by the modeler. This corrected resolution component improves as the mean event rates within each group of observations are differentiated from each other and from the overall event prevalence. The Sanders resolution may be high simply because low prevalence makes division into homogeneous groups easy. Most groups may have zero events because few events occur. Such groups contribute little to the Murphy resolution, however, if their mean rate is nearly the same as the overall mean rate.

Yates [21] described a third decomposition of the Brier score as

$$BS = \overline{y}(1-\overline{y}) + (\hat{p}-\overline{y})^2 + \frac{\sum_j n_j(\hat{p}_j - \hat{p})^2}{N} - 2\frac{\sum_j n_j(\hat{p}_j - \hat{p})(\overline{y}_j - \overline{y})}{N}.$$

The first term is the variance of the outcomes as in Murphy's representation. The second term involves the simplest global measure of calibration, the **bias**, which is the difference between the mean predicted value and the mean event rate. Yates calls it *calibration-in-the-large* to distinguish it from the Sanders/Murphy calibration. Models that are biased may systematically over- or underpredict the true outcome rate, even when discrimination is very good. In **logistic regression**, the bias is zero. Even when a model is unbiased, however, it may still be poorly calibrated if some groups of individuals are badly overpredicted while others are underpredicted. The third term in the Yates decomposition is the variance of the predicted values and the last term is twice the covariance between the predicted and observed values. Yates calls this the covariance decomposition of the Brier score. The covariance term can also be written as $\overline{y}(1-\overline{y})(\hat{p}_1 - \hat{p}_0)$ in terms of the *mean discrimination*, the difference $\hat{p}_1 - \hat{p}_0$ between the average predicted probabilities in the positive and negative outcome groups. Yates called mean discrimination the *slope* because it is the slope estimate if the predicted probabilities are regressed against a dummy variable representing outcome status. A good model should have a large slope, with a maximum of 1 for binary variables coded as 0 or 1, and therefore the sign of the covariance term above is negative.

Yates also noted that the predicted variance in the third term of his decomposition could be made zero if the model always predicted the same value, but that this would lead to a mean discrimination of zero. Therefore the third term in the decomposition can be rewritten as

$$\frac{\sum_j n_j(\hat{p}_j - \hat{p})^2}{N} = \frac{n_0\text{var}(\hat{p}_0) + n_1\text{var}(\hat{p}_1)}{N} + \overline{y}(1-\overline{y})(\hat{p}_1 - \hat{p}_0)^2,$$

the sum of the pooled variance in the predicted values across the two outcome groups and a term involving the slope. For a given slope, the second term, $\overline{y}(1-\overline{y})(\hat{p}_1 - \hat{p}_0)^2$, is the minimum that the prediction variance can achieve. This minimum variance is reached only if within each outcome class the predicted values are the same. The pooled variance term, which Yates called the *scatter*, measures the consistency of the predictions in the two outcome groups. High values of scatter indicate predictions that vary substantially. Taken together, the Yates decomposition is then composed of terms representing prevalence, bias, scatter, and slope. For logistic regression, a model can be described by the scatter and the slope. The slope describes how well the model responds to signals that discriminate events from nonevents (i.e. positive from negative outcomes) and the scatter describes how well the model filters out noise.

One disadvantage to the Brier score and its decompositions is that because all the relevant sampling distributions are not known, **hypothesis tests** and **confidence intervals** may be unavailable [22]. A test of mean discrimination, $\hat{p}_1 - \hat{p}_0$, can be made by performing a **Student's *t* test** comparing the predicted probabilities in the two outcome groups. The pooled variance for this test is simply the scatter measure, $[n_0\text{var}(\hat{p}_0) + n_1\text{var}(\hat{p}_1)]/N$. A test of overall bias, $\hat{p} - \overline{y}$, can be made by comparing the sample bias to its standard error $\left[\sum p_i(1-p_i)/N\right]^{1/2}$ assuming that the bias follows a normal distribution based on the use of $\hat{p}$ and $\overline{y}$ [8]. Spiegelhalter [19] describes a test of calibration based on the Brier score that can be used to determine if the observed score is significantly different from the score expected under the hypothesis of perfect model calibration that the expected value of $y_i = \hat{p}_i$ for all individuals. Because the Brier score is a weighted average of independent Bernoulli random variables (*see* **Binary Data**), an asymptotic test may be constructed on the basis of a standardized normal test statistic with expectation $\sum p_i(1-p_i)/N$ and variance $\sum p_i(1-p_i)(1-2p_i)^2/N^2$. Redelmeier et al. [14] have also developed a test on the basis of a normal approximation for comparing Brier scores from two different models.

Model Discrimination

The Sanders and Murphy resolution statistics measure how well models assign different predicted probabilities to groups of observations with different event rates, but fail as true discrimination measures because they do not consider the correct ordering of the probabilities. For example, a model that assigns predicted values less than 0.5 to all observations on which an event was recorded and predicted values greater than 0.5 to all observations on which an event was not recorded would be perfectly resolved, but would mean quite the opposite of what the probabilities were intended to mean.

A simple discrimination measure that does preserve ordering is the *nonerror rate*, the proportion of observations for which the outcome falls in that category with the higher predicted value. For a binary outcome this is the probability that among events the predicted value was greater than 0.5 and among nonevents the predicted probability was less than 0.5. Predictions of 0.5 get scored as one-half. A similar type of test statistic can be formed by computing the average probability across all observations assigned to the outcome that occurs. Both these tests are discussed in Hilden et al. [8] who give appropriate standard errors.

A good measure of discrimination should also be independent of model calibration. The nonerror rate has perfect **sensitivity** and **specificity** if 0.5 completely separates the two outcome categories. Recalibrating the predictions to a uniformly lower or higher level, however, may destroy the perfect discrimination. Sensitivity and specificity defined with respect to a fixed cutpoint would also fall into this category. Mean discrimination also suffers by this criterion because its magnitude depends on the levels of the predicted probabilities in the outcome groups.

The *c*-index, or *ROC curve area*, has become a standard of model discrimination for multivariate logistic regression because it summarizes a model's pairwise discrimination and depends only on the

rank ordering of the predicted values. It is calculated as the probability that among all possible pairs of individuals with different outcomes the predicted probability for the one with positive outcome is higher than for the one with negative outcome. Any pair with equal predicted probabilities gets half credit. Hanley & McNeil [6] showed for binary outcomes that this Wilcoxon rank sum statistic (*see* **Wilcoxon–Mann–Whitney Test**) is numerically equivalent to the area under the ROC curve formed by plotting the true positive rate against the false positive rate for all possible cutpoints that divide the [0, 1] probability interval into two parts. A model with perfect discrimination has a value of 1.0 for this statistic, while a model with no discrimination in which probabilities are assigned randomly has a value of 0.5. The c-index can also be expressed as Somers' D rank correlation statistic using the linear transformation $D = 2(c - 0.5)$ [7]. Standard errors are then readily available for these statistics using, for example, formulas for the Wilcoxon statistic [11].

The ROC area statistic (as well as other discrimination and calibration measures) can be affected by specifics of the population used in the development of a predictive model, such as its prevalence and case mix. Consider a population consisting of a mixture of two groups, one with an event rate of 0.2 and the other with a rate of 0.8. The true ROC area for the population depends on the mixture proportions of the groups. A 1:1 mixture has an ROC area of 0.8, but a 4:1 mixture has an ROC area of 0.72. Thus a model developed from the first population would appear better than one from the second population even though the only difference was the composition of the population.

Another measure of discrimination that can be classified as a rank-order statistic takes the ratio of outcomes that occur among observations with predictions in a high percentile with those among observations with predictions in the corresponding low percentile. The lowest and highest quartiles, quintiles, or deciles could also be used (*see* **Quantiles**). This measure ignores the middle part of the data and so is more sensitive to discrepancies in the tails of the predicted distribution. This may be of interest in models where definitive decisions are made if the model indicates a very high or very low risk, but no decision is made otherwise.

Model Calibration

Calibration measures may be characterized as statistics that partition the data into groups and check how the average predicted risk compares with the outcome prevalence in each group. The Sanders and Murphy statistics form the groups as the sets of observations with the same predicted values. When all the predicted values are unique (as might occur in a regression model with continuous predictors), the Sanders and Murphy decompositions degenerate so that the calibration component is simply the Brier score. Another type of calibration measure defines groups of similar, but not identical, predicted values. Patients are divided either into equal-sized groups that span the probability scale with unequally sized ranges of probabilities or into unequally sized groups that split the probability scale into equally sized increments. By describing the degree of accuracy over the entire range of probabilities, calibration statistics reflect how well an instrument predicts for patients with very different likelihoods of the outcome of interest.

The most common form of calibration statistic is based on the Pearson χ^2 statistic (*see* **Chi-square Tests**) used to summarize model fit by comparing observed and expected outcomes within K groupings defined by the predictors (*see* **Goodness of Fit**). It is written

$$\sum_{j=1}^{K} \frac{(O_j - E_j)^2}{n_j \hat{p}_j (1 - \hat{p}_j)},$$

where for n_j individuals in the jth group, O_j, is the observed number of events and $E_j = n_j \hat{p}_j$ is the expected number. Hosmer & Lemeshow [9] suggest that division using equal-sized groups is preferable especially when many of the predicted probabilities are small and that the test statistic be compared with a **chi-square distribution** having eight **degrees of freedom**.

Model-Based Validation of Calibration and Discrimination

Miller et al. [10] suggest a model for checking both calibration and discrimination using an idea of Cox [3] to examine the coefficients from a logistic regression of Y_i on the logit of $\hat{p}_i$ so that $\log[\Pr(Y_i = 1)/\Pr(Y_i = 0)] = \alpha + \beta \log[\hat{p}_i/(1 - \hat{p}_i)]$. In this model the intercept, α,

is a measure of calibration and the slope, β, is a measure of discrimination. Perfect calibration and discrimination correspond to a model with $\alpha = 0$ and $\beta = 1$. The predictive probability is too low if $\alpha > 0$ and too high if $\alpha < 0$. If $\beta > 1$, then the $\hat{p}_i$ show the correct direction but do not vary enough; if $0 < \beta < 1$, then the $\hat{p}_i$ vary too much; and if $\beta < 0$, then the $\hat{p}_i$ show the wrong general direction.

Three **likelihood ratio tests** can be constructed to test discrimination and calibration: (i) the test of $H_0 : \alpha = 0$ and $\beta = 1$ is a global test for calibration and discrimination; (ii) the test of $H_0 : \alpha = 0$ given $\beta = 1$ is a test for calibration given appropriate discrimination; and (iii) the test of $H_0 : \beta = 1$ given $\alpha = 0$ is a test of discrimination given appropriate calibration. From this model, Miller et al. [10] develop regression **diagnostics** for assessing **outliers**, influence, and leverage points as they affect calibration and discrimination.

Graphical Representations of Calibration and Discrimination

Many graphs have been developed to represent calibration and discrimination (*see* **Graphical Displays**). Yates [21] describes a covariance graph for representing the components of his decomposition of the Brier score plotting the predicted values on the vertical axis against the outcome values on the horizontal axis. Because there are only two possible outcomes, this plot collapses to a vertical dotplot for each outcome group. When the number of data points is large, it is better to represent the distributions of predicted values for each outcome state as histograms. The spread of these histograms describes the scatter component. A line is then drawn connecting the means of the two distributions. This is the slope component. The bias is represented by the distance between the 45° line indicating equality of predicted and observed, and the intersection of the horizontal line drawn across from the mean predicted value and the vertical line drawn up from the mean event rate. Arkes et al. [1] describe the use of this graph in evaluating the prognosis of patients in the SUPPORT study.

The ROC curve formed by plotting the true positive rate on the vertical axis against the false positive rate on the horizontal axis gives a good depiction of the sensitivity and specificity of the diagnostic tests set up by specifying cutpoints along the probability scale.

Calibration can be represented either by a barplot giving observed and average predicted probabilities for each grouping of the observations [17] or as a continuous curve across all possible predicted values. Harrell et al. [7] have suggested using a data smoother to describe the relationship between observed and predicted in such plots. Schmid et al. [16] use a second-degree loess smoother [2]. A **moving average** could also be used. Hilden et al. [8] plot the cumulative number of events against the expected number as the predicted values increase from 0 to 1. For each of these plots the departure of the continuous curve from the 45° line of equality describes the lack of calibration evidenced by the data.

Extensions to Multistate Outcomes

Many of the calibration and discrimination measures may be easily extended to outcomes for which more than two events are possible. The Brier score is written as $(1/N)\sum(\hat{p}_i - y_i)^{\mathrm{T}}(\hat{p}_i - y_i)$, where $\hat{p}_i - y_i$ is a column vector with each element corresponding to one of the possible events that could occur on the ith individual. For the two-event case, this value is actually twice the Brier score computed previously because the complementary event state is also included in the calculation. The Brier score decompositions are also straightforward upon noting that the squared terms in the two-state case can be replaced with vector extensions. The measure of bias can be extended by forming the column vector $\mathbf{Z} = \hat{\mathbf{p}} - \overline{\mathbf{y}}$ of mean predicted and observed in each of the k states. Then $\mathbf{Z}^{\mathrm{T}}\mathbf{V}^{-1}\mathbf{Z}$ follows a χ^2 distribution with k - 1 degrees of freedom. The calibration χ^2 statistics can be extended in the same way. For more than two states, the c-index is defined as in the two-state case, since a pair of individuals can still have only two outcomes. But the equivalence with the ROC curve area is lost. Good references for these multivariate extensions can be found in Yates [22], Winkler [20], Harrell et al. [7], and Hilden et al. [8]. Habbema et al. [5] discuss the use of a simplex to present the distribution of predicted and observed values in the three-state case.

Conclusion

Many calibration and discrimination statistics are available to measure how well binary (and multistate)

outcomes are classified by models. The *c*-index and the Hosmer–Lemeshow χ^2 statistic are the most widely used, but the careful data analyst should assess model performance in many different ways, bearing in mind that test statistics may vary from dataset to dataset. Good performance is usually easier to achieve on data with a wide variation in the covariates. For example, if individuals are either very sick or very well, it will be easier to categorize them. Performance may also suffer when a model fit to one set of data is tested on a new set, especially if the new set displays less variation in the covariates than the old one. When prediction is the goal of the modeling process, in fact, model performance should never be reported solely from the data used to develop the model. Instead, it is wisest to choose the model that displays the best calibration and discrimination on the new data [7].

Multivariate Distributions, Overview

Multivariate distributions are defined on finite-dimensional spaces. They serve as probabilistic models for dependent outcomes of random experiments. Biometric data typically comprise observations on multiple characteristics for each experimental subject, and joint distributions are central to the modeling and analyses of such data. Multivariate distributions derive from other distributions through operations including **transformations**, projections, **conditioning**, convolutions, **extreme values**, mixing, compounding, **truncating**, and **censoring**. From them derive the distributions of various sample statistics of note in statistical **inference**. In addition, multivariate distributions characterize the behavior of **stochastic processes** through properties of their finite-dimensional projections. Occasionally, multivariate distribution theory supports probabilistic proofs for mathematical theorems. In short, multivariate distributions arise throughout statistics and applied probability, and their properties are essential to an understanding of those and related fields.

Basic Concepts

Origins and Uses

To fix ideas, suppose that a pharmacologist focuses primarily on the cardiovascular system and secondarily on neurology and musculature. Let $\mathbf{X} = [X_1, X_2, X_3, X_4, X_5]'$ represent observations on the systolic X_1, and diastolic, X_2, pressures, pulse rate, X_3, and gross, X_4, and fine, X_5, motor skills. Prospects for altering the cardiovascular state of a subject through medication may be negated in part by adverse side-effects on motor skills, for example. A complete probabilistic description of the system entails the joint distribution of the variables $[X_1, X_2, X_3, X_4, X_5]$.

The origins of this topic trace to studies beginning in the early nineteenth century on **multivariate normal distributions** and their applications [1, 2, 10, 11, 18, 19, 24, 43, 50–52, 55, 57], including early biometrical investigations. Systematic studies of such distributions in two and three dimensions are credited to Bravais [2] and Schols [52], and in any finite dimensions to Edgeworth [11], including such essential concepts as **regression** and partial **correlations**.

Multivariate distributions merit scrutiny at several levels of detail. At one extreme are basics such as the stochastic **convergence** of vector sequences and multidimensional Chebychev inequalities under weak moment assumptions, which are genuinely **nonparametric**. At the other extreme are rigidly parametric models with distributions having specified functional forms. A survey of the latter follows subsequently. In between are classes of distributions exhibiting common structural features such as symmetry or unimodality, giving rise to *semiparametric* models. For many purposes it suffices to know only the structural properties of distributions rather than their explicit functional forms. For example, various concepts of multivariate unimodality are developed in Dharmadhikari & Joag-Dev [8]; some of these enable a sharpening of selected multidimensional Chebychev bounds. Further examples are cited here with reference to distributions exhibiting suitable symmetries, i.e. invariance under specified transformation groups.

Notions of stochastic ordering likewise admit several realizations in higher dimensions. These in turn give rise to useful multivariate probability inequalities. A systematic account of the latter is found in Tong [59], including many results for distributions listed here. Results pertaining to multivariate normal and related distributions are found in Tong [60]; brief surveys appear in the articles on the **Multivariate Normal Distribution** and **Multivariate *t* Distribution**. In particular, the comparative concentration of probabilities, as a stochastic ordering, is an essential concept for distributions on $\mathbb{R}^k$. Following Sherman [54], the probability measure $\mu(\cdot)$ is said to be *more peaked about* $\mathbf{0} \in \mathbb{R}^k$ than $\nu(\cdot)$ if and only if $\mu(A) \geq \nu(A)$ for every set A in the class C_k comprising the compact convex subsets of $\mathbb{R}^k$ that are symmetric under reflection about $0 \in \mathbb{R}^k$, i.e. $\mathbf{x} \in A$ implies $-\mathbf{x} \in A$. We return to this ordering subsequently.

Multivariate distributions exhibit many properties. A property is said *to characterize* a distribution if the property is unique to that distribution. A standard reference here is Kagan et al. [39], with connections to some distributions surveyed in the present article.

The choice of model is often critical in practice. Sometimes there is a clear mandate; more often the choice must be guided by experience, conjecture, and empirical validation. To aid in this choice,

numerous discrete and continuous multivariate distributions are now known, and others may be expected to emerge in the future. Our purpose here is to set forth basic concepts, to survey the principal known multivariate distributions of discrete and continuous types, and to give some insight regarding their use. It will be seen that numerous multivariate distributions arise through mixtures and compounding, in keeping with complexities intrinsic to modern experiments in many fields of inquiry. Such experiments often may be modeled conditionally in a random environment, so that unconditional distributions emerge as mixtures. Details are noted subsequently. Standard references for mixture models, their structure, analysis, and applications, are Everitt & Hand [12], Titterington et al. [58], McLachlan & Basford [46], and Lindsay [44].

Several topics encountered here are covered in greater detail elsewhere in this encyclopedia, as noted. Excellent references on the coverage of this article, including overviews for both discrete and continuous multivariate distributions and myriad technical details, are Johnson & Kotz [37, 38] and Patil & Joshi [49].

Notation

To fix notation, $\mathbb{R}^k$ designates Euclidean k-space and $\mathbb{R}^k_+$ its positive orthant; $F_{n\times k}$ is the collection of real $(n \times k)$ matrices; S_k consists of real symmetric $(k \times k)$ matrices; and S_k^0 and S_k^+ comprise the positive semidefinite and the positive definite varieties in S_k. Special arrays include the $(k \times k)$ identity $\mathbf{I}_k$, the unit vector $\mathbf{1}_k = [1, \ldots, 1]' \in \mathbb{R}^k$, the diagonal matrix diag $(a_1, \ldots, a_k)$, and the Kronecker product $\mathbf{A} \times \mathbf{B} = [a_{ij}\mathbf{B}]$. Specifically, $\mathbf{a} \in R^k$ is a column vector and $\mathbf{a}' = [a_1, \ldots, a_k]$ its transpose. The transpose, inverse, trace, and determinant of $\mathbf{A} \in F_{k\times k}$ are denoted by $\mathbf{A}', \mathbf{A}^{-1}, \mathrm{tr}\,(\mathbf{A})$, and $|\mathbf{A}|$, respectively. If $\mathbf{y} \in \mathbb{R}^k$ is random, its vector of expected values and its dispersion (or **covariance**) **matrix** are designated by $\mathrm{E}(\mathbf{y}) \in \mathbb{R}^k$ and $\mathrm{var}(\mathbf{y}) \in S_k^+$ when defined. If $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_n]' \in F_{n\times k}$, then conventions for the corresponding arrays are $\mathrm{E}(Y) = [\mathrm{E}(Y_{ij})] \in F_{n\times k}$ and $\mathrm{var}(\mathbf{Y}) = \mathrm{var}(\mathbf{y}) \in S_{nk}^+$ such that $\mathbf{y} = [\mathbf{y}_1', \ldots, \mathbf{y}_n']' \in \mathbb{R}^{nk}$.

The notation $\mathcal{L}(\mathbf{X})$ designates the law of distribution of $\mathbf{X} \in \mathbb{R}^k$ or $\mathbf{X} \in F_{n\times k}$, as appropriate. Abbreviations for probability density, cumulative distribution, and characteristic functions are *pdf, cdf*, and *chf*, respectively, whereas *iid* refers to a sequence of independent, identically distributed random elements (*see* **Random Variable**).

The Basic Tools

Let X_0 be a set and (Ω, B, P) a probability space with Ω as an event set, B a field of subsets of Ω, and P a probability measure. An X_0-valued random element is a measurable mapping $\mathbf{X}(\omega)$ from Ω to X_0 which, when X_0 is finite-dimensional such as the Euclidean space $\mathbb{R}^k$, is multivariate. The cumulative distribution function (cdf) of $\mathbf{X}(\omega) = [X_1(\omega), \ldots, X_k(\omega)]'$ on $\mathbb{R}^k$ is given by

$$F(x_1, \ldots, x_k) = P(\omega : X_1(\omega) \le x_1, \ldots, X_k(\omega) \le x_k), \quad (1)$$

with values in the unit interval. Corresponding to each cdf is a probability measure P_x and conversely, giving the model $(\mathbb{R}^k, B_k, P_x)$ in which B_k is the Borel field of subsets of $\mathbb{R}^k$. This provides a formal framework for multivariate distribution theory, although the details are typically suppressed in the discussion that follows.

The study of multivariate distributions draws heavily on the calculus of $\mathbb{R}^k$, on integral transforms of Fourier, Laplace, and Mellin, including **characteristic functions** on $\mathbb{R}^k$ (see [45]), and on embedding other finite-dimensional spaces in $\mathbb{R}^k$. Distributions often emerge through a change of variables and integral transforms, and their properties through inverse images. **Generating functions** for joint moments, cumulants, factorial moments, and probabilities are used routinely (*see* **Moment Generating Function**). Projection methods apply, as the distribution of $\mathbf{X}(\omega)$ on $\mathbb{R}^k$ is determined completely by the one-dimensional distributions of every linear transformation of it.

Some multivariate distribution functions admit simple expressions in closed form. More commonly, many others require expansions in multiple series fraught with problems of convergence and stability. Limit theorems (*see* **Large-sample Theory**) often suggest simple approximations. Asymptotic expansions, as well as expansions of the Cornish–Fisher and Edgeworth types, are available for many otherwise intractable multivariate distributions. Clearly, a complete catalog of probability functions would be

desirable for the distributions surveyed here. Unfortunately, this is overly ambitious owing to the aforementioned difficulties. Instead, we list functional forms where tractable, and otherwise refer the reader to excellent monographs which do supply complete details as well as further references to the archival literature.

Types of Distributions

Discrete distributions arise with counting data such as pulse rates and numbers of adult and larval insects. Continuous distributions typically associate with measurements such as systolic and diastolic pressures. A formal statement follows.

Suppose that X_0 is finite-dimensional. Each probability measure P on $[X_0, B(X_0), \cdot]$ is decomposable as a mixture

$$P = a_1 P_1 + a_2 P_2 + a_3 P_3,$$
$$a_i \geq 0,\ a_1 + a_2 + a_3 = 1, \tag{2}$$

such that P_1 assigns positive probability to the mass points of P, P_2 has absolute continuity with respect to the Lebesgue (i.e. volume) measure on $(X_0, B(X_0), \cdot)$, and P_3 is purely singular on a set in X_0 having a Lebesgue measure zero, often a linear subspace of X_0.

Corresponding to P_1, P_2, and P_3 on (R^k, B_k, P) are cdfs F_1, F_2, and F_3, respectively, as in (1). Here $F_1(x_1, \ldots, x_k)$ has a probability mass function (pmf) as given by

$$p(x_1, \ldots, x_k) = P(X_1 = x_1, \ldots, X_k = x_k), \tag{3}$$

giving the jumps of $F_1(x_1, \ldots, x_k)$ at its mass points, whereas $F_2(x_1, \ldots, x_k)$ has a corresponding probability density function (pdf) given by

$$f_2(x_1, \ldots, x_k) = \frac{\partial^k}{\partial x_1, \ldots, \partial x_k} F_2(x_1, \ldots, x_k) \tag{4}$$

for almost all $\{x_1, \ldots, x_k\}$.

Partition $\mathbf{X} \in \mathbb{R}^k$ as $\mathbf{X} = [\mathbf{X}_1', \mathbf{X}_2']'$ such that $\mathbf{X}_1 \in \mathbb{R}^r$ and $\mathbf{X}_2 \in \mathbb{R}^s$, with $r + s = k$. Then the marginal cdf of X_1 is given by $F_{m1}(x_1, \ldots, x_r) = F(x_1, \ldots, x_r, \infty, \ldots, \infty)$ for either discrete, absolutely continuous, or singular distributions. The pmf for the conditional distribution $\mathcal{L}(\mathbf{X}_1|\mathbf{x}_2)$ of $\mathbf{X}_1$, given that $\mathbf{X}_2 = \mathbf{x}_2$, is given by

$$p_1(x_1, \ldots, x_r|x_{r+1}, \ldots, x_k) = \frac{p(x_1, \ldots, x_k)}{p_2(x_{r+1}, \ldots, x_k)}, \tag{5}$$

with $p_2(x_{r+1}, \ldots, x_k)$ as the marginal function for $\mathbf{X}_2 = [X_{r+1}, \ldots, X_k]'$. A similar expression holds in the absolutely continuous case in terms of the joint pdf $f(x_1, \ldots, x_k)$ and the marginal pdf $f_2(x_{r+1}, \ldots, x_k)$.

The study of multivariate distributions is concerned mainly with functions of the discrete (3) and continuous (4) types; the principal distributions of these types are surveyed in this article under sections labeled "Discrete Distributions" and "Continuous Distributions". In practice, P_3 typically is a degenerate distribution, often concentrated on a subspace of R^k and absolutely continuous there. These pure types may be combined by mixture as in (2).

Continuous Distributions

Scope

Some finite-dimensional distributions arise from multidimensional limit theorems; many others serve as models for outcomes of random experiments; and still others originate primarily as derived distributions, often pertaining to sample statistics. Prominent among limit distributions and those from which others derive are multivariate normal distributions. Their basic features, including marginal and conditional distributions, regression functions, selected probability inequalities, central limit theorems, and Berry–Esseen bounds on convergence rates to a multivariate normal limit, are summarized under **Multivariate Normal Distribution**. Many basic distributions derived from these are known to be identical, and thus invariant, for all parent distributions in a structured class containing symmetric multivariate stable laws and numerous others. An impressive list of normal-theory statistical procedures, both univariate and multivariate, are thus genuinely semiparametric, in the sense that it suffices to identify only the structural symmetry of underlying distributions rather than their explicit functional forms. These facts bear heavily on the **robustness** and validity of normal-theory procedures for use with nonnormal data, including linear statistical models, various

data-analytic multivariate procedures, and the **multivariate Bartlett test** for equal dispersion matrices, to cite telling examples. Symmetric multivariate distributions are surveyed next; special mappings of practical note that are known to induce invariant distributions are then characterized; and derived distributions having these properties are identified subsequently. We then undertake a systematic survey of the principal distributions of random vectors and matrices of continuous types. The principal reference for these is Johnson & Kotz [38]; vector and matrix distributions having structural symmetry are found in many sources, including Dempster [6], Kariya & Sinha [40], Fang & Anderson [13], Fang et al. [15], and Fang & Zhang [14], and other references to be cited.

Symmetric Distributions

Multivariate data often are scattered more heavily away from the center of location than are multivariate normal data. Indeed, many models for contaminated errors are so. Symmetric distributions that are either more or less scattered than multivariate normal laws are described here, where by "symmetry" is meant *invariance under a specified group of transformations* acting on the space of observations. In many applications these are seen to supply useful semiparametric models, *in lieu of* overly restrictive multivariate normal models, as being germane to the outcomes of random experiments.

Distributions on $\mathbb{R}^n$. Let $S_n(\boldsymbol{\theta}, \boldsymbol{\Sigma}) = [S_n(\boldsymbol{\theta}, \boldsymbol{\Sigma}, \psi); \psi \in \Psi]$ be the class of *elliptical distributions* on $\mathbb{R}^n$, having location-scale parameters $(\boldsymbol{\theta}, \boldsymbol{\Sigma})$ and the typical pdf

$$f(\mathbf{y}) = |\boldsymbol{\Sigma}|^{-1/2}\psi[(\mathbf{y}-\boldsymbol{\theta})'\boldsymbol{\Sigma}^{-1}(\mathbf{y}-\boldsymbol{\theta})], \quad (6)$$

where $\psi(\cdot) \in \Psi$, with Ψ as the class of all such functions on $[0, \infty)$. The class $S_n(\mathbf{0}, \mathbf{I}_n)$ contains *isotropic distributions* on $\mathbb{R}^k$ for which $\mathbf{z}$ and $\mathbf{Q}\,\mathbf{z}$ have the same distribution for every real orthogonal matrix $\mathbf{Q}$ $(n \times n)$. Examples of elliptical distributions on $\mathbb{R}^n$ are given in Table 1, where **Student's *t*, Cauchy**, and stable laws with $\alpha < 2$ have tails heavier than those of multivariate normal distributions. It is known that $\mathrm{E}(\mathbf{y}) = \boldsymbol{\theta}$ and $\mathrm{var}(\mathbf{y}) = \gamma\boldsymbol{\Sigma}$, with $\gamma > 0$, whenever these moments are defined. Further properties are given in the references cited, together with review articles by Devlin et al. [7] and Chmielewski [4]. An original source is the penetrating work of Cambanis et al. [3].

Distributions on $F_{n\times k}$. Let $S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma}) = [S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma}, \psi); \psi \in \Psi]$, with parameters $(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$ such that $\boldsymbol{\Gamma} \times \boldsymbol{\Sigma} = [\gamma_{ij}\boldsymbol{\Sigma}]$, be the class of distributions on $F_{n\times k}$ having the typical pdf

$$f(\mathbf{Y}) = |\boldsymbol{\Gamma}|^{-k/2}|\boldsymbol{\Sigma}|^{-n/2}\psi \times [\mathrm{tr}\,(\mathbf{Y}-\boldsymbol{\Theta})'\boldsymbol{\Gamma}^{-1}(\mathbf{Y}-\boldsymbol{\Theta})\boldsymbol{\Sigma}^{-1}], \quad (7)$$

where $\mathrm{tr}\,(\cdot)$ is the trace and $\psi(\cdot)$ belongs to the class Ψ consisting of all such functions on $[0, \infty)$. This class contains symmetric stable distributions including matrix normal distributions of the type $N_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$, as given in Table 2, having $\mathrm{E}(\mathbf{Y}) = \boldsymbol{\Theta}$ and $\mathrm{var}(\mathbf{Y}) = \boldsymbol{\Gamma} \times \boldsymbol{\Sigma}$, as well as matrix versions of other examples from Table 1, and many others. Independence of the rows of $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_n]'$ and multivariate normality are linked: if $L(\mathbf{Y}) \in S_{n,k}(\boldsymbol{\Theta}, \mathbf{I}_n \times \boldsymbol{\Sigma})$, then $\{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$ are mutually independent if and only if $\mathbf{Y}$ is matrix normal on $F_{n\times k}$; see James [26].

More generally, $L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma})$ designates the class of matrix distributions on $F_{n\times k}$ having the typical pdf

$$f(\mathbf{Y}) = |\boldsymbol{\Gamma}|^{-k/2}|\boldsymbol{\Sigma}|^{-n/2}\phi(\mathbf{D}'\boldsymbol{\Gamma}^{-1}\mathbf{D}), \quad (8)$$

Table 1 Examples of spherical distributions on $\mathbb{R}^n$ having probability density functions $f(\mathbf{x})$ or characteristic functions $\xi(\mathbf{t})$

Type	Description	Comments
Multivariate normal	$f(\mathbf{x}) = c_1 \exp(-\mathbf{x}'\mathbf{x}/2)$	
Pearson type II	$f(\mathbf{x}) = c_2(1-\mathbf{x}'\mathbf{x})^{\gamma-1}$	$\gamma > 1$
Pearson type VII	$f(\mathbf{x}) = c_3(1+\mathbf{x}'\mathbf{x})^{-\gamma}$	$\gamma > n/2$
Student's t	$f(\mathbf{x}) = c_4(1+\nu^{-1}\mathbf{x}'\mathbf{x})^{-(\nu+n)/2}$	ν a positive integer
Cauchy	$f(\mathbf{x}) = c_5(1+\mathbf{x}'\mathbf{x})^{-(n+1)/2}$	
Scale mixtures	$f(\mathbf{x}) = c_6 \int_0^\infty t^{-n/2}\exp(-\mathbf{x}'\mathbf{x}/2t)\,\mathrm{d}G(t)$	$G(t)$ a cdf
Stable laws	$\xi(\mathbf{t}) = c_7 \exp[\gamma(\mathbf{t}'\mathbf{t})^{\alpha/2}]$	$0 < \alpha < 2$ the index

Table 2 Standard pdfs for some continuous matrix distributions

Type	Description[a]	Comments
Normal $N_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$	$k_1 \exp\{-[\mathrm{tr}\,(\mathbf{Y}-\boldsymbol{\Theta})'\boldsymbol{\Gamma}^{-1}(\mathbf{Y}-\boldsymbol{\Theta})\boldsymbol{\Sigma}^{-1}]\}$	$\mathbf{Y} \in F_{n\times k}$
Wishart $W_k(\nu, \boldsymbol{\Sigma})$	$k_2\lvert\mathbf{W}\rvert^{(\nu-k-1)/2}\exp(-\mathrm{tr}\,\mathbf{W}\boldsymbol{\Sigma}^{-1}/2)$	$\mathbf{W} \in S_k^+$
Matrix T	$k_3\lvert\mathbf{I}_k + \nu^{-1}\mathbf{T}'\mathbf{T}\rvert^{-(\nu+r)/2}$	$\mathbf{T} \in F_{r\times k}$

[a] $k_1 = [(2\pi)^{nk/2}\lvert\boldsymbol{\Gamma}\rvert^{k/2}\lvert\boldsymbol{\Sigma}\rvert^{n/2}]^{-1}$, $k_2 = \{(2)^{\nu k/2}\pi^{k(k-1)/4}\lvert\boldsymbol{\Sigma}\rvert^{\nu/2}\prod_{i=1}^{k}\Gamma[(\nu-i+1)/2]\}^{-1}$, and $k_3 = \{(\nu\pi)^{rk/2}\prod_{i=1}^{k}\Gamma[(\nu-i+1)/2]/\Gamma[(\nu+r-i+1)/2]\}^{-1}$.

with $\mathbf{D} = (\mathbf{Y}-\boldsymbol{\Theta})\boldsymbol{\Sigma}^{-1/2}$, where $\phi(\cdot)$ is a function on S_k^+ and where $\boldsymbol{\Sigma}^{-1/2}$ is a factor of $\boldsymbol{\Sigma}^{-1}$. A subclass of these is $S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$. Distributions in $L_{n,k}(\boldsymbol{\Theta}, \mathbf{I}_n, \boldsymbol{\Sigma})$ have the property that $(\mathbf{Y}-\boldsymbol{\Theta})$ and $\mathbf{Q}(\mathbf{Y}-\boldsymbol{\Theta})$ have the same distribution for every real orthogonal matrix $\mathbf{Q}(n \times n)$. For a treatment of the class $L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma})$ and its extensions, see Dempster [6], Dawid [5], Jensen & Good [34], and selected sections of monographs on symmetric distributions as cited earlier.

Invariance properties. Basic distributions induced from the foregoing classes through mappings of selected types are invariant. It remains to identify these. To be precise, let M be a subspace of $\mathbb{R}^n$ or $F_{n\times k}$, as appropriate; let T be a mapping to a finite-dimensional space V; and consider classes of parametric families to be generated from $S_n(\boldsymbol{\theta}, \boldsymbol{\Sigma})$, $S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$, and $L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma})$ as their parameters are varied. We are concerned with distributions for V-valued random elements induced through $T(\cdot)$. The following summary is taken from Jensen & Good [34] as a primary source, where proofs are provided. Applications appear subsequently for families exhibiting suitable symmetries. These facts in turn may be used to determine, essentially by inspection, the invariance properties of numerous derived distributions beyond those to be considered here.

Property 1. If $T[c(\mathbf{y}+\mathbf{m})] = T(\mathbf{y})$ for each $c > 0$ and $\mathbf{m} \in M \subset \mathbb{R}^n$, then the distribution of $T(\mathbf{y})$ is invariant for all distributions $\mathcal{L}(\mathbf{y})$ in the class $[S_n(\boldsymbol{\theta}, \boldsymbol{\Sigma}); \boldsymbol{\theta} \in M, \boldsymbol{\Sigma} \in S_n^+]$ consisting of elliptical families on $\mathbb{R}^n$.

Property 2. If $T[c(\mathbf{Y}+\mathbf{M})] = T(\mathbf{Y})$ for each $c > 0$ and $\mathbf{M} \in M \subset F_{n\times k}$, then $\mathcal{L}[T(\mathbf{Y})]$ is invariant for all distributions $\mathcal{L}(\mathbf{Y})$ in the class $[S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma}); \boldsymbol{\Theta} \in M, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma} \in S_{nk}^+]$ consisting of elliptical families on $F_{n\times k}$.

Property 3. If $T[(\mathbf{Y}+\mathbf{M})\mathbf{B}] = T(\mathbf{Y})$ for each $\mathbf{M} \in M \subset F_{n\times k}$ and each nonsingular matrix $\mathbf{B}(k \times k)$, then $\mathcal{L}[T(\mathbf{Y})]$ is invariant for all distributions L $(\mathbf{Y})$ in the class $[L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma}); \boldsymbol{\Theta} \in M, \boldsymbol{\Gamma} \in S_n^+, \boldsymbol{\Sigma} \in S_k^+]$ consisting of left-invariant distributions on $F_{n\times k}$.

Stochastic orderings. Stochastic order relations among distributions in the classes $S_n(\mathbf{0}, \boldsymbol{\Sigma})$ and $S_{n,k}(\mathbf{0}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$ are of note. To fix ideas, consider $S_n(\mathbf{0}, \boldsymbol{\Sigma}, \psi)$ and $S_n(\mathbf{0}, \boldsymbol{\Omega}, \psi)$; let $P_{\boldsymbol{\Sigma}}(\cdot; \psi)$ and $P_{\boldsymbol{\Omega}}(\cdot; \psi)$ be their corresponding probability measures; and recall the concentration ordering of Sherman [54] for sets in the class C_n comprising the symmetric convex subsets of R^n. Then a necessary and sufficient condition that $P_{\boldsymbol{\Sigma}}(\cdot; \psi)$ should be more concentrated about $\mathbf{0}$ than $P_{\boldsymbol{\Omega}}(\cdot; \psi)$, is that $\boldsymbol{\Sigma}$ and $\boldsymbol{\Omega}$ should be ordered so that $\boldsymbol{\Omega} - \boldsymbol{\Sigma}$ is positive semidefinite. Sufficiency is shown in Fefferman et al. [16], and necessity in Jensen [33]. Further such orderings apply when both $(\boldsymbol{\Sigma}, \psi)$ are allowed to vary in $[S_n(\mathbf{0}, \boldsymbol{\Sigma}, \psi); \boldsymbol{\Sigma} \in S_n^+, \psi \in \Psi]$; for further details see Jensen [33]. These order relations in turn extend directly, without further difficulty, to include matrix distributions in the class $[S_{n,k}(\mathbf{0}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma}); \boldsymbol{\Gamma} \in S_n^+, \boldsymbol{\Sigma} \in S_k^+, \psi \in \Psi]$.

The principal multivariate continuous distributions are surveyed next by name, although terminology is not yet completely standardized. The multivariate normal members of $S_n(\boldsymbol{\theta}, \boldsymbol{\Sigma})$ and $S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$ are denoted respectively by $N_n(\boldsymbol{\theta}, \boldsymbol{\Sigma})$ and $N_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma} \times \boldsymbol{\Sigma})$ as before. The notation $\chi^2(\nu, \lambda)$ designates the noncentral **chi-square distribution** having ν degrees of freedom and noncentrality parameter λ, whereas the central case is abbreviated as $\chi^2(\nu)$.

Gamma Distributions

Gamma, chi-square, and **exponential** distributions on R_+^1 are well known. Matrix and vector versions of these are considered next.

Matrix distributions. Suppose that $\mathbf{\Sigma}(k \times k)$ is positive definite, $\mathbf{W}$ is random with values in S_k^+, and $K(\cdot)$ is a constant. The pdf with $\lambda > 0, \mathbf{W} \in S_k^+$, as given by

$$f(\mathbf{W}) = K(\lambda, \mathbf{\Sigma})|\mathbf{W}|^{\lambda-1} \exp(-\mathrm{tr}\mathbf{W}\mathbf{\Sigma}^{-1}), \qquad (9)$$

$f(\mathbf{W}) = 0$ otherwise, is that of a *matric gamma distribution* [45, p. 40 ff.] Here $K(\lambda, \mathbf{\Sigma}) = \{\pi^{k(k-1)/4} \prod_{r=0}^{k-1} \Gamma[(2\lambda + r)/2]|\mathbf{\Sigma}|^{\lambda+(k-1)/2}\}^{-1}$. If $\mathbf{W} = \mathbf{Y}'\mathbf{Y}$ with $L(\mathbf{Y}) \in L_{n,k}(\mathbf{0}, \mathbf{I}_n, \mathbf{\Sigma})$ as in (8) such that $n \geq k$, then the pdf of $\mathbf{W}$ is

$$f(\mathbf{W}) = K(n, k, \mathbf{\Sigma})|\mathbf{W}|^{(n-k-1)/2}\phi(\mathbf{\Sigma}^{-1/2}\mathbf{W}\mathbf{\Sigma}^{-1/2}) \qquad (10)$$

for $\mathbf{W} \in S_k^+$, $f(\mathbf{W}) = 0$ otherwise, a result of Hsu [25]. Here $K(n, k, \mathbf{\Sigma}) = \pi^{nk/2-k(k-1)/4}/|\mathbf{\Sigma}|^{n/2} \prod_{i=1}^{k} \Gamma[(n - i + 1)/2]$. Moreover, if $\mathcal{L}(\mathbf{Y}) = N_{n,k}(\mathbf{M}, \mathbf{I}_n \times \mathbf{\Sigma})$ with $n \geq k$, and if $\mathbf{W} = \mathbf{Y}'\mathbf{Y}$, then $\mathbf{W}$ has a *noncentral* **Wishart distribution**, denoted by $W_k(n, \mathbf{\Sigma}, \mathbf{\Lambda})$, with noncentrality matrix $\mathbf{\Lambda} = \mathbf{M}'\mathbf{M}$. The central version is denoted by $W_k(n, \mathbf{\Sigma})$; its pdf is a special case of (9) and (10) as given in Table 3; whereas the noncentral pdf has a series expansion in special polynomials (see [38, p. 170 ff.]).

Wishart matrices arise in multivariate normal sampling, e.g. as the scaled sample dispersion matrix, and otherwise in multivariate distribution theory. Parallel remarks apply to (10) and the class $L_{n,k}(\mathbf{M}, \mathbf{I}_n, \mathbf{\Sigma})$. The noncentral Wishart distribution, although rather intractable numerically, admits approximations based on the following. As $n \to \infty$, its limit distribution is multivariate normal for standardized central and noncentral matrices, and for fixed n it is asymptotically multivariate normal as the noncentrality parameters grow in a specified manner [30].

Distributions on $\mathbb{R}_+^k$. Joint distributions for the diagonal elements of $W = [W_{ij}]$ arise in the **analysis of variance** for nonorthogonal designs, in **time series analyses**, in **multiple comparisons**, in the analysis of multidimensional **contingency tables**, in extensions of Friedman's chi-square test in two-way data based on ranks (*see* **Mantel–Haenszel Methods**), and elsewhere in statistical methodology. There is a multivariate gamma distribution on $\mathbb{R}_+^k$ for diagonal elements corresponding to expression (9), a multivariate chi-square distribution when $\mathbf{W}$ is Wishart, and a multivariate exponential distribution in the central case of the latter for the case $n = 2$. The joint distribution of $[W_{11}^{1/2}, W_{22}^{1/2}, \ldots, W_{kk}^{1/2}]$, known as a multivariate Rayleigh distribution, arises in the detection of signals from noise [47]. More general Rayleigh distributions are known [28], as are more general multivariate chi-square distributions with differing marginal degrees of freedom. The latter arise as the joint distributions of traces of diagonal blocks of a block-partitioned Wishart matrix [29].

Densities for these distributions are rather intractable, apart from special cases, typically entailing multiple series expansions in special functions from applied mathematics. Details are given in Johnson & Kotz [38, Chapter 40]. However, as $n \to \infty$, the standardized chi-square and Rayleigh distributions in the limit are multivariate normal for both central and noncentral cases, and for fixed n, the limits again are multivariate normal as the noncentrality

Table 3 Standard pdfs for some continuous distribution on $\mathbb{R}^k$

Type	Description[a]	Comments
Student's t	$k_1[1 + \nu^{-1}(\mathbf{t} - \boldsymbol{\mu})'\mathbf{R}^{-1}(\mathbf{t} - \boldsymbol{\mu})]^{-(\nu+k)/2}$	$\mathbf{t} \in \mathbb{R}^k$
Dirichlet	$k_2(1 - \sum_{j=1}^k u_j)^{\alpha_0-1} \prod_{j=1}^k u_j^{\alpha_j-1}$	$\{0 \leq u_j \leq 1, \sum_{j=1}^k u_j \leq 1\}$
Inverted Dirichlet	$k_2 \prod_{j=1}^k \nu_j^{\alpha_j-1}/[1 + \sum_{j=1}^k \nu_j]^{\alpha/2}$	$\{0 \leq \nu_j < \infty, \alpha = \sum_{j=0}^k \alpha_j\}$
Roots of $\lvert\mathbf{W} - w\mathbf{\Sigma}\rvert$	$k_3 \prod_{i=1}^k w_i^{(\nu-k-1)/2} \prod_{i<j}(w_i - w_j) \exp[-(\sum_{i=1}^k w_i)/2]$	$\{w_1 > \cdots > w_k > 0\}$
Roots of $\lvert\mathbf{S}_1 - l\mathbf{S}_0\rvert$	$k_4 \prod_{i=1}^k l_i^{(m-k-1)/2} \prod_{i=1}^k (l_i + 1)^{-(m+n)/2} \prod_{i<j}(l_i - l_j)$	$\{l_1 > \cdots > l_k > 0\}$

[a] $k_1 = \Gamma[(\nu + k)/2]/(\pi\nu)^{k/2}\Gamma(\nu/2)|\mathbf{R}|^{1/2}$, $k_2 = \Gamma(\alpha)/\prod_{j=0}^k \Gamma(\alpha_j)$, $\alpha = \alpha_0 + \alpha_1 + \cdots + \alpha_k$,

$k_3 = \pi^{k/2}/2^{\nu k/2} \prod_{i=1}^k \{\Gamma[(\nu - i + 1)/2]\Gamma[(k - i + 1)/2]\}$, and

$k_4 = \pi^{k/2} \prod_{i=1}^k \Gamma[(m + n - i + 1)/2]/\{\prod_{i=1}^k \{\Gamma[(n - i + 1)/2]\Gamma[(m - i + 1)/2]\Gamma[(k - i + 1)/2]\}\}$.

parameters grow [27]. Alternate approximations are found through multivariate normalizing transformations of the Wilson–Hilferty type; see Jensen [31] and Jensen & Solomon [35] for further details.

Student Distributions

Vector and matrix versions of **Student's *t* statistic** are considered next. Further details are given in the article on the **Multivariate *t* Distribution**, based on normal sampling models. However, multivariate normality need not be assumed here, since central versions of these distributions are seen to be invariants under symmetry of the underlying parent distributions, as noted subsequently.

Distributions on $\mathbb{R}^k$. There are two basic types. Suppose that $[X_1, \ldots, X_k]$ is multivariate normal with means $[\mu_1, \ldots, \mu_k]$, unit variances, and correlation matrix $\mathbf{R}(k \times k)$. A *type I distribution* is that of $\{T_j = X_j/S,\ j = 1, \ldots, k\}$ such that the distribution of νS^2 is $\chi^2(\nu)$ independently of $[X_1, \ldots, X_k]$. The typical pdf for this type is listed in Table 3. To consider type II distributions, suppose that $\nu\mathbf{S} = \nu[S_{ij}]$ has the central Wishart distribution $W_k(\nu, \mathbf{R})$ independently of $[X_1, \ldots, X_k]$. A *type II distribution* on $\mathbb{R}^k$ is that of $\{T_j = X_j/S_{jj},\ j = 1, \ldots, k\}$. Both types are central whenever $\mu_1 = \cdots = \mu_k = 0$ and are noncentral otherwise. These distributions arise in multiple comparisons procedures, in the construction of rectangular confidence sets for means, in the Bayesian analysis of multivariate normal data (*see* **Multivariate Analysis, Bayesian**), and in various multistage procedures. Further details are given in Johnson & Kotz [38, Chapter 37] and Tong [60, Chapter 9].

More generally, if $\mathcal{L}(X_1, \ldots, X_k, Z_1, \ldots, Z_\nu)$ is in the class $S_n(\boldsymbol{\theta}, \boldsymbol{\Gamma})$ with $\boldsymbol{\theta}' = [\mu_1, \ldots, \mu_k, 0, \ldots, 0]$ and $\boldsymbol{\Gamma} = diag(\mathbf{R}, \mathbf{I}_\nu)$, a block-diagonal matrix, then with $\nu S^2 = Z_1^2 + \cdots + Z_\nu^2$, the central joint distribution of $\{T_j = X_j/S;\ j = 1, \ldots, k\}$ is type I multivariate t for all distributions in $S_n(\boldsymbol{\theta}, \boldsymbol{\Gamma})$ having the required structure. This follows from invariance Property 1, so that normal-theory multiple comparisons using $\{T_1, \ldots, T_k\}$ are exact in level for linear models having spherical errors [32]. Similarly, if $L(\mathbf{Y}) \in S_{n,k}(\boldsymbol{\Theta}, \mathbf{I}_n \times \boldsymbol{\Sigma})$ with parameters $\boldsymbol{\Theta} = [\theta, \ldots, \theta]', \boldsymbol{\theta} \in R^k$; if $X_j = n^{1/2}\overline{Y}_j$ with $\{\overline{Y}_j = (Y_{1j} + \cdots + Y_{nj})/n;\ j = 1, \ldots, k\}$, and if $\mathbf{S}$ is the sample dispersion matrix, then invariance Property 2 asserts that the central distribution of $\{T_j = X_j/S_{jj}^{1/2};\ j = 1, \ldots, k\}$ is type II multivariate t for every L $(\mathbf{Y})$ in $S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \boldsymbol{\Sigma})$. Noncentral distributions generally depend on the particular distribution in $S_{n,k}(\boldsymbol{\Theta}, \mathbf{I}_n \times \boldsymbol{\Sigma})$.

Matric t distributions. Let $\mathbf{Y}$ and $\mathbf{W}$ be independent with $\mathcal{L}(\mathbf{Y}) = N_{r,k}(\mathbf{0}, \mathbf{I}_r \times \boldsymbol{\Sigma})$ and $\mathcal{L}(\mathbf{W}) = W_k(\nu, \boldsymbol{\Sigma})$ such that $\nu \geq k$, and let $\mathbf{T} = \mathbf{Y}\mathbf{W}^{-1/2}$ using any factorization $\mathbf{U}'\mathbf{U}$ of $\mathbf{W}$ with $\mathbf{W}^{1/2} = \mathbf{U}$. Then $\mathbf{T}$ has a *matric t distribution with* pdf as listed in Table 2. Alternatively, consider $\mathbf{X} = [\mathbf{Y}', \mathbf{Z}']'$ with distribution in $S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \boldsymbol{\Sigma})$ such that $n = r + \nu$ and $\nu \geq k$, and again let $\mathbf{T} = \mathbf{Y}\mathbf{W}^{-1/2}$ with $\mathbf{W} = \mathbf{Z}'\mathbf{Z}$. These variables arise from distributions in $S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \boldsymbol{\Sigma})$ in the same manner as for the multivariate normal case. From invariance Property 2, $\mathbf{T}$ has a matric t distribution for every distribution $\mathcal{L}(\mathbf{Y})$ in $S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \boldsymbol{\Sigma})$. This invariance property of $\mathcal{L}(\mathbf{T})$ transfers directly to the scaled distribution $\mathcal{L}(\mathbf{ATB})$ considered by Dickey [9] with $\mathbf{A}$ and $\mathbf{B}$ nonsingular.

Beta and F Distributions

Let X and Y be independent random gamma variates having a common scale. Then $U = X/(X + Y)$ has a **beta distribution** and $V = X/Y$ has an inverted beta distribution, with the Snedecor–Fisher ***F* distribution** as a special case of the latter. This section treats vector and matrix extensions of these distributions.

Dirichlet distributions. Let $\{Z_0, Z_1, \ldots, Z_k\}$ be independent gamma variates having a common scale and the shape parameters $\{\alpha_0, \alpha_1, \ldots, \alpha_k\}$, and let $T = Z_0 + Z_1 + \cdots + Z_k$. Then the joint distribution of $\{U_j = Z_j/T;\ j = 1, \ldots, k\}$ is the *k-dimensional Dirichlet distribution* $D(\alpha_0, \alpha_1, \ldots, \alpha_k)$ with pdf as given in Table 3. An important special case is that $\{\alpha_j = \nu_j/2;\ j = 0, 1, \ldots, k\}$ with $\{\nu_0, \nu_1, \ldots, \nu_k\}$ as positive integers and with $\{Z_0, Z_1, \ldots, Z_k\}$ as independent chi-square variates. However, in this case neither independence nor chi-square distributions are required. For if $\mathbf{y} = [\mathbf{y}_0', \mathbf{y}_1', \ldots, \mathbf{y}_k']' \in R^n$ with $\{\mathbf{y}_j \in R^{\nu_j};\ j = 0, 1, \ldots, k\}$ and $n = \nu_0 + \nu_1 + \cdots + \nu_k$ such that $L(\mathbf{y}) \in S_n(\mathbf{0}, \mathbf{I}_n)$, then invariance Property 1 ensures that $\{U_j = \mathbf{y}_j'\mathbf{y}_j/T;\ j = 1, \ldots, k\}$, but now with $T = \mathbf{y}_0'\mathbf{y}_0 + \mathbf{y}_1'\mathbf{y}_1 + \cdots + \mathbf{y}_k'\mathbf{y}_k$, has the distribution $D(\nu_0/2, \nu_1/2, \ldots, \nu_k/2)$.

A matric Dirichlet distribution is known [48] for which the random matrices $\{\mathbf{S}_0, \mathbf{S}_1, \ldots, \mathbf{S}_r\}$ in S_k^+ are independent Wishart matrices as given by $\{L(\mathbf{S}_j) =$

$W_k(\nu_j, \mathbf{\Sigma}); \nu_j \geq k,\ j = 0, 1, \ldots, r\}$. If

$$\mathbf{W}_j = \left(\sum_{j=0}^{r} \mathbf{S}_j\right)^{-1/2} \mathbf{S}_j \left(\sum_{j=0}^{r} \mathbf{S}_j\right)^{-1/2} \tag{11}$$

for $j = 1, 2, \ldots, r$, then for the lower triangular square root their joint pdf is

$$f(\mathbf{W}_1, \ldots, \mathbf{W}_r) = K(\boldsymbol{\nu}) \prod_{j=1}^{r} |\mathbf{W}_j|^{(\nu_j - k - 1)/2} \times |\mathbf{I}_k - \sum_{j=1}^{r} \mathbf{W}_j|^{(\nu_0 - k - 1)/2} \tag{12}$$

for $\mathbf{W}_j$ and $(\mathbf{I}_k - \sum_{j=1}^{r} \mathbf{W}_j)$ positive definite; $f(\mathbf{W}_1, \ldots, \mathbf{W}_r) = 0$, otherwise; see [38, p. 234]. Here with $\boldsymbol{\nu} = [\nu_0, \nu_1, \ldots, \nu_k]'$ and $\nu = \nu_0 + \nu_1 + \cdots + \nu_r$, $K(\boldsymbol{\nu}) = K(\nu_0, \nu_1, \ldots, \nu_k) = \prod_{i=1}^{k} \Gamma[(\nu - i + 1)/2] / \prod_{i=0}^{r} \prod_{j=1}^{k} \Gamma[(\nu_i - j + 1)/2]$. As before, neither independence nor Wishart distributions are required. For if $\mathbf{Y} = [\mathbf{Y}_0', \mathbf{Y}_1', \ldots, \mathbf{Y}_r'] \in F_{n \times k}$ with $n = \nu_0 + \nu_1 + \cdots + \nu_r$, such that $\nu_j \geq k$ and $\mathcal{L}(\mathbf{Y}) \in S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \mathbf{\Sigma})$, then invariance Property 2 ensures that the joint pdf of $\{\mathbf{W}_1, \ldots, \mathbf{W}_r\}$ as in (11), with $\{\mathbf{S}_j = \mathbf{Y}_j' \mathbf{Y}_j;\ j = 0, 1, \ldots, r\}$, is identical to (12) for every distribution $\mathcal{L}(\mathbf{Y})$ in $S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \mathbf{\Sigma})$.

Connections among these distributions follow. When $k = 1$, (12) is Dirichlet. The ratios of quadratic forms,

$$U_j(\mathbf{a}) = \frac{\mathbf{a}' \mathbf{S}_j \mathbf{a}}{\mathbf{a}' (\mathbf{S}_0 + \mathbf{S}_1 + \cdots + \mathbf{S}_r) \mathbf{a}}, \tag{13}$$

for $j = 1, \ldots, r$ and for fixed $\mathbf{a} \in R^k$, and the ratios of traces,

$$U_j = \frac{\operatorname{tr} \mathbf{S}_j}{\operatorname{tr} (\mathbf{S}_0 + \mathbf{S}_1 + \cdots + \mathbf{S}_r)}, \tag{14}$$

for $j = 1, 2, \ldots, r$, are both Dirichlet. The special case of (12), with $r = 1$, is sometimes called a *type I multivariate beta distribution*.

Inverted Dirichlet and F distributions. The inverted Dirichlet distribution is that of $\{V_j = Z_j / Z_0;\ j = 1, \ldots, r\}$ whenever $\{Z_0, Z_1, \ldots, Z_r\}$ are independent gamma variates having a common scale and the shape parameters $\{\alpha_0, \alpha_1, \ldots, \alpha_r\}$ (see [38, p. 238]). The typical pdf is listed in Table 3. The scaled variates given by $\{V_j = \nu_0 Z_j / \nu_j Z_0;\ j = 1, \ldots, r\}$ then have a *multivariate F distribution* whenever $\{\alpha_j = \nu_j / 2;\ j = 0, 1, \ldots, r\}$ with $\{\nu_0, \nu_1, \ldots, \nu_r\}$ as positive integers. This arises in the analysis of variance in conjunction with ratios of independent mean squares to a common denominator [17]. As before, neither independence nor multivariate normality is required; take $\{V_j = \nu_0 \mathbf{y}_j' \mathbf{y}_j / \nu_j \mathbf{y}_0' \mathbf{y}_0;\ j = 1, \ldots, k\}$ with $\mathcal{L}(\mathbf{y}) \in S_n(\mathbf{0}, \mathbf{I}_n)$ as stipulated for Dirichlet distributions.

An inverted matric Dirichlet distribution due to Olkin & Rubin [48] takes $\{\mathbf{S}_0, \mathbf{S}_1, \ldots, \mathbf{S}_r\}$ as before and defines $\{\mathbf{V}_j = \mathbf{S}_0^{-1/2} \mathbf{S}_j \mathbf{S}_0^{-1/2};\ 1 \leq j \leq r\}$ using the symmetric root of $\mathbf{S}_0$. The pdf $f(\mathbf{V}_1, \ldots, \mathbf{V}_r)$ is known allowing $\mathbf{S}_0$ to be noncentral. For the central case the joint pdf is given by

$$f(\mathbf{V}_1, \ldots, \mathbf{V}_r) = K(\boldsymbol{\nu}) \prod_{j=1}^{r} |\mathbf{V}_j|^{(\nu_j - k - 1)/2} | \times \left| \mathbf{I}_k + \sum_{j=1}^{r} \mathbf{V}_j \right|^{(\nu - k - 1)/2} \tag{15}$$

with $\nu = \nu_0 + \nu_1 + \cdots + \nu_r$ and $K(\boldsymbol{\nu})$ as defined following expression (12). The special case with $r = 1$ is sometimes called a *type II multivariate beta distribution*. Neither independence nor the Wishart character is required in the central case. To see this, take $\{\mathbf{S}_j = \mathbf{Y}_j' \mathbf{Y}_j;\ j = 0, 1, \ldots, r\}$ as for matric Dirichlet distributions with $\mathbf{Y} = [\mathbf{Y}_0', \mathbf{Y}_1', \ldots, \mathbf{Y}_r']'$, and conclude that $f(\mathbf{V}_1, \ldots, \mathbf{V}_r)$, as given in (15), is invariant for every $\mathcal{L}(\mathbf{Y})$ in $S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \mathbf{\Sigma})$.

Some connections among the foregoing distributions follow. When $k = 1$, $f(V_1, \ldots, V_r)$ is the pdf of the inverted Dirichlet distribution. The collections of ratios $\{V_j(\mathbf{a}) = \mathbf{a}' \mathbf{S}_j \mathbf{a} / \mathbf{a}' \mathbf{S}_0 \mathbf{a};\ 1 \leq j \leq r\}$, for fixed $\mathbf{a} \in \mathbb{R}^k$, and $\{V_j = \operatorname{tr} \mathbf{S}_j / \operatorname{tr} \mathbf{S}_0;\ 1 \leq j \leq r\}$, both have inverted Dirichlet distributions.

Other distributions of these types are known. Multivariate F distributions having correlated numerators have been found as ratios of multivariate chi-square variates to a common denominator (see [38, p. 240 ff.]), with applications in linear inference.

Distributions of latent roots. Many problems in statistics and applied probability entail the latent roots (**eigenvalues**) of random matrices. These include various topics in multivariate analysis pertaining to reduction by invariance, and in the study of energy levels of physical systems. Suppose that $\mathcal{L}(\mathbf{W}) = W_k(\nu, \mathbf{\Sigma})$, and consider the joint distribution of the

ordered roots $\{w_1 > w_2 > \cdots > w_k\}$ of the determinantal equation $|\mathbf{W} - w\boldsymbol{\Sigma}| = 0$. These entities arise in tests for hypotheses about dispersion parameters, for example. Their joint pdf is listed in Table 3. Occasionally ratios of these roots are required (see [38, p. 205]), for example in simultaneous inferences for the dispersion parameters, in which case an invariance result holds for the joint distributions of all such ratios. For if $\mathbf{W} = \mathbf{Y}'\mathbf{Y}$, such that $\mathcal{L}(\mathbf{Y}) \in S_{n,k}(\mathbf{0}, \mathbf{I}_n \times \boldsymbol{\Sigma})$, then the joint distributions of ratios of the roots of $|\mathbf{W} - w\boldsymbol{\Sigma}| = 0$ are invariant for all such matrix distributions by invariance Property 2.

To continue, suppose that $\mathbf{S}_0$ and $\mathbf{S}_1$ are independent Wishart matrices having the distributions $W_k(\nu_0, \boldsymbol{\Sigma})$ and $W_k(\nu_1, \boldsymbol{\Sigma}, \boldsymbol{\Lambda})$, respectively. Then central ($\boldsymbol{\Lambda} = \mathbf{0}$) and noncentral joint distributions of the roots of

$$|\mathbf{S}_1 - l\mathbf{S}_0| = 0 \tag{16}$$

are known (see [38, pp. 181–188]), as given in Table 3 for the central case. These are the latent roots of $\mathbf{W}_1$ at (11) when $r = 1$. A further invariance property holds for the central case. For if $\mathbf{Y} = [\mathbf{Y}_0', \mathbf{Y}_1']'$ with $n = \nu_0 + \nu_1$, $\mathbf{S}_0 = \mathbf{Y}_0'\mathbf{Y}_0$, and $\mathbf{S}_1 = \mathbf{Y}_1'\mathbf{Y}_1$, then by invariance Property 3, the latent root distribution is the same for all $\mathcal{L}(\mathbf{Y})$ in $L_{n,k}(\mathbf{0}, \mathbf{I}_n, \boldsymbol{\Sigma})$.

Other Distributions

Numerous other multivariate continuous distributions are known. Multivariate versions of *Burr distributions* arise through gamma mixtures of independent **Weibull distributions** [38, pp. 288–291]. Various *multivariate exponential distributions* are known; some properties and examples are found on specializing the **multivariate Weibull distributions** treated elsewhere in this encyclopedia. Various *multivariate stable distributions* are known, as are other types of symmetric distributions mentioned earlier. *Multivariate* **extreme-value distributions** are treated in Johnson & Kotz [38, pp. 249–260], with emphasis on the bivariate case. The *Beta-Stacy distribution* (see [38, pp. 273–284]) yields a *multivariate Weibull distribution* as a special case. *Multivariate* **Pareto distributions** (see [38, pp. 285–288]) have their origins in econometrics. The *multivariate logistic distribution* (refer to [38, pp. 291–294]) is used to model binary data in the analysis of quantal responses. Kibble [41] used properties of characteristic functions to derive a bivariate distribution having normal and gamma marginals.

Discrete Distributions

Many discrete distributions have multivariate extensions. These serve as building blocks for other distributions through *compounding*, in which distributions are assigned to some or all parameters of a family. Here the principal distributions are surveyed and connections among them noted. Generic names are used including "negative" and "inverse" types, in keeping with conventional usage for univariate cases.

Few discrete multivariate probability mass functions are known in closed form, notable exceptions being the multinomial and multivariate hypergeometric functions as given in many standard textbooks. More common are multiple series expansions in special functions, or cases where joint factorial moment, or joint probability generating, functions are available. To catalog these here would require much explanation of notation and concepts, and considerable overlap with excellent sources now available. Instead we undertake a careful description of each class of distributions and relations among them. The principal references are Johnson & Kotz [37, Chapter 11] and selections from Patil & Joshi [49], to be referenced by page numbers to aid the reader. Additional citations include the inequalities of Jogdeo & Patil [36] for a number of discrete multivariate distributions, and others to be noted on occasion.

Binomial Distributions

The number of successes in n independent Bernoulli trials, each having the probability π of success, has the **binomial distribution** $B(n, \pi)$. The number of trials to k successes has a **negative binomial distribution**. Some extensions follow.

Multivariate binomial distributions. The outcome of a random experiment is classified as having or not having each of s attributes $\{A_1, \ldots, A_s\}$. If $\{X_1, \ldots, X_s\}$ are the numbers having these attributes in n independent trials, then theirs is an s-dimensional binomial distribution with parameters

$$\pi_i = \Pr(A_i) \quad i = 1, \ldots, s,$$

$$\pi_{ij} = \Pr(A_i A_j), \quad i \neq j, i, j = 1, \ldots, s, \quad (17)$$

$$\ldots$$

$$\pi_{12\ldots s} = \Pr(A_1 A_2 \ldots A_s).$$

The marginal distribution of X_i is $B(n, \pi_i)$, all having the same index n, for $i = 1, \ldots, s$. Bivariate distributions having different indices are studied in Hamdan [20] and Hamdan & Jensen [22].

For sequences of identical experiments, the limiting standardized distribution is multivariate normal as $n \to \infty$. For nonidentical sequences such that $\pi_i \to 0$ as $n \to \infty, i = 1, \ldots, s$, the limit is a multivariate Poisson distribution under conditions given later. For further developments, see [49, p. 81].

Multivariate Pascal distributions. Independent trials of the preceding type are continued until exactly k trials exhibit none of the s attributes. The joint distribution of the numbers $\{Y_1, \ldots, Y_s\}$ of occurrences of $\{A_1, \ldots, A_s\}$ during these trials is an s-dimensional Pascal distribution (see [49, p. 83]).

Multivariate negative binomial distributions. Begin with an s-variate **Poisson distribution** with parameters $\mathbf{\Lambda}$ to be defined in expression (18). Next scale each parameter using a random gamma variate with parameters (α, k). The resulting mixture is an s-variate negative binomial distribution (see [49, p. 83]), its marginals negative binomial. It reduces to the multivariate Pascal distribution when k is an integer and to the negative multinomial distribution on mixing multiple Poisson distributions to be defined.

Multinomial Distributions

Let $\{A_0, A_1, \ldots, A_s\}$ be exclusive and exhaustive outcomes having probabilities $\{\pi_0, \pi_1, \ldots, \pi_s\}$ with $0 < \pi_i < 1$ and $\pi_0 + \pi_1 + \cdots + \pi_s = 1$. The numbers $\{X_1, \ldots, X_s\}$ of occurrences of $\{A_1, \ldots, A_s\}$ in n independent trials have the **multinomial distribution** with parameters $(n, \pi_1, \ldots, \pi_s)$.

Negative multinomial distributions. If independent trials are repeated until A_0 occurs exactly k times, then the numbers of occurrences of $\{A_1, \ldots, A_s\}$ during these trials have a negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$. This distribution arises through mixtures: first as a gamma mixture of multiple Poisson distributions as noted, and secondly as a negative binomial mixture on n of multinomials. As $k \to \infty$ and $\pi_i \to 0$ such that $\{k\pi_i \to \lambda_i, 0 < \lambda_1 < \infty, i = 1, \ldots, s\}$, the negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$ converges to the multiple Poisson distribution with parameters $(\lambda_1, \ldots, \lambda_s)$. Further properties are developed in standard references (see [37, p. 292] and [49, p. 70]).

Multivariate multinomial distributions. These are the joint distributions of marginal sums in multidimensional contingency tables. Classify an outcome according to each of k criteria having the exclusive and exhaustive classes $\{A_{i0}, A_{i1}, \ldots, A_{is_i}\}$ for $i = 1, \ldots, k$. If in n independent trials $\{X_{i1}, \ldots, X_{is_i}; i = 1, \ldots, k\}$ are the numbers occurring in $\{A_{i1}, \ldots A_{is_i}; i = 1, \ldots, k\}$, then their joint distribution is called a *multivariate (also multivector) multinomial distribution*, including the k-variate binomial distribution when $s_1 = s_2 = \cdots = s_k = 1$. Further developments are given in [37, p. 312] and [49, p. 86].

Multivariate negative multinomial distributions. Continue independent trials of the preceding type until exactly t trials are classified in all of $\{A_{10}, A_{20}, \ldots, A_{k0}\}$. The numbers occurring in $\{A_{i1}, \ldots, A_{is_i}; i = 1, \ldots, k\}$ during these trials have a *multivariate negative multinomial distribution*, reducing to the negative multinomial distribution when $k = 1$, and to the multivariate Pascal distribution when $s_1 = s_2 = \cdots = s_k = 1$. For further discussion see [37, p. 314].

Hypergeometric Distributions

A collection of N items consists of $s + 1$ types: N_0 of type A_0, N_1 of type $A_1, \ldots, N_s$ of type A_s, with $N = N_0 + N_1 \cdots + N_s$. Random samples are taken from this collection.

Multivariate hypergeometric distributions. In a random sample of n items drawn without replacement, the joint distribution of the numbers of items of types $\{A_1, \ldots, A_s\}$ is an s-dimensional **hypergeometric distribution** with parameters $(n, N, N_1, \ldots, N_s)$. With replacement, their distribution is multinomial with parameters $(n, N_1/N, \ldots, N_s/N)$. As $N \to \infty$ and $N_i \to \infty$ such that $N_i/N \to \pi_i$, with $0 < \pi_i < 1$ and $\pi_1 + \cdots + \pi_s < 1$, the hypergeometric converges to the multinomial distribution with parameters $(n, \pi_1, \ldots, \pi_s)$. If instead, $N \to \infty, N_i \to \infty$, and $n \to \infty$ such that $N_i/N \to 0$ and $nN_i/N \to \lambda_i$, with $\{0 < \lambda_i < \infty, i = 1, \ldots, s\}$, then the limit distribution is multiple Poisson with parameters $(\lambda_1, \ldots, \lambda_s)$. For further properties, see [37, p. 200] and [49, p. 76].

Multivariate inverse hypergeometric distributions. If successive items are drawn without replacement until

exactly k items of type A_0 are drawn, then the numbers of types $\{A_1, \ldots, A_s\}$ thus drawn have an *s-variate inverse hypergeometric distribution* with parameters $(k, N, N_1, \ldots, N_s)$. As $N \to \infty, N_i \to \infty$, such that $N_i/N \to \pi_i$ with $0 < \pi_i < 1$ and $\pi_1 + \cdots + \pi_s < 1$, this distribution converges to the s-variate negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$.

If, instead, $N \to \infty, N_i \to \infty$, and $k \to \infty$ such that $N_i/N \to 0$ and $kN_i/N \to \lambda_i$ with $\{0 < \lambda_i < \infty, i = 1, \ldots, s\}$, then the multivariate inverse hypergeometric converges to the multiple Poisson distribution with parameters $(\lambda_1, \ldots, \lambda_s)$ (see [49, p 76].

Multivariate negative hypergeometric distributions. Sampling proceeds in two stages. First m items are drawn without replacement, giving $(x_1, \ldots, x_s)$ items of types $\{A_1, \ldots, A_s\}$. Without replacing the first sample, n additional items are drawn without replacement at the second stage, giving $(Y_1, \ldots, Y_s)$ items of types $\{A_1, \ldots, A_s\}$. The conditional distribution of $(Y_1, \ldots, Y_s)$, given that $\{X_1 = x_1, \ldots, X_s = x_s\}$, is a multivariate negative hypergeometric distribution. It arises on compounding the multinomial distribution, with parameters $(n, \pi_1, \ldots, \pi_s)$, by assigning to $(\pi_1, \ldots, \pi_s)$ an s-dimensional Dirichlet distribution and then mixing. Under alternate conditions, this distribution converges either to the multinomial or to the product of negative binomial distributions. See [49, p. 77] for further details.

Poisson Distributions

Poisson distributions on R^1 admit the following extensions.

Multiple Poisson distributions. If $\{X_1, \ldots, X_s\}$ are independent Poisson random variables with parameters $\{\lambda_1, \ldots, \lambda_s\}$, then their joint distribution is a *multiple Poisson distribution* with parameters $(\lambda_1, \ldots, \lambda_s)$.

Multivariate Poisson distributions. Let $\{X_1, \ldots, X_s\}$ have the multivariate binomial distribution with parameters as in (17), and suppose that $n \to \infty, \pi_i \to 0, i = 1, \ldots, s$, such that

$$n\left\{\pi_i - \sum_j \pi_{ij} + \sum_{j<k} \pi_{ijk} - \cdots + (-1)^{s-1}\pi_{12\ldots s}\right\} \to \lambda_i,$$

$$n\left\{\pi_{ij} - \sum_k \pi_{ijk} + \sum_{k<1} \pi_{ijkl} - \cdots + (-1)^{s-2}\pi_{12\ldots s}\right\} \to \lambda_{ij}, \qquad (18)$$

$$\ldots$$

$$n\pi_{12\ldots s} \to \lambda_{12\ldots s}.$$

Then the limiting distribution of $\{X_1, \ldots, X_s\}$ is a *multivariate Poisson distribution* with parameters given by (18). This distribution also can be derived as the joint distribution of various partial sums of 2^{s-1} independent Poisson random variables with parameters as appropriate. See Johnson & Kotz [37, p. 297] and Patil & Joshi [49, p. 82] for additional references and further details.

Multivariate Series Distributions

Further classes of discrete multivariate distributions are identified by types of their pmfs.

Multivariate logarithmic series distributions. These distributions arise through truncation and limits. If $[X_1, \ldots, X_s]$ has the s-variate negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$, then the conditional distribution of $[X_1, \ldots, X_s]$, given that $[X_1, \ldots, X_s] \neq [0, \ldots, 0]$, converges to the *s-variate logarithmic series distribution* with parameters $(\theta_1, \ldots, \theta_s)$ as $k \to 0$, where $\{\theta_i = 1 - \pi_i; i = 1, \ldots, s\}$. See [49, p. 71] for details. A modified multivariate logarithmic series distribution arises as a mixture, on n, of the multinomial distribution with parameters $(n, \pi_1, \ldots, \pi_s)$, where the mixing distribution is a logarithmic series distribution (see [49, p. 73]).

Multivariate power series distributions. A class of distributions with parameters $(\theta_1, \ldots, \theta_s) \in \Theta$, derived from convergent power series, has pmfs of the form

$$p(x_1, \ldots, x_s) = \frac{a(x_1, \ldots, x_s)\theta_1^{x_1} \ldots \theta_s^{x_s}}{f(\theta_1, \ldots, \theta_s)}, \qquad (19)$$

for $\{x_i = 0, 1, 2, \ldots; i = 1, \ldots, s\}$, $p(x_1, \ldots, x_s) = 0$, otherwise. The class of such distributions, called *multivariate power series distributions*, contains the s-variate multinomial distribution with parameters $(n, \pi_1, \ldots, \pi_s)$; the s-variate logarithmic series distribution with parameters $(\theta_1, \ldots, \theta_s)$; the s-variate

Table 4 Some discrete multivariate compound distributions

Basic distribution	Mixing parameters	Mixing distribution	References	Comments
Bivariate binomial $(n, \pi_{01}, \pi_{10}, \pi_{11})$	n	Poisson	[23]	Gives bivariate Poisson distribution
Multinomial $(n, \pi_1, \ldots, \pi_s)$	$\pi_1, \ldots, \pi_s$	Dirichlet	[37, p. 309] [49, p. 69]	Gives s-variate negative hypergeometric distribution
Multinomial $(n, \pi_1, \ldots, \pi_s)$	n	Logarithmic series	[49, p. 69]	Gives s-variate modified logarithmic series distribution
Multinomial $(n, \pi_1, \ldots, \pi_s)$	n	Negative binomial	[49, p. 68]	Gives s-variate negative multinomial distribution
Multinomial $(n, \pi_1, \ldots, \pi_s)$	n	Poisson	[49, p. 69]	Gives multiple Poisson distribution
Multiple Poisson $(u\lambda_1, \ldots, u\lambda_s)$	u	Gamma	[49, p. 70]	Gives s-variate negative multinomial distribution
Multiple Poisson $(\lambda_1, \ldots, \lambda_s)$	$\lambda_1, \ldots, \lambda_s$	Multinormal	[56]	Gives s-variate Poisson–normal distribution
Multiple Poisson $(\lambda, \ldots, \lambda)$ $\lambda = \alpha + (\beta - \alpha)u$	u	Rectangular on (0,1)	[49, p. 80]	Gives s-variate Poisson–rectangular distribution
Multivariate Poisson $(u\lambda_1, u\lambda_{12}, \ldots, u\lambda_{12\ldots s})$	u	Gamma	[49, p. 82]	Gives s-variate negative binomial distribution
Negative multinomial $(k, \pi_1, \ldots, \pi_s)$	$\pi_1, \ldots, \pi_s$	Dirichlet	[37, p. 311] [49, p. 80]	Gives s-variate negative multinomial-Dirichlet distribution
Convolution of multinomials $(\gamma_1, \ldots, \gamma_{2^k}, \theta_1, \ldots, \theta_s)$	$\gamma_1, \ldots, \gamma_{2^k}$	Multivariate hypergeometric	[42]	Gives the distribution of numbers judged defective of k types in lot inspection

negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$; and others. See Patil & Joshi [49, p. 74] for further properties.

A nonexhaustive sampling of other discrete multivariate distributions is given next.

Bivariate Borel–Tanner distributions. A typical Borel–Tanner distribution is the distribution of the number of customers served before a queue vanishes for the first time. If service in a single-server queue begins with r customers of type I and s of type II with different arrival rates and service needs for each type, then the joint distribution of the numbers served is the *bivariate Borel–Tanner distribution* studied by Shenton & Consul [53].

Compound multivariate distributions. In many applications compound distributions arise from experiments undertaken in random environments, where the mixing distribution describes the variation of parameters of a specified model over the possible environments. Numerous bivariate and multivariate discrete distributions have been obtained through compounding, many motivated by the structure of the problem at hand. Some examples are listed in Table 4, together with references and brief comments. Series expansions, using suitable sets of orthogonal polynomials, are given in [20]– [23] for several discrete bivariate distributions.

Multivariate Graphics

The domain of multivariate graphics could span about everything envisioned by mankind. Images are inherently multivariate. A satellite image can be treated as a single observation with multispectral and spatial structure. Today's computing power allows processing and manipulation of such observations. Many of today's visualization targets were unthinkable a few decades ago. For example, the human genome with over two billion base pairs is a prime visualization target. While today's popular graphics challenge is to develop visualization methods for massive data sets, the old prime objective remains: to communicate to ourselves and others.

This brief article cannot begin to cover the domain of multivariate graphics. Rather, it tours a simple trail covering a small fraction of the landscape. The visited landscape primarily concerns static graphics. The tour provides little discussion of animation and direct manipulation methods. Even for static graphics the tour calls out a few highlights and provides pointers to other highlights that, unfortunately, are left to the imagination.

The chosen trail emphasizes places that are best known by the guide, who provides a personal view about key multivariate encoding issues that extend to places not visited. A few examples are drawn for other applications, but the methods have ready application to biostatistics. Along the tour, the discussion touches on important graphic design activities with words like *focus, simplify, link*, and *enhance*. These activities are universally important.

A few pointers to the literature may help the reader explore several facets of multivariate graphics. MacEachren [57] provides a readily accessible primer on symbolization and design. The classic work covering a wide variety of visual symbols and signs is Bertin [9]. Grinstein & Levkowitz [49] cover perceptual issues in visualization. Kosslyn [55] provides a gentle introduction to application of human perception and cognition in graph design. MacEachren [58] gives an extended treatment that is a valuable resource for more advanced students.

Foley et al. [43] provide an extensive overview of computer graphics methods. The methods are most immediately relevant to low-dimensional visualization. Wegman & Carr [76] cover selected computer graphic methods and address issues in perception and connections to statistical graphics.

Gnanadesikan [47] covers many of the basics in multivariate statistics, and numerous texts have followed. The multivariate analysis literature deals with important methods such as **clustering**, **classification**, **factor analysis**, **discriminant analysis**, and dimension reduction (*see* **Battery Reduction**) that are not described here. (For a discussion of these, *see* **Classification, Overview**; **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**; **Rotation of Axes**).

Early work in multivariate statistical graphics provides a continuing source of ideas. Fienberg [41] provides an early review. Barnett [6] contains a stimulating collection of papers. The work of John Tukey (see [32]) had a profound influence on statistical graphics and is a third resource worth revisiting.

Cleveland's recent books [30, 31] capture much of his long efforts to guide scientists toward superior statistical graphics methods. Cleveland & McGill [33] provide an early survey on dynamic multivariate graphics that foreshadows the visualization revolution in computer science. Tufte [67–69] has done much to expand interest in statistical graphics and to draw attention to works of elegance and beauty that appear on the printed page (*see* **Graphical Displays**).

Many additional resources are available. The computing revolution has increased access to and usage of visualization methodology by all disciplines. Professional societies churn out videos, proceedings on CDs, and collections of papers. Wood [81] reminds us that different maps have a different agenda (*see* **Statistical Map**). Similarly, papers on graphics have different agendas. While important work appears in medical imaging and other areas (*see* **Image Analysis and Tomography**), the entertainment industry now drives much work in visualization. Establishing fruitful connections between visualization techniques and scientific applications can involve significant additional research. This tour is more about graphical methods closely connected to probabilistic inference (*see* **Inference**; **Inference, Foundations of**) than about data and model-free visualization methods.

The Goal of Multivariate Graphics: Apparently Simple Comparisons

As an overview statement at the beginning of the tour, the dominant goal of multivariate graphics is comparison. Comparisons come in three forms: (i) comparison of external images with each other; (ii) comparisons of external images with external references; and (iii) comparison of external images with the analyst's internal references. These internal references include scientific knowledge and statistical expectations or models. The multivariate graphics design goal is to facilitate meaningful comparisons. This includes converting internal references into external visual references subject to further manipulation. With external images and references available, the next step often involves transformation to simpler forms. Typically the goal is to produce simple comparison graphics that involve juxtaposition, superimposition, or the direct display of differences.

A major goal in statistical graphics design is to reduce the cognitive effort required to make comparisons. In terms of statistical graphics design, Kosslyn [55] warns "the spirit is willing, but the mind is weak". Graphic design must do everything it can to help people to understand.

One important effort reduction strategy is to re-express the standard for comparison in simpler form. For example, in a simple **regression** involving one independent variable, one can compare observed (x, y) pairs to a predicted curve $y = f(x)$. However, to assess **residuals**, humans should not have to assess differences from a changing reference line $y = f(x)$. It is better to plot the residuals directly. The reference line for residuals is a horizontal straight line, and that is as simple as a visual reference can be. As a second example the line $x = y$ is the common reference line in $Q-Q$ plots (*see* **Normal Scores**). Tukey's mean–difference plot (see [30]) transforms the reference line into a horizontal straight line. More generally, Tukey [70] says "less than fully adjusted variates should not be plotted". While the statement's context is mapping of mortality rates for exploratory analysis (*see* **Mapping Disease Patterns**), the strategy of simplifying the human cognitive tasks by removing known structure applies to all facets of multivariate graphics.

In multivariate graphics we seek apparently simple views of comparisons. The path to these apparently simple views can involve deep insights about the phenomena involved, sound statistical summaries, and careful attention to issues of human perception and cognition.

Communication Objectives

Multivariate graphics can have many different communication objectives. Communication objectives influence graph design choices. Four common objectives are to provide an overview, to tell a story, to suggest hypotheses, and to criticize a model. In providing an overview, coverage is important. Hiding details is often crucial to achieve clarity in the coverage shown. Similarly, in telling a story the predetermined message must shine through. Tufte [69] is an important resource on the topic of visual explanations. Newspapers sometimes have good graphics and these can provide valuable lessons in communication. Scientists often fail to tell simple stories because they are reluctant to suppress caveats and a host of details that qualify the basic results. Interactive network software (see [25]) alleviates the problem by showing the basic graphics and by giving access to metadata that provide the basis for appropriate interpretation.

This article emphasizes discovery objectives that include suggesting hypotheses and criticizing models. For discovery, balanced visual emphasis of the variables helps the data to speak. Once known effects have been removed, display methods that are asymmetric in visual weighting of variables tend to be poor in terms of discovery objectives. Of course a fortuitous emphasis of some variables over others occasionally leads to insight, but even then the careful analyst will move toward the symmetric position of trying all permutations of the variables.

The same method that is poor for discovery may be used to advantage in telling a story. As an example, Chernoff faces [28] provide a very asymmetric representation and are poor at conveying multivariate interpoint distances. Nonetheless, people have used them to communicate effectively by, for example, equating high salaries to smiles.

Basic Design Considerations

With Kosslyn's warning in mind, we come to multivariate graphics prepared to do battle. Our willing spirit uses the best tools in the arsenal to discover the important patterns. As Cleveland [30] says, "tools

matter". The tools include encoding variables with high perceptual accuracy of extraction, using easily discriminated symbols, reducing memory and calculation burdens, grouping information into more manageable units, and layering the information so it can be dealt with in stages. The discussion below introduces some of this in the context of univariate and bivariate graphics.

Univariate Guidelines

Cleveland & McGill [34] discuss the perceptual accuracy of extraction and indicate preferred methods for univariate comparisons. Their research had subjects judge relative magnitudes of graphically encoded univariate variables. Their results ranked the graphic encoding methods into three classes, described here as best, good, and poor.

The two best encoding methods represent variables using position along a common scale, as shown in Figure 1, and position along identical nonaligned scales. That humans do well in judging the position of a point relative to a scale should come as no surprise. Marr [59] notes the "quintessential fact of human vision – that it tells about shape and space and spatial arrangement". Locating the position of objects is a fundamental visual task. Map makers have long used position along a scale as the fundamental encoding for spatial coordinates. MacEachren's [58] review of the perception literature attests to the power and primacy of positional encoding.

Length, angle, and orientation are good encodings. Figure 2 shows that transforming line segments into a standard position converts the task of judging length into a task of judging the position of one endpoint against a scale. While this is not necessarily what people do, the example suggests that judging line length is more complicated than judging position.

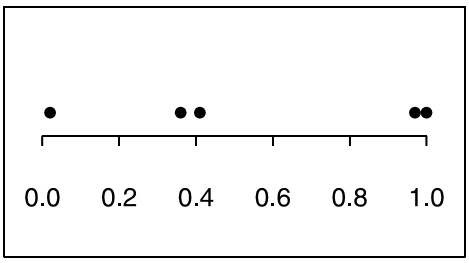

Figure 1 The best continuous univariate encoding: position along a scale

Figure 3 shows angle encoding. Rotation of the angles puts them in a position for comparison against equivalent angular scales, shown in gray. The transformation suggests that while angle comparisons work pretty well, they are more complicated than direct comparison against angle scales.

Area, volume, point density, and color saturation are poor encodings. The reader familiar with the experimental results involving Steven's Law will not be surprised by the poor results for the area and volume encodings. Steven's Law states that the perceived magnitude of a stimulus follows a power law,

$$p(x) = ax^b,$$

where x is the magnitude of the true stimulus (i.e. length, area, volume), and where the constants a and b depend on the type of stimulus. Table 1, adapted from Baird & Noma [5], provides the range of the characteristic exponents b for length, area, and volume. That is, people's perception of length tends to be directly proportional to object length. However,

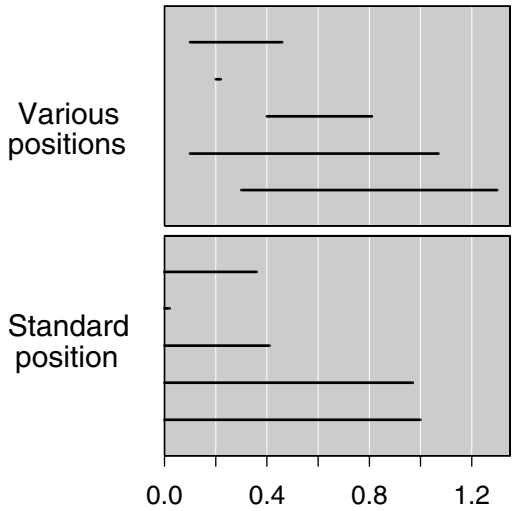

Figure 2 A good continuous univariate encoding: line length

Table 1 Exponents for Steven's Law

Encoding	Exponent range (b)
Length	(0.9, 1.1)
Area	(0.6, 0.9)
Volume	(0.5, 0.8)

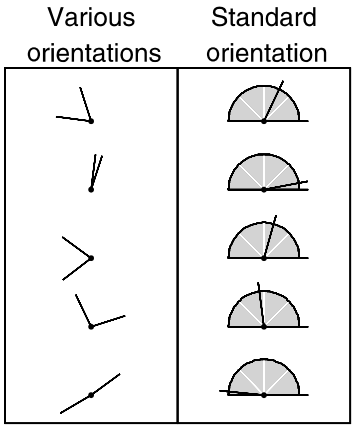

Figure 3 A good continuous univariate encoding: angle

we tend to judge area and volume nonlinearly. Consider comparing areas, one of 4 square units and the other of 1 square unit. With an exponent of 0.75, the ratio of perceived magnitudes is not 4 to 1, but 2.8 to 1. One way of describing our comparisons is that we underjudge the large areas relative to small areas. If everyone had the same exponent, then graphic encoding could adjust for systematic human bias. However, the range of values for b in Table 1 indicates substantial variability from person to person. Providing a set of reference symbols in a legend helps people calibrate to the intended interpretation, but the best strategy is to use better encodings when possible.

Weber's law is a fundamental law in human perception that has extensive ramifications concerning encoding information for accurate human decoding. A simple example gives the basic notion of the law. The probability of detecting that a 1.05 in. line is longer than a 1 in. line is about the same as the probability of detecting that a 1.05 ft. line is longer than a 1 ft. line. In absolute terms 0.05 in. is much smaller than 0.05 ft. The use of a finer resolution scale allows more accurate judgments on an absolute scale. In static graphics Cleveland [30] uses visual grid lines to provide a finer resolution scale for comparison purposes. In interactive graphics, zooming in provides a finer scale. Computer–human interface implementations that narrow focus to provide more accurate judgements include sliders (e.g. Ahlberg & Schneiderman [1] and Eick et al. [40]) and lenses (Rao & Card [63]).

Bivariate Guidelines

Tufte [67] notes that it took over 5000 years to generalize from early clay tablet maps to representing general variables using a scatterplot. Now the scatterplot is the standard for representing continuous bivariate data. The two orthogonal axes allow two coordinates to be independently encoded as a position along a common scale. In the statistical context, the bivariate visualization tasks are often to observe a functional relationship or to assess point density. These are not the most natural visual tasks. Enhancement methods reduce the amount of human visual processing required and help different humans to see the same summary.

Functional Relationships and Smoothing

When y is considered a function of x, common practice is to enhance scatterplots of (x, y) pairs by adding a smooth curve. To avoid the considerable human variability in sketching an eyeballed fit, the standard procedure is to fit the data using a computational procedure that others can replicate. Figure 4 shows a scatterplot with a smooth line generated using loess (see Cleveland et al. [35] for more details). Loess smoothes the data using weighted local regression. That is, the regression uses data local to x_0 to predict a value at x_0. Points closest to x_0 receive the greatest weight. Each smoother has many prediction points and so involves many local regressions. Each regression in the smoother shown

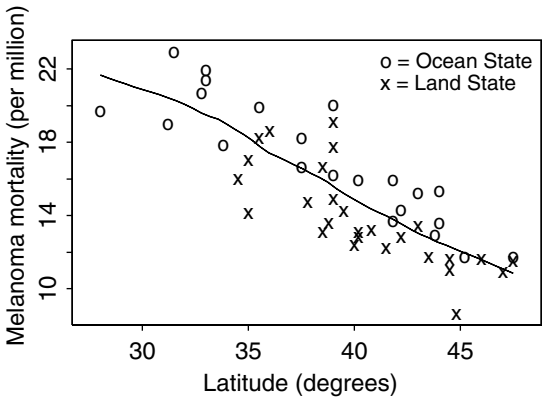

Figure 4 A smoother for scatterplots. An explicit smoother suggests the same functional relationship to different people. State mortality rates, 1950–1959

in Figure 4 used a linear model in x and included the closest 60% of the observations to the prediction point x_0. Those with the data (see Fisher & van Belle [42]) and the algorithm can reproduce the smoother. The smoother in Figure 4 draws further attention to the distinction between ocean and land states and additional modeling is appropriate. A first step might be to smooth the ocean and land states separately.

Smoothing is an extremely important enhancement technique (*see* **Nonparametric Regression**). The decomposition of data into smooth and residual parts is fundamental in statistical modeling. Hastie & Tibshirani [50] provide a good introduction to smoothing methods. Their description includes **generalized additive models** that cover the case of multiple independent variables.

Numerous smoothers are available. Historically, many researchers used cubic **splines** as smoothers. Cubic splines have a continuous second derivative, and that is sufficient to make curves appear smooth to humans. The elegant mathematical formulation behind splines *increased their popularity in segments of* the statistical community. However, there is no a priori best smoother. New methods, such as **wavelet** smoothing [11], keep appearing in statistical software. Different smoothers have different merits. Recently developed wavelets smoothers are better than many smoothers (but not necessarily all smoothers) at tracking discontinuities in the functional form.

Smoothers typically have some form of smoothing parameter that needs to be estimated or specified by the user. With computational power at hand, **cross-validation** methods have become increasingly popular as a community standard. This reduces the judgment burdens on the analyst, but of course does not guarantee a match between an empirical curve and a hypothesized true but unknown underlying curve. Hastie & Tibshirani [50] discuss cross-validation for moderate-sized applications. Golub & von Matt [48] discuss generalized cross-validation for large-scale problems.

Data Density and Density Estimates

When one looks at observations in scatterplots, one often looks for density patterns such as clusters, gaps, and outliers. However, humans are not good at visually assessing point density, so we again turn to a replicable computational method to provide an enhancement. Scott [64] provides a good introduction to **density estimation**. Like smoothing, density estimation has associated smoothing parameters and cross-validation methods to help in their selection. Scott [64] provides a discussion of cross-validation in the density estimation context.

A common task in statistics is to compare univariate distributions. Figure 5 shows a set of boxplots (*see* **Graphical Displays**). The boxplots show a caricature of the distribution. The features shown include the **median**, quartiles (*see* **Quantiles**), adjacent values, and **outliers**. Variations (see Frigge et al. [45]) may show extrema rather than adjacent values and outliners. The variation in Figure 5 uses a white line (see [15]) to provide intervals for comparing medians. If two **confidence intervals** do not overlap, then the medians are significantly different.

$Q-Q$ plots provide the preferred graphic to make detailed continuous distribution comparisons [30]. Computing a set of probability–quantile (p, q) pairs for each distribution lies behind the construction $Q-Q$ plots. For theoretical distributions, the cumulative distribution function, $F(\cdot)$, provides the correspondence between the pairs via $p = F(q)$. In simple cases the quantile function, $Q(\cdot)$, is the inverse of $F(\cdot)$ and $Q(p) = q$. Familiar p, q pairs from the standard normal distribution are (0.5, 0) and (0.975, 1.96). Order statistics approximations provide pairs for sampled data. A common approximation is $((i - 0.5)/n, x_{(i)})$, where $x_{(i)}$ is the ith order statistic and n is the sample size. Linear interpolation approximates values between the n pairs. Comparison of two distributions, denoted 1 and 2, proceeds by plotting quantile pairs $(Q_1(p), Q_2(p))$ over a range of probabilities. Figure 6 shows a $Q-Q$ plot for two batches of data. The x-axis shows quantiles from batch 1 and the y-axis shows quantiles from batch 2.

A strong merit of $Q-Q$ plots is that in simple cases they have a nice interpretation. If points fall on a straight line, then the distributions have the same shape (basically, the same moments higher than two) and the distributions differ only in the first two moments. This is the case in Figure 6, since the robust fit thin line matches the quantiles quite well. The thick line is the reference line for identical distributions. The slope of the thin line indicates the ratio of the scale estimates (for example, standard deviations). The lines are not quite parallel in Figure 6. Graphical fitting can proceed by

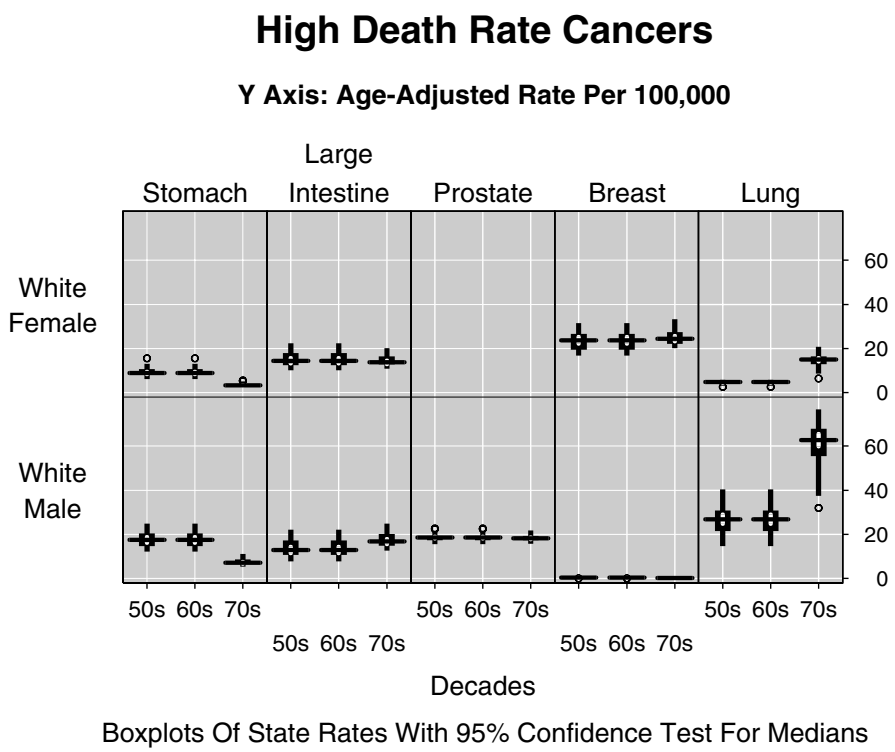

Figure 5 A variation on boxplots. The median: a long horizontal line; first and third quartiles: ends of thicker boxes; adjacent values: ends of thinner boxes; outliers: open circles; test intervals for different medians: white lines inside boxes

guessing at the ratio and multiplying this times the y-axis quantiles until the lines are parallel. When the lines are parallel, the vertical distance between the two lines gives the difference in location (or means) between the scale-adjusted distributions. In Figure 6 the lines are nearly parallel so a reasonable guess is that the distributions differ in location by about 0.5. As indicated earlier, Tukey used a mean and difference calculation to rotate the points in the plot. This simplifies the identical distribution reference line to a horizontal line with a zero intercept.

$Q-Q$ plots get around the deceptive procedure of superimposing two distribution functions or two survival curves (*see* **Survival Analysis, Overview**). As Figure 7 suggests, we are really poor at judging the distance between curves. Our visual systems naturally assess the closest differences between curves rather than the correct vertical distances (see [31]). Adding grid lines can help, but it is often better to

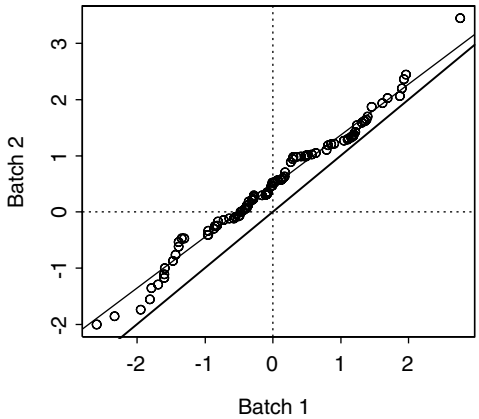

Figure 6 A two-sample $Q-Q$ plot. A good straight line fit suggests similar distributional shapes. Given similar shapes, the slope shows the ratio of scale parameters, such as standard deviations. Given a slope of one, the intercept shows the difference of location parameters, such as means. Thin line: robust fit; thick line: same distribution line

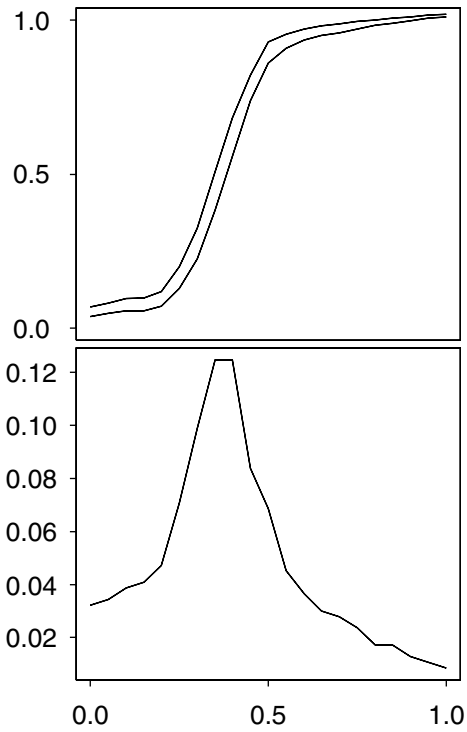

Figure 7 Explicit difference of two curves. Humans tend to see the closest differences between curves, not differences in the y direction

plot the difference explicitly or make comparisons using $Q-Q$ plots.

Jones & Cook [53] have recently generalized $Q-Q$ plots to higher dimensions and this is worth considering. Currently, analysts are more accustomed to looking at densities than cumulative distributions in higher dimensions.

Estimating point density adds another variable. For two variables, the estimated density is a third variable and can be represented as the surface $z = f(x, y)$. Many surface representations are available, such as color draped perspective wireframes and highlighted rendered polygons. For example, see Cleveland [30]. Wegman & Luo [77] note that specular reflection highlights call attention to local density anomalies. Intersecting surfaces with translucent planes help to focus attention on surface cross-sections. In fact, Cleveland et al. [35] recommend studying a sequence of two-dimensional (2D) cross-section plots to increase understanding of surface trends.

Tufte [68] notes that the pairing of contour and surface plots can aid understanding. Iso-density contour plots derive from cross-sections at fixed densities. Given a density, z_0, a contour line consists of pairs (x, y) that satisfy the equation $z_0 = f(x, y)$. A typical contour plot shows approximate contour lines for several values of z. Labeled contour lines do not have much visual impact. Several methods can provide visual impact. An easy approach is to communicate contour values by contour line thickness. Another option is to fill the regions between contour lines with color. The colors should be ordered.

A brief digression to discuss color is appropriate because color often comes into play in density representation and other facets of multivariate representation. Much literature is available on color. Good starting points are Brewer [10] and Levkowitz [56]. Humans are very sensitive to a dark-to-light scale that is referred to in the literature with terms like value, lightness, or brightness. This is an ordered scale and very important in visual interpretation. Friedhoff & Benzon [44] describe three visual processing channels, especially a high resolution dark-to-light channel. Humans get their shape information and many depth cues (linear perspective, interposition, shadow, and detail perspective) through this dark-to-light channel. Tufte [69] and others warn that when rainbow colors represent an ordered variable, lightness jumps and inconsistencies create unintended edges and patterns that can be confusing. Familiar color orderings, such as the rainbow ordering, have merit simply because they are familiar. However, the cognitive advantages of familiarity need to be balanced against the other facets of cognitive processing.

The literature also describes two other color dimensions: saturation and hue. A saturation scale goes from an achromatic color, such as medium gray, to a saturated color, such as vivid red. This scale is also ordered, but allows fewer distinctions than the dark-to-light scale. The hue dimension can be thought of as a circle that includes points between the colors of red, yellow, green, cyan, blue, magenta, and red. Hue is not an ordered scale and is good for distinguishing six or fewer categorical variables.

Returning to density representation, note that since contour plots reside in the dimension of the data, they require one fewer dimension than density surface plots. For trivariate data the estimated density

constitutes a fourth variable. Scott [64] provides density representations using sectioned, nested three-dimensional (3D) contour shells. He shows three contours distinguished by different hues. Sectioning reduces the shell to lines or ribbons and allows the viewer to see through the shell surfaces. Alternatively, surface translucence enables the viewer to see more than one surface simultaneously. In other work using four-dimensional data, Scott conditioned on the fourth variable to produce an animated sequence of 3D contour shell views. Directly showing the density surface for four-dimensional data would require a five-dimensional display.

As we push toward higher dimensions, enhancement methods remain important. Options include representing points, smoother, densities, residuals, and selected features.

Geometric Interpretation, Distance Judgments, Overplotting, and Scaling

In the multivariate context, accurate interpoint distance judgments are crucial to geometrically based visual interpretation. In dimensions above one, interpoint distance judgments are no longer equivalent to judging two values along a single scale and subtracting. For example, two points in a bivariate scatterplot are rarely parallel to an axis. The cognitive task becomes one of judging the length of an implicit line between the two points. As indicated above, humans perceive length in a plane with good perceptual accuracy of extraction. For higher-dimensional representations, assessing interpoint distances becomes increasingly difficult. The position here is that multivariate encodings for continuous variables should be ranked based on the ability of humans to judge interpoint distances.

At first, a stereo 3D scatterplot might seem ideal for representing continuous 3D data. Judging distance between points equates to judging the length of a line segment. On closer inspection, there is substantial change from two to three dimensions. Depth perception for the third coordinate derives from horizontal binocular discrepancies (parallax). The horizontal discrepancies involve only a small fraction of our full horizontal field of view. Horizontal visual acuity within this small window determines how many distinct depth planes we can resolve. This cannot match the horizontal position distinctions we make across the full field of view. Stereo 3D plots are less than ideal since humans do not judge depth as accurately as they judge vertical and horizontal position.

While stereo 3D distance judgments are not as accurate as 2D distance judgments, we live in a 3D world and have strong intuitions about 3D relationships. There are numerous cues that help us to assess depth in the real world. In the description of Friedhoff & Benzon [44], humans have three different visual processing channels: a dark-to-light high-resolution monocular shape channel described earlier; a binocular and motion parallax channel; and a low resolution color channel. Depth cues from the monocular shape channel, such as shadow, add to our depth perception. Since our depth judgment is calibrated by many depth cues and much experience, stereo 3D plots are only mildly asymmetric in the variables and this plot remains a strong candidate as the best representation for three continuous variables.

Historically, most analysts created depth views via rotation (motion parallax). This approach is very powerful. The main drawbacks are that moving points are harder to study than stationary points and that interacting with moving data is awkward. Using both stereo and rotation maintains the depth when rotations stops. The different viewing angles provided through rotation can be informative. Mostly one sees the edges of the data cloud. Different views reveal different edges. Slicing (discussed later as sectioning) helps to reveal the inside of the cloud. In the virtual reality (VR) settings one can fly through data clouds and touch points (or density features) to gain additional detail.

The first criterion for ranking multivariate encodings is the ability to convey interpoint distances. The second criterion for assessing multivariate encodings is the ability to represent many observations quickly without severe breakdown or distortion due to overplotting. Multivariate data can embody complex relationships that translate into complex geometric structure. Representing complex structure with data can require large samples just to cover the applicable domain. Seeing the structure through the noise that results from measurement error and changing measurement conditions can require much larger samples. In low dimensions a common approach uses density representations to reduce overplotting problems and to focus on the density structure (see Carr [12], Carr et al. [1], and Scott [64]).

As we move beyond five dimensions or so, our ability to judge interpoint distances deteriorates so badly that we are forced to use clustering algorithms and other computational methods to bring out patterns. Simple graphical methods do not work well except when there is a very simple geometric structure embedded in high-dimensional space. For complex multivariate structure we can lower the viewing dimensionality by sectioning (adding linear constraints – see Furnas & Buja [46]), conditioning on **categorical** variables, or by focusing attention on computed features such as local modes. This divide-and-conquer approach can reveal a plethora of patterns, but it is only the rare individual that can integrate a catalog of low-dimensional views into a coherent high-dimensional framework. Few of us claim to understand the full richness of a four-dimensional structure.

The ability to see structure depends on many factors that include scaling of data prior to graphical representation. Analysts often scale coordinates individually when they are measured in different units and jointly when measured in identical units. Transformations, such as using a **power transformation** to bring in the long tail of positive data, are common. Scaling often standardizes variables to mean zero and standard deviation one. Other options include replacing observation by ranks or normal scores. Joint scaling may spherize the data to remove **correlation** structure. The host of options includes methods for imputing values for **missing data**. Typically, graphical encoding involves scaling coordinates into the interval [0, 1] somewhere along the way. For the discussion of graphical representations below, assume that the coordinates have been scaled into [0, 1] or some other suitable interval such as $[-\pi/2, \pi/2]$.

Multivariate Representation Methods

While researchers continue to develop new multivariate representations, the representations tend to fall into a few classes. The classes include glyph plots, linked plots, nested plots, conditioned plots, geometric section plots, series plots, and composite plots. Some of the classes break into subclasses.

Glyph Plots

Glyph plots are symbol plots in which data values control the symbol parameters. For example, a circle is a glyph when one coordinate of a multivariate observation controls the circle size.

Multivariate glyph encodings typically fall into classes, namely those that use the spatial position to represent at least two of the multivariate coordinates and those that do not. A stereo scatterplot falls in the first class by representing three coordinates using the spatial position. Of the various stereo projections described in Carr [13], the infinity-enlarged (nonperspective) stereo projection has a particularly simple description as a glyph plot. The stereo projection uses two multivariate coordinates to determine the glyph position, and the glyph consists of left-eye and right-eye dots with horizontal separation (parallax) determined by the third coordinate. After appropriate routing to the eyes, the eye–brain system fuses the two dots into one dot in three dimensions.

Figure 8 is a monochrome side-by-side stereo plot adapted from the color version in Carr et al. [24]. Many can learn to fuse such images without the aid of the viewer. In a VR environment, shuttering glasses route separate full screen width images to

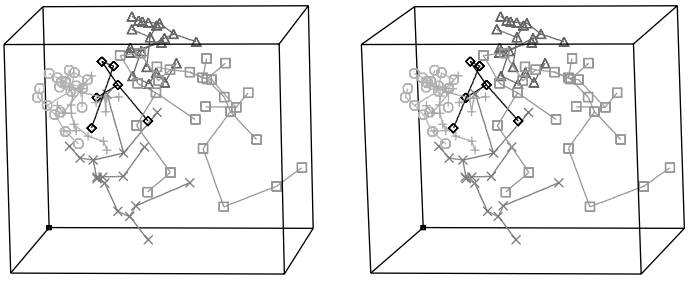

Figure 8 A side-by-side stereo pairs plot. Many can fuse the image without the aid of a viewer. The square dot should appear in the back left corner. The coordinates are principal components. Symbols represent six proposed clusters. The open squares on the right are not tightly clustered. The points connecting lines are minimal spanning tree lines

the eyes and the analyst does not have to learn the visual trick of decoupling eye convergence and lens focusing.

Figure 8 shows six clusters derived from rat spinal-chord gene-expression data, as shown later in Figure 12. The coordinates for the plot are the first three principal components derived from the nine summary measurements over time on each type of gene. In this case showing three coordinates rather than two increases the variability represented from 50% to 65%. Much variability is not captured in the plot, but looking at a flattened 2D plot is worse.

In Figure 8 the symbols distinguish the algorithmically defined clusters. A minimal spanning tree (*see* **Dendrogram**) connects the points in each cluster to provide a repeatable visual path from point to point. The visual task is to assess between-cluster separation and within-cluster tightness. While color would help to distinguish groups and overplotting is a bit of a problem, one can still see that the "octagon" and "plus" groups at mid-depth on the left are very close. The split between the two groups seems somewhat arbitrary. The "square" group on the right occupies much of the volume of the graphic. A reasonable conjecture is that this group will be divided into subgroups when a few thousand more genes are added to the analysis. A direct visual approach provides an alternative to algorithmic evaluation approaches based on questionable assumptions such as **multivariate normality**.

Carr et al. [22] suggest that glyphs using the best encoding, position along a scale, to represent coordinates will provide better judgments of interpoint distances than other glyph encodings. This motivates extending the stereo scatterplot to higher dimensions. To represent a fourth coordinate, Carr et al.selected from the class of good encodings. They chose the ray angle over line length to encode a fourth coordinate because this creates fewer ambiguities in overplotting situations.

The ray glyph has many other uses. Since people perceive ray angle more accurately than stereo depth, it is a reasonable choice for encoding a third variable, especially when the third variable is the dependent variable. For large data sets, Carr et al. [23] use hexagon binning to provide symbol congestion control. The ray angle provides a summary for a hexagon region, and with only one symbol per hexagon overplotting is not a problem. When rays represent estimated values that have confidence intervals, the authors represent the confidence intervals using arcs. Small reference wheels at the base of the ray provide an unobtrusive angular scale for comparison. Angles can be judged accurately. The drawback in the three independent variable setting is that interpoint distance assessment is not as natural as judging length in stereo plots.

For representing two dependent variables and two spatial position variables, Carr [12] uses a bivariate ray glyph. (Chambers et al. [27] describe many graphical representations, including a closely related metroglyph that represents both wind direction and speed; see also Anderson [2].) A ray pointing to the right encodes one variable (for small values the ray points down and for large values it points up) and a ray pointing to the left encodes the other. Simple ray plots provide an effective way to show four-dimensional (4D) information.

For five variables, Carr et al. [22] use ray angle and length to represent the last two coordinates. They show the ray angle in the plane of the display, for all rotations of the data to provide maximum visibility of the ray angle. The rays have to have a minimum length the keep the angle visible. Mapping the two coordinates into two spherical coordinate angles is inferior because it is difficult to decode the angle away from the display surface. The stereo parallax difference between the two ends of the ray encodes the depth angle information, and with a short ray there is almost no depth resolution. Length is a reasoned choice.

Carr et al. [22] suggest encoding a sixth coordinate using a carefully selected double-ended color scale going through gray. Color encoding, no matter how well chosen, is inferior to many other choices for representing a continuous variable. However, after five choices the options are extremely limited.

Few researchers have seriously tackled the visualization of six-dimensional data. The power of using a single glyph with well-chosen encoding remains little appreciated. A notable exception is Bayly et al. [7]. They successfully used colored stereo ellipsoids to evaluate problems in improving an electrostatic potential model. Their article includes color side-by-side stereo figures. In a long sequence of efforts Bayly (personal communication) failed to obtain insight using many of the encodings described in the entry. The breakthrough came when using

a carefully chosen stereo glyph. Understanding six-dimensional relationships is nontrivial. The selection of good encoding can be crucial.

Stereo-glyph encodings are good encodings for a difficult visualization problem. The encodings are asymmetric in terms of the coordinates. Interpoint distance assessment becomes progressively more difficult as one adds the angle, length, and color encodings. However, interpoint distance assessment using some of the methods below pales by comparison.

Glyph encodings that typically do not use coordinates to determine glyph position include Chernoff faces [28], star plots, profile plots or line-height plots, trees and castles [54], and cone plots [37]. Figure 9 shows a few examples of three encoding approaches. Chernoff faces encode variables using area of the face, shape of the face, length of the nose, location of the mouth, curve of mouth, and so on. Star plots, profile plots, and line-height plots are all variants of k-sided polygons [65]. In early work, Bertin [9] shows profile plots and Anderson [2] uses a restricted variant of star plots. Star plots have implicit [0, 1] axes at equal angles around a circle. The length of the segment along each implicit axis encodes the respective variable. Profile plots have implicit [0, 1] axes orthogonal to a horizontal base line. Segment heights indicate the magnitude of corresponding variables. Profile plots appear with minor variations. Here, the "profile" plot connects the tips of the segments and may optionally fill the polygon, hiding the construction. The version in Kleiner & Hartigan [54] draws adjacent boxes of the given height. The line-height version is a thin, detached box variation.

As one demonstration of the inferior nature of nonpositional glyphs in low dimensions, one can

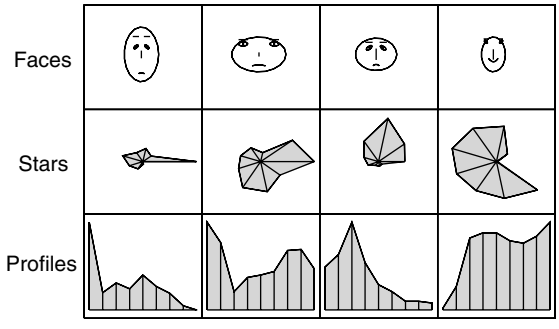

Figure 9 Three types of multivariate glyphs

generate, say, a thousand points of 3D data embedded in four dimensions. That is, select triples (u, v, w) randomly, say from a normal distribution, and then let $x_1 = f_1(u, v, w), x_2 = f_2(u, v, w), x_3 = f_3(u, v, w)$, and $x_4 = f_4(u, v, w)$, where the four functions are simple distinct polynomials. The structure in the stereo-ray glyph plot will immediately suggest the existence of a constraint and the fact that the data are not four-dimensional. Looking at 1000 Chernoff faces laid out in an two-way array using a happenstance order is not likely to give the slightest clue.

Almost any graphic can be improved. Much can be done to improve the nonpositional glyph encodings. In terms of faces, research has revealed much about our special face recognition "hardware". For example, face recognition improves if the faces are smiling and turned 15 degrees. (See Takacs [66] for a survey of the literature.) An improved face encoding might reduce the error rates cited in Chernoff & Haseeb [29]. The high similarity rankings reported in a paired comparison in an experiment by Wilkinson [80] might get even better. However, pair-comparison results do not necessarily extend to seeing patterns in a dense plot. Issues include seeing inside face outlines, judging distances when faces are not closely juxtaposed, and judging distances through interposed sequences of faces. A better layout often helps.

Like faces, the star representation is reasonably popular. The area of the star conveys a general notion of coordinate magnitude. Stars communicate when bigger is better.

In terms of layout, plotting round symbols such as faces and stars on a hexagon lattice seems reasonable. Variants of the algorithm discussed by Eick & Wills [39] can exchange icons such as stars with the objective of placing similar stars together. Taking this one step further, some of the hexagon lattice points can be strategically blank, to emphasize clusters. Basically, the notion is to use a modified stress criterion and a lattice-based variant of multidimensional scaling to strengthen the representations of interpoint distance.

Nonpositional glyphs come into their own in higher dimensions. Figure 10 is a line-height plot from Carr & Olsen [19] and shows the relative area of 159 vegetation classes for each of 26 continental US ecoregions. The area determination for each ecoregion followed after classifying 8 million pixels of a continental US AVHRR image into the

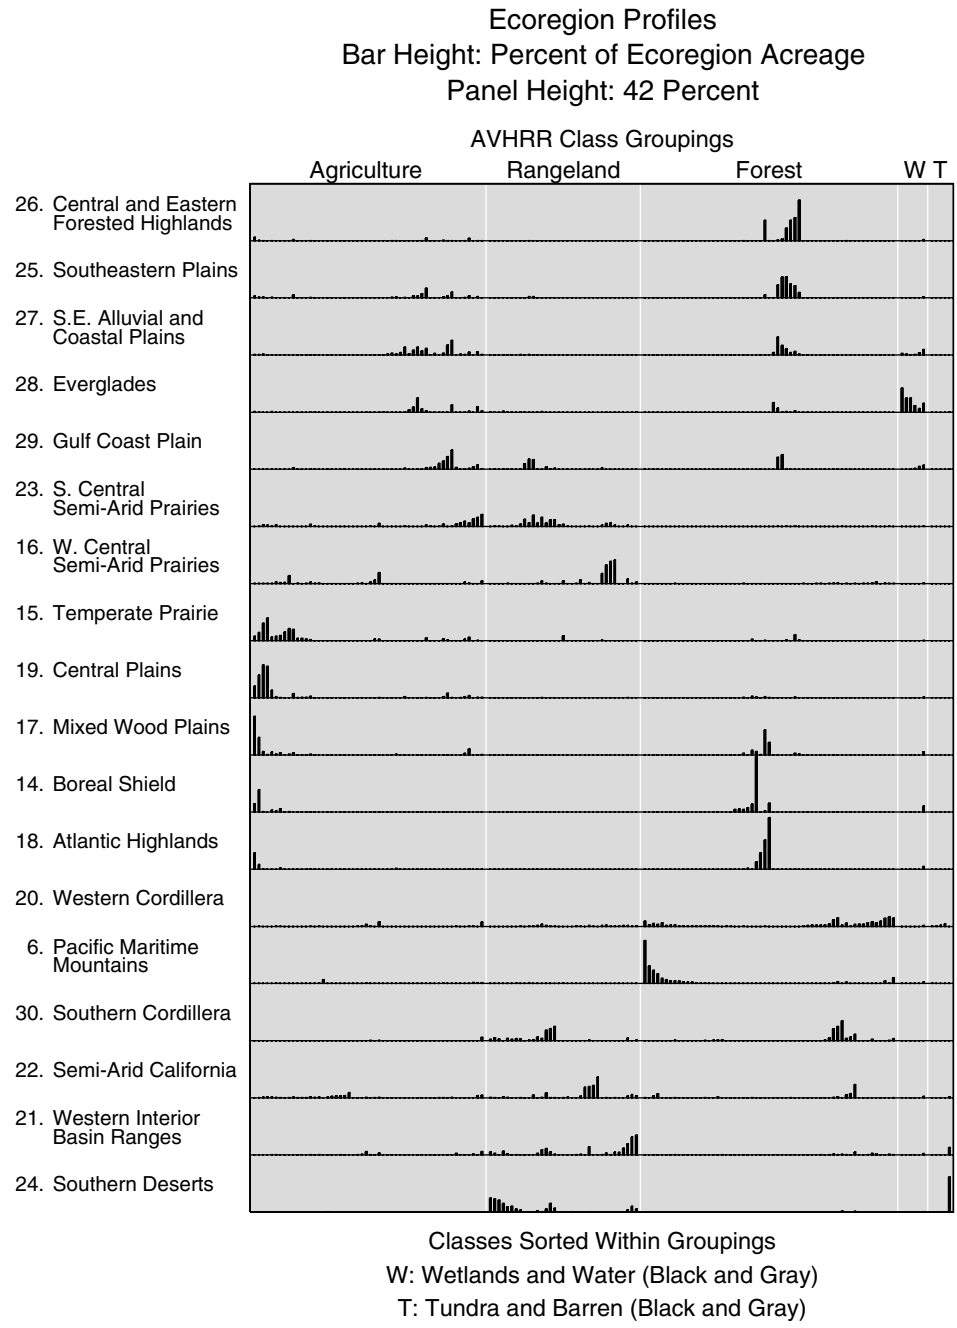

Figure 10 Line heights representing 159 variables. Separate row and column sorting creates visual clusters and simplifies appearance. Here the sorting order is the minimal spanning tree traversal order

159 vegetation classes. The theme of the article is on simplifying plot appearance by sorting rows and columns. One can infer from the example that representing 500 variables using line heights is not a problem for a small number of cases. The primary representation problem is in showing the labels. Mousing on a variable can reveal its label in an interactive setting. The real difficulty is in assessing the patterns presented.

In general, nonpositional glyphs show interpoint distances poorly. While stars and line-height glyphs are better balanced with respect to the coordinates than Chernoff faces, Kleiner & Hartigan [54] point out that most such representations remain asymmetric. That is, one can compare adjacent coordinates more easily than nonadjacent coordinates. Reordering can make a difference.

Nonpositional glyphs can represent a large number of variables. An extreme case is to encode each variable as the color of a pixel on a monitor. Thus, it is possible to represent a single case with over a million variables. The basic two problems remains: how to represent many cases, and how to interpret the graphic.

Linked Plots

Linking points across plots provides a way to connect the variables that are represented in different plots. Linking provides a weaker binding of the multivariate components than glyphs. Linking methods include linking by lines, colors, names, and pointers, and spatial linking by juxtaposition. The following discussion emphasizes line linking and color linking.

Diaconis & Friedman [38] discuss M and N plots that link points in different plots with lines. For example, they represent 4D data using two 2D scatterplots. The first plot represents the first two coordinates and the second plot represents the remaining two coordinates. A line between a bivariate point in one plot and a bivariate point in the second plot indicates that bivariate points really represent one four-coordinate point. Their general description includes linking across multiple plots of varying dimensionality. For example, a 4D representation might link a 1D plot to a 2D plot to a 1D plot.

Parallel coordinate plots are the only variation of M and N plots that have caught on. The parallel coordinate plot for p dimensions is a sequence of p univariate plots. The representation connects p coordinates with $p-1$ line segments. An early example appears in Bertin [9]. Inselberg [51] and Wegman [74] introduce the mathematical and statistical aspects of parallel coordinate plots. They and Inselberg & Dimsdale [52] describe the point-line duality and other mathematical relationships that provide a basis for extended interpretation. For example, Inselberg has used the representation to find the closest distance between two lines in four dimensions. Interpretation of some patterns requires significant background. Other patterns are easy. For example, Wegman notes that one can readily assess the correlation between adjacent variables. Many crossing segments between adjacent axes indicates a high negative correlation, and many parallel segments indicates a high positive correlation.

Carr & Olsen [18] found parallel coordinates useful for representing two variables in a map legend when space was at a premium. The parallel coordinate representation has particular merit in terms of labeling and reading selected value pairs. However, the scatterplot remains the preferred way of providing the gestalt of a functional relationship.

Parallel coordinate plots have particular merit in dynamic graphics. Carr & Nicholson [17] use unlinked parallel coordinates axes as a multivariate coordinate input device, in their case providing direct manipulation of a 4D stereo ray glyph cursor. The cumulative selection of points within a ball of the cursor and cursor movement allows higher-dimensional subset selection without the usual cross-product set restrictions. Carr & Nicholson also display marginal densities on the axes. As rotation and masking alter the 4D view, this provides information about multimodality in margin views. Parallel coordinates are very useful for dynamic subset selection.

The line-linked plot paradigm has several weaknesses. First, coordinate representation is not symmetric. That is, assessing relationships within plots is easier that assessing relationships between plots. Owing to the difficulty in following links from plot to plot, the relationships between variables in adjacent plots are easier to assess than relationships to variables in distant plots. Following lines from plot to plot is sometimes impossible owing to line overplotting. Diaconis & Friedman [38] suggest reducing the line density by connecting coordinates of only one point of each small cluster of points in the p-dimensional space. Miller & Wegman [62] take a different approach by calculating and representing

line density. The line density plots convey much more information about clusters than overplotted lines. The line density approach extends to large data sets and dynamic cluster selection, as described by Wegman & Luo [78]. However, the approach does not solve the problem of poor linking to nonadjacent plots.

In terms of understanding geometric structure, line-linked plots leave much to be desired. Humans are exceedingly poor at tomographic reconstruction. In the simplest of cases, clear structure in 2D scatterplots can be hard to fathom by looking at linked 1D margin plots. The assessment of distance between two multivariate points requires integration across all the coordinate axes, and this is complicated enough when all the coordinates are available at a glance, as in glyph displays. Beyond suggesting clusters by line overplotting density, the line-linked plots have not caught on for understanding geometric structure.

A more popular linking technique is color linking. The common application is the dynamic brushing of points in a scatterplot matrix [8]. The points brushed (selected) in one panel become highlighted in all views of their coordinates. Brushing is a focusing technique. It also serves as a conditioning technique that often lowers dimensionality.

Since preattentive vision can handle the location of distinctively colored points, color is a faster link than lines. Of course, overplotting and multiple multivariate points with the same color cause ambiguities. Color linking has several problems, some relating to color perception limitations (for example, color guidelines suggest working with six or fewer distinct hues) and some relating to poor software implementations.

In terms of implementations, the plotting order of points may not be controlled and overplotting can hide selected points. Subset memberships may not be well represented. Carr et al. [22] discuss a color scheme for representing disjoint subsets of three nonexclusive, interactively defined subsets. Their example identified a two-coordinate symmetry in a seven-dimensional particle physics data set. Sophisticated color treatment can provide subset representation and color mixing for overplotted points. Advanced graphics workstations have four color channels, red, green, blue, and alpha. The alpha channel is there specifically to provide color-blending options. Statistical graphics software has been slow to exploit the capability.

Positional linking is another option. The layout of the scatterplot matrix enables positional linking. Suppose the x coordinate of a point is 0 and well separated from the x values for other points. Then it is possible to identify the other views of the point in the scatterplot matrix by looking along the line $x = 0$. When the x coordinate is not well separated from other x coordinates, identifying the remaining coordinates of a point can be difficult unless they are highlighted by color or other means. The difficulty in finding coordinates suggests that assessing interpoint distances in a scatterplot matrix will be next to impossible, except in pathologically simple cases. While the scatterplot matrix is useful in the context of brushing, and as a multiple window display for viewing many 2D projections, the scatterplot matrix is not a good choice for perceiving higher-dimensional geometric structure. Random points on a mobius strip have obvious structure in a stereo plot, while the structure is obscure in a scatterplot matrix.

Positional linking comes into its own for small perceptual groups. Figure 11 shows positional linking of labels and dots in a dot plot. One can easily match the middle label of a group to the middle dot of a group. The grouping of labels and dots into small units of five reduces the chances of matching error. A solid list of 62 names is visually intimidating, so the groups encourage reading. More generally, Carr & Pierson [20] describe micromap designs that use position and color to link statistical summaries with small maps. The position region and shape in a small map can also link to the corresponding position and shape in a large map. Positional linking is a powerful and underutilized tool.

Nested Plots

The classic example of nesting is the casement display [72]. The basic casement display is a matrix of scatterplots, each with identical scales. The casement display partitions the data into a crossed two-way layout using two of the four coordinates. The two layout coordinates define panel membership, and the two remaining coordinates appear in the scatterplot. The casement display is not symmetric in the coordinates, sacrificing resolution for the two coordinates defining the layout.

The nesting template can be varied in many ways. Panels can show a higher-dimensional relationship. Carr [16] provides a five-dimensional nested display.

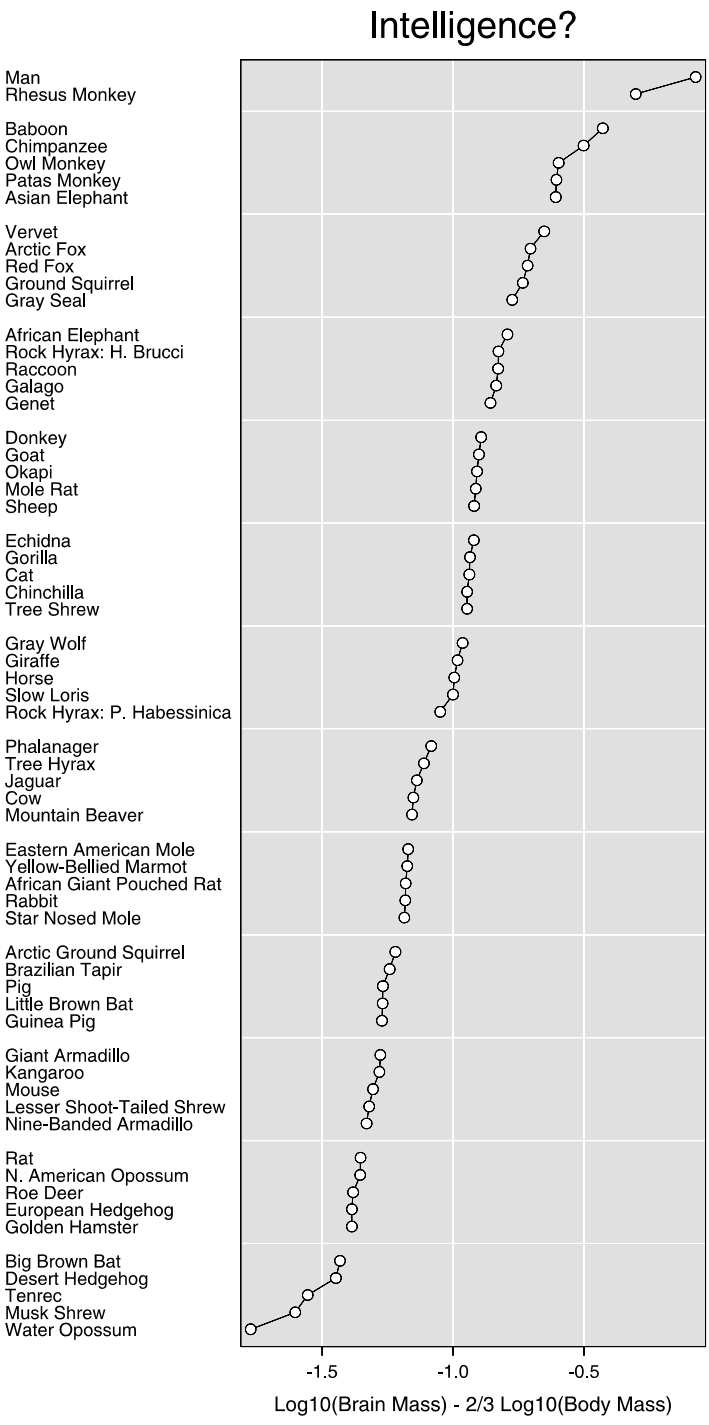

Figure 11 A dot plot with positional linking. Perceptual grouping into small units obviates the need for lines from labels to dots. The Owl Monkey is a third label, and finding the corresponding third dot is trivial even across the page. Vertical grid lines increase the perceptual accuracy of extraction

The data set concerns a dependent variable, namely protein folding energy, and four independent variables. The independent variables have seven levels and are fully crossed. The seven-by-seven panel layout presents all combinations for two of the independent variables. Each panel within the layout panel uses x and y coordinates to represent the two remaining independent variables and a ray angle to represent the folding energy. Highlighted rays distinguish local minima as computed using eight neighboring points, two for each dimension. The highlighted rays call attention to both local minima and saddlepoint troughs through space.

With only one layer of nesting in each of the horizontal and vertical directions, nested plots are equivalent to the conditioned plots described further below. The two-way layout is one of the most powerful templates available for getting two extra variables into a graph. While the resolution is typically poor for the two variables defining the layout, the resolution loss is often overshadowed by that fact that many people readily understand two-way conditioning.

Nested views can be nested. Mihalisin et al. [60, 61] describe deeper layers of nesting to handle up to 10 variables. With study, people can learn to spot certain classes of mathematical relationships in deeply nested views. Nested views are not variable-balanced views, but have a role in the arsenal of tools.

Conditioned Plots

Casement displays generalize to plots conditioned by many variables. An early exposition on conditioned plot (or coplots) appears in Cleveland et al. [35]. Conditioned plots are typically 2D plots, but they can be 3D wireframe plots or other higher-dimensional plots. People readily understand one-and two-way layouts and conditioned plots build upon this understanding.

Trellis Graphics™ automate the multiple-panel plot production process. This includes labeling of panels by factor names and graphical representation of factor levels. Trellis layout capabilities also address the issue of panel shape. Panel shape can strongly affect the perception of line slope, and banking of slopes to be close to $\pm 45^{\circ}$ is important in some problems [30]. Trellis graphics provide many sound defaults and a good framework for multivariate graphics.

Conditioned (and nested) views do not have to partition the data strictly to produce different panels. Cleveland et al. [35] introduces the notion of shingles that allow the same observations to appear in more than one panel. This is helpful when smoothing a scatterplot because it increases the number of points in the plots and addresses poor smoothing at the plot edges.

Laying out multiway panels in rows and columns across many pages is often a good start. However, general-purpose algorithms have not yet captured all the current graphical design expertise. Methods for simplifying visual appearance remain applicable. These include grouping of information, sorting and presenting the information in layers, and removal of redundant information [14, 55]. The graphics tools make it easy to apply thoughtful sorting, but the analyst still has to do the thinking.

The difficulty of seeing patterns across levels of conditioning factors and pages needs to be recognized. As indicated above, humans are not good at integrating low-dimensional relationships into higher-dimensional or overview patterns. When the information appears across pages, the limits of our short-term memories compound the difficulty. When across-panel insights occur, they are likely to be based on panels juxtaposed closely in space or time. Careful attention to the choice of layout is often the key to obtaining multivariate insights.

Geometric Section Plots

Multiple univariate sectioning is a standard technique for lowering dimensionality and seeing through objects. The cone plot [37] provides an interesting example of a nonstandard sectioned plot. One picks a vertex in p-space and a reference line through the vertex (typically defined by selecting a data point as a second point on the line through the vertex). The reference line becomes the center line for a set of cones. Connecting a different data point to the vertex creates a second line. Rotating this line around the center line defines two cones with tips that touch at the vertex. Each data point is then associated with the angle between its line and the cone center line. Each point also has a distance to the vertex. Thus, the selection of a vertex and a reference line associates an angle and a distance with each data point. Dawkins uses the natural plot for a distance and an angle, the polar coordinate plot. A

different plot results from each selection of a center line. Typically, Dawkins uses each case to define the center line and this generates a plot (or panel) for each case. Dawkins lays the panels out as a matrix and describes the geometric relationships, such as hyperplanes, observable within panels. Like nested plots and parallel-coordinate plots, a certain amount of knowledge is required before the plots are fully appreciated, and this limits the audience.

Series Plots

Andrews [3] provides a series transformation that represents a continuous multivariate observation as a curve. If X_i is the ith coordinate of an observation, then the curve for the observation is

$$y(t) = \frac{x_1}{\sqrt{2}} + x_2 \sin(t) + x_3 \cos(t) + x_4 \sin(2t) + x_5 \cos(2t) + \cdots$$

for $-\pi < t < \pi$. Nearly identical observations will plot similar curves. The plot can be used to assess the clustering of observations. However, the first coordinates are assigned to the lowest frequencies and the low frequencies tend to be visually dominant. Hence, the variation in the first coordinates is visually dominant. The representation is not symmetric in the variables.

The encoding can be modified to provide an animation. Slicing through the curves with a line at time t yields a set of points. Varying t then leads to the animation of points along a scale. Some have thought this might be a one-dimensional analog of the 2D grand tour mentioned below. However, Wegman & Shen [79] note that the curves are not properly defined to provide a grand tour. They provide a generalization that shows curves in three dimensions and illustrate direct manipulation of a sectioning plane. The curves intersect the plane to create a 2D scatter of points. This is advantageous in that clusters can separate better in a 2D sectioned view than they do in a 1D sectioned view.

Functions have numerous series approximations. Different series approximations can lead to different graphics. One might even try wavelet encoding.

Composite Plots

Composite plots provide a good way to look at higher dimensions. These plots often involve elements of conditioning and exploit the capacity of the analyst to understand two-way layouts. Figure 12, adapted from Carr et al. [24], provides a composite plot example. The data are rat spinal-chord gene-expression values observed at nine times. The times are gestation days 11, 13, 15, 18, 21; postbirth days 0, 7, 14, and adult. The gene-expression values range from 0 to 1 and indicate how fully the gene is functioning. The basic plot is a time-series line plot, which is equivalent to a parallel coordinate plot with axes at the time points. The overplotting of all the data in a single parallel coordinate plot is not acceptable in looking at individual genes. Figure 12 uses small multiples (see Tufte [67]) to avoid heavy overplotting. Grouping into units of four or fewer is cognitively advantageous. With four or fewer easily discriminated line textures, it is simple to match lines with the gene labels. (The original used four colors rather than four textures.) Arbitrary grouping into units of four can raise questions and miss an opportunity. Figure 12 starts the grouping process by conditioning on membership in 14 gene function groups. The gene function group name is at the left of each corresponding set of panels. Thus, Figure 12 combines elements of conditioned plots, parallel coordinates plots, and line texture linking. Showing $1008 = 112 \times 9$ values on a page is no problem.

Multiple Views, Dimensionality, Cognostics, and Projection Searches

The above review of graphics representations suggests a large number of view options. Cross these viewing options with today's data explosion and the number of possible graphics seems overwhelming. We are not going to look at all potentially insightful plots. Something needs to give.

In most fields of endeavor one feels obliged to find the obvious. Failing to find the complex is forgivable in the rare cases that someone notices. In multivariate graphics, is it important to look at low-dimensional views of the data to see if there are obvious patterns.

Frequently data relationships consist of a low-dimensional geometric structure embedded in much higher-dimensional data. For example, simple mixtures of two multivariate points generate a line segment. Mixture of three multivariate points generates a triangle. The observational process can lead

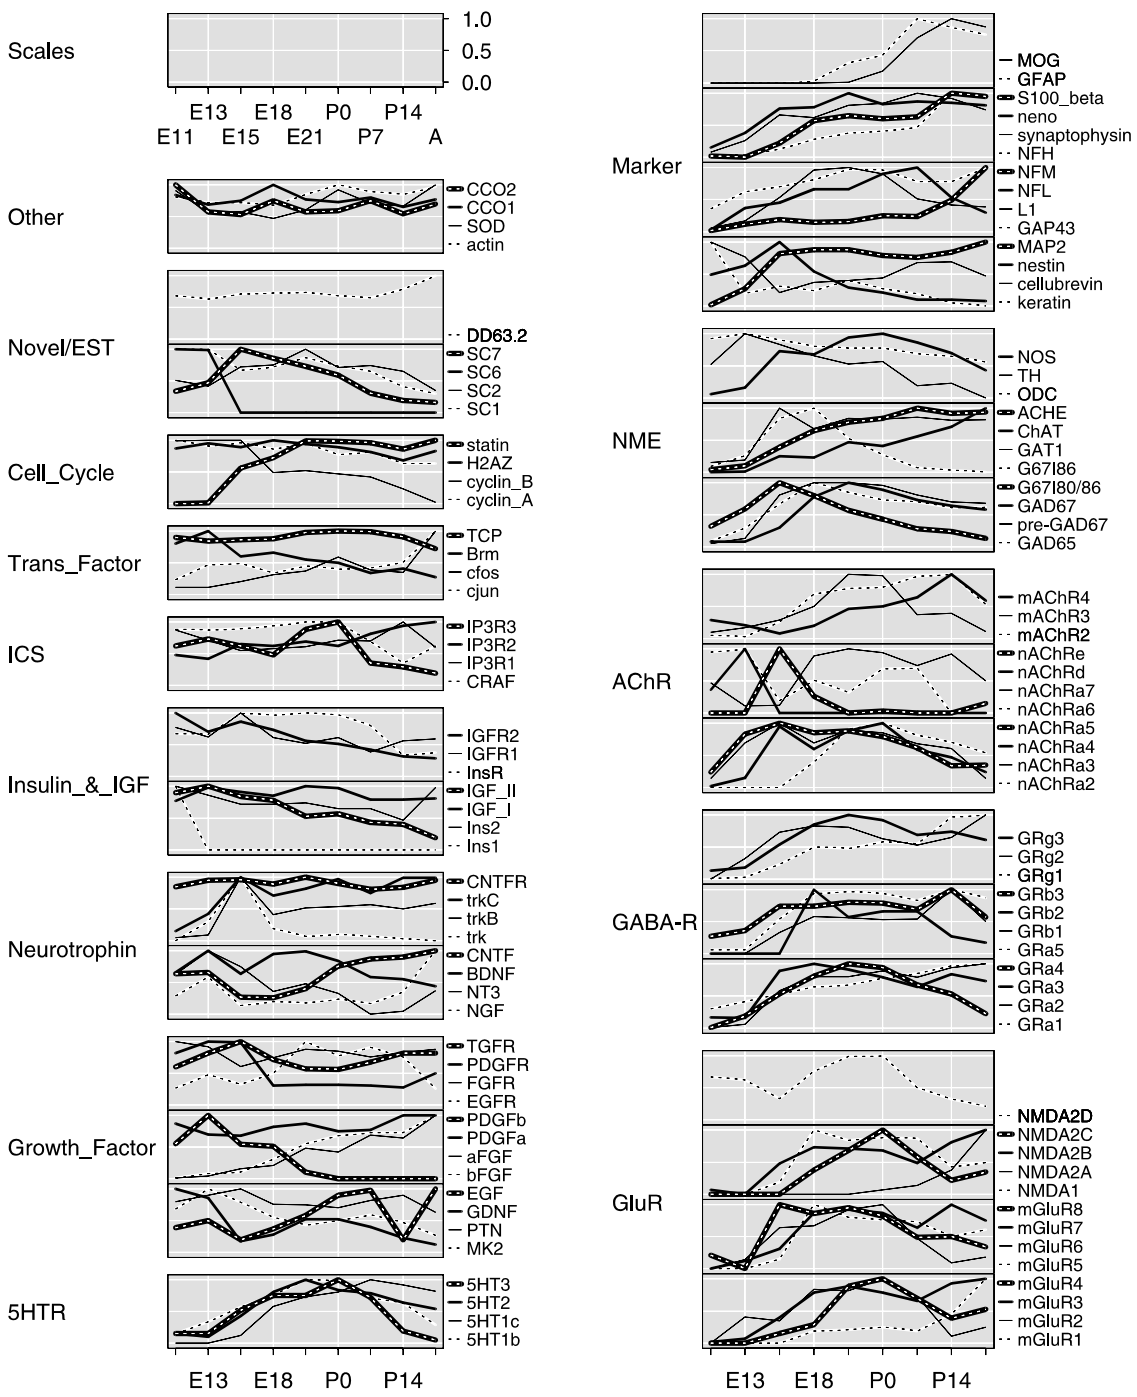

Figure 12 A multiple panel plot showing 112 time series with grouping and individual series labels

to recording a mixture value. For example, the spectral bands for pixels in a satellite image may reflect the mixture of two vegetation classes with distinct spectral signatures. Cook et al. [34] report an example of seven coordinate particle physics data that geometrically consists of a triangle with two line segments at each vertex. Since the structure was embedded in seven dimensions, the discovery process using 2D plots was nontrivial. Nonetheless, looking for the simple patterns sometimes produces results.

Carr et al. [21] advocate looking at low-dimensional margin views in part because the coordinates have an immediate interpretation. A systematic approach involves looking at 1D margin views, scatterplot matrices, stereo-scatterplot triples, and 4D plots such as the stereo-ray glyph plots. For a large number of variables, there can be layout problems. In a single screen view, panels in a scatterplot matrix can become too small to be useful. Also, increasing the dimensionality of the view causes problems. Given, say, 10 variables there are 45 2D panels and 120 3D panels. Approaches such as pan and zoom help in the 2D cases and sectioning helps in the 3D cases. However, with increasing dimensionality the notion of a quick visual sweep over the whole space is quickly lost.

In thinking about the future, Tukey [71] coined the term *cognostics* (diagnostics interpreted by a computer rather than a human). The idea was to compute features of merit and have a computer rank the plots by their potential interest to humans. Paul Tukey [73] developed some early features of merit for prioritizing scatterplots. Carr [12] developed different features of merit oriented toward large data sets. The cognostics involved binning 2D and 3D data as a starting step. One of the more nontraditional cognostics used extensions of thinning (an image processing technique) to assess the extent of skeletal structure in low-density regions. The application involved views of computational fluid dynamics (CFD) variables and the features of merit were computed in parallel, one time step behind the CFD model. The strategy was to store information and later to instantiate only high interest virtual plots. The general concept applies to looking for patterns in biological databases.

Asimov [4] proposed grand tour methods that provide an infinite sequence of 2D projected views. Wegman [75] discusses a generalized grand tour with the number of resulting coordinates being the same number as in the original data. Thus, tour views are not restricted to 2D projected views. The many views provided by grand tour sequences tend to overwhelm the mind rather than to facilitate quick insight. Similar to the cognostics idea, **projection pursuit** (see Cook et al. [36]) assists the analysts in finding interesting views.

When one is looking for structure (and constraints) in low-dimensional plots, an understanding of what happens in projection to low dimensions is very helpful. Furnas & Buja [46] shed insight into what can be seen in low-dimensional views using projection and sectioning. For example, lines in high dimensions project into lines in low dimensions.

Sectioning (also called slicing and masking in the graphics literature) adds mathematical constraints that typically lower the dimensionality. For example, adding the constraint $x = 2$ to the line $y = mx + b$ reduces the line to a point. Typically, sectioning is implemented as a logical "and" among constraints on individual coordinates. Direct manipulation provides one way of controlling the bounds $a_i < x_i < b_i$ on the ith coordinate x_i. Sectioning can apply to computed variables, including those constructed in touring sequences. Carr & Nicholson [17] describe software that enables hyperplane sectioning in the form of $a < \mathbf{c}'(\mathbf{x} - \mathbf{x}_0) < b$, where $\mathbf{c}$, $\mathbf{x}$, and $\mathbf{x}_0$ are vectors. Graphical methods, using parallel axes, define the normal vector to the hyperplane, $\mathbf{c}$, and a multivariate point, $\mathbf{x}_0$, in the hyperplane. Direct manipulation controls the scalars a and b. (An extension of the software providing stereo-ray glyph, scatterplot matrix and parallel coordinate views, alpha blending for color mixing, and other options is available; see Carr et al. [26].) Sectioning can reveal holes and other structures in the data that remain hidden in projected views.

A geometric structure is easier to identify when the viewing dimension is higher than the dimension of the structure. For example, points on a surface projected in a 2D scatterplot can saturate the plot, while the surface remains evident in a 3D scatterplot. Stereo 3D plots are the natural environment for viewing the 2D structures of such surfaces. 4D plots, such as the stereo-ray glyph plot, provide a way to look for 3D structures. Sectioning is useful to lower the dimensionality of the data until it falls below the dimensionality of the display.

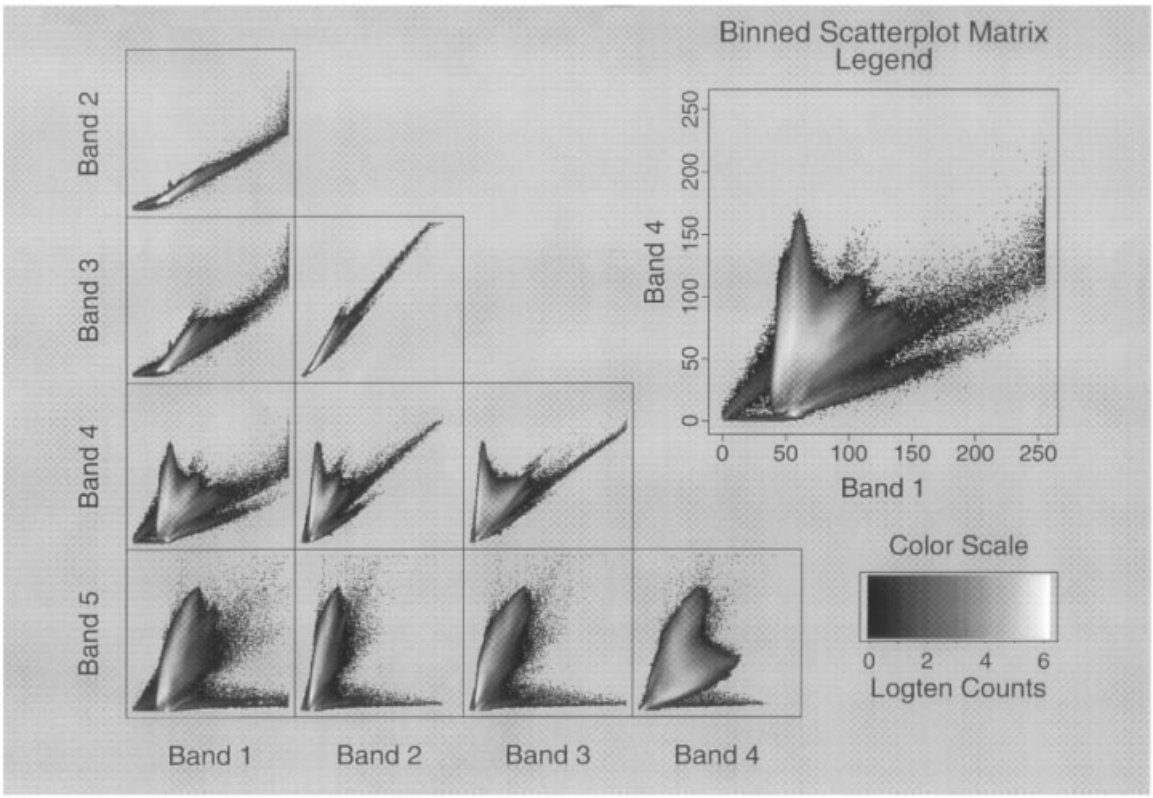

Figure 13 A binned scatterplot matrix showing over one-third of a billion nonzero point pairs. This overview crudely represents density features using gray level for counts on a log 10 scale. A pure white dot represents over a million satellite image pixels with the same bivariate spectral intensity

Massive Data Sets and Closing Remarks

Massive data sets pose new challenges. Some of the old methods work for selected problems. As one example, Figure 13 is a gray level version of a binned data scatterplot matrix presented at the 1995 American Statistical Association annual meeting. Each panel represents intensities for two spectral bands (wavelength intervals) for 54 million pixels of a multispectral satellite image. The recorded values are intensities for each spectral band, as a measure on a scale from 0 to 255. The different panels correspond to different pairings of the first five spectral bands from the seven spectral band image. (The binning discussion for six variables below omits band 6 because it has a different spatial resolution.) The approach of 2D binning and density representation scales well in terms of the sample size. Binning 54 million 2D points for each of the 15 pairings is not a problem. Visualization gets a bit more challenging since the bivariate densities (shown on a log scale) vary over five orders of magnitude. Thus, interactive methods become useful in bringing out density features.

Some tasks do not scale well to massive data sets. Challenges in this satellite data problem include six-dimensional (6D) binning without sacrificing 256 value resolutions per channel, viewing the higher-dimensional density structures, and linking density patterns in the binned panels back to the spatial coordinates of the pixels to benefit from the spatial information. With six spectral channels (variables) of interest, each with 2^8 possible intensities, there are 2^{48} potential cells. Straightforward binning that allocates space for all possible cells breaks down. Methods have to focus more on occupied cells. In this example there will be at most 54 million occupied cells. It turns out, via sorting and then binning, that there are over 12 million occupied cells. This is too many cells

for conventional methods. Making progress almost inevitably involves sacrificing intensity resolution via univariate rescaling or via use of a large number of clusters.

With resolution reduction, viewing the 6D binned density becomes feasible using a combination of conditioning and positional glyphs. For example, a two-way layout of panels can represent levels for two variables. Individual panels can show three coordinates using the 3D position. The ray angle can represent a few levels of a discrete fourth variable, and the ray length can be proportional to the log of the count. This is similar to showing small histograms in 3D space. The ray representation is advantageous owing to ambiguities resulting from overplotted histograms. Conceptually it is possible to zoom in to get higher resolution detail. A common trick in very low dimensions is to implement zooming with precomputed images. However, massive data sets require significant processing and the increased dimensionality makes it harder to anticipate where attention will be focused.

A large problem arises when it is time to link the density feature back to the 54 million spatial coordinates. Brushing in geographic space or attributing density space and viewing the result in the opposite space is no longer a trivial task. Since a typical (1280×1024) workstation screen has about 1.3 million pixels, one has to pan through many screens just to view all the pixels indicating spatial position. The next satellite, with 36 channels, possesses an even more formidable challenge. Challenges abound as we attempt to bring visualization methods to increasingly larger, higher-dimensional, higher resolution data sets.

The above description has been a whirlwind tour. We can represent a million variables. We can represent millions of cases. Finding and communicating multivariate patterns is another story. We have to work hard to find meaningful patterns. There are many barriers to the discovery of important patterns, not the least of which is the plethora of accidental patterns that will not replicate. We need statistical methods to help us find our way, and results from cognitive science so that we can more fully use the power of our minds to see.

Having found meaningful patterns does not mean that we will be able to communicate those patterns. A picture may be worth a thousand words, but in this electronic era neither a picture nor a thousand words is worth very much. Unless graphics are apparently simple, they are not likely to survive the first glance. Communicating a complex multivariate structure to a world seeking simple solutions is a major challenge. This article provides some guidance toward graphics that communicate, but much work remains ahead.

DANIEL B. CARR

Multivariate Median and Rank Sum Tests

Multivariate **nonparametric** procedures were mostly developed in the 1960s. There were some impasses from the univariate to the multivariate channels, and a basic *rank-permutation principle*, developed by Chatterjee & Sen [6], opened up the broad avenue to multivariate nonparametrics. These include the multivariate one-sample model, two- and several-sample problems, as well as **multivariate analysis of variance** (and covariance) models. In the following, we briefly review univariate nonparametric procedures, and then present more extensively their multivariate extensions using chiefly the rank-permutation principle.

Precursors of Multivariate Nonparametrics

The classical **sign test** in the univariate case, followed by the **Wilcoxon signed-rank test**, laid down the foundation of distribution-free tests for the one-sample location model, and there were subsequent developments relating to alternative tests which are characterized by *local* or *asymptotic optimality* properties against specific parametric type of alternatives; Hájek & Šidák [13] is an excellent source for these theoretical developments. In the same vein, in the two-sample case, Mood's **median** test and the **Wilcoxon–Mann–Whitney** rank sum test are, respectively, the analogs of the sign and signed rank tests; the Brown & Mood [4] and Kruskal & Wallis [15] extensions cover the multisample problems and, later on, similar tests have also been proposed for the **analysis of variance** (ANOVA) as well as the **analysis of covariance** (ANCOVA) models. A general account of multivariate nonparametrics, with some mathematical abstractions, is given in Puri & Sen [19]. Interestingly, the developments in ANCOVA nonparametrics rest heavily on the multivariate nonparametric methodology, and hence, it will be to our advantage to outline the univariate tests first, then to motivate their multivariate analogs in a coherent manner, and finally to cover **general linear models** relating to multivariate AN(C)OVA problems. We shall also include the *two-way layout* problems covering both univariate and multivariate models, where such rank tests play an important role. The median test has some nice applications in the *multivariate association* problem, and we shall touch on that too.

Sign and Signed-Rank Statistics

Consider n observations $X_1, \ldots, X_n$ from a continuous distribution F, and let θ be the median of F, i.e. θ is the unique solution of the equation $F(x) = 0.5$. We want to test for a null hypothesis $\mathrm{H}_0 : \theta = \theta_0$ (known) against an alternative H_1 that θ is $>$ (or $<$ or $\neq$) θ_0. Without loss of generality, we set $\theta_0 = 0$ (otherwise, we work with the residuals $X_i - \theta_0$). Define the sign statistic as

$$S_n = \sum_{i=1}^{n} I(X_i \leq 0), \tag{1}$$

where $I(A)$ denotes the indicator function of the set A. Note that S_n has the simple **binomial distribution** with sample size n and probability $\pi = F(0)$, where, under H_0, $F(0) = 1/2$, irrespective of the functional form of F, and F need not be symmetric about its median. This provides a simple distribution-free test for H_0 vs. H_1, based on a one-sided or two-sided critical region for binomial distributions, depending on the alternative. Moreover, note that for every α : $0 < \alpha \leq 1/2$, and $n(\geq 1)$, there exists a nonnegative $r(\leq n/2)$, such that

$$2^{-n} \sum_{i=r+1}^{n-r-1} \binom{n}{i} \leq 1 - \alpha \leq 2^{-n} \sum_{i=r}^{n-r} \binom{n}{i}. \tag{2}$$

Then, if we denote the sample order statistics by $X_{n:1} < \cdots < X_{n:n}$ (where by virtue of the assumed continuity of F, the equality signs are neglected with probability 1), we have the following *distribution-free* **confidence interval** for the population median:

$$P_F\{X_{n:r} \leq \theta \leq X_{n:n-r+1}\} \geq 1 - \alpha, \quad \text{for all } F. \tag{3}$$

As a special case, letting $r = [(n+1)/2]$, we obtain that a nonparametric point estimator of θ is given by the *sample median*:

$$\tilde{X}_n = X_{n:(n+1)/2} \text{ or } \frac{X_{n:n/2} + X_{n:n/2+1}}{2}, \quad \text{according as } n \text{ is odd or even.} \tag{4}$$

In this development neither the symmetry nor the form of F is assumed as a part of the model, and we have a distribution-free test, as well as point and interval estimators. For large values of n, we could use the **convergence** of the binomial law to a normal one, and claim that under H_0, $n^{-1/2}[S_n - n/2]$ converges in law to a standard normal one, so that the critical values can be approximated by using tables for the standard normal distribution. For n up to 50 or so, exact binomial tables can be used, although for $n \geq 20$ a normal approximation works out well. For F possibly having discontinuities, ties among the observations may occur with a positive probability, and hence some adjustments for ties are to be made. Assuming F to be symmetric about its median, adjustment for ties can be made by *sign-inversions*, and this will be described later on in a general context.

Consider next the Wilcoxon signed rank statistic. Here we assume that the cumulative distribution function (cdf) F is symmetric about its median, and write $F(x) = F_\theta(x) = F(x - \theta)$, $x \in \mathbf{R}$, where $F(x) + F(-x) = 1$, for all $x \in \mathbf{R}$. Let $R_{ni}^+ = \sum_{j=1}^n I(|X_j| \leq |X_i|)$ be the **rank** of $|X_i|$ among the n observations $|X_i|$, $j = 1, \ldots, n$, for $i = 1, \ldots, n$. Also let $S_i = \text{sign}(X_i)$ be the sign of X_i, for $i = 1, \ldots, n$. Then define

$$W_n = (n+1)^{-1} \sum_{i=1}^n S_i R_{ni}^+. \tag{5}$$

Under the null hypothesis $H_0 : \theta = 0$, the two vectors $\mathbf{S}_n = (S_1, \ldots, S_n)'$ (of signs) and $\mathbf{R}_n^+ = (R_{n1}^+, \ldots, R_{nn}^+)'$ (of absolute ranks) are distributed independently, where $\mathbf{S}_n$ takes on each of the 2^n sign-inversions with the common probability 2^{-n}, and $\mathbf{R}_n^+$ takes on each permutation of $\{1, \ldots, n\}$ with the common probability $(n!)^{-1}$. Thus, W_n is distribution-free under H_0 and, furthermore,

$$E_0\{W_n\} = 0 \quad \text{and} \quad \text{var}_0\{W_n\} = \frac{n(2n+1)}{6(n+1)}. \tag{6}$$

The exact permutation distribution of W_n can well be approximated by a normal distribution when n is large and, surprisingly, the approximation is quite good for sample size as small as 10.

If we define $X_i(a) = X_i - a$, $i \geq 1$, $a \in \mathbf{R}$, and denote the Wilcoxon signed-rank statistic based on these aligned observations by $W_n(a)$, then it is easy to see that $W_n(a)$ is a nonincreasing (step-)function of a and, hence, virtually equating $W_n(a)$ to 0, we arrive at the following rank (R-)estimator of θ:

$$\hat{\theta}_n = \text{median } \left\{\tfrac{1}{2}(X_i + X_j) : 1 \leq i \leq j \leq n\right\}. \tag{7}$$

This estimator is consistent, median unbiased and asymptotically normal for all continuous and symmetric F. This is asymptotically optimal when F is a **logistic** cdf, about 95% **efficient** when F is normal, and is usually more efficient than the sample mean when F has a heavier tail than the normal law. This R-estimator has a bounded influence function and is globally **robust**. There are other signed-rank tests based on scores $a_n(R_{ni}^+)$ instead of the R_{ni}^+, where $a_n(\cdot)$ can be skillfully chosen to have asymptotic optimality against specific F (the normal scores correspond to a normal F); but they may not have a closed expression for the derived R-estimator. Moreover, whenever the score generating function is unbounded, we may have an unbounded influence function for the derived estimators, and hence, from robustness considerations, the Wilcoxon test and estimator may dominate the scenario.

Two-Sample Location Model

Suppose that we have two independent samples: $X_1, \ldots, X_{n_1}$ are independent and identically distributed random variables with a continuous cdf F, and $Y_1, \ldots, Y_{n_2}$ are independent and identically distributed random variables with a continuous cdf G, where both F and G are unknown, but not necessarily symmetric. In a two-sample location model, we set $G(x) = F(x - \theta)$, $x \in \mathbf{R}$, and treating F as a nuisance parameter (function), we like to test for the null hypothesis H_0 that $\theta = 0$ against θ positive (or negative or nonnull); and also, we like to estimate the *shift parameter* θ in a robust, nonparametric fashion. Note that in this setup, the null hypothesis actually relates to the homogeneity of F and G.

Median Statistics

We let $N = n_1 + n_2$ and denote the combined sample order statistics by $Z_{N:1} \leq \cdots \leq Z_{N:N}$ where, by virtue of the assumed continuity of F and G, ties among the observations (and hence the $Z_{N:i}$) can be neglected with probability 1. Also let us define

$$M = \frac{N+1}{2} \text{ or } \frac{N}{2}, \quad \text{according as } N \text{ is odd or even.} \tag{8}$$

Then we consider a **two-by-two table**; where m_1 and m_2 denote the number of observations of the first and second samples having values not exceeding $Z_{N:M}$, so that $n_1 - m_1$ and $n_2 - m_2$ are the complementary entries in this table. Under the null hypothesis $F = G$, all the N observations are independent and identically distributed, and hence their joint distribution remains invariant under any (of the $N!$) permutations of the coordinates. Using this (discrete) uniform permutation probability law, Mood [17] showed that

$$P\{m_1, m_2|H_0\} = \frac{\binom{n_1}{m_1}\binom{n_2}{m_2}}{\binom{N}{M}},$$
$$m_1 = 0, 1, \ldots, \min(M, n_1). \tag{9}$$

Both one-sided and two-sided tests, known as the Mood median test, can be made based on this **hypergeometric** probability distribution and a version of the statistic $M_n = \{m_2 - n_2 M/N\}$. The convergence of hypergeometric to normal laws paves the way for asymptotic normality of the test statistics (under H_0). Next, we note that if we replace the Y_i by $Y_i - a$, a real, and denote the resulting median statistic by $M_n(a)$, a real, then under the shift model $G(x) = F(x - \theta), \theta$ real, (i) $M_n(a)$ is a nonincreasing (step-)function of $a, a \in \mathbf{R}$, and (ii) $M_n(\theta)$ has the same distribution as M_n under H_0. This leads to the following estimator of θ:

$$\tilde{\theta}_N = \tilde{Y}_{n_2} - \tilde{X}_{n_1}, \tag{10}$$

where $\tilde{X}_{n_1}(\tilde{Y}_{n_2})$ is the sample median of the first (second) sample observations. $\tilde{\theta}_N$ is a robust, **consistent** and asymptotically normal estimator of θ. It is quite clear that both the sample medians are least sensitive to **outliers** or gross errors in the respective samples, and hence, this median estimator scores very high with respect to robustness perspectives; the conventional difference of the sample means, although optimal for the normal shift model, is highly nonrobust to such outliers or gross errors.

Rank Sum Statistics

We denote by $R_i(S_j)$ the rank of $X_i(Y_j)$ among the N combined sample observations, for $i = 1, \ldots, n_1 (j = 1, \ldots, n_2)$. Then the Wilcoxon–Mann–Whitney rank sum statistic can be expressed in the following form:

$$W_N = n_2^{-1} \sum_{j=1}^{n_2} S_j - n_1^{-1} \sum_{i=1}^{n_1} R_i. \tag{11}$$

An equivalent representation for W_N is a generalized ***U*-statistic**

$$U_{n_1,n_2} = (n_1 n_2)^{-1} \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} I(X_i \le Y_j), \tag{12}$$

which automatically adjusts for ties, if there are any, while in W_N, minor adjustments for ties are needed to define the R_i and S_j properly. Note that under $H_0 : F = G$, the same permutation law as in the case of the median test prevails, and hence W_N is genuinely distribution-free under H_0. Furthermore, $E[W_N|H_0] = 0$, $V[W_N|H_0] = N^2(N+1)/\{12 n_1 n_2\}$, and under H_0, the standardized form of W_N is asymptotically normal; this convergence holds quite well even when n_1 and n_2 are as small as 9 or 10. The asymptotic distribution of W_N is normal even when the null hypothesis is not true, although its mean and variance functions would depend on the cdfs F and G. The test based on W_n is consistent against a very broad class of alternatives that $\Pr\{X < Y\}$ is not equal to 1/2, and this includes, besides the shift alternative, the *stochastic ordering* of X and Y, defined in terms of an ordering of the cdfs F and G, without necessarily being of the shift type. An important alternative in this context is known as the **Lehmann alternative**: $\overline{G}(x) = 1 - G(x) = [\overline{F}(x)]^c$, for some c (> 0), and the null hypothesis relates to $c = 1$. In this case, the alternative hypothesis distribution of W_N is also independent of F and depends on the triplet (n_1, n_2, c).

Let us now replace the Y_i by $Y_i - a$, where a is real, and denote the resulting Wilcoxon statistic by $W_N(a)$, a real. Then it is easy to check that (i) $W_N(a)$ is a nonincreasing step-function of $a \in \mathbf{R}$, and (ii) under $G(x) = F(x - \theta)$, $W_N(\theta)$ has the same distribution as W_N has under H_0. Therefore, virtually equating $W_N(a)$ to 0, we arrive at the following R-estimator of the shift parameter θ:

$$\hat{\theta}_N = \tfrac{1}{2}\{\inf[a : W_N(a) < 0] + \sup[a : W_N(a) > 0]\}$$
$$= \text{median } [(Y_i - X_j) : 1 \le i \le n_2; 1 \le j \le n_1]. \tag{13}$$

This estimator is translation-invariant, median-unbiased, consistent, robust, and asymptotically normally distributed. This is asymptotically optimal

when F is a logistic cdf and, for a normal F, it is about 95% efficient. Again, this R-estimator has a bounded influence function and is globally robust. There are other R-estimators based on **logrank** or **normal scores** statistics which are to be solved by iterative methods, and which possess asymptotic optimality properties against some specific F (namely **exponential** or normal), but in terms of robustness may not be preferable to the Wilcoxon score estimator.

Several Sample Location Models

Now consider the case of c (≥ 2) independent samples of sizes $n_1, \ldots, n_c$ respectively, drawn from populations having continuous cdfs $F_1, \ldots, F_c$, where we set

$$F_j(x) = F(x - \theta_j), \quad x \in \mathbf{R}, j = 1, \ldots, c; \quad (14)$$

the θ_j are real (location) parameters, and F need not be symmetric. In testing the homogeneity of the F_j under this shift model, we really want to test for the identity of the θ_j. On the other hand, use of specific multisample rank statistics may lead to tests for the homogeneity of the F_j against alternatives that may be broader than such shift ones. Note that under H_0, all of the samples come from a common distribution, and hence their joint distribution remains invariant under any permutation of the coordinates over the entire combined set. This generates a discrete uniform probability measure, independent of F, so that tests based on this law are distribution-free under H_0.

Brown–Mood Median Statistic

We denote the jth sample observations by X_{ji}, $i = 1, \ldots, n_j$, for $j = 1, \ldots, c$, let $N = n_1 + \cdots + n_c$, and denote the combined sample order statistics by $Z_{N:1} \leq \cdots \leq Z_{N:N}$; by virtue of the assumed continuity of the F_j, ties are neglected with probability 1. Let M be a positive integer, typically, close to $(N+1)/2$, and let m_j be the number of X_{ji} in the jth sample with values $\leq Z_{N:M}$, for $j = 1, \ldots, c$. Note that $M = m_1 + \cdots + m_c$, and we have a $2 \times c$ **contingency table** with the first-row entries $m_1, \ldots, m_c$, marginal total M, second-row entries $n_1 - m_1, \ldots, n_c - m_c$ and total $N - M$, and the bottom marginal with entries $n_1, \ldots, n_c$ and total N. The usual $2 \times c$ contingency **chi-square test** statistic (along with the **Fisher exact testing** procedure) applies to this scenario [4]. The test is consistent against possible nonhomogeneity of the c population medians.

Kruskal–Wallis Statistic

We denote the rank of X_{ji} in the combined sample by R_{ji}, for $i = 1, \ldots, n_j$, $j = 1, \ldots, c$. Let then $R_{j\cdot} = \sum_{i=1}^{n_j} R_{ji}$, $j = 1, \ldots, c$. Then the Kruskal–Wallis [15] (rank sum) statistic can be written as

$$K_N = \frac{12}{N(N+1)} \sum_{j=1}^{c} n_j^{-1} \left[R_{j\cdot} - \frac{n_j(N+1)}{2} \right]^2 \quad (15)$$

(*see* **Nonparametric Methods**). The test based on K_n is distribution-free under H_0, and when the n_j are large, it has closely central **chi-square distribution** with $c - 1$ **degrees of freedom** (df). Consistency and efficiency properties run parallel to the two-sample case.

Simple Regression Models

Another extension of the two-sample model relates to the simple **linear regression** model [12] where $X_1, \ldots, X_N$ are independent random variables with continuous dfs $F_1, \ldots, F_N$ respectively, all defined on $\mathbf{R}$, and these F_j are linearly related in their arguments; namely,

$$F_j(x) = F(x - \beta c_j), \quad j = 1, \ldots, N, \quad (16)$$

where the c_j are known (regression) constants, not all equal, and β is an unknown regression parameter. By virtue of the translation invariance of ranks, we may absorb the intercept parameter in the unknown cdf F itself, and the null hypothesis of homogeneity of all the N cdfs reduced to that of $\beta = 0$. Define R_i as the rank of X_i among the N observations, for $i = 1, \ldots, N$, and let $\bar{c}_N = N^{-1} \sum_{i=1}^{N} c_i$. Then consider a *linear rank statistic*

$$\mathcal{L}_N = \sum_{i=1}^{N} (c_i - \bar{c}_N) a_N(R_i), \quad (17)$$

where $a_N(k)$, $k = 1, \ldots, N$ are suitable **scores**, not all equal. A statistic of the median type can be defined by letting

$$a_N(k) = \text{sign}\left(k - \frac{N+1}{2}\right), \quad k = 1, \ldots, N, \quad (18)$$

while a Wilcoxon-type statistic is based on scores

$$a_N(k) = \left(k - \frac{N+1}{2}\right), \quad \text{for } k = 1, \ldots, N. \tag{19}$$

These definitions extend readily to the **multiple regression** model, in which, for some $p \geq 1$, $\boldsymbol{\beta}$ is a p-vector and so are the $\mathbf{c}_j$.

Even in the simple regression model or the several sample case, there may be certain technical problems in defining suitable R-estimators (even based median or Wilcoxon-type scores) in a closed form. There is another statistic, known as the Kendall tau statistic (*see* **Association, Measures of**), which is a mixture of median and Wilcoxon scores, and which may have some advantages. We define this as

$$T_N = \sum_{i=1}^{N} \sum_{j=1}^{N} \text{sign}(c_i - c_j)\ \text{sign}(X_i - X_j). \tag{20}$$

The double summation in the above formula can be replaced by a summation over all $\{1 \leq i < j \leq N\}$. It follows from Sen [21] that

$$\hat{\beta}_n = \text{median}\left[\frac{X_i - X_j}{c_i - c_j} : \{i, j : c_i \neq c_j\}\right] \tag{21}$$

is a robust, consistent, median-unbiased and asymptotically normal estimator of β, and that in the particular case of binary c_i (i.e. the two-sample location model), this estimator reduces to the Wilcoxon scores estimator $\hat{\theta}_N$, considered in (13). A distribution-free confidence interval for β (and hence θ) can also be obtained by using the Kendall tau statistic based on the aligned observations $X_i - bc_i$, $i \geq 1$, b real.

Two-Way Layouts

The method of *n-rankings* and *ranking after alignment* are the two popular nonparametric methods for statistical modeling and analysis of two-way layouts, covering complete **randomized block** as well as **incomplete block** designs. Both the median and rank sum procedures are popular in this context. The method of n-rankings is presented here, while the other method depending on a multivariate approach will be presented later. In that way, the impact of multivariate nonparametrics will be clearer.

Consider $n(\geq 2)$ blocks of $p(\geq 2)$ plots receiving p different treatments. Let X_{ij} be the response of the jth treatment in the ith block, for $j = 1, \ldots, p$; $i = 1, \ldots, n$. Let r_{ij} be the rank of X_{ij} within the ith block (p) observations, for $j = 1, \ldots, p$, and let $\mathbf{r}_i = (r_{i1}, \ldots, r_{ip})'$, $i = 1, \ldots, n$. The method of n-rankings is based on these n rank vectors. In fact, this does not even require that all the X_{ij} are observable; it suffices to have the realizations of the within-block ranks. This situation may arise, for example, when n judges are asked to rank, independently of each other, p objects (e.g. players), and the judgment may involve some subjective elements too. Even when the X_{ij} are observable, we do not need to assume that they come from homoscedastic normal distributions, and the treatment or block effects may not be additive. The null hypothesis H_0 of interest is the *interchangeability* of the observations within each block, so that under H_0, the $\mathbf{r}_i$ are independent and identically distributed random vectors, and each $\mathbf{r}_i$ takes on each permutation of $\{1, \ldots, p\}$ with the common probability $(p!)^{-1}$. (The adjustments for tied ranks can be made easily.) Two popular test statistics based on the method of n-ranking are the following:

1. Friedman's [10] rank sum statistic

$$\chi_r^2 = \frac{12n}{p(p+1)} \sum_{j=1}^{p} \left(\overline{r}_{j,n} - \frac{p+1}{2}\right)^2, \tag{22}$$

where $\overline{r}_{j,n} = n^{-1} \sum i = 1^n r_{ij}$, $j = 1, \ldots, p$; and

2. Brown & Mood's [4] median statistic:

$$B_r = \frac{np(p-1)}{a(p-a)} \sum_{j=1}^{p} \left(\overline{M}_{j,n} - \frac{a}{p}\right)^2, \tag{23}$$

where a is a positive integer, typically close to $(p+1)/2$, and $\overline{M}_{j,n} = n^{-1} \sum_{i=1}^{n} I(r_{ij} \leq a)$, $j = 1, \ldots, p$.

For both the statistics, null distributions are generated by the $(p!)^n$ equally likely realizations of $(\mathbf{r}_1, \ldots, \mathbf{r}_n)$, and hence they are distribution-free under H_0. Both are consistent against alternatives that are more general than the conventional ANOVA differences in the treatment effects. Moreover, for large values of n, the exact null distribution of either statistic converges to central chi-squared distribution df with $p - 1$ df. Asymptotic properties of such tests have been studied in detail in Puri & Sen [19, Chapter 7]. Extensions to incomplete block designs and more than one observation per cell have also been presented there.

Bivariate Independence Problem

This bivariate problem is essentially reducible to a quasi-univariate one, and both rank sum and median-type statistics are popular in this respect. Let $(X_i, Y_i), i = 1, \ldots, n$ be n independent and identically distributed random vectors having a continuous bivariate cdf $F(x, y)$, $(x, y) \in \mathbf{R}^2$. The hypothesis of stochastic independence of X and Y can be stated as

$$\mathrm{H}_0 : F(x, y) = F(x, \infty) \cdot F(\infty, y), \quad \text{for all} (x, y) \in \mathbf{R}^2. \tag{24}$$

Recall that independence implies uncorrelation, but the converse may not be true (without normality of F) (*see* **Correlation**). Moreover, alternatives to H_0 may be of diverse types, and naturally different test statistics may behave differently under such alternatives. One of the simple and appealing classes of alternatives is the *positive (negative) dependence* which specifies that $F(x, y) \geq (\leq) F(x, \infty) F(\infty, y)$, for all x, y, with strict inequality at least on a set of positive measure. Recall that $F_1(x) = F(x, \infty)$ and $F_2(y) = F(\infty, y)$ are the two marginal cdfs, and as a suitable measure of dependence, known as the *grade correlation* coefficient, we have the following

$$\rho_g = 12 \int \int \left[F_1(x) - \tfrac{1}{2}\right]\left[F_2(y) - \tfrac{1}{2}\right] \mathrm{d}F(x, y). \tag{25}$$

If $R_i (S_i)$ denotes the rank of $X_i (Y_i)$ among the X's (Y's), for $i = 1, \ldots, n$, then the sample counterpart of ρ_g is

$$r_{g,n} = \frac{12}{n(n^2 - 1)} \sum_{i=1}^{n} \left(R_i - \frac{n+1}{2}\right) \times \left(S_i - \frac{n+1}{2}\right), \tag{26}$$

and this is known as the **Spearman rank correlation** coefficient. A related measure of dependence is the *quadrant measure*

$$\rho_q = 4[P(X > \theta_1, Y > \theta_2) - 1], \tag{27}$$

where θ_1 and θ_2 are the population medians of X and Y. The sample counterpart of this is the following

$$Q_n = n^{-1} \sum_{i=1}^{n} \operatorname{sign}\left(R_i - \frac{n+1}{2}\right) \times \operatorname{sign}\left(S_i - \frac{n+1}{2}\right), \tag{28}$$

and is known as the quadrant test statistic. A related measure, the Kendall tau statistic, can be expressed as

$$K_n = \binom{n}{2}^{-1} \sum_{\{1 \leq i < j \leq n\}} \operatorname{sign}(R_i - R_j) \operatorname{sign}(S_i - S_j). \tag{29}$$

In each case, under H_0, the two rank vectors $(R_1, \ldots, R_n)$ and $(S_1, \ldots, S_n)$ are independently distributed with a discrete uniform distribution over the permutations of $\{1, \ldots, n\}$, and hence these tests are all distribution-free under H_0. Various properties of these tests have been studied in detail in Hájek & Šidák [13] and in other contemporary nonparametric texts.

The First Spark of Multivariate Nonparametrics

The simplicity of rank-based statistical procedures in the univariate cases mentioned above stumbles into roadblocks in the bivariate or genuine multivariate cases; this impasse is primarily due to the fact that, in a bivariate or multivariate case, neither the distribution of the vector of coordinatewise signs nor the coordinatewise ranks (or absolute ranks) are generally independent of the underlying distribution, even when suitable hypotheses of invariance (similar to the univariate cases) hold. For example, suppose that we have a sample of n observations from a bivariate distribution, and we want to test the null hypothesis that both the marginal medians are equal to 0. Thus, a simple extension of the sign test would be a suitable function of the two coordinatewise sign statistics. However, the two sign-functions sign (X_i) and sign (Y_i) for an observation (X_i, Y_i) are not necessarily independent, and hence a bivariate sign test may not be genuinely distribution-free. Chatterjee [5] eliminated this drawback by an appeal to a conditional procedure based on a partitioning of the set of observations into *concordant* and *discordant* ones,

and showed that such conditional tests are conditionally distribution-free and have nice properties too. Earlier, Chatterjee & Sen [6] considered the bivariate two-sample (location/association) problem, and demonstrated that a simple *rank-permutation principle* renders conditional distribution-freeness of a large class of rank statistics, including both the median and rank sum tests. Subsequent developments in multivariate nonparametrics, reported in Puri & Sen [19], exploit this Chatterjee–Sen rank-permutation principle as extended to more complex setups, and here we shall confine ourselves to specific problems in this domain.

Multivariate Multisample Tests

Let $\mathbf{X}_{ij} = (X_{ij}^{(1)}, \ldots, X_{ij}^{(p)})'$, $j = 1, \ldots, n_i$ be n_1 independent and identically distributed random vectors having a continuous p-variate cdf $F_i(\mathbf{x})$, $\mathbf{x} \in \mathbf{R}^p$, for $i = 1, \ldots, c\,(\geq 2)$. We want to test for the null hypothesis $\mathrm{H}_0 : F_1 = \cdots = F_c = F$ (unknown), against plausible alternatives that these cdfs differ in location/scale and or association measures. We shall mainly discuss the multivariate rank sum and median procedures, studied in detail by Chatterjee & Sen [6–8] and reported in more mathematical abstraction in Puri & Sen [19]). Let $R_{ij}^{(k)}$ be the rank of $X_{ij}^{(k)}$ among the $N(= \sum_{1=1}^{c} n_i)$ observations on the kth characteristic, for $j = 1, \ldots, n_i; / i = 1, \ldots, c; k = 1, \ldots, p$. Define the *rank collection matrix* $\mathbf{R}_N$ as the $p \times N$ matrix the kth row of which contains the elements $(R_{11}^{(k)}, \ldots, R_{1n_1}^{(k)}, \ldots, R_{cn_c}^{(k)})$, for $k = 1, \ldots, p$. Thus, each row of $\mathbf{R}_N$ contains the number $\{1, \ldots, N\}$, permuted in some order, and there are $(N!)^p$ such possible realizations of $\mathbf{R}_N$. Multisample multivariate rank statistics are typically based on this rank-collection matrix, so that the distribution theory of $\mathbf{R}_N$ governs the same for such coordinatewise rank-based statistics. For $p = 1$ – that is a single characteristic – under H_0, all possible $N!$ realizations of the rank vector are equally probable. However, for $p \geq 2$, unless the p coordinates of the $\mathbf{X}_{ij}$ are independent (wherein we have only a quasi-multivariate setup), the distribution of the rank-collection matrix depends on the underlying $F_1, \ldots, F_c$, even under the null hypothesis. This characterizes the lack of distribution-freeness of multivariate multisample rank-based procedures. The Chatterjee–Sen rank permutation principle removes this impasse through a conditional approach which is easy to interpret and implement in practice. Let us permute the columns of $\mathbf{R}_N$ in such a way that the top row is in the natural order $(1, \ldots, N)$. We denote the resulting element in the kth row and rth column by $R_{Nr}^{(k)*}$, for $r = 1, \ldots, N$; $k = 2, \ldots, p$; note that $R_{Nr}^{(1)*} = r$, $1 \leq r \leq N$. We denote the derived $p \times N$ matrix by $\mathbf{R}_N^*$ and term it the *reduced rank collection* matrix. Note that the cdf of $\mathbf{R}_N^*$ depends, even under H_0, on the underlying F, but the conditional distribution of $\mathbf{R}_N$, given $\mathbf{R}_N^*$, under H_0, is independent of the underlying F, and is uniform (discrete) over the $N!$ permutations of the columns of $\mathbf{R}_N^*$. We denote this permutational (conditional) probability measure by $\mathcal{P}_N$, and advocate the use of the same in the construction of some permutationally (conditionally) distribution-free tests.

As in the univariate case, we consider the individual sample coordinatewise rank sum statistics:

$$\overline{R}_i^{(k)} = n_i^{-1} \sum_{j=1}^{n_i} R_{ij}^{(k)}, \quad k = 1, \ldots, p; \quad i = 1, \ldots, c. \tag{30}$$

Let us also define the *rank covariance* matrix $\mathbf{V}_N = ((v_{N,kq}))$ (of order $p \times p$) by

$$\mathbf{V}_N = N^{-1}(\mathbf{R}_N)(\mathbf{R}_N)' - \left(\frac{N+1}{2}\right)^2 \mathbf{1}\mathbf{1}', \tag{31}$$

and denote by $\mathbf{V}_N^-$ a generalized inverse of $\mathbf{V}_N$; under very mild regularity conditions, $\mathbf{V}_N$ is positive definite in probability, and hence, we may as well work with the actual inverse $\mathbf{V}_N^{-1} = ((v_N^{kq}))$. It is easy to verify that under $\mathcal{P}_N$, the $\overline{R}_i^{(k)}$ have all expected value $(N+1)/2$, and, furthermore,

$$\mathrm{cov}\left[\overline{R}_i^{(k)}, \overline{R}_j^{(q)} | P_N\right] = \frac{N\delta_{ij} - n_i}{n_i(N-1)} v_{N,kq}, \tag{32}$$

for $k, q = 1, \ldots, p$; $i, j = 1, \ldots, c$ where δ_{ij}, the Kronecker delta, is 1 or 0 according as $i = j$ or not. Then the multivariate generalization of the Kruskal–Wallis [15] rank sum statistic is given by

$$\mathcal{L}_N = \sum_{i=1}^{c} n_i \sum_{k=1}^{p} \sum_{q=1}^{p} v_N^{kq} \left[\overline{R}_i^{(k)} - \frac{N+1}{2}\right] \times \left[\overline{R}_i^{(q)} - \frac{N+1}{2}\right]. \tag{33}$$

The conditional (permutational) distribution of $\mathcal{L}_N$, given $\mathbf{R}_N^*$, can be obtained by enumeration of all possible $N!$ conditionally equally likely realizations of $\mathbf{R}_N$, and this provides a conditionally distribution-free test for H_0. The task becomes prohibitively laborious when N becomes large. However, it has been shown that the permutation distribution of $\mathcal{L}_N$ converges (in probability) to the central chi-square distribution with $p(c-1)$ df when N is large. The test statistic reduces to the Kruskal–Wallis statistic when $p = 1$. For $c = 2$, this corresponds to the Wilcoxon–Mann–Whitney statistics [16] and it is consistent against the same class of alternatives as in univariate case, but simultaneously for all the coordinates. The test is robust against nonnormality of F as well as for error contaminations, although unlike the parametric tests based on the characteristic roots of the between-sample sum of product matrix, normalized by the pooled within-sample sum of product matrix, it is not invariant to affine transformations on the original observations. This lack of affine-invariance is, of course, shared by most of the tests based on coordinatewise rank vectors (which are themselves not affine invariant). Also, unlike the univariate case, here tables for the exact null distribution of $\mathcal{L}_N$ are difficult to construct, as they generally depend on the reduced rank-collection matrix $\mathbf{R}_N^*$ and there are $(N!)^{p-1}$ such matrices which are themselves not necessarily equally likely, even conditionally. Nevertheless, the conditional distribution-freeness, robustness properties, simple asymptotic distribution theory, and good power properties make this multivariate rank sum test a good competitor of the classical parametric tests.

Let us present the multivariate multisample median tests side by side. As in the univariate case, we consider the coordinatewise median statistics for each sample relative to the pooled one. Let M be a positive integer, close to $(N+1)/2$, and let

$$M_i^{(k)} = \sum_{j=1}^{n_i} I(R_{ij}^{(k)} \le M), \quad k = 1, \ldots, p; \quad i = 1, \ldots, c. \tag{34}$$

We also introduce the $p \times p$ matrix $\mathbf{V}_N^0 = ((v_{N,kq}^0))$ by letting $v_{N,kk}^0 = M(N-M)/N^2, k = 1, \ldots, p$, and for $k \ne q$, defining the reduced rank collection matrix $\mathbf{R}_N^*$ as before,

$$v_{N,kq}^0 = N^{-1} \sum_{r=1}^{N} I(R_r^{(k)*} \le M, R_r^{(q)*} \le M) - \left(\frac{M}{N}\right)^2, \quad k \ne q = 1, \ldots, p. \tag{35}$$

Again under very mild regularity conditions, $\mathbf{V}_N^0$ is positive definite in probability, and we therefore assume that its inverse $(\mathbf{V}_N^0)^{-1} = ((v_N^{kq,0}))$ is well defined (otherwise, we work with a generalized inverse). Then we consider the following three types of median tests. These tests are very robust against error contaminations or outliers, but in general, for nearly multinormal distributions, they may not be asymptotically as efficient as the multivariate rank sum test, although in terms of robustness we have an opposite relative picture.

1. *Omnibus median procedure*. Recall that by letting $M_i^{(k)*} = N - M_i^{(k)}$, for $k = 1, \ldots, p, i = 1, \ldots, c$, we arrive at p sets of $2 \times c$ contingency table with the cell entries $M_i^{(k)}, M_i^{(k)*}, i = 1, \ldots, c$, for each $k = 1, \ldots, p$. Unfortunately, these tables are not necessarily stochastically independent, and hence we need to appeal to higher-dimensional categorical data models and analysis schemes to formulate appropriate test statistics; we refer to Chatterjee & Sen [6, 7] for further details. For $p \ge 2$, such a test is consistent not only against possible heterogeneity of location parameters (or medians) of the c populations, but also against possible heterogeneity of their association parameters of various orders. Note that the total df for such a complex categorical data model is much higher than $p(c-1)$, so that such an omnibus test statistic carries too many degrees of freedom. Hence, for location/shift alternatives, it may not be efficient. For this reason, we shall find it more convenient to deal more explicitly with the other two types of median procedures, which are geared toward such location alternatives and/or pairwise association alternatives only, and are generally more efficient than an omnibus procedure.

2. *Multisample multivariate median test for location*. This procedure is directed for location alternatives, and the test statistic is given by

$$\mathcal{L}_N^0 = \sum_{i=1}^{c} n_i \sum_{k=1}^{p}\sum_{q=1}^{p} v_N^{kq,0} \left(n_i^{-1} M_i^{(k)} - \frac{M}{N}\right) \times \left(n_i^{-1} M_i^{(q)} - \frac{m}{N}\right), \tag{36}$$

so that, for $p = 1$, it reduces to Brown & Mood's test statistic considered earlier. As in the case of the multivariate multisample rank sum test, for small values of $n_1, \ldots, n_c$, one can appeal to the permutational probability measure $\mathcal{P}_N$, and obtain a conditionally (permutationally) distribution-free test for the null hypothesis of homogeneity of the cdfs $F_1, \ldots, F_c$; for large sample sizes, the permutational distribution of $\mathcal{L}_N$ converges, in probability, to the central chi-square distribution with $p(c-1)$ df. Thus, for large sample sizes, the critical level of this median test can be well approximated by appropriate quantiles of this simple limiting distribution.

3. *Median tests for homogeneity of association parameters*. In addition to the p measures of marginal locations, there are $\binom{p}{2}$ measures of pairwise associations of the p variates, and similarly for higher-order associations when $p \geq 2$. In many situations, particularly when p is not so small, inclusion of all such measures results in a large-dimensional parameter space, and that in turn pulls down the level of precision that can be acquired from a given data set. For this reason, often, multivariate models are conceived wherein only first-order or pairwise association measures are included along with the location measures, so that essentially the number of parameters for each cdf is reduced to

$$p + \binom{p}{2} = \binom{p+1}{2},$$

and in the given multisample model we would therefore have

$$(c-1)\binom{p+1}{2}$$

degrees of freedom. Tests for this broader (than location) type of alternatives can be based on the collection of the entries $\{M_i^{(kq)} = \sum_{j=1}^{n_i} I(R_{ij}^{(k)} \leq M, R_{ij}^{(q)} \leq M), \quad k, q = 1, \ldots, p; i = 1, \ldots, c\}$. Moreover, such a test statistic can be decomposed into two orthogonal components, $\mathcal{L}_N^0$ described before, for location alternatives, and the complementary part for association alternatives. For further details, we refer to Chatterjee & Sen [7].

There is a basic difference in the **asymptotic relative efficiency** (ARE) picture between the univariate and multivariate cases. In both cases, for local (Pitman-type) alternatives the test statistics have appropriate noncentral chi-square distributions with comparable degrees of freedom and noncentrality parameters. However, in the univariate case, for two such test statistics under a common local alternative their noncentrality parameters are proportional to each other over the entire parameter space, so that the ratio of noncentrality parameters provides a meaningful measure of the (Pitman) ARE of one test with respect to the other (*see* **Pitman Efficiency**). In the multivariate case, the ratio of the two noncentrality parameters may depend not only on the underlying distributions through appropriate dispersion matrices that appear in their expressions, but also on the actual alternatives (namely, the direction cosines in the location case). Therefore a single measure of ARE may not be tenable for the entire parameter space under (local) alternatives, and hence one of the basic interpretations of the ARE of such tests in terms of the sample sizes needed to have equal (asymptotic) power may no longer be possible. This drawback has been minimized to a certain extent by using suitable lower and upper bounds for the ratio of noncentrality parameters, and then incorporating the univariate concepts on such bounds. However, that may not convey a definitive picture in all situations. We refer to Puri & Sen [19, Chapters 4– 5] for a comprehensive discussion of ARE of statistical tests in the multivariate case.

In the univariate case, estimators of difference of location parameters based on rank tests, particularly the median and rank sum statistics, have already been discussed earlier. These estimators extend to the multivariate case in a straightforward manner, as for each of the p coordinates, the same univariate estimation procedure can be adopted. The basic difference comes

in the interval estimation problem as extended to confidence sets in the multivariate case. The distribution-freeness of the confidence intervals in the univariate case may no longer hold in the multivariate case (as the coordinatewise rank statistics are generally not independent). However, asymptotic confidence sets may still be achieved by using the Scheffé or Tukey method along with the asymptotic chi-square distributions of related test statistics (under H_0). These asymptotic procedures are generally more robust than the classical parametric procedures, though for small sample sizes, there may not be a good resolution. We refer to Puri & Sen [19, Chapter 6] for details.

Multivariate One-Sample Rank Tests

We now present rank statistics which are the multivariate extensions of the sign and Wilcoxon signed-rank statistics in the univariate case, treated earlier. Let $\mathbf{X}_i = (X_{i1}, \ldots, X_{ip})'$, $i = 1, \ldots, n$, be independent and identically distributed random vectors having a $p(\geq 1)$ variate continuous cdf, F. We denote the marginal cdfs corresponding to F by $F_{[1]}, \ldots, F_{[p]}$ respectively, and let $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_p)'$ be the vector of the marginal medians. Suppose that we want to test for the null hypothesis $H_0 : \boldsymbol{\theta} = \boldsymbol{\theta}_0$ (specified) against alternatives that $\boldsymbol{\theta} \neq \boldsymbol{\theta}_0$; without any loss of generality, we let $\boldsymbol{\theta}_0 = \mathbf{0}$. Different rank tests for this hypothesis testing problem entail different regularity conditions on the cdf. First, we consider multivariate sign tests entailing least restrictive conditions in this respect.

To motivate the scenario, we start with the bivariate sign tests, and then present the general multivariate case. Hodges [14] considered an association invariant and genuinely distribution-free sign test, although its distributions on null or alternative hypotheses are not very simple. Another association invariant bivariate sign test is due to Blumen [3], and this also shares the drawbacks of the Hodges' sign test to a certain extent. Bennett [1] used the classical likelihood ratio principle to arrive at an asymptotically distribution-free sign test. Chatterjee's [5] treatment include a conditionally distribution-free and strictly unbiased bivariate sign test, basically related to the Bennett version when the observations are iid, a condition not needed in the Chatterjee case. If we create a two-by-two table by drawing perpendicular axes through the median vector ($\mathbf{0}$ under H_0), the positive (negative) orthant $\mathbf{X} \geq (\leq)\, \mathbf{0}$ constitutes the first (second) type of *concordance* set, while the second and fourth quadrants relate to the first and second type of *discordance* sets. Although Chatterjee [5] considered independent but not necessarily identically distributed random variables, for simplicity of presentation, we consider here the independent and identically distributed case. Let $\Pr(C)$ and $\Pr(D) = 1 - \Pr(C)$ be the probabilities of concordance and discordance, respectively. Furthermore, let

$$\tau = \frac{\Pr\{\text{first type concordance}\}}{\Pr\{\text{concordance}\}} \quad \text{and}$$
$$\gamma = \frac{\Pr\{\text{first type discordance}\}}{\Pr\{\text{discordance}\}} \tag{37}$$

Then the null hypothesis of $\boldsymbol{\theta} = \mathbf{0}$ can be equivalently stated as

$$H_0^* : \tau = \gamma = \tfrac{1}{2}. \tag{38}$$

In the sample, let C_1, C_2, D_1, and D_2 be the number of observations which are concordant of the first and second types and discordant of the first and second type respectively. Note that $n = C_1 + C_2 + D_1 + D_2$. Under H_0, given $C = c$, we have

$$\Pr\{C_1 = c_1, D_1 = d_1 | C = c\} = \binom{c}{c_1} \times \binom{n-c}{d_1} 2^{-n}, 0 \leq c_1 \leq c, 0 \leq d_1 \leq n - c, \tag{39}$$

which is a product of two independent binomial distributions, and is independent of the underlying df. Therefore, a test based on this conditional law is conditionally distribution-free. Chatterjee [5] considered the test statistic

$$T_n = 4\left[C^{-1}\left(C_1 - \frac{C}{2}\right)^2 + (n-C)^{-1}\left(D_1 - \frac{n-C}{2}\right)^2\right], \tag{40}$$

and constructed a randomized test to achieve unbiasedness; he showed that, under H_0, the conditional distribution of T_n converges (in probability) to the central chi-square distribution with 2 df when n is large. With a view to presenting the general multivariate case in the same vein, we rewrite T_n in the form

$T_n = n\mathbf{S}_n'\mathbf{V}_n^{-1}\mathbf{S}_n$, where $\mathbf{S}_n' = n^{-1}\sum_{i=1}^n$ (sign (X_{i1}), sign (X_{i2})), and $\mathbf{V}_n$ has the diagonal elements equal to 1 and the off-diagonal elements equal to $n^{-1}\sum_{i=1}^n$ sign $(X_{i1}X_{i2})$. Adjustment for ties (at 0) can be made easily under this conditional setup. In this setup, we now proceed to the general p variate case, and define

$$\mathbf{S}_n = n^{-1}\sum_{i=1}^n [\text{sign}(X_{i1}), \ldots, \text{sign}(X_{ip})]',$$

$$\mathbf{V}_n = ((v_{nkq})) = \left(\left(n^{-1}\sum_{i=1}^n \text{sign}(X_{ik}X_{iq})\right)\right)_{k,q=1,\ldots,p},$$

$$\mathcal{T}_n = n\mathbf{S}_n'\mathbf{V}_n^{-1}\mathbf{S}_n, \tag{41}$$

where $\mathbf{V}_n^{-1}$ is a (generalized) inverse of $\mathbf{V}_n$. The concordance–discordance picture in the bivariate case extends to a reflection picture (over 2^p possible cells) in the multivariate case, and generates a similar conditional distribution as a product of 2^{p-1} binomial distributions. This provides the genesis of conditionally distribution-free sign tests in the multivariate case. Again, the conditional null distribution of $\mathcal{T}_n$ converge (in probability) to the central chi-square distribution with p df, so that critical levels may well be approximated by chi-square percentile points. The asymptotic power and efficiency properties of such sign tests have been presented in Puri & Sen [19, Chapter 4]. This test exploits only the reflection property of the vector of signs of the observations (under H_0). There are some other sign tests, as would be briefly introduced later on, that are based on more stringent group-invariance structures, and are appropriate only under some additional regularity assumptions on the underlying distributions that validate such invariance properties.

We consider next the multivariate signed-rank statistics [26] and exhibit their (conditional) distribution-freeness under suitable groups of transformations. As in the univariate case, we consider for each coordinate the vector of signs and absolute ranks. Also, we need to assume some sort of symmetry of the cdf F, which at least implies that all the p marginal $F_{[1]}, \ldots, F_{[p]}$ are symmetric. For the rank-permutation principle to work out, we need a more stringent symmetry-condition that the cdf is *diagonally symmetric*, implying that both $\mathbf{X} - \boldsymbol{\theta}$ and $\boldsymbol{\theta} - \mathbf{X}$ have the same distribution. In the asymptotic case, this may be relaxed to marginal symmetry.

Let R_{ij}^+ be the rank of $|X_{ij}|$ among the n observations $|X_{rj}|, r = 1, \ldots, n, i = 1, \ldots, n$, for $j = 1, \ldots, p$, and let

$$T_{nj} = n^{-1}\sum_{i=1}^n \text{sign}(X_{ij})R_{ij}^+, \quad j = 1, \ldots, p;$$

$$v_{njk} = n^{-1}\sum_{i=1}^n \text{sign}(X_{ij}X_{ik})R_{ij}^+R_{ik}^+, \quad j,k = 1, \ldots, p;$$

$$\mathbf{T}_n = (T_{n1}, \ldots, T_{np})',$$

$$\mathbf{V}_n = ((v_{njk}))_{j,k=1,\ldots,p}. \tag{42}$$

Then the multivariate signed-rank statistic is

$$\mathcal{L}_n = n\mathbf{T}_n'\mathbf{V}_n^{-1}\mathbf{T}_n. \tag{43}$$

Conditional on the rank collection matrix $\mathbf{R}_n^+$ and the collection of the n sign vectors, under H_0, the permutation (conditional) distribution of $\mathcal{L}_n$ is generated by the 2^n conditionally equally likely sign-inversions, and hence, it is a conditionally distribution-free test. For large values of n, the permutation distribution of $\mathcal{L}_n$ converges (in probability) to the central chi-square distribution with p df, so simple approximations to the critical levels can be obtained from the percentile points of this limit law. The test is consistent against the same alternative as in the univariate case, extended coordinatewise to the multivariate case. The asymptotic properties (including ARE) of this signed rank tests are essentially the same as in the case of the multisample rank sum test, and we refer to Puri & Sen [19, Chapter 4] for details. As in the multisample model, here also, estimates of the coordinatewise location parameters can be based on the coordinatewise sign or signed-rank statistics, so that there are closed expressions for them. The situation with confidence sets is somewhat more complex (as the distribution-freeness does not hold in the multivariate case); nevertheless, asymptotic solutions based on the Scheffé method work out well; we refer to Puri & Sen [19, Chapter 6] and Bickel [2] for details.

The sign and signed-rank tests are not *rotationally* or *affine-invariant*, although in the bivariate case, the Hodges [14] sign test has some invariance property. Incorporating the idea of Oja's *simplex median* [18], some rotation invariant bivariate sign tests have been developed in the recent past, and its multivariate generalizations are nicely wrapped up

by Chaudhuri & Sengupta [9], who also extended the Hodges sign test to the multivariate case, and also cited other pertinent references. While for rotationally invariant rank tests the sphericity of the underlying distribution is needed, for affine invariance elliptical symmetry, less restrictive than the sphericity, suffices, but then the resulting tests are only asymptotically distribution-free (as opposed to the conditionally distribution-freeness of the tests presented earlier). In biostatistical applications, often, the coordinate variables may relate to different types of responses or characteristics which may not be linearly compoundable, and hence the assumption of sphericity or elliptical symmetry may run contrary to the experimental setup – and hence such invariant tests having mostly mathematical appeals for large sample sizes may not be of much use. Incidentally, the permutation version of the **Hotelling T^2 test**, considered by Wald & Wolfowitz [27] more than 50 years ago, possesses the affine-invariance property, is computationally simpler, and asymptotically optimal too (when the underlying df are multinormal). On the other hand, such affine-invariant sign or signed rank tests share the nonrobustness properties of the T^2 statistics (to outliers or error contaminations as well as nonnormality). In a multivariate setup, such model departures can occur in many more ways than in an univariate model, and hence should be carefully examined before deciding on a suitable test statistic, solely on its asymptotic optimality against a specific distributional alternative.

Multivariate Paired Comparisons Tests

A natural extension of the sign test relates to **paired comparison** studies, in which $t(\geq 2)$ objects are considered in pairs $(i, j) : 1 \leq i < j \leq t$, and judged with respect to some performance characteristic(s) on a relative basis for each pair. In the case of multiple characteristics (say, p), for each pair of objects, we have a p-vector $\mathbf{X}_{ij} = (X_{ij}^{(1)}, \ldots, X_{ij}^{(p)})'$, where $X_{ij}^{(k)}$ takes on the value $+1$ or -1 according as the ith object is judged better (or not) than the jth one with respect to the kth trait, for $k = 1, \ldots, p; 1 \leq i < j \leq t$. Therefore, we are given $\binom{t}{2}$ sets of multivariate sign vectors, where for each such table we have generally multiple observations. It is possible to use a conventional (multidimensional) contingency table to analyze such paired comparisons experiments. However, the degrees of freedom for such tests would be considerably larger when t is not small. The practice is to combine these subsets in such a way that the object contrasts are highlighted with a considerable reduction of the df to enhance the power. Since we have a multivariate situation, genuinely distribution-free procedures may not be available. Sen & David [25] incorporated the Chatterjee [5] sign-inversion principle, and derived a simple paired comparison test for the homogeneity of the t objects in the bivariate case. This test statistic is conditionally (permutationally) distribution-free and has $2(t-1)$ df [compared with $t(t-1)$ in the classical contingency table approach]. An extension of this paired comparison test in the general multivariate case has been considered by Sen [24], and it contains an unifying account of the developments in this area.

Multivariate Friedman χ_r^2 Test

A direct extension of the Friedman χ_r^2 test to the multivariate case is due to Gerig [11]. He incorporated the Chatterjee–Sen rank-permutation principle to construct the permutational dispersion matrix of the individual treatment rank sums $(\sum_{i=1}^{n} r_{ij}^{(s)} = p\bar{r}_{n,j}^{(s)},\ j = 1, \ldots, p,$ for each coordinate $(s = 1, \ldots, q)$ separately, and incorporated this in the construction of a quadratic norm:

$$\mathcal{L}_n = n \sum_{s=1}^{m} \sum_{s'=1}^{m} v_n^{ss'} \sum_{j=1}^{p} \left[\bar{r}_{n,j}^{(s)} - \frac{p+1}{2} \right] \times \left[\bar{r}_{n,j}^{(s')} - \frac{p+1}{2} \right], \tag{44}$$

where the $v_{n,ss}$ are all equal to $p(p+1)/12$, while

$$v_{n,ss'} = \frac{1}{n(p-1)} \sum_{i=1}^{n} \sum_{j=1}^{p} \left[r_{ij}^{(s)} - \frac{p+1}{2} \right] \times \left[r_{ij}^{(s')} - \frac{p+1}{2} \right], \quad s \neq s' = 1, \ldots, q. \tag{45}$$

Again, this test is permutationally (conditionally) distribution-free and under the null hypothesis of homogeneity of the treatment vectors, $\mathcal{L}_n$ has asymptotically the central chi-square distribution with $q(p-1)$ df. For detailed study of the asymptotic properties of this test, we refer the reader to Puri & Sen [19, Chapter 7].

Aligned Rank Tests

An inherent problem of the method of n-ranking, be it in the univariate or multivariate case, is that it does not properly incorporate *interblock information* (as the within-block rankings are independent for different blocks). Thus, whenever the block effects are additive, it seems that if these are estimated, and *alignment* is made by subtracting these estimated block-effects from the respective block observations, then these aligned observations can be ranked across the entire set of blocks, permitting interblock comparisons to a greater extent. Rank tests based on such aligned observations are termed "aligned rank tests". Again, the process of alignment generally distorts the exact distribution-freeness of such aligned rank tests. Nevertheless, the Chatterjee–Sen rank-permutation principle can be adopted to show that such aligned rank tests are permutationally (conditionally) distribution-free. We denote the aligned rank of the jth observation in the ith block (within the entire set of $N = np$ aligned observations) by $R_{n,ij}$, and compute the averages $\overline{R}_{n,j} = n^{-1}\sum_{i=1} R_{n,ij}$, $j = 1, \ldots, p$. Also let $\overline{R}_{n,i\cdot} = p^{-1}\sum_{j=1}^{p} R_{n,ij}$, $i = 1, \ldots, n$, and define

$$V_n = [n(p-1)]^{-1}\sum_{i=1}^{n}\sum_{j=1}^{p}(\overline{R}_{n,j} - \overline{R}_{n,i\cdot})^2. \quad (46)$$

Then the aligned rank sum test for the univariate case is based on

$$\mathcal{L}_N^0 = \frac{n}{V_n}\sum_{j=1}^{p}\left(\overline{R}_{n,j} - \frac{N+1}{2}\right)^2. \quad (47)$$

A similar statistic in the multivariate case with general scores has been worked out in Sen [22], and reported in detail in Puri & Sen [19, Chapter 7]. In the particular case of aligned rank sum procedure, the test statistic involves the aligned rank average of each treatment, for each coordinate, averaged over the n blocks, and the rank correlation matrix of these aligned ranks, so the analogy with the multivariate χ_r^2 statistic is quite apparent. The asymptotic null distributions of these aligned rank tests are the same as those based on the method of n rankings, but in the nonnull case, particularly, for local alternatives, they fare better than the intrablock rank tests in terms of ARE. On the other hand, the method of n rankings does not require block-additivity, and hence in situations in which this additivity is in question, they may fare better than aligned rank tests. In passing, we may remark that median-type and rank-sum-type statistics, based either on within block rankings or aligned ones, have also been considered for **factorial designs**. These tests are also (conditionally for aligned ranks) distribution-free and possess some nice properties. For a detailed account of these procedures for replicated 2^m experiments, we refer to Sen [23].

Rank MANCOVA

One of the major advantages of the Chatterjee–Sen rank-permutation principle in the multivariate case is that it provides an access to handling the analysis of covariance in a general multivariate setup, termed MANCOVA, without any further complication. Suppose that there are p primary variates and q concomitant or **covariates**, so that we have a $(p+q)$-variate distribution of the responses. A minimal requirement for a variable to qualify as covariable or concomitant variable is that its distribution is not affected by the treatment differences that are likely to arise with the primary response variates. Therefore, granted this basic assumption, the homogeneity of the conditional distributions of the primary response variables, given the concomitant variables, across the treatment regimen, implies the homogeneity of the $(p+q)$-variate distributions over the treatment regimen. On the other hand, the concomitant variates may not contribute to any significant differences in the treatment regimen, and hence, not to lose any power, should not be treated as primary response variables. The resolution is quite simple. First, consider an appropriate rank statistic, say $\mathcal{L}_N$, for testing the homogeneity of the $(p+q)$-variate distributions for the different treatment. Next, consider the parallel test statistic just confining attention to the concomitant variates, and let it be denoted by $\mathcal{L}_N^0$. Then the covariate adjusted rank test statistic for the primary variates, denoted by $\mathcal{L}_N^*$, is given by

$$\mathcal{L}_N^* = \mathcal{L}_N - \mathcal{L}_N^0. \quad (48)$$

By the Cochran theorem on quadratic forms (*see* **Chi-square, Partition of**), $\mathcal{L}_N^*$ is easily shown to be nonnegative, and clearly, for different score functions, we would obtain different such MANCOVA test statistics. For example, if $p = 1$ and $q \geq 1$, and we use the Wilcoxon scores (for the c sample problem), we will get a version which resembles the Kruskal–Wallis

statistic, adjusted for covariates; this was considered by Quade [20], and a unified theory based on their rank-permutation principle is covered in Puri & Sen [21]. The same thing can be done for Friedman's χ_r^2 statistic, via the multivariate extension due to Gerig [11]. For aligned rank statistics too, a similar picture holds. Basically these MANCOVA rank tests are conditionally (permutationally) distribution-free), have asymptotically chi-square distributions, and are more efficient than their MANOVA counterparts where the concomitant variates are ignored (leading to possible loss of information). For details, we refer the reader to Puri & Sen [19, Chapter 5].

We conclude with the remark that for both the sign (median) and rank-sum-type procedures, the statistics can be handled as suitable functions of (generalized) U-statistics, and hence, their distribution theory (under the null as well as alternatives) can be studied under much less restrictive regularity conditions than in the case of general rank statistics. Moreover, adjustments for ties can also be made without much pain. Finally, being based on bounded scores, they have excellent robustness properties, and they are reasonably efficient for a broad class of underlying distributions, including the normal, Laplace, and the logistic cdfs. In applications in the general field of biostatistics, we therefore advocate the use of such procedures whenever the underlying distribution is suspected to be different from a normal one, as well as when we have ranked data sets.

Multivariate Methods for Binary Longitudinal Data

In many studies one measures a dichotomous (or **binary**) response variable and a set of **covariates** at several times for each of many individuals. When the outcome can occur only once or only the first occurrence is of interest, then methods of **survival analysis** are commonly used. However, the subject of binary longitudinal data considers the situation when the outcome can recur and the relationship of covariates with the multiple occurrences of the outcome is of interest. Examples of diseases or clinical outcomes that can recur in the same patient are common and include asthma attacks, skin cancers, urinary tract infections, myocardial infarctions, injuries, migraines, seizures in epileptics, and admissions to hospital.

The challenge to the multivariate analysis of such data arises because some individuals are more prone to recurrences than others. Thus, the repeated measures of the response variable will generally be positively correlated and regression approaches must account for these correlations (*see* **Longitudinal Data Analysis, Overview**). A variety of regression models appropriately account for these correlations and several excellent reviews have compared and discussed their alternative indications and performance [4, 9, 12, 14, 15].

Types of Models

Marginal Models

The scientific question of interest dictates the choice of model. Consider, for example, a longitudinal study in which use of antihypertensive drugs is assessed at three different times in each member of an elderly cohort. One question of interest is whether use of these drugs differs by age and sex and also changes over time because of the publication between the surveys of evidence from large-scale clinical trials demonstrating the efficacy of antihypertensive treatment in the elderly. This suggests the following model:

$$\log\left[\frac{\mu_{it}}{1-\mu_{it}}\right] = \beta_0 + \beta_1 age_{it} + \beta_2 sex_i + \beta_3 weight_{it} + \beta_4 time_t, \qquad (1)$$

where μ_{it} is the probability that the ith individual is using antihypertensive drugs at the tth survey, age_{it} and $weight_{it}$ are age and weight of the ith individual at the tth survey, sex_i is the sex of this individual, and $time_t$ is an indicator variable denoting whether the survey is before or after the demonstration of efficacy from randomized trials. Note that the model contains time-varying as well as fixed covariates. Parameters in the model are interpretable in terms of the odds of using antihypertensive drugs; for example, $\exp(\beta_4)$ is the odds of using antihypertensive drugs in the later time period relative to the earlier period, for persons of the same age, sex, and weight.

Eq. (1) is called a **marginal model** because it does not include among the independent variables the previous levels of the response variable. It commonly relates levels of covariates at each observation time to the dichotomous outcome at that time, although previous levels of covariates can also be included. The interrelationship among the repeated measures of the response variable is usually considered to be a nuisance. To complete the specification of model (1), one must also specify the relationship between the variance of the response variable and the independent variables and the association between the repeated measures of the dichotomous response variable. Commonly used and interpretable choices are that $\text{var}(Y_{it}) = \lambda\mu_{it}(1-\mu_{it})$, where λ is a constant, and that $\text{corr}(Y_{it}, Y_{is})$ depends only on the time interval between measures, $t-s$, where Y_{it} is the response variable of the ith individual at time t. Alternatively, one may parameterize the interrelationship between repeated measures of the response variable in terms of an odds ratio or allow the strength of this interrelationship to vary according to levels of the independent variables [3, 13, 18].

Mixed-Effects Models

The above marginal model is sometimes called the population-averaged approach because it assumes common regression parameters β for all individuals in the population. One may prefer to include random effects terms and the model is then called a subject-specific model (*see* **Marginal Models**). A simple model of this type is

$$\log\left[\frac{\mu_{it}}{1-\mu_{it}}\right] = \beta_{0i} + \beta_1 age_{it} + \beta_2 sex_i + \beta_3 weight_{it} + \beta_4 time_t, \qquad (2)$$

where μ_{it} is the expectation of Y_{it} conditional on a subject-specific intercept β_{0i} that is assumed to vary according to a known distribution, e.g. normal $(0, \sigma^2)$ [2, 17, 25, 26]. The repeated measures Y_{it} and Y_{is} are then assumed to be independent, conditional on the individual random effect β_{0i}.

The parameters β in models (1) and (2) have different interpretations. Consider, for example, the parameter β_3 which indexes the effect of weight in the two models. In the population-averaged approach this coefficient summarizes the average effects over the whole population of a unit difference in weight. In the subject-specific model this coefficient summarizes the effect of a unit change in weight within an individual. Neuhaus et al. [16] studied the relationship between parameters from the two models and found that, as long as the correlation between repeated response variables is positive, parameters in model (1) are always smaller in absolute value than the corresponding parameters in model (2), unless that parameter is identically zero.

Transition Models

An alternative question of scientific interest focuses on transitions between categories of the dependent variable. In the above example one may be interested in determinants of new use of antihypertensive drugs or in withdrawal or noncompliance among previous users of these drugs. In this case a model of interest may be

$$\begin{aligned}\log\text{it}[\Pr(Y_{it} = 1)] = {} & \beta_0 + \beta_1 age_{it} + \beta_2 sex_i \\ & + \beta_3 weight_{it-1} + \beta_4 time_t \\ & + \beta_5 Y_{it-1}. \end{aligned} \tag{3}$$

Or, more generally, one may assume that the current value of the response variable depends not only on the most recent values, but on all previous values of this variable [1]. Interpretation of regression coefficients for age, sex, weight, and time differs from the marginal model because in the transition model effects are conditional on the previous value of the response variable. Hence, this model is called a conditional model. Because the relationship of covariates with initiation of therapy is likely to differ from their relationship with withdrawal or noncompliance, interactions between the effects of the covariates and the previous response variables may be of particular interest.

A related conditional model is of interest when one focuses on the interrelationship among the values of the repeated responses. This model conditions on subsequent as well as previous values of the response variable:

$$\begin{aligned}\log\text{it}[\Pr(Y_{it} = 1 | Y_{-it})] & \\ = F\left(\sum_{k \neq t} Y_{ik}, \theta\right) & + \beta_1\ age_{it} + \beta_2\ sex_i \\ + \beta_2\ weight_{it} & + \beta_3\ time_t, \end{aligned} \tag{4}$$

where Y_{-it} denotes all response values for the ith person except that at the tth time and F is an arbitrary function of $\sum_{k \neq t} Y_{ik}$ and parameters θ [5, 20, 22]. This conditional expression allows for specification of the joint distribution of the repeated response variables and so this model can also be used to estimate the probability that a person uses antihypertensive drugs at all three times or at no time.

Approaches to Inference

In describing the above models we have presented only the relationship of the first and second moments of the response variable to the independent variables. Because of the interrelationships among the repeated measures, additional assumptions are often required to specify the complete likelihood. A challenge for the estimation of the marginal model (1) is the absence of joint probability distributions for multivariate binary data that yield simple expressions for marginal means [6]. Because of the intractability of the likelihood, Liang & Zeger [11] have recommended use of the **generalized estimating equations** (GEE) method, a form of **quasi-likelihood**, for estimation and inference. Estimates of the parameters β are solutions of the GEE:

$$U(\boldsymbol{\beta}) = \sum_{i=1}^{N} \mathbf{D}_i^T \mathbf{V}_i^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i) = 0, \tag{5}$$

where N is the number of subjects, $\mathbf{D}_i = \partial \boldsymbol{\mu}_i / \partial \boldsymbol{\beta}^{\mathrm{T}}$, and $\mathbf{V}_i$ is an approximate or "working" covariance matrix of Y_i. Several alternative forms of $\mathbf{V}_i$ are commonly used, including the assumption that the correlation between any two different measures in the same person is independent of time (**exchangeable** correlation), that it depends only on the time interval

(autoregressive correlation), or that it is completely unspecified. Liang & Zeger showed that the GEE approach yields consistent estimates of the parameters $\boldsymbol{\beta}$ in (1), provided only that the specification of the expected value of the dependent variable is correct. Even if the covariance matrix is misspecified, the following robust estimate of the variance of the parameters is available:

$$\hat{V}(\hat{\boldsymbol{\beta}}) = H_1^{-1}(\hat{\boldsymbol{\beta}}) H_2(\hat{\boldsymbol{\beta}}) H_1^{-1}(\hat{\boldsymbol{\beta}}),$$

where

$$H_1(\hat{\boldsymbol{\beta}}) = \sum_{i=1}^{N} \hat{\mathbf{D}}_i^{\mathrm{T}} \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i,$$

$$H_2(\hat{\boldsymbol{\beta}}) = \sum_{i=1}^{N} \hat{\mathbf{D}}_i^{\mathrm{T}} \hat{\mathbf{V}}_i^{-1} (\mathbf{y}_i - \boldsymbol{\mu}_i)(\mathbf{y}_i - \boldsymbol{\mu}_i)^{\mathrm{T}} \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i,$$

and $\hat{\mathbf{V}}_i$ and $\hat{\mathbf{D}}_i$ are $\mathbf{V}_i$ evaluated at $\hat{\boldsymbol{\beta}}$.

An extension of the estimating equation approach allows for a parameterization of the covariance $\mathbf{V}_i$, or alternatively of pairwise odds ratios between repeated measures, as functions of independent variables [18, 29]. Prentice & Zhao presented estimating equations for the joint estimation of both mean and covariance parameters. They also showed that these estimating equations correspond to the score equations under a quadratic exponential **likelihood** for the joint distribution of the repeated measures. Fitzmaurice & Laird [8] have also presented a likelihood-based approach that is closely related to the GEE method.

For the mixed-effects model (2), the logistic-normal likelihood is identified by the specification that the random intercept follows a normal distribution and, conditional on this intercept, the repeated measures for an individual are independent and have a logistic relationship with the independent variables. However, the likelihood does not have a closed-form expression and thus a full maximum likelihood analysis requires numerical integration [7]. One alternative is the use of Gibbs sampling techniques [27] (*see* **Markov Chain Monte Carlo**). Other approximate methods are based on penalized quasi-likelihood or marginal quasi-likelihood approaches [2, 25, 26, 28].

Transition models such as model (3) can be easily fitted with available software for logistic regression analysis if the model adequately captures the dependence on previous levels of the outcome variable. For example, Bonney has presented straightforward methods for estimation under his proposed conditional model [1]. Rosner [22] has described likelihood-based estimation under the related conditional model (4).

Two issues that frequently complicate estimation in analysis of longitudinal data are the presence of missing data and of multiple levels of clustering in the data. Laird [10] discussed general issues of missing data in longitudinal studies, focusing on likelihood-based methods. Rotnitzky & Wypij [24] presented methods to quantify the bias that can arise from missing data in both likelihood and quasi-likelihood estimation approaches. Robins et al. [21] have given modifications to the GEE approach which yield consistent estimates when missing data are missing at random (*see* **Nonignorable Dropout in Longitudinal Studies**).

Multiple levels of clustering would arise in the example presented above if siblings or spouses whose use of antihypertensive drugs might be associated were included in the longitudinal surveys. Alternatively, in hypertension studies one often takes multiple measures of blood pressure of hypertension status within a short time interval and then repeats these measures after a longer interval. In this case subjects have repeated assessments at intervals such as one year and each assessment is composed of replicate measures a short time (e.g. one week) apart. Rosner presented an extension of his model to account for such multiple levels of clustering [23]. Qaqish & Liang [19] described GEE approaches with multiple measures on individuals who are clustered within families.

ROBERT J. GLYNN & BERNARD ROSNER

Multivariate Multiple Regression

Multiple regression analysis is used whenever we wish to model the relationship between a *dependent* (**response** or *endogenous*) variable y and a set of p **explanatory** (*regressor* or *exogenous*) variables $x_1, \ldots, x_p$. Many different forms of relationship are possible, but the overwhelming emphasis in practical applications is on the *linear* relationship $y = \beta_0 + \beta_1 x_1 + \cdots + \beta_p x_p$, where the β_j are parameters (since such a relationship often will hold approximately for some suitable **transformations** of the measured variables even if it does not hold for the variables themselves) (*see* **Multiple Linear Regression**).

In a typical application, values of each of these variables are observed on each of n sample individuals. Let us suppose that y_i denotes the value of the dependent variable and that $x_{i1}, \ldots, x_{ip}$ denote the corresponding values of the explanatory variables for the ith individual in the sample. The explanatory variables are usually assumed to be measured without error, but the dependent variable is subject to measurement errors. The statistical model for this situation is thus written

$$y_i = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_p x_{ip} + \varepsilon_i,$$

for $i = 1, 2, \ldots, n$. Here ε is a random *departure* term which represents the measurement errors; since random sampling is assumed, the ε_i are taken to be independent and identically distributed random variables each having mean zero and constant variance σ^2.

If we collect together all the y_i, β_j, and ε_i into the vectors

$$\mathbf{y} = (y_1, \ldots, y_n)',$$
$$\boldsymbol{\beta} = (\beta_0, \beta_1, \ldots, \beta_p)',$$
$$\boldsymbol{\varepsilon} = (\varepsilon_1, \ldots, \varepsilon_n)',$$

and write the explanatory variable values in the $n \times (p+1)$ matrix $\mathbf{X} = (x_{ij})$ for $i = 1, \ldots, n$ and $j = 0, 1, \ldots, p$, where $x_{i0} = 1$ for all i, then the above model can be written in the compact form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}.$$

In this formulation $\boldsymbol{\varepsilon}$ is a random vector whose mean is $\mathbf{0}$ and whose dispersion (or **covariance matrix**) is $\sigma^2\,\mathbf{I}$.

The main interest in practical applications is the estimation of the parameters $\boldsymbol{\beta}$, **hypothesis tests** and/or **confidence intervals** for them, and perhaps **variable selection** in order to model the relationship between dependent and explanatory variables as **parsimoniously** as possible. **Least squares** estimates of the parameters are given by

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}$$

provided that $\mathbf{X}$ is of full rank (which is the case that we assume). For all the remaining objectives it is also necessary to assume either normality of the departures ε_i or large samples. In the case of normality, **maximum likelihood** estimates of the parameters coincide with the least squares estimates, $\hat{\boldsymbol{\beta}}$ has a **multivariate normal distribution** with mean vector $\boldsymbol{\beta}$ and dispersion matrix $\sigma^2(\mathbf{X}'\mathbf{X})^{-1}$, and σ^2 is estimated from the residual mean square in the **analysis of variance** associated with the regression. For **large samples**, the least squares estimates have asymptotic normality with $\sigma^2(\mathbf{X}'\mathbf{X})^{-1}$ as the dispersion matrix. These facts enable confidence regions and hypothesis tests to be constructed for elements of $\boldsymbol{\beta}$, while variable selection procedures are built out of various statistics arising in the associated analysis of variance.

Multivariate multiple regression analysis arises when we have q (> 1) dependent variables, and we wish to model the relationship between *each* of these variables and the set of explanatory variables. Attention is again focused almost exclusively on *linear* relationships. If the dependent variables are $y_1, y_2, \ldots, y_q$, the explanatory variables are $x_1, x_2, \ldots, x_p$, and all these variables are observed on each of n sample individuals, then we have to allow each y_i to have its own linear relationship with all the x_i. Thus we have to specify q different linear models, one between each y_i and the set of x_i. By analogy with the above formulation we can write these models as

$$\mathbf{y}_i = \mathbf{X}\boldsymbol{\beta}_i + \boldsymbol{\varepsilon}_i,$$

where

$$\mathbf{y}_i = (y_{i1}, \ldots, y_{in})',$$
$$\boldsymbol{\beta}_i = (\beta_{i0}, \beta_{i1}, \ldots, \beta_{ip})',$$
$$\boldsymbol{\varepsilon}_i = (\varepsilon_{i1}, \ldots, \varepsilon_{in})',$$

for $i = 1, \ldots, q$. Here y_{ij} is the value observed for the ith dependent variable on the jth sample member, ε_{ij} is the departure term corresponding to the ith dependent variable and jth sample member, $\boldsymbol{\beta}_i$ are the parameters appropriate to the ith dependent variable, and $\mathbf{X}$ is the same as before. Even more compactly, putting the q columns $\mathbf{y}_i$ side by side into the $n \times q$ matrix $\mathbf{Y}$, the q columns $\boldsymbol{\beta}_i$ similarly into the $(p+1) \times q$ matrix $\mathbf{B}$, and the q columns $\boldsymbol{\varepsilon}_i$ into the $n \times q$ matrix $\boldsymbol{\Xi}$, we can write all q linear models in the single expression

$$\mathbf{Y} = \mathbf{XB} + \boldsymbol{\Xi}.$$

Once again the sample individuals are independent, but now there is association among the departure terms $\varepsilon_{1j}, \ldots, \varepsilon_{qj}$ corresponding to the same sample member. Consequently, we can treat the *rows* of $\boldsymbol{\Xi}$ as independent observations from a distribution with mean vector zero and dispersion matrix $\boldsymbol{\Sigma}$, and for most practical purposes this distribution is assumed to be multivariate normal.

Maximizing the likelihood for this model produces the estimator

$$\hat{\mathbf{B}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y},$$

and the same estimator results from various possible definitions of matrix least squares, also. Moreover, since $\hat{\mathbf{B}} = (\hat{\boldsymbol{\beta}}_1, \ldots, \hat{\boldsymbol{\beta}}_q)$, on picking out appropriate columns from the above equation we find that

$$\hat{\boldsymbol{\beta}}_i = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}_i,$$

for $i = 1, \ldots, q$. That is to say, the regression coefficients have the same estimates as they would if each dependent variable was regressed *separately* on the set of explanatory variables. However, all the individual $\hat{\beta}_{ij}$ in $\hat{\mathbf{B}}$ are now intercorrelated – those within a column of $\hat{\mathbf{B}}$ because of the **correlations** among the $\mathbf{x}_i$, and those in different columns of $\hat{\mathbf{B}}$ because of the correlations among the $\mathbf{y}_i$. Hence, to control type I error rates (*see* **Level of a Test**), we cannot conduct hypothesis tests separately on each column of $\hat{\mathbf{B}}$ but instead we need *multivariate* tests for hypotheses about $\mathbf{B}$.

These tests are the analogs in **multivariate analysis of variance** (MANOVA) of the **analysis of variance** (ANOVA) ***F* tests** for multiple regression. General theory is given in the article Multivariate Analysis of Variance in the discussion on multivariate **general linear models**; we content ourselves here with specifying the relevant matrices from which the test statistics are obtained. The error matrix, by analogy with multiple regression, is given by

$$\mathbf{E} = (\mathbf{Y} - \mathbf{X}\hat{\mathbf{B}})'(\mathbf{Y} - \mathbf{X}\hat{\mathbf{B}}) = \mathbf{Y}'\mathbf{Y} - \hat{\mathbf{B}}'\mathbf{X}'\mathbf{Y}$$

[from which an **unbiased** estimate of $\boldsymbol{\Sigma}$ is given by $\mathbf{E}/(n-p-1)$]. The total matrix is $\mathbf{T} = \mathbf{Y}'\mathbf{Y} - n\overline{\mathbf{y}}\overline{\mathbf{y}}'$ (where $\overline{\mathbf{y}}$ is the vector of sample means of the $\mathbf{y}_i$), so the hypothesis matrix for testing the overall significance of regression is the difference of $\mathbf{T}$ and $\mathbf{E}$, namely

$$\mathbf{H} = \hat{\mathbf{B}}'\mathbf{X}'\mathbf{Y} - n\overline{\mathbf{y}}\overline{\mathbf{y}}'.$$

Any of the standard test statistics can be used to test the significance of $\mathbf{H}$, e.g. Wilks' **lambda**:

$$\Lambda = \frac{|\mathbf{E}|}{|\mathbf{E} + \mathbf{H}|}.$$

To test the hypothesis that the $\mathbf{y}_i$ only depend on a subset of the $\mathbf{x}_i$, partition $\mathbf{B}$ into $\mathbf{B}' = (\mathbf{B}_{\mathrm{r}}'\mathbf{B}_{\mathrm{d}}')$, where $\mathbf{B}_{\mathrm{r}}$ denotes the subset of the β_{ij} that are to be retained, while $\mathbf{B}_{\mathrm{d}}$ denotes the subset of the β_{ij} that are to be deleted from the full model. If $\mathbf{X}_{\mathrm{r}}$ contains the columns of $\mathbf{X}$ corresponding to $\mathbf{B}_{\mathrm{r}}$, then the hypothesis matrix for testing $\mathrm{H}_0 : \mathbf{B}_{\mathrm{d}} = \mathbf{0}$ is

$$\mathbf{H} = \hat{\mathbf{B}}'\mathbf{X}'\mathbf{Y} - \hat{\mathbf{B}}_{\mathrm{r}}'\mathbf{X}_{\mathrm{r}}'\mathbf{Y},$$

while the error matrix is $\mathbf{E}$ as before.

Finally, the above test provides a basis for stepwise selection of a subset of the $\mathbf{x}_i$ for the most parsimonious prediction of all the $\mathbf{y}_i$, by either adding at each stage the x variable that has the most significant (partial) lambda, or by deleting the x variable that has the least significant (partial) lambda. Full details of such a scheme are given by, for example, Rencher [1].

W.J. KRZANOWSKI

Multivariate Normal Distribution

Biometric data typically entail observations on multiple characteristics for each experimental subject. Multivariate normal distributions (or multinormal distributions) are often central to the modeling and analysis of such data. Reasons abound: multivariate normal distributions are tractable; they have been studied extensively; their properties are widely known; and they support a variety of known derived distributions. Indeed, many standard problems in statistical inference initially were posed in terms of multinormal distributions. Empirical evidence often points towards the normality of multivariate data. Biometric measurements, especially, may emerge as the result of many small increments due to heredity and environment, so that the approximate multivariate normality of such data rests on multidimensional **central limit** theory. In addition, it is now known that many normal-theory procedures, both univariate and multivariate, remain exact for many nonnormal multivariate distributions exhibiting suitable symmetries. Further details may be found in the article on **multivariate distributions**. Not only do multinormal distributions support an impressive list of known derived distributions, but the limiting joint distributions of numerous statistics arising in data analysis are themselves multinormal in view of central limit theory. The latter include statistics employed in **large-sample theory**, **nonparametrics**, **robust** statistics, and elsewhere. In short, a working knowledge of multivariate normal distributions and their properties is essential to the knowledgeable use and development of statistical methodologies.

Multivariate normal distributions and their applications have a rich history. Origins of these distributions, beginning with two and three dimensions, trace to the early nineteenth century [1, 5, 7, 11, 13, 21, 23, 26]. Studies in heredity, culminating in the work of Galton [10], treat bivariate **correlation** analysis in a biometric setting. Systematic developments in two and three dimensions are credited to Bravais [5] and Schols [26]. Multivariate extensions in current usage are credited to Edgeworth [8], including such essential concepts as **regression** and partial correlations under multinormality. For further details and an excellent overview, see Johnson & Kotz [18, Chapters 35 and 36] and Tong [29].

To fix notation: $\mathbb{R}^k$ designates a Euclidean k-space; $F_{n\times k}$ is the collection of real $(n \times k)$ matrices; S_k consists of real symmetric $(k \times k)$ matrices; and S_k^0 and S_k^+ comprise the positive semidefinite and the positive definite varieties in S_k, respectively. Special arrays include the $(k \times k)$ identity $\mathbf{I}_k$, the unit vector $\mathbf{1}_k = [1, \ldots, 1]' \in \mathbb{R}^k$, and the diagonal matrix diag $(a_1, \ldots, a_k)$. $\mathscr{L}(\mathbf{X})$ designates the law of distribution of $\mathbf{X} \in \mathbb{R}^k$. Abbreviations for probability density, cumulative distribution, and characteristic functions are *pdf, cdf*, and *chf*, respectively, whereas *iid* refers to a sequence of independent identically distributed random elements.

A brief survey of essential properties follows. These are listed under basic properties, probability inequalities, characterizations, and central limit theory.

Basic Properties

Suppose that $\mathbf{X} \in \mathbb{R}^k$ is random having the chf $\phi_X(\mathbf{t}) = \exp(i\mathbf{t}'\boldsymbol{\mu} - \mathbf{t}'\boldsymbol{\Sigma}\mathbf{t}/2)$. Then $\mathbf{X}$ is said to have the *multivariate normal distribution* on $\mathbb{R}^k$ with parameters $(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \in \mathbb{R}^k \times S_k^0$, to be designated as $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. **Moments** of all orders are defined; the mean vector and dispersion **covariance matrix** are given by $\mathrm{E}(\mathbf{X}) = \boldsymbol{\mu}$ and $\mathrm{var}(\mathbf{X}) = \boldsymbol{\Sigma}$, respectively; and odd central moments of all orders vanish by symmetry. The class of all finite-dimensional multinormal distributions is closed under affine transformations, in the sense that, if $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ on $\mathbb{R}^k$, and if $\mathbf{Y} = \mathbf{AX} + \mathbf{b}$ with $\mathbf{A} \in F_{r\times k}$ and $\mathbf{b} \in \mathbb{R}^r$ fixed, then $\mathscr{L}(\mathbf{Y}) = \mathrm{N}_r(\mathbf{A}\boldsymbol{\mu} + \mathbf{b}, \mathbf{A}\boldsymbol{\Sigma}\mathbf{A}')$ on $\mathbb{R}^r$. This follows directly from elementary properties of chfs.

The distribution $\mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ is said to be *singular of rank r*, or to be *nonsingular*, according as $\boldsymbol{\Sigma}$ has rank $\mathbf{r} < k$ or rank k, respectively. For the nonsingular case, the pdf exists and is given by

$$f(\mathbf{x}) = [(2\pi)^k |\boldsymbol{\Sigma}|]^{-1/2} \exp\left[\frac{-(\mathbf{x}-\boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu})}{2}\right]. \tag{1}$$

A reduction to **principal components** proceeds on letting $\mathbf{Y} = \mathbf{PX}$ such that $\mathscr{L}(\mathbf{Y}) = \mathrm{N}_k(\boldsymbol{\theta}, \mathbf{D}_\xi)$, where $\mathbf{P}$ is $(k \times k)$ orthogonal such that $\boldsymbol{\theta} = \mathbf{P}\boldsymbol{\mu}$, and $\mathbf{D}_\xi = \mathbf{P}\boldsymbol{\Sigma}\mathbf{P}' = \mathrm{diag}(\xi_1, \ldots, \xi_k)$ contains the ordered **eigenvalues** $\{\xi_1 \geq \xi_2 \geq \cdots \geq \xi_k \geq 0\}$ of $\boldsymbol{\Sigma}$. In particular,

for the case that $\mathscr{L}(\mathbf{X})$ is singular of rank r, the last $k-r$ elements of $\mathbf{Y}$ are concentrated at the last $k-r$ elements of $\boldsymbol{\theta}$ with unit probability.

Joint marginal and conditional distributions of $\mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ emerge as follows (see the article on **multivariate distributions**). Partition $\mathbf{X} = [\mathbf{X}_1', \mathbf{X}_2']'$, $\boldsymbol{\mu} = [\boldsymbol{\mu}_1', \boldsymbol{\mu}_2']'$, and $\boldsymbol{\Sigma} = [\boldsymbol{\Sigma}_{ij}]$ conformably, with $\mathbf{X}_1 \in \mathbb{R}^r$ and $\mathbf{X}_2 \in \mathbb{R}^t$ such that $r + t = k$. Then the joint marginal distribution of $\mathbf{X}_1$ is itself multivariate normal on $\mathbb{R}^r$ as given by $\mathscr{L}(\mathbf{X}_1) = \mathrm{N}_r(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_{11})$, and similarly $\mathscr{L}(\mathbf{X}_2) = \mathrm{N}_t(\boldsymbol{\mu}_2, \boldsymbol{\Sigma}_{22})$ on $\mathbb{R}^t$. In like manner, the conditional distributions $\mathscr{L}(\mathbf{X}_1|\mathbf{x}_2)$ for $\mathbf{X}_1$, given that $\mathbf{X}_2 = \mathbf{x}_2$, are themselves multinormal on $\mathbb{R}^r$ for every fixed $\mathbf{x}_2$. Specifically, $\mathscr{L}(\mathbf{X}_1|\mathbf{x}_2) = \mathrm{N}_r(\boldsymbol{\mu}_{1\cdot 2}, \boldsymbol{\Sigma}_{11\cdot 2})$, having the linear regression functions $\mathrm{E}(\mathbf{X}_1|\mathbf{x}_2) = \boldsymbol{\mu}_{1\cdot 2} = \boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-}(\mathbf{x}_2 - \boldsymbol{\mu}_2)$, and dispersion parameters $\boldsymbol{\Sigma}_{11\cdot 2} = (\boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-}\boldsymbol{\Sigma}_{21})$ (Cambanis et al. [6]). Here $\boldsymbol{\Sigma}_{22}^{-}$ is any generalized inverse of $\boldsymbol{\Sigma}_{22}$. For distributions having full rank k, $\boldsymbol{\Sigma}_{22}^{-}$ becomes the unique inverse $\boldsymbol{\Sigma}_{22}^{-1}$. The matrix $\boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-}$ comprises the *partial regression coefficients* of $\mathbf{X}_1$ on $\mathbf{x}_2$. The squared **canonical correlations** between elements of $\mathbf{X}_1$ and $\mathbf{X}_2$ are the eigenvalues of $\boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}\boldsymbol{\Sigma}_{11}^{-1}$. For the case $r = 1$, the single eigenvalue is called the squared *multiple correlation coefficient* between $\mathbf{X}_1$ and $\mathbf{X}_2$.

Many further details are provided in Johnson & Kotz [18] and Tong [29], for example. These include sources for special aid tables and computational **algorithms** for evaluating various multinormal probabilities, as well as extensive reference lists.

Probability Inequalities

Basic Inequalities

Basic inequalities for multivariate normal distributions are essential. In practice, there is an excess of parameters, since $(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ consist of $k(k+3)/2$ distinct parameters. Owing to limitations of special aid tables and the software now available, access to probability inequalities enables the user to employ approximate values from existing tables or algorithms, giving bounds on the required probabilities. In this spirit, some useful inequalities may be summarized as follows. Basic sources are [28, Chapter 2] and [29, Chapters 5 and 7], together with extensive reference lists provided there.

In what follows, $\boldsymbol{\Sigma} = (\sigma_{ij})$ designates any positive-definite $(k \times k)$ matrix, whereas $\mathbf{R} = (\rho_{ij})$ signifies a positive-definite correlation matrix. The special equicorrelation matrix is denoted by $\boldsymbol{\Xi}(\rho) = [(1-\rho)\mathbf{I}_k + \rho\mathbf{1}_k\mathbf{1}'_k]$ for $[-(k-1)^{-1} < \rho < 1]$. On occasion we suppose that $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k[\mathbf{0}, \mathbf{R}(\kappa)]$, its correlation matrix $\mathbf{R}(\boldsymbol{\kappa})$ having the structure $(\rho_{ij} = \kappa_i\kappa_j\omega_{ij}, i \neq j)$ such that $(|\kappa_i| \leq 1; 1 \leq i \leq k)$, where $\boldsymbol{\Omega} = (\omega_{ij})$ is a positive-definite correlation matrix. With these conventions in place, let $P_{\boldsymbol{\Sigma}}(\cdot)$ be the probability measure for $\mathscr{L}(X_1, \ldots, X_k) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$; let $F_{\boldsymbol{\Sigma}}(x_1, \ldots, x_k)$ be its cdf; and let $\overline{F}_{\boldsymbol{\Sigma}}(x_1, \ldots, x_k) = P_{\boldsymbol{\Sigma}}(X_1 > x_1, \ldots, X_k > x_k)$. In addition, let $F_{\mathbf{D}}(x_1, \ldots, x_k)$ be the cdf of $\mathrm{N}_k(\boldsymbol{\mu}, \mathbf{D})$, with $\mathbf{D} = \mathrm{diag}\,(\sigma_{11}, \ldots, \sigma_{kk})$, and similarly for $\overline{F}_{\mathbf{D}}(x_1, \ldots, x_k)$. Furthermore, identify $G_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k) = P_{\boldsymbol{\Sigma}}(|X_1| \leq a_1, \ldots, |X_k| \leq a_k)$ for the case $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\mathbf{0}, \boldsymbol{\Sigma})$, and similarly $G_{\mathbf{D}}(a_1, \ldots, a_k)$ with $\mathbf{D} = \mathrm{diag}\,(\sigma_{11}, \ldots, \sigma_{kk})$ as before. Basic probability inequalities may be summarized as follows:

Inequality 1. If $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, then for fixed but arbitrary $(a_1, \ldots, a_k)$, the function $F_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k)$ is increasing in each σ_{ij} for all $i \neq j$ while other values are held fixed.

Inequality 2. Suppose that $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. If $\sigma_{ij} \geq 0$ for all $i \neq j$, then $F_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k) \geq F_{\mathbf{D}}(a_1, \ldots, a_k) \geq \prod_{i=1}^{k} F_i(a_i)$ holds for each fixed $(a_1, \ldots, a_k)$, where $F_i(\cdot)$ is the marginal cdf of X_i.

Inequality 3. Suppose that $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. If $\sigma_{ij} \geq 0$ for all $i \neq j$, then $\overline{F}_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k) \geq \overline{F}_{\mathbf{D}}(a_1, \ldots, a_k) \geq \prod_{i=1}^{k}[1 - F_i(a_i)]$ for arbitrarily fixed $(a_1, \ldots, a_k)$.

Inequality 4. Suppose that $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\mathbf{0}, \boldsymbol{\Sigma})$. Then $G_{\boldsymbol{\Sigma}}(c_1, \ldots, c_k) \geq G_{\mathbf{D}}(c_1, \ldots, c_k) \geq \prod_{i=1}^{k} G_i(c_i)$ for each fixed set $(c_1, \ldots, c_k)$ of positive constants, where $G_i(\cdot)$ is the marginal cdf of $|X_i|$.

Inequality 5. Suppose that $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k[\mathbf{0}, \boldsymbol{\Xi}(\rho)]$ with $P_\rho(\cdot)$ as the corresponding probability measure. Then for each fixed $a > 0$ and for all real numbers $(c_1, \ldots, c_k)$ such that $c_1 + \cdots + c_k = 0$, $P_\rho(|\sum_{i=1}^{k} c_i X_i| \leq a)$ is an increasing function of ρ.

Inequality 6. Suppose that $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k[\mathbf{0}, \mathbf{R}(\boldsymbol{\kappa})]$. Then for each fixed set of positive numbers

$(c_1, \ldots, c_k)$, the function $G_k(c_1, \ldots, c_k)$: (i) is strictly increasing in each $\kappa_i \in [0, 1]$ with other parameters held fixed; and (ii) is strictly decreasing in each $\kappa_i \in [-1, 0]$ with other parameters held fixed.

Concentration Properties

The comparative concentration of probabilities on $\mathbb{R}^k$ is an essential concept. Following Sherman [27], the probability measure $\mu(\cdot)$ is said to be *more peaked about* $\mathbf{0} \in \mathbb{R}^k$ than $\nu(\cdot)$ if and only if $\mu(\mathrm{A}) \geq \nu(\mathrm{A})$ for every set A in the class $\mathbf{C}_k$ consisting of the compact convex subsets of $\mathbb{R}^k$ that are symmetric under reflection about $\mathbf{0} \in \mathbb{R}^k$, i.e. $\mathbf{x} \in \mathrm{A}$ implies $-\mathbf{x} \in \mathrm{A}$. For two multivariate normal distributions $\mathrm{N}_k(\mathbf{0}, \boldsymbol{\Sigma})$ and $\mathrm{N}_k(\mathbf{0}, \boldsymbol{\Omega})$ on $\mathbb{R}^k$ having ordered scale matrices, the following inequality applies. Sufficiency is shown in [2], and necessity in [17].

Inequality 7. Let $\mathrm{N}_k(\mathbf{0}, \boldsymbol{\Sigma})$ and $\mathrm{N}_k(\mathbf{0}, \boldsymbol{\Omega})$ be multivariate normal distributions on $\mathbb{R}^k$ having ordered scale matrices such that $\boldsymbol{\Omega} - \boldsymbol{\Sigma}$ is positive semidefinite, and let $P_{\boldsymbol{\Sigma}}(\cdot)$ and $P_{\boldsymbol{\Omega}}(\cdot)$ be their corresponding probability measures. Then $P_{\boldsymbol{\Sigma}}(\cdot)$ is more concentrated about $\mathbf{0}$ than $P_{\boldsymbol{\Omega}}(\cdot)$ in the sense that $P_{\boldsymbol{\Sigma}}(A) \geq P_{\boldsymbol{\Omega}}(A)$ for every set A in the class $\mathbf{C}_k$.

Characterizations

Multivariate distributions exhibit many properties. Various characterizations of multivariate normality are concerned with properties unique to multinormal distributions on $\mathbb{R}^k$ and samples therefrom. To survey such results let $\mathbf{X} \in \mathbb{R}^k$ be random with pdf $p(\mathbf{x})$. Then its *entropy* is defined as $-\mathrm{E}[\ln p(\mathbf{X})]$. Furthermore, let $\{\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n\}$ be random vectors in $\mathbb{R}^k$; write $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)' \in F_{n\times k}$; let $(\overline{\boldsymbol{X}}, \mathbf{S})$ be the sample mean vector and the sample dispersion matrix, i.e. $\overline{\boldsymbol{X}} = n^{-1}(\mathbf{X}_1 + \cdots + \mathbf{X}_n)$ and $\mathbf{S} = \sum_{i=1}^{n}(\mathbf{X}_i - \overline{\boldsymbol{X}})(\mathbf{X}_i - \overline{\boldsymbol{X}})'/(n-1)$; and let $(\mathbf{A}_1, \ldots, \mathbf{A}_n, \mathbf{B}_1, \ldots, \mathbf{B}_n)$ be nonsingular $(k \times k)$ matrices. The following characterizations are known, a basic reference being [20].

Characteristic 1. Suppose that $\mathbf{X} \in \mathbb{R}^k$ has the pdf $p(\mathbf{x})$ with finite dispersion matrix $\mathrm{var}(\mathbf{X}) = \boldsymbol{\Sigma}$. Then $\mathscr{L}(\mathbf{X})$ has maximal entropy among all distributions on $\mathbb{R}^k$ with dispersion matrix $\boldsymbol{\Sigma}$, if and only if $\mathscr{L}(\mathbf{X})$ is multinormal, i.e. $\mathscr{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ [24].

Characteristic 2. Given that $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ are iid on $\mathbb{R}^k$, then $(\overline{\boldsymbol{X}}, \mathbf{S})$ are independent if and only if each of $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ is multinormal on $\mathbb{R}^k$.

Characteristic 3. Given that $(\mathbf{X}_1, \mathbf{X}_2)$ are independent on $\mathbb{R}^k$, then $\mathbf{W} = \mathbf{X}_1 + \mathbf{X}_2$ is multivariate normal on $\mathbb{R}^k$ if and only if each of $(\mathbf{X}_1, \mathbf{X}_2)$ is multinormal on $\mathbb{R}^k$.

Characteristic 4. Let $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ be independent random vectors on $\mathbb{R}^k$. If the linear forms $\mathbf{W}_1 = \mathbf{A}_1\mathbf{X}_1 + \cdots + \mathbf{A}_n\mathbf{X}_n$ and $\mathbf{W}_2 = \mathbf{B}_1\mathbf{X}_1 + \cdots + \mathbf{B}_n\mathbf{X}_n$ are independent, then each of $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ is multivariate normal on $\mathbb{R}^k$ [12].

Characteristic 5. Suppose for $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)' \in F_{n\times k}$ that its distribution is invariant under left-orthogonal transformations, i.e. $\mathscr{L}(\mathbf{X}) = \mathscr{L}(\mathbf{PX})$ for every $(n \times n)$ orthogonal matrix $\mathbf{P}$. Then $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ are independent if and only if each of $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ is multinormal on $\mathbb{R}^k$ [14].

Characteristic 6. For $\mathbf{X} \in \mathbb{R}^k$, the distribution $\mathscr{L}(\mathbf{X})$ is multivariate normal if and only if every linear combination $L = a_1X_1 + \cdots + a_kX_k$ is normal on $\mathbb{R}^k$.

Characteristic 7. The conditional expectation $\mathrm{E}(\overline{\boldsymbol{X}} | \mathbf{X}_2 - \mathbf{X}_1, \ldots, \mathbf{X}_n - \mathbf{X}_1)$ is constant, independently of values of the conditioning variables, if and only if $(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ are multinormal on $\mathbb{R}^k$ [19].

Central Limit Theory on $\mathbb{R}^k$

Central Limit Theorems

The simplest central limit theorem on $\mathbb{R}^k$ is for iid random vectors having finite means and dispersion parameters. Details follow.

Theorem 1. Let $(\mathbf{X}_1, \mathbf{X}_2, \ldots)$ be iid random vectors on $\mathbb{R}^k$ having the finite mean vector $\boldsymbol{\mu}$ and dispersion matrix $\boldsymbol{\Sigma}$, and let $\overline{\boldsymbol{X}}_n = n^{-1}(\mathbf{X}_1 + \cdots + \mathbf{X}_n)$. Then, as $n \to \infty$, the limit distribution of $n^{1/2}(\overline{\boldsymbol{X}}_n - \boldsymbol{\mu})$ is multivariate normal on $\mathbb{R}^k$, i.e. $\mathscr{L}_\infty(n^{1/2}[\overline{\mathbf{X}}_n - \boldsymbol{\mu}]) = \mathrm{N}_k(\mathbf{0}, \boldsymbol{\Sigma})$.

Limit theorems on $\mathbb{R}^k$ are also known for nonidentical summands and even for certain dependent

vector sequences. An example of the former is the following.

Theorem 2. Let $(\mathbf{X}_1, \mathbf{X}_2, \ldots)$ be a sequence of independent random vectors in $\mathbb{R}^k$ having cdfs $[F_i(\cdot), i = 1, 2, \ldots]$ with finite means and dispersion parameters $[(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i), i = 1, 2, \ldots]$; let $\overline{\boldsymbol{X}}_n = n^{-1}(\mathbf{X}_1 + \cdots + \mathbf{X}_n)$ and $\overline{\boldsymbol{\mu}}_n = n^{-1}(\boldsymbol{\mu}_1 + \cdots + \boldsymbol{\mu}_n)$. Suppose that, as $n \to \infty$: (i) $n^{-1}\sum_{i=1}^n \boldsymbol{\Sigma}_i \to \boldsymbol{\Sigma} \neq \mathbf{0}$; and (ii) for every $\varepsilon > 0$, $n^{-1}\sum_{i=1}^n \int_{||\mathbf{x}|| > \varepsilon\sqrt{n}} ||\mathbf{x}||^2 \, \mathrm{d}F_i(\mathbf{x}) \to 0$. Then, as $n \to \infty$, the random vector $n^{1/2}(\overline{\mathbf{X}}_n - \overline{\boldsymbol{\mu}}_n) \in \mathbb{R}^k$ **converges** in law to the normal distribution $\mathrm{N}_k(\mathbf{0}, \boldsymbol{\Sigma})$ on $\mathbb{R}^k$.

Multivariate normality is thus assured in the limit under the existence of second moments. If third moments are defined, then it is often possible to get bounds on the rate of convergence of standardized vector sums to a multinormal limit. Such bounds are called *Berry–Esseen bounds*, to be considered next.

Berry–Esseen Bounds

To proceed, let $\mathbf{C}$ be the class of all measurable convex sets in $\mathbb{R}^k$, and let $\mathbf{C}_N \subset \mathbf{C}$ be the subclass consisting of continuity sets of some probability measure $P_N(\cdot)$ to be identified. The following lemma is basic; for a proof see [16].

Lemma 1. Let $(\mathbf{X}_1, \ldots, \mathbf{X}_N)$ be an iid sequence in $\mathbb{R}^k$ whose typical member $\mathbf{X} = [X_1, \ldots, X_k]'$ has zero means, the nonsingular dispersion matrix $\boldsymbol{\Sigma}$, and finite absolute third moments $[\mathrm{E}(|X_i|^3) = \beta_{3i}; 1 \leq i \leq k]$. Let $P_N(\cdot)$ be the probability measure associated with $N^{-1/2}(\mathbf{X}_1 + \cdots + \mathbf{X}_N)$, and let $P(\cdot)$ be its multivariate normal limit having zero means and dispersion matrix $\boldsymbol{\Sigma}$. Then, for each $N = 1, 2, \ldots,$

$$\sup_{A \in C} |P_N(A) - P(A)| \leq c(k) \sum_{i=1}^k \frac{\gamma_i^{3/2}\beta_{3i}}{N^{1/2}}, \qquad (2)$$

where $\boldsymbol{\Gamma} = (\gamma_{ij}) = \boldsymbol{\Sigma}^{-1}$ and $c(k)$ is a finite positive constant depending only on k. Moreover, if $A \in C_N$, then

$$\sup_{A \in C_N} |P_N(A) - P(A)| \leq 1.595k^3 \sum_{i=1}^k \frac{\gamma_i^{3/2}\beta_{3i}}{\delta N^{1/2}}, \quad (3)$$

where δ^2 is the ratio of the smallest to the largest eigenvalue of $\boldsymbol{\Sigma}$.

Inequality (2) was given independently by Bhattacharya [4], Sazonov [25], and, in a somewhat different form, by Bergström [3]. Moreover, Bergström [3] has shown that $c(k)$ can be replaced by $c_0 k^3/\delta$, where c_0 is an absolute constant and δ^2 is as defined.

The foregoing results admit numerous applications in statistical inference in assessing the accuracy of large-sample approximate procedures. To fix ideas, consider Pearson's [22] **chi-square test** for **goodness of fit** in testing $\mathrm{H} : \boldsymbol{\pi} = \boldsymbol{\pi}_0$ against general alternatives, where $\boldsymbol{\pi} = [\pi_1, \ldots, \pi_k]'$ are the actual and $\boldsymbol{\pi}_0 = [\pi_{10}, \ldots, \pi_{k0}]'$ the hypothetical **multinomial** probabilities. Let X_N^2 be Pearson's statistic based on a sequence of N independent trials, and let $F_N(\cdot)$ be its actual, and $\Psi_\nu(\cdot)$ its limiting cdf – central or noncentral as appropriate. Then Lemma 1 applies directly to the following effect. Suppose that the test is carried out at the nominal level α based on asymptotics, whereas its actual level is α_N, typically unknown. Then lower and upper bounds on the actual level, in terms of the nominal level α and the natural parameters of the problem, as supported by Lemma 1, are given by

$$\alpha - \frac{B(\pi_0)}{N^{1/2}} \leq \alpha_N \leq \alpha + \frac{B(\pi_0)}{N^{1/2}}, \qquad (4)$$

where

$$B(\pi) = c(\nu) \sum_{i=1}^{\nu} \left[\left(\frac{1}{\pi_i}\right) + \left(\frac{1}{\pi_k}\right)\right] \pi_i \times (1 - \pi_i)[1 - 2\pi_i(1 - \pi_i)] \qquad (5)$$

is to be evaluated at π_0, and $\nu = k - 1$. Similar bounds may be found for the actual power of the test in a sequence of N independent trials at a fixed alternative to H. Moreover, these bounds may be evaluated numerically in particular cases using expression (3). For further details see [15].

Similar developments apply in the case of Friedman's [9] test in a two-way analysis of variance based on ranks (*see* **Nonparametric Methods**). Details are given in [16].

There is by now a considerable literature pertaining to multivariate normal distributions, multidimensional limit theory with and without moments, and Berry–Esseen bounds on rates of convergence to a multinormal limit. A lengthy and detailed reference list is omitted here; access is readily available through

searching electronic databases such as the *Current Index to Statistics*, for example.

Multivariate Normality, Tests of

The **multivariate normal** density is

$$f(\mathbf{X}) = [(2\pi)^{m/2}|\boldsymbol{\Sigma}|^{1/2}]^{-1} \times \exp[-\left(\tfrac{1}{2}\right)(\mathbf{X}-\boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{X}-\boldsymbol{\mu})],$$

where $\mathbf{X}$ is an m-variate random variable, $\boldsymbol{\mu}$ is the mean vector, and $\boldsymbol{\Sigma}$ is the symmetric **covariance matrix**. Most tests for multivariate normality take advantage of properties that are unique to the multivariate normal distribution. One property is the necessary, though not sufficient, condition that the marginal distributions of $\mathbf{X}$ are univariate normal. This permits the use of a univariate test of normality to determine if there is nonnormality in any of the marginals (*see* **Normality, Tests of**). However, **correlation** among the variates results in correlation between the m univariate tests, causing difficulty in determining their joint distribution. D'Agostino [6] suggests a **Bonferroni** approach, i.e. applying each test for marginal normality at the α/m level (*see* **Multiple Endpoints, *P* Level Procedures**).

A second property is that if there exists correlation between any pair of variates, then the relation is strictly linear. A third property is that any linear combination of the variates is normally distributed.

A fourth property of the multivariate normal distribution is that the quadratic form $(\mathbf{X}_i-\boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{X}_i-\boldsymbol{\mu}) = c$ forms an ellipse of constant probability in m-space. A related property is that the angles between the marginal projection of the n observation vectors $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ onto any of the variate planes and an arbitrary fixed vector through the mean have a **uniform distribution** over the interval $(0, 2\pi)$, denoted $\mathrm{U}(0, 2\pi)$, and these angles are independent of the vector lengths.

Based on these properties, the *scaled* **residuals** from a sample of size n,

$$\mathbf{Z}_i = \boldsymbol{\Sigma}^{-1/2}(\mathbf{x}_i - \boldsymbol{\mu}),$$

where $\boldsymbol{\Sigma}^{1/2}$ is the symmetric square root of the covariance matrix, are m-variate standard normal, $\mathrm{N}(\mathbf{0}_m, \mathbf{I}_m)$. The squared **Mahalanobis distance** (*squared radii*)

$$R_i^2 = \mathbf{Z}_i'\mathbf{Z}_i = (\mathbf{x}_i-\boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x}_i-\boldsymbol{\mu})$$

is the squared length of the vector from the mean $\boldsymbol{\mu}$ to the observation in m-space relative to the probability ellipses. Under multivariate normality the R_i^2 follow a **chi-square distribution** with m **degrees of freedom** (χ_m^2). More commonly, when the true parameters are unknown, the $\mathbf{Z}_i$ and R_i^2 can be estimated by

$$\mathbf{z}_i = \mathbf{S}^{-1/2}(\mathbf{x}_i - \bar{\mathbf{x}}), \tag{1}$$

where $\mathbf{S}^{1/2}$ is the symmetric square root of $\mathbf{S}$, and

$$r_i^2 = \mathbf{z}_i'\mathbf{z}_i = (\mathbf{x}_i-\bar{\mathbf{x}})'\mathbf{S}^{-1}(\mathbf{x}_i-\bar{\mathbf{x}})$$

for some efficient estimators $\bar{\mathbf{x}}$ of $\boldsymbol{\mu}$ and $\mathbf{S}$ of $\boldsymbol{\Sigma}$. The $\mathrm{N}(\mathbf{0}_m, \mathbf{I}_m)$ and χ_m^2 only approximate the distributions of the $\mathbf{z}_i$ and r_i^2; the r_i^2 are more closely related to an appropriately parameterized **beta distribution**.

Multivariate analyses are sometimes distinguished by whether they are invariant under linear transformations or dependent upon the original data coordinate system. Therefore, while most of the tests described are affine-invariant, in certain cases tests which are coordinate-dependent may be more pertinent to a specific situation.

Plots

One approach to assessing multivariate normality is to use univariate probability plots to assess each of the marginal variables (*see* **Graphical Displays**). Scatter plots of all variables taken two at a time are an effective way to identify **outliers** and nonlinear relations between variables. A third approach includes ordering the marginal observations independently and plotting the ordered observations against each other taking the variates two at a time. These plots are equivalent to normal probability plots and should follow a linear pattern.

One common type of probability plot, called quantile–quantile (Q–Q) plots, is produced by plotting the **order statistics**, or sorted observations, of a sample on the horizontal axis against the expected values of the order statistics from the reference (e.g. normal) distribution on the vertical axis (*see* **Normal Scores**). Probability paper is also available for some distributions, where the probabilities are scaled to the expected values on the vertical axis. If a sample comes from the reference distribution, the plot should be approximately linear. Healy [9] suggested using probability plots of the r_i^2 relative to a χ_m^2 distribution.

However, especially for smaller samples, the r_i^2 are better approximated by a beta variable of the first kind with parameters $a = m/2$ and $b = (n - m - 1)/2$. In particular, if

$$y = \frac{nr^2}{(n-1)^2},$$

then y has the density given by

$$f(y) = \frac{y^{a-1}(1-y)}{B(a,b)},$$

where $B(a, b)$ is the beta function, given by

$$B(a,b) = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}$$

and $\Gamma(\cdot)$ is the **gamma** function.

In the bivariate case the angles θ_i made by the observation vectors with the x_1 axis are uniform over the interval $(0, 2\pi)$. Therefore, a uniform probability plot of $\theta_i^* = \theta_i/2\pi$ can provide another indication of nonnormality in the data. By defining $u_i = F(r_i^2)$, where F is the χ_2^2 distribution function, a bivariate plot of (u_i, θ_i^*) should be uniform over the unit square, although here also F may be better defined as the appropriate beta distribution. For $m > 2$, one of the $m - 1$ angles made between the projections of the data onto each of the variate planes and, say, the x_1 axis is $U(0, 2\pi)$. The remaining $m - 2$ angles have a distribution proportional to $\sin^{m-1-j}\theta_j$, $0 \le \theta_j \le \pi$, $j = 1, \ldots, m-2$ [1].

Also for the bivariate case, the distribution of the R_i^2 under normality is given by $F(R^2) = 1 - \exp(R^2/2)$, where F is the cdf of the χ_2^2 distribution. Then, the plot of $(R_{(i)}^2, Y_{(i)})$ should fall randomly about the line

$$Y_{(i)} = \log_{10}[1 - F(R_{(i)}^2)] = 0.271R_{(i)}^2 \qquad (2)$$

[11, 22], where the estimate of $Y_{(i)}$ is $\log_{10}[(n - i + 0.5)/n]$. If the r_i^2 are compared with the beta distribution, then the plot of $(R_{(i)}^2, Y_{(i)})$ should approximate the curve

$$Y_{(i)} = 0.217(n-3)\log_e\left[\frac{1 - nr_{(i)}^2}{(n-1)^2}\right], \qquad (3)$$

which reduces to (2) as n gets large. The line described by (3) gradually curves away from the straight line with slope -0.217, with more and earlier curvature for small n.

Easton & McCulloch [7] presented a multivariate Q–Q plot based on matching the observed data with a multivariate reference sample. By assigning the Euclidean distance between two points as the cost function of matching the observed $\mathbf{x}_i$ with $\mathbf{y}_j$ from the reference sample, the "best" matching is found by identifying that permutation of the data, σ^*, in the set P of all permutations which solves

$$\min_{\sigma \in P} \sum_{1}^{n} ||\mathbf{y}_i - \mathbf{x}_{\sigma(i)}||^2.$$

If the data and the reference sample have the same shape, then $\mathbf{X}$ and $\mathbf{Y}$ will have the same shape if there is an $m \times m$ matrix $\mathbf{A}$, an m-vector $\mathbf{b}$, and a permutation σ such that $\mathbf{A}\mathbf{x}_{\sigma(i)} + \mathbf{b} \approx \mathbf{y}$. Given a reference sample, the matching problem can be solved by alternating between optimizing the permutation for fixed $\mathbf{A}$ and $\mathbf{b}$, and then reoptimizing $\mathbf{A}$ and $\mathbf{b}$ for the current permutation σ. They used an assignment **algorithm** to obtain the optimal permutation at each step and a multivariate normal random sample as the reference.

If $\mathbf{x}_i{}^* = \mathbf{A}^*\mathbf{x}_{\sigma^*(i)} + \mathbf{b}^*$ is the best matching of the data to the reference sample, then the first displays to consider are probability plots of each of the components of $\mathbf{x}^*$ vs. $\mathbf{y}$. These plots will have a fuzzy appearance, but the usual deviations from linearity will appear in the presence of outliers, skewness, or heavy/light-tailedness of the data. Isolated points may stand out in the middle of these plots, and large or heterogeneous variability around the 45° line may indicate deviation from normality.

A second display from this matching procedure is a distance Q–Q plot. For this, a second reference sample $\mathbf{U}$ is drawn. Then the n Euclidean distances between $\mathbf{X}^*$ and $\mathbf{Y}$ are plotted against those obtained from matching $\mathbf{U}$ and $\mathbf{Y}$, since the distances should be similar.

Skewness and Kurtosis

Because of the popularity and good power properties of univariate moment tests for normality, it seems only natural that the first tests for assessing multivariate normality would extend the notion of **skewness** and **kurtosis** to a multivariate setting. Small [29] combined the marginal skewness and the marginal kurtosis values to obtain combined skewness and combined kurtosis tests, respectively. Let

$\mathbf{B}_1$ and $\mathbf{B}_2$ be the m-vectors of marginal skewness and kurtosis values, respectively. By applying the Johnson S_u transformations [4], component-wise to $\mathbf{B}_1$ and $\mathbf{B}_2$ as univariate transformations to normality, the transformed vectors $\mathbf{y}(\mathbf{B}_1)$ and $\mathbf{y}(\mathbf{B}_2)$ can be used to obtain

$$Q_1 = \mathbf{y}(\mathbf{B}_1)'\mathbf{U}_1^{-1}\mathbf{y}(\mathbf{B}_1)$$

and

$$Q_2 = \mathbf{y}(\mathbf{B}_2)'\mathbf{U}_2^{-1}\mathbf{y}(\mathbf{B}_2)$$

as test statistics, where $\mathbf{U}_1 = (\hat{\rho}_{ij}^3)$, $\mathbf{U}_2 = (\hat{\rho}_{ij}^4)$, and the $\hat{\rho}_{ij}$ are the sample correlations. Q_1 and Q_2 are each approximated by a χ_m^2 distribution, and an omnibus test $Q = Q_1 + Q_2$ is approximately χ_{2m}^2.

Mardia [18] presented sample estimates of multivariate skewness and kurtosis, calculated from generalized versions of the squared radii,

$$r_{ij} = \mathbf{z}_i'\mathbf{z}_j = (\mathbf{x}_i - \overline{\mathbf{x}})'\mathbf{S}^{-1}(\mathbf{x}_j - \overline{\mathbf{x}}).$$

Note that, using this notation, $r_{ii} = r_i^2$. Mardia's skewness and kurtosis measures are, respectively,

$$b_{1,m} = n^{-2}\sum_{i,j=1}^{n} r_{ij}^3$$

and

$$b_{2,m} = n^{-1}\sum_{1}^{n} r_{ii}^2 = n^{-1}\sum_{1}^{n}(r_i^2)^2.$$

Under multivariate normality the exact moments of the two tests are

$$\mathrm{E}(b_{1,m}) = \frac{m(m+2)[(n+1)(m+1)-6]}{(n+1)(n+3)}$$

with unknown variance, while

$$\mathrm{E}(b_{2,m}) = \frac{m(m+2)(n-1)}{(n+1)}$$

$$\mathrm{var}(b_{2,m}) = \frac{8m(m+2)(n-3)(n-m-1)(n-m+1)}{(n+1)^2(n+3)(n+5)}$$

Mardia [19]. Mardia & Zemroch [21] gave a FORTRAN subroutine for calculating $b_{1,m}$ and $b_{2,m}$.

Mardia & Foster [20] presented several omnibus tests based on combinations of $b_{1,m}$ and $b_{2,m}$. $C_w^2 = \mathbf{w}^{\mathrm{t}}\mathbf{W}^{-1}\mathbf{w}$ accounts for correlation between $b_{1,m}$ and $b_{2,m}$, where the vector $\mathbf{w}$ has elements $b_{1,m}$ and $b_{2,m}$ under transformations to normality and $\mathbf{W}$ is the correlation matrix associated with $\mathbf{w}$; entries of $\mathbf{w}$ are

$$w(b_{1,m}) = \frac{1}{6}(2f)^{1/2}6\left[\frac{4nf^2}{3}b_{1,m}\right]^{1/3} - 18f + 4$$

and

$$w(b_{2,m}) = 3\left[\frac{f_1}{2}\right]^{1/2} \times \left(\frac{(1-2)/f_1}{1 + s[2/(f_1-4)^{1/2}]^{1/3} + 2/9f_1 - 1}\right),$$

where

$$s = \frac{b_{2,m} - \mathrm{E}(b_{2,m})}{[\mathrm{var}(b_{2,m})]^{1/2}},$$

$$f = \frac{m(m+1)(m+2)}{6},$$

and

$$f_1 = 6 + [8m(m+2)(m+8)^{-2}]^{1/2} \times \sqrt{n}\{[m(m+2)/2]^{1/2}/(m+8)(n)^{1/2} + [1 + 0.5nm(m+2)/(m+8)^2]^{1/2}\}.$$

$\mathbf{W}$ is a matrix with 1s on the diagonal and $c = \mathrm{cov}[W(b_{1,m}), W(b_{2,m})]$ as the off-diagonal elements, where

$$c = (f_1/16f) - (40/9)(1 - 2/f_1) \times [1/(f_1-4)] + (n/3\sigma)(1-2/f_1)^{1/3} \times [2/(f_1-4)^{1/2}]\mathrm{cov}(b_{1,m}b_{2,m}) + \cdots$$

by Taylor expansion and $\sigma^2 = \mathrm{var}(b_{2,m})$. Alternatively, the omnibus test, $S_w^2 = W(b_{1,m}) + W(b_{2,m})$, can be used.

Two other omnibus tests are based on a normal approximation to a χ^2 variable for $b_{1,m}$,

$$\mathrm{U}(b_{1,m}) = \frac{n(b_{1,m} - 6f/n)}{(72f)^{1/2}}$$

and a transformation to normality of $b_{2,m}$,

$$\mathrm{U}(b_{2,m}) = \frac{(n)^{1/2}[b_{2,m} - m(m+2)(n-1)/(n+1)]}{[8m(m+2)]^{1/2}}.$$

The omnibus tests are

$$S_n^2 = \mathrm{U}^2(b_{1,m}) + \mathrm{U}^2(b_{2,m})$$

and

$$C_n^2 = \mathbf{b}'\mathbf{V}^{-1}\mathbf{b},$$

where

$$\mathbf{b}' = [b_{1,m} - 6f/n, \quad b_{2,m} - m(m+2)(n-1)/(n+1)]$$

and

$$\mathbf{V} = \begin{bmatrix} 72f/n^2 & 12m(8m^2 - 13m + 23)/n^2 \\ 12m(8m^2 - 13m + 23)/n^2 & 8m(m+2)/n \end{bmatrix}.$$

These four omnibus tests are approximately χ_2^2 under the null hypothesis.

Malkovich & Afifi [17] defined the distribution of a random vector $\mathbf{X}$ to have multivariate skewness if

$$\beta_1(\mathbf{C}) = \frac{\mathrm{E}\{[\mathbf{C}'\mathbf{X} - \mathbf{C}'\mathrm{E}(\mathbf{X})]^3\}^2}{\mathrm{var}(\mathbf{C}'\mathbf{X})^3} > 0$$

for some vector $\mathbf{C}$; without loss of generality, we can assume that $\mathbf{C}'\mathbf{C} = 1$. Similarly, multivariate kurtosis was defined as

$$\beta_2(\mathbf{C}) = \frac{\mathrm{E}[\mathbf{C}'\mathbf{X} - \mathbf{C}'\mathrm{E}(\mathbf{X})]^4}{\mathrm{var}(\mathbf{C}'\mathbf{X})^2} \neq 3$$

for some vector $\mathbf{C}$.

They derived ${b_1}^*$ and $({b_2}^*)^2$, based on

$$b_{1,y} = \frac{n\left[\sum_1^n (y_j - \overline{y})^3\right]^2}{\left[\sum_1^n (y_j - \overline{y})^2\right]^3}$$

and

$$b_{2,y} = \frac{n\sum_1^n (y_j - \overline{y})^4}{\left[\sum_1^n (y_j - \overline{y})^2\right]^2},$$

with $y_i = \mathbf{C}'\mathbf{x}_i$; the hypothesis of no multivariate skewness is accepted if

$${b_1}^* = \max_{\mathbf{C}} b_{1,y}(\mathbf{C}) \leq K_1.$$

The hypothesis of no multivariate kurtosis is accepted if

$$({b_2}^*)^2 = \max_{\mathbf{C}}[b_{2,y}(\mathbf{C}) - K]^2 \leq K_2,$$

where K and K_2 are appropriate constants. Since kurtosis is not symmetrically distributed, K and K_2 should be chosen to weight the minimum and maximum values (over all $\mathbf{C}$) of $b_{2,y}$, evenly, so that the probabilities of finding a significant low or high value of kurtosis when the null hypothesis is true are each $\alpha/2$; as the sample size gets large, K converges to 3. For computational purposes, let

$$\mathbf{A} = \sum_1^n (\mathbf{x}_i - \overline{\mathbf{x}})(\mathbf{x}_i - \overline{\mathbf{x}})' \tag{4}$$

and $(\mathbf{A}^*)'\mathbf{A}\mathbf{A}^* = \mathbf{I}$, and define

$$y_j = (\mathbf{A}^*)'(\mathbf{x}_j - \overline{\mathbf{x}}), \quad j = 1, \ldots, n.$$

Then

$${b_1}^* = \max_{\mathbf{C}'\mathbf{C}=1} n\left[\sum_1^n (\mathbf{C}'\mathbf{y}_i)^3\right]^2$$

and

$$({b_2}^*)^2 = \max_{\mathbf{C}'\mathbf{C}=1} n\left[\sum_1^n (\mathbf{C}'\mathbf{y}_i)^4 - K\right]^2.$$

Computational details for the iterative method of calculating ${b_1}^*$ and $({b_2}^*)^2$ are given in Malkovich [16].

Under certain parametric restrictions, the multivariate **Pearson distribution** reduces to the multivariate normal. Bera & John [3] used Rao's score principle [25] (*see* **Likelihood**) to test those restrictions, in principle developing tests for Pearson alternatives. They defined

$$T_j = \sum_{i=1}^n \frac{z_{ij}^3}{n},$$

$$T_{jj} = \sum_{i=1}^n \frac{z_{ij}^4}{n},$$

and

$$T_{jk} = \sum_{i=1}^n \frac{z_{ij}^2 z_{ik}^2}{n},$$

where the z_{ij} are the jth component of the scaled residual $\mathbf{z}_i$, given by (1). T_j, T_{jj}, and T_{jk} are asymptotically independent and normal with means 0, 3, and

1 and variances $6/n$, $24/n$, and $4/n$, respectively. T_j is the univariate skewness test and T_{jj} is the univariate kurtosis test for the jth component of $\mathbf{z}$. Because of consistency conditions, they recommend first testing the m T_j values, using

$$C_1 = n \sum_1^m \frac{T_j^2}{6}$$

as a test for skewness, which is asymptotically χ^2_m. If C_1 is not significant, then test

$$C_2 = n \left[\frac{1}{24} \sum_1^m (T_{jj} - 3)^2 + \frac{1}{4} \sum_{j=1}^m \sum_{k=1}^{j-1} (T_{jk} - 1)^2 \right],$$

which is approximately $\chi^2_{m(m+1)/2}$. Omnibus tests are

$$C_3 = n \left[\frac{1}{6} \sum_1^m T_j^2 + \frac{1}{24} \sum_1^m (T_{jj} - 3)^2 \right]$$

and

$$C_4 = C_1 + C_2,$$

which can be tested using χ^2_{2m} and $\chi^2_{m(m+3)/2}$, respectively.

Koziol [13, 14] considered multivariate tests based on the theory of Neyman's smooth tests (*see* **Chi-square Tests**). His smooth test for skewness is algebraically equivalent to Mardia's $b_{1,m}$,

$$\hat{U}_3^2 = \frac{n b_{1,m}}{6},$$

while $\hat{U}_4^2$, the smooth test for kurtosis, contains $b_{2,m}$ as one of its components. Koziol [15] proposed

$$\tilde{b}_{2,m} = n^{-2} \sum_1^n \sum_1^n r_{ij}^4$$

and showed that

$$24n\hat{U}_4^2 = n^2 \tilde{b}_{2,m} - 6n^2 b_{2,m} + 3n^2 m(m+2).$$

Since the distribution of $\hat{U}_4^2$ is less complex than that of $\tilde{b}_{2,m}$, $\tilde{b}_{2,m}$ is only used to calculate the former statistic. $\hat{U}_3^2$ and $\hat{U}_4^2$ are asymptotically independent χ^2 variables with $\binom{p+2}{3}$ and $\binom{p+3}{4}$ df, respectively, under the null hypothesis.

Regression and Correlation Tests

The popularity and good power properties of regression and correlation tests for univariate normality suggested the extension of those methods to the multivariate case. Royston [27] proposed combinations of marginal Shapiro–Wilk W tests (*see* **Normal Scores**) for assessing multivariate normality. Using Royston's [26] **transformation** of W to normality, the test for each marginal is calculated using

$$z_i = \frac{(1 - W_i)^\lambda - \mu}{\sigma},$$

where λ, μ, and σ are functions of n. The values

$$k_i = \{\Phi^{-1}[(\tfrac{1}{2})\,\Phi(-z_i)]\}^2$$

are each approximately distributed as a χ^2_1 random variable. If the m variables were uncorrelated, then $G = \sum_1^m k_i/m \sim \chi^2_m/m$; at the other extreme, if the variates were perfectly correlated, then $G \sim \chi^2_1$. For intermediate correlations, Royston used $G \sim \chi^2_e/e$, where

$$e = \frac{m}{1 + (m-1)\overline{c}}$$

and

$$\overline{c} = \sum_1^m \sum_1^m \frac{\hat{c}_{ij}}{m^2 - m}.$$

The $\hat{c}_{ij}$ are estimates of the correlation between the k_i, which for $10 \le n \le 2000$ are calculated as

$$\hat{c}_{ij} = r_{ij}^5 \left[\frac{1 - 0.715(1 - r_{ij})^{0.715}}{0.35v} \right].$$

Malkovich & Afifi [17] presented a multivariate Shapiro–Wilk criterion, where multivariate normality is accepted if

$$\min_{\mathbf{D}} W_{\mathbf{D}} \ge K_W,$$

where $W_{\mathbf{D}}$ is the univariate Shapiro–Wilk test for the observations reduced by $z_i = \mathbf{D}'\mathbf{x}_i$. The vector $\mathbf{D}$ which gives a lower bound is given by

$$\mathbf{D}'(\mathbf{x}_1 - \overline{\mathbf{x}}) = \frac{(n-1)}{(na_1)},$$

$$\mathbf{D}'(\mathbf{x}_j - \overline{\mathbf{x}}) = -(na_1)^{-1}, \quad j > 1.$$

An approximate solution can be found by using

$$\mathbf{D} = a_1^{-1} \mathbf{A}^{-1} (\mathbf{x}_1 - \overline{\mathbf{x}}),$$

where a_1 is the first coefficient for the Shapiro–Wilk test and $\mathbf{A}$ is the matrix (4). Since any observation can be designated as x_1, the generalized statistic W^* can be obtained by identifying $\mathbf{x}_k$ as that observation for which

$$(\mathbf{x}_k - \overline{\mathbf{x}})'\mathbf{A}^{-1}(\mathbf{x}_k - \overline{\mathbf{x}}) = \max_{1 \le i \le n} (\mathbf{x}_i - \overline{\mathbf{x}})'\mathbf{A}^{-1}(\mathbf{x}_i - \overline{\mathbf{x}}). \tag{5}$$

Then the order statistics $G_{(i)}$ are found, where

$$G_i = (\mathbf{x}_k - \overline{\mathbf{x}})'\mathbf{A}^{-1}(\mathbf{x}_i - \overline{\mathbf{x}})$$

and the univariate Shapiro–Wilk test is applied to the $G_{(i)}$,

$$W^* = \frac{\left(\sum_1^n a_{n,j} G_{(j)}\right)^2}{(\mathbf{x}_k - \overline{\mathbf{x}})'\mathbf{A}^{-1}(\mathbf{x}_k - \overline{\mathbf{x}})}.$$

Of the set of n vectors used in (5), Fattorini [8] proposed using the vector $\mathbf{C}_M$ which minimized the Shapiro–Wilk statistic, so that $W_F{}^* \le W^*$.

Royston [27] suggested using either a χ^2 or beta distribution to transform the r_i^2 to approximate normality by

$$r_i' = \Phi^{-1}[F(r_i^2)],$$

where F is the selected cdf. Using the Shapiro–Wilk W and the normality transformation, Royston proposed the Ω test for m-normality. He further proposed examining all subsets of the m variates of size k, $k = 1, \ldots, m$. Each value of k gives $K = \binom{m}{k}$ non-independent tests $\Omega_1, \ldots, \Omega_k$. These tests may be inspected individually or further combined into a single test for each value of k:

$$\theta_k = \sum_1^k \{\Phi^{-1}[(\tfrac{1}{2})\,\Phi(-\Omega_i)]\}^2,$$

where $\theta_k \sim \chi_k^2$.

Tsai & Koziol [30] proposed a multivariate Shapiro–Francia [28] correlation test,

$$r_{m;n} = \frac{\sum_1^n (r_{(i)}^2 - \overline{r}^2)(Q_i - \overline{Q})}{\left[\sum_1^n (r_{(i)}^2 - \overline{r}^2)^2 \sum_1^n (Q_i - \overline{Q})^2\right]^{1/2}},$$

where the Q_i are the expected values of the χ_m^2 order statistics. Small values of $r_{m;n}$ indicate deviation from normality.

Other Tests

Univariate empirical distribution tests have been suggested for use with the $r_{(i)}^2$ (*see* **Goodness of Fit**; **Kolmogorov–Smirnov Test**). These include the Anderson–Darling A^2 and the Cramér–von Mises test [24], given by

$$J_n = \frac{1}{12n} + \sum_1^n \left[\frac{u_{(i)} - (i - 0.5)}{n}\right]^2,$$

where $u_{(i)} = F_m(r_{(i)})^2$, F_m being the χ_m^2 distribution function. A test of the uniformity of the angles θ_i using Rayleigh's test [12] is obtained by letting

$$\hat{\mathbf{l}}_i = r_i^{-1}\mathbf{z}_i.$$

Rayleigh's statistic is

$$\hat{\mathbf{R}} = n^{-1/2} \sum_1^n \hat{\mathbf{l}}_i.$$

$\hat{\mathbf{R}}$ is normal with mean vector $\mathbf{0}$ and covariance given by $\mathbf{V} = v\mathbf{I}$ with

$$v = m^{-1}[1 - 2/m(\{\Gamma[(m+1)/2]/\Gamma(m/2)\})^2].$$

$R_y = \hat{\mathbf{R}}'\mathbf{V}^{-1}\hat{\mathbf{R}}$ can be compared to a χ_m^2 distribution to obtain probability levels. Since they are independent, if $p_1 = \Pr(x > J_n)$ and $p_2 = \Pr(x > R_y)$, where the probabilities are obtained for the observed test statistics J_n and R_y, then $-2(\log p_1 + \log p_2) \sim \chi_4^2$.

Ward [31] proposed estimating the cumulative distribution function of $\mathbf{X}$,

$$y_i = \hat{F}(\mathbf{x}_i) = \prod_{j=1}^m \Phi(z_{ij}),$$

and using the Kolmogorov–Smirnov D or Anderson–Darling A^2 test to test the goodness of fit of the y_i to the density

$$g(y) = \frac{(-\log y)^{m-1}}{\Gamma(m)}, \quad 0 < y < 1.$$

Here, the y_i have an inherently different ordering from the r_i^2: while the r_i^2 are minimized at the point $\mathbf{x} = \overline{\mathbf{x}}$, y_i tends towards its minimum value of 0 as each of the m variates goes away from $\overline{\mathbf{x}}$.

The χ^2 test is adaptable to any null distribution, including those that are multivariate in nature. As in the univariate case, cells must be defined and the expected and observed numbers of observations found in each must be ascertained. The problems with the univariate χ^2 test, however, must also be addressed in the multivariate setting, i.e. cell size and number of cells.

For the bivariate case, Kowalski [11] used the χ_2^2 distribution to determine cell sizes. If $2c^2 = (\mathbf{X} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu})$ is an ellipse of constant probability based on a multivariate normal distribution, then the volume of a ring between the ellipses defined by $2c^2$ and $2(c + dc)^2$ is

$$V = \exp(-c^2) - \exp[-(c + dc)^{-2}],$$

and nV observations would be expected to occur within the ring. Comparison of expected with observed of observations within rings can then be made using the standard χ^2 test. Mason & Young [22] used the beta approximation for the r_i^2,

$$W_c = \Pr(r_i^2 < 2c^2) = 1 - \left[\frac{1 - 2c^2 n}{(n-1)^2}\right]^{(n-3)/2}.$$

To obtain rings of equal size, the approximate relationship

$$2c^2 = n\left[1 - \frac{1-i}{k}\right]^{2/(n-3)}$$

can be used for a specified number, k, of cells and $n(W_{c+dc} - W_c)$ observations will be within the ring defined by c and $c + dc$. Moore & Stubblebine [23] extended Kowalski's χ^2 test to a general dimension m.

Cox & Small [5] proposed pairwise testing for linearity between components of a multivariate distribution using Q_{ij}, the **Student's *t* statistic** of significance for the coefficient of x_j^2 when x_i is regressed on x_j and x_j^2. For the purpose of symmetry, the joint statistic $(Q_{ij}, Q_{j,i})$ is used. Then (for large samples),

$$\max(|Q_{i,j}|, |Q_{j,i}|)$$

can be referred to tables of the bivariate normal distribution, or

$$\mathbf{Q}'\mathbf{R}^{-1}\mathbf{Q}$$

can be used as a χ_2^2 test, where $\mathbf{Q} = [Q_{i,j}\ Q_{j,i}]$,

$$\mathbf{R} = \begin{bmatrix} 1 & \tilde{\rho}_{ij}(2 - 3\tilde{\rho}_{ij}^2) \\ \tilde{\rho}_{ij}(2 - 3\tilde{\rho}_{ij}^2) & 1 \end{bmatrix},$$

and $\tilde{\rho}_{ij}$ is the observed correlation between the components. An alternative is a regression of each component x_i on all other components x_k and x_j^2. From the $m(m-1)$ regressions, the Q values may be ordered and plotted on a normal probability plot, provided the sample size is sufficiently large.

Andrews et al. [1] projected the data along directions which are chosen to be sensitive to particular types of nonnormality. Since nonnormality in the data may result in nonnormal clustering of points, the vector

$$\mathbf{d}_\alpha = \frac{\sum_1^n w_i \mathbf{z}_i}{\left\| \sum_1^n w_i \mathbf{z}_i \right\|}$$

may be used to point to these clusters, where $w_i = ||\mathbf{z}_i||^\alpha$ and α is a constant to be chosen which will determine the region of sensitivity. In particular, if $\alpha < 0$, then d_α points in the direction of nonnormal clusters near the mean, while for $\alpha > 0$, d_α points to clusters far from the mean. The observations can be projected onto the direction identified by ${d_\alpha}^* = S^{1/2} d_\alpha$, and the lengths of the projections ${d_\alpha}^*$ will, under the null hypothesis, form a univariate normal sample which can be tested using any univariate test for normality.

Andrews et al. [2] proposed the nearest distance test for ascertaining joint normality. The initial step consists of transforming the data to the unit hypercube by using the $\mathbf{z}_i$ and calculating the vector $\mathbf{y}_i$, where the entries are defined by $y_{ij} = \Phi(z_{ij})$. After calculating the distances

$$d(i, i') = \max_k \left[\min(|y_{ki} - y_{ki'}|, ||y_{ki} - y_{ki'}| - 1|)\right],$$

the nearest distance is found:

$$d_{\min} = \min_{i' \neq i} d(i, i').$$

These distances are further transformed to standard normal deviates: for each y_i let

$$w_i = \Phi \frac{1 - \exp\{-n[2d_{\min}(i)]^p\}}{1 - \exp(-1)},$$

if and only if $d_{\min}(i) < 1/2n^{1/p}$ and $d(i, i') > 1/2n^{1/p}$, $i' < i$. Under the null hypothesis, the transformed distances are independent of the coordinates from which they are measured; this independence can be measured using multiple regression. For all of the $n' \leq n$ points that follow these two conditions, fit the regression model

$$w_i = \beta_0 + \sum_{j=1}^{m} \beta_j x_{ij} + \sum_{j=1}^{m} \sum_{k=1}^{m} \beta_{jk} x_{ij} x_{ik}.$$

The regression sum of squares should be compared with a $\chi^2_{(p+1)(p+2)/2}$.

Henze & Zirkler [10] presented a class of invariant consistent tests for composite multivariate normality, based on the weighted integral of the difference between the empirical characteristic function and its pointwise limit. The test is given by

$$T_\beta = n(4I_{(\mathbf{S} \text{ singular})} + D_{n,\beta} I_{(\mathbf{S} \text{ nonsingular})}),$$

where I is the indicator function and

$$D_{n,\beta} = n^{-2} \sum_{j,k=1}^{n} \exp\left[-\frac{\beta^2}{2} ||\mathbf{z}_j - \mathbf{z}_k||^2\right] + (1 + 2\beta^2)^{-m/2} - 2(1 + \beta^2)^{-m/2} n^{-1} \times \sum_{j=1}^{n} \exp\left\{\frac{-\beta^2}{[2(1 + \beta^2)]r_j^2}\right\},$$

where

$$||\mathbf{z}_j - \mathbf{z}_k||^2 = (\mathbf{x}_j - \mathbf{x}_k)' \mathbf{S}^{-1} (\mathbf{x}_j - \mathbf{x}_k)$$

and

$$\beta = \frac{1}{\sqrt{2}} \left[\frac{n(2m + 1)}{4}\right]^{1/(m+4)}.$$

T_β rejects the null hypothesis when the test value is too large. When $\mathbf{S}$ is singular, $D_{n,\beta}$ is undefined, so T_β is set to its maximum value of 4, causing rejection of the null hypothesis.

Recommendations

Since there are many types of departures from multivariate normality, a single best test may not exist. A multivariate test may dilute the effects of a subset of nonnormal components, while marginal tests may miss departures in multivariate combinations of variables. Because many of the testing procedures are difficult to program and are not included in available statistical packages, and critical values are not always available, and because of the lack of definitive power studies, it is difficult to evaluate the relative usefulness of the tests. However, the Bera & John [3] tests and Mardia's skewness, kurtosis, and omnibus tests seem to have relatively high **power** against a variety of alternatives. The T_β tests, and in particular the parameterization with $\beta = 0.5(T_{0.5})$, also seem to have good power properties over a wide variety of alternatives [10].

Multivariate Outliers

Outlier *rejection* based on an appropriate *test of discordancy* is just one prospect; alternatives include *accommodation* (outlier-robust) procedures, which limit the effects of possible contamination on inferring properties of the principal uncontaminated data source, or *identification* of the nature of the contamination as an interest in its own right. Such approaches need appropriate *outlier models* to reflect the possible uncontaminated or contaminated forms of the underlying population.

This same range of possible actions (rejection, accommodation, identification), of procedures and of models applies to *multivariate* also, but with a crucial difference. For univariate data outliers are extremes: they "stick out at the ends of the sample". For multivariate data, there is no natural concept of an extreme, and *outlier-detection procedures* will be needed to reveal outlying data points.

Multivariate data may contain outliers, of course. They appear as observations lying well out on the periphery of the data cloud. But what is "well out"? We need appropriate formalizations of this notion for *detecting* multivariate outliers before examining the range of models procedures for the statistical analysis of multivariate outliers (a comprehensive review is provided in Chapter 7 of [7]).

Interest in **outliers** (or "spurious observations" or "mavericks") goes back to the origins of statistical enquiry. As observations in a univariate sample, they are not only extreme but are "extremely extreme" – they trigger concern for whether they are truly part of the population under investigation or reflect "contamination" from some other low-incidence source. Early preoccupation with rejecting such observations "to restore the integrity of the sample", or of steadfastly retaining them, so as not to "distort the message of the data" has been replaced in modern times by more sophisticated considerations.

Thus, whilst *rejection* based on an appropriate statistical procedure (a *test of discordancy*) is still a prospect, alternatives include *accommodation* (outlier-robust) procedures which limit the effects of possible contamination on inferring properties of the principal uncontaminated data source, or *identification* of the nature of the contamination as an interest in its own right. Such approaches need to be based on appropriate *outlier models* to reflect the possible uncontaminated or contaminated forms of the underlying population and its distributional characteristics. Such attitudes and approaches to outlier study provide a sound basis for handling outliers (see, for example, Barnett [3]) and for the vast array of specific statistical inference procedures which have been developed for studying outliers in recent times. Barnett & Lewis [7] provide a comprehensive review of the field, not only for basic univariate data, but for more structured relational models such as linear models (**regression** and designed experiments), **time series**, directional data (*see* **Circular Data Models**), **categorical data**, and general multivariate data (*see* **Diagnostics**; **Multivariate Analysis, Overview**).

In all these cases the ranges of possible actions (rejection, accommodation, identification), of procedures, and of models are essentially similar to those for univariate data. A crucial difference, however, is in the indication provided by the data of the presence of outlying observations. For univariate data the outliers are extreme values: they "stick out at the ends of the sample". In more structured or higher-dimensional data the stimulus is less obvious. Outliers in regression data may be detected by extreme residuals as distinctly breaking the pattern of relationship. For general multivariate data there is no natural concept of an extreme, and *outlier detection procedures* will be needed to reveal outlying data points.

The fact that multivariate data may contain outliers is not in dispute. They are often clearly signaled by observations lying well out on the periphery of the data cloud. See, for example, the observations marked A and B on the two-dimensional scatter plot shown in Figure 1. But what do we mean by "lying well out"? We need to consider appropriate formalizations of this notion for *detecting* multivariate outliers, and then proceed to examine the range of procedures for the statistical analysis of multivariate outliers (a comprehensive review is provided in [7, Chapter 7].

Principles for Multivariate Outlier Detection

We need some way of essentially "ordering" the multivariate data. No natural unambiguous ordering principle is possible in more than one dimension; but progress can be made using more modest *subordering principles*. Barnett [2] categorizes these in four

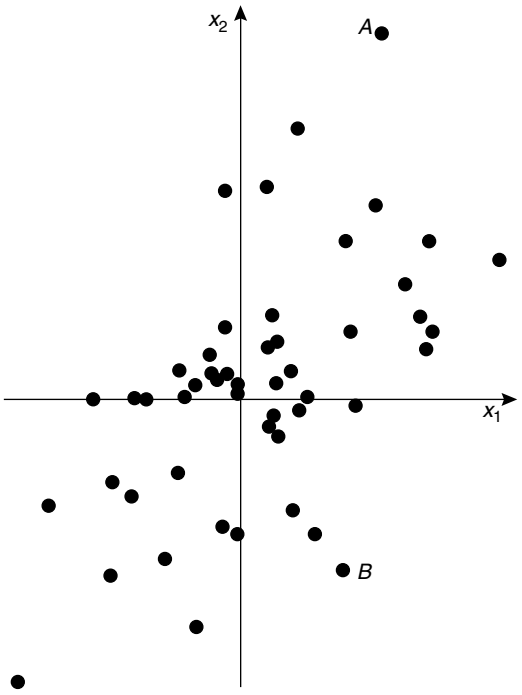

Figure 1 A bivariate sample

types: *marginal, reduced* (or *aggregate*), *partial*, and *conditional*. For outlier study, *reduced subordering* is almost the only principle that has been employed.

With reduced subordering we transform any multivariate observation $\mathbf{x}$, of dimension p, to a scalar quantity $R(\mathbf{x})$. We can then order a sample $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ in terms of the values $R_j = R(\mathbf{x}_j)$, $j = 1, 2, \ldots, n$. That observation $\mathbf{x}_i$ which yields the maximum value $R_{(n)}$ is then a candidate for declaration as an outlier – provided its extremeness is surprising relative to the basic model F. Specifically, an outlier $\mathbf{x}_i$ will be adjudged *discordant* if $R_{(n)}$ is unreasonably (statistically) large in relation to the distribution of $R_{(n)}$ under F. Thus the principle of a *test of discordance* is the same as it was for a univariate outlier.

However, many problems now arise which are specific to the multivariate case. Clearly, we may lose useful information on multivariate structure by employing reduced (or any other form of) subordering. So how are we to choose the reduction measure $R(\mathbf{x})$? Subjective choice is fraught with danger; multivariate data do not reveal their structure readily (or reliably) to casual observation.

Barnett [4] has considered general principles for the detection of multivariate outliers. He proposes two possibilities as follows.

Principle A

The most extreme observation is the one, $\mathbf{x}_i$, whose omission from the sample $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ yields the largest incremental increase in the maximized **likelihood** under F for the remaining data. If this increase is surprisingly large, declare $\mathbf{x}_i$ to be an outlier.

This principle requires only the basic model F to be specified. If we are prepared to adopt an alternative (contamination) model $\overline{F}$, e.g. of *slippage type* with one contaminant, we can set up a more sophisticated principle, as follows.

Principle B

The most extreme observation is the one, $\mathbf{x}_i$, whose assignment as the contaminant in the sense of $\overline{F}$ maximizes the difference between the log likelihoods of the sample under F and $\overline{F}$. If this difference is surprisingly large, declare $\mathbf{x}_i$ to be an outlier.

Such principles have been applied: Barnett & Lewis [7, Section 7.3] discuss applications to **multivariate normal, exponential,** and **Pareto** models. Often, however, the reduction metric $R(\mathbf{x})$ is chosen in an ad hoc (if intuitively supported) manner. For example, it is common to represent a multivariate observation $\mathbf{x}$ by means of a *distance measure*,

$$R(\mathbf{x}; \mathbf{x}_0, \boldsymbol{\Gamma}) = (\mathbf{x} - \mathbf{x}_0)' \boldsymbol{\Gamma}^{-1} (\mathbf{x} - \mathbf{x}_0),$$

where $\mathbf{x}_0$ reflects the location of the underlying distribution and $\boldsymbol{\Gamma}^{-1}$ applies a differential weighting to the components of the multivariate observation inversely related to their scatter or to the population variability. For example, $\mathbf{x}_0$ might be the zero vector, the true mean $\boldsymbol{\mu}$, or the sample mean $\bar{\mathbf{x}}$, and $\boldsymbol{\Gamma}$ might be the **covariance matrix** $\mathbf{V}$ or its sample equivalent $\mathbf{S}$, depending on the state of our knowledge about $\boldsymbol{\mu}$ and $\mathbf{V}$.

If the basic model F were multivariate normal, $\mathrm{N}(\boldsymbol{\mu}, \mathbf{V})$, the corresponding form,

$$R(\mathbf{x}; \boldsymbol{\mu}, \mathbf{V}) = (\mathbf{x} - \boldsymbol{\mu})' \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu}),$$

has substantial practical appeal in terms of probability density ellipsoids and turns out to have much broader statistical support, including accord with *Principle A*. In fact, the sample shown in Figure 1 is from a

bivariate normal distribution, and the appropriate elliptic density contours in Figure 2 highlight any intuitive concern we had for the observations A and B. For other distributions, $R(\mathbf{x}; \mathbf{x}_0, \mathbf{\Gamma})$ may or may not be appropriate, as we shall find later, but it is nonetheless widely used.

A **Bayesian** approach to outlier detection ("detection of spuriosity") arises from the work of Guttman [23]. It is interesting to note that the implicit concept of extremeness used to detect the outlier is again expressible in terms of the distance metric $R(\mathbf{x}; \boldsymbol{\mu}, \mathbf{V})$.

We now proceed to consider *accommodation procedures* and then *tests* of *discordancy* for multivariate outliers. With the greater complexity of the multivariate case, however, there also exist a wide range of *informal proposals* for outlier detection and processing – we shall consider some of these.

Accommodation

For multivariate data we often need statistical methods that are specifically robust against (i.e. which *accommodate*) outliers as manifestations of contamination. Such accommodation procedures exist for estimating parameters (often with specific regard to the multinormal distribution) and for various multivariate procedures (such as **principal components** and **discriminant analysis**).

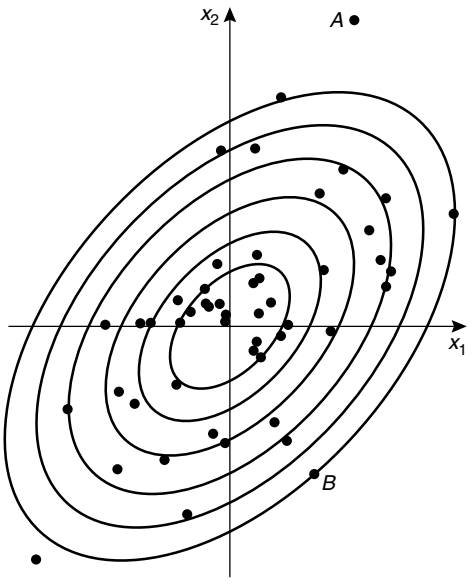

Figure 2 The sample with probability density ellipses

Suppose that, under a basic model F, $\mathbf{X}$ has mean vector $\boldsymbol{\mu}$ and covariance matrix $\mathbf{V}$. Outlier robust estimation of $\boldsymbol{\mu}$ and of $\mathbf{V}$ (also the correlation matrix, $\mathbf{R}$) has been widely examined, both in terms of individual components, and of the overall forms, of the mean vector and covariance matrix. For $\boldsymbol{\mu}$, the starting point is in an obvious generalization of the work of Anscombe [1]. For $\mathrm{N}(\boldsymbol{\mu}, \mathbf{V})$, we order the sample, and if $R_{(n)}(\mathbf{x}; \bar{\mathbf{x}}, \mathbf{V})$ (or $R_{(n)}(\mathbf{x}; \bar{\mathbf{x}}, \mathbf{S})$, depending on our knowledge about $\mathbf{V}$, is sufficiently large, then we omit the observation $\mathbf{x}$, yielding $R_{(n)}$, before estimating $\boldsymbol{\mu}$ from the residual sample; if $R_{(n)}$ is not sufficiently large, then we use the overall sample mean, $\bar{x}$. Such *adaptive trimming* is revised by Golub et al. [21], who employ a similar approach but based on *Winsorization* or "*semi-Winsorization*" (*see* **Trimming and Winsorization**). This approach can be extended to sequential trimming or Winsorization of several sufficiently extreme values. Guttman [23] considers the posterior distribution of $\mathbf{a}$ for a basic model $\mathrm{N}(\boldsymbol{\mu}, \mathbf{V})$ and mean-slippage alternative $\mathrm{N}(\boldsymbol{\mu} + \mathbf{a}, \mathbf{V})$ for at most one of the observations.

Some qualitative effects of outliers on estimation of $\mathbf{V}$, and corresponding attitudes to **robust** estimation, are considered by Devlin et al. [15] and by Campbell [11], who claims that outliers "tend to deflate correlations and possibly inflate variance", although this may be rather too simplistic a prescription. A tangible form for outlier-robust M-estimators of $\boldsymbol{\mu}$ and $\mathbf{V}$, relevant to an elliptically symmetric basic model, is considered by Maronna [28] and by Campbell [11].

An early proposal for *direct* robust estimation of the matrix $\mathbf{V}$ in positive-definite form was made by Gnanadesikan & Kettenring [20]. It involves selective iterative *trimming* of the sample based on values of some measure $R(\mathbf{x}; \mathbf{x}^*, \mathbf{I})$, where $\mathbf{x}^*$ is a robust estimator of $\boldsymbol{\mu}$. The procedure is intuitively appealing, but only limited empirical investigation is reported.

Rousseeuw & van Zomeren [30] are also concerned with outlier robust estimation of $\boldsymbol{\mu}$ and $\mathbf{V}$. Rejecting the M-estimators of Campbell [11] in view of the low breakdown point, they suggest alternative robust estimators with a higher breakdown point.

Gnanadesikan [19, Section 5.2.3] includes detailed proposals for constructing robust estimators of the *individual elements* of $\boldsymbol{\mu}$ and $\mathbf{V}$ as well as for directly "multivariate" estimators of $\boldsymbol{\mu}$ and $\mathbf{V}$. One difficulty

with such an approach is that, if we form estimators of **V** or of **R** from separate robust estimators of their elements, the resulting **V** and **R** may not be positive-definite. Devlin et al. [14] propose a remedy involving "shrinking" **R** until it is positive-definite, and rescaling it if an estimate of **V** is required. (They also review various ad hoc estimators of the correlation coefficient, for a bivariate normal distribution, based on partitioning the sample space, on transformations of Kendall's τ (*see* **Association, Measures of**) or on **normal scores**; see also [26]).

Another approach to outlier-robust estimation of correlation uses the ideas of convex hull "peeling" or ellipsoidal peeling (see [8, 32] for details) following the suggestion by Barnett [2] that the most extreme group of observations in a multivariate sample are those lying on the convex hull (with those on the convex hull of the remaining sample, the second most extreme group, etc). Figure 3 shows the successive convex hulls for the bivariate sample presented in Figure 2.

Any form of multivariate analysis is, of course, likely to be susceptible to outliers as the manifestation of contamination. Proposals for modified forms of multivariate analysis which give protection against outliers include those for *principal component analysis* using M-estimators [11], for *canonical variate analysis* (*see* **Canonical Correlation**) [12], and for *discriminant analysis* [10]. Critchley & Vitiello [13] further examine Campbell's approach to the influence of outliers in linear discriminant analysis with particular regard to estimates of misclassification probabilities. Outlier robust (accommodation) methods have also been advanced for **analysis of covariance** [9], **correspondence analysis** [16], and **multidimensional scaling** [31].

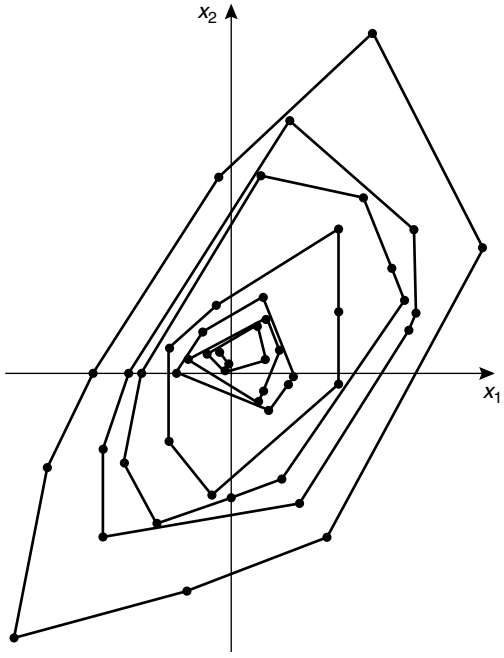

Figure 3 Convex hulls for the sample

Discordancy Tests

The notion of a test of discordancy is as relevant to multivariate data as it is to univariate samples, although conceptual and manipulative difficulties have limited the number of formal and specific proposals. Most work centres on the normal distribution, which proves amenable to the construction of tests of discordancy with desirable statistical properties and a useful degree of unity of form.

Suppose $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$ is a sample of n observations from a p-dimensional normal distribution, $N(\boldsymbol{\mu}, \mathbf{V})$. A possible alternative model which would account for a single contaminant is the slippage alternative, obtained as a multivariate adaptation of the univariate *models A* (slippage of the mean) and *B* (slippage of the variance) discussed by Ferguson [18]. A test of discordancy can be based on the *two-stage maximum likelihood ratio* principle (i.e. Principle B, above). Models A and B have been studied extensively with various assumptions about what parameter values are known [7, Section 7.3].

As an example, consider model A with **V** known. Here we are led to declare as the outlier $\mathbf{x}_{(n)}$ the observation $\mathbf{x}_i$ for which $R_i(\overline{\mathbf{x}}, \mathbf{V}) = (\mathbf{x}_i - \overline{\mathbf{x}})'\mathbf{V}^{-1}(\mathbf{x}_i - \overline{\mathbf{x}})$ is a maximum, so that implicitly the observations have been ordered in terms of the reduced form of subordering based on the distance measure $R(\mathbf{x}; \overline{\mathbf{x}}, \mathbf{V})$. Furthermore, we will declare $\mathbf{x}_{(n)}$ a *discordant* outlier if

$$R_{(n)}(\overline{\mathbf{x}}, \mathbf{V}) = (\mathbf{x}_{(n)} - \overline{\mathbf{x}})'\mathbf{V}^{-1}(\mathbf{x}_{(n)} - \overline{\mathbf{x}}) = \max R_j(\overline{\mathbf{x}}, \mathbf{V})$$

is significantly large.

The null distribution of $R_{(n)}(\overline{\mathbf{x}}, \mathbf{V})$ is neither readily determined in exact form nor very tractable, but

it has been widely studied. Critical values for discordancy tests for models A and B under various assumptions about parameter values being known or unknown are given in [7, Tables XXX–XXXIV].

For model A with $\mathbf{V}$ unknown, using a similar likelihood approach, it seems at first sight that quite a different principle is advanced for the declaration of an outlier $\mathbf{x}_i$ and for the assessment of its discordancy. Here we lead to implicitly ordering the multivariate observations in terms of reduced subordering based on the values of $|\mathbf{A}^{(j)}|$, which are $\sum(\mathbf{x}_i - \overline{\mathbf{x}})(\mathbf{x}_i - \overline{\mathbf{x}})'$, where the sum is taken over all observations *except* $\mathbf{x}_j$. The $|\mathbf{A}^{(j)}|$ are ordered, and the observation corresponding to the smallest value of $|\mathbf{A}^{(j)}|$ is declared an outlier.

Thus the outlier is the observation whose removal from the sample effects the greatest reduction in the "internal scatter" of the data set, and it is adjudged discordant if this reduction is sufficiently large. This approach was first advanced by Wilks [33], but the distinction of principle for declaring an outlier in the case of unknown $\mathbf{V}$, compared with the case where $\mathbf{V}$ is known, turns out to be less profound than might appear at first sight since it is possible to reexpress the internal scatter in terms of the distance measure $R(\overline{\mathbf{x}}, \mathbf{S})$.

Thus the outlier is *again* that observation whose "distance" from the body of the data set is a maximum, provided we replace $\boldsymbol{\mu}$ and $\mathbf{V}$ by $\overline{\mathbf{x}}$ and $\mathbf{S}$.

Frequently we encounter multivariate data for which the normal distribution is quite unsuitable, in view of manifest **skewness**. Thus we might need to consider models expressing skewness. Two such prospects are provided by a *multivariate exponential* model and a *multivariate Pareto* model.

Many forms of multivariate exponential distribution have been proposed. One of these, due to Gumbel [22], has for the bivariate case a probability density function

$$f(x_1, x_2) = [(1 + \theta x_1)(1 + \theta x_2) - \theta] \times \exp(-x_1 x_2 - \theta x_1 x_2).$$

Applying a directional form of Principle A, an appropriate reduction measure,

$$R(\mathbf{X}) = X_1 + X_2 + \theta X_1 X_2,$$

is obtained. Thus an upper outlier is detected as the observation (x_{1i}, x_{2i}) which yields the largest value of $R(\mathbf{x})$ over the sample of n observations. It is judged discordant if the corresponding $R_{(n)} = \max R(\mathbf{x}_i)$ is sufficiently large. The distribution of $R_{(n)}$ is tractable. See Barnett [4], who also considers a discordancy test for an "upper" outlier in another skew bivariate distribution: namely, the (one of the two) Pareto distribution(s) considered by Mardia [27] which has probability density function

$$f(x_1, x_2) = a(a + 1)(\theta_1 \theta_2)^{a+1} \times (\theta_2 x_1 + \theta_1 x_2 - \theta_1 \theta_2)^{-(a+2)},$$

for $x_1 \geq \theta_1 \geq 0$, $x_2 \geq \theta_2 \geq 0$, and $a > 0$. The correlation coefficient is $\rho = a^{-1} (a > 2)$.

This time the appropriate restricted form of Principle A (assuming θ_1, θ_2, and a are known) yields a reduction measure

$$R(\mathbf{X}) = \left(\frac{x_1}{\theta_1}\right) + \left(\frac{x_2}{\theta_2}\right) - 1.$$

This is again tractable and yields the critical value γ_α for a level-α discordancy test for an upper outlier, satisfying

$$\delta \gamma_\alpha^{(a+1)} - (a + 1)\gamma_\alpha + a = 0,$$

with $\delta = 1 - (1 - \alpha)^{1/n}$.

Informal Methods for Multivariate Outliers

A host of informal proposals have been made for detecting outliers in multivariate data by quantitative or graphical methods (*see* **Graphical Displays**). These cannot be regarded as tests of discordancy; they may be based on derived reduction measures (but with no supporting distribution theory) or, more commonly, they are presented simply as aids to intuition in picking out multivariate observations which are suspiciously aberrant from the bulk of the sample.

Various forms of initial processing of the data, involving transformation, study of individual marginal components of the observations, judicious reduction of the multivariate observations to scalar quantities in the forms of reduction measures or linear combinations of components, changes in the coordinate bases of the observations, and appropriate methods of graphical representation, can all help to identify or highlight suspicious observations. If

several such procedures are applied simultaneously (or separately) to a set of data they can help to overcome the difficulty caused by the absence of a natural overall ordering of the sample members. An observation which clearly stands out on one, or preferably more, processed re-representations of the sample becomes a firm candidate for identification as an outlier.

An early example of an informal graphical procedure is described by Healy [25], who proposes plotting the *ordered* $R_j(\bar{\mathbf{x}}, \mathbf{S})$ against the expected values of the **order statistics** of a sample of size n from χ_p^2.

We should not underestimate the importance of the *marginal samples* (that is, the univariate samples of each component value in the multivariate data) in the occurrence of outliers. It is perfectly plausible for contamination to occur in one of the marginal variables alone – for example, by misreading or an error of recording. It could even happen that a single marginal variable is intrinsically more liable to contamination. We must be careful, however, not to adopt too simplistic an approach in examining this prospect. This is illustrated in some work by Barnett [5], who considers a sample from a bivariate normal distribution where contamination may have occurred by slippage of the mean of the *first component only* for one observation. The detection of such an outlier is by no means simple.

Graphical and pictorial methods are often advanced in relation to multivariate outliers. Rohlf [29] remarks as follows:

> Despite the apparent complexity of the problem, one can still characterize outliers by the fact that they are somewhat isolated from the main cloud of points. They may not "stick out on the end" of the distributions as univariate outliers must, but they must "stick out" somewhere.

With this emphasis it is natural to consider different ways in which we can merely *look at the data* to see if they seem to contain outliers. A variety of methods employing different forms of pictorial or graphical representation have been proposed with varying degrees of sophistication. Review of such methods of "informal inference" applied to general problems of analysis of multivariate data including the detection of outliers are presented by Gnanadesikan [19] and by Barnett [6]. (See [7, Section 7.4], for further details on published contributions in this spirit.)

It can be useful to perform a preliminary principal components analysis on the data, and to look at sample values of the projection of the observations on to the principal components of different order. Gnanadesikan & Kettenring [20] discuss this in some detail, remarking how the first few principal components are sensitive to outliers inflating variances or covariances (or correlations, if the principal components analysis has been conducted in terms of the sample correlation matrix, rather than the sample covariance matrix), whilst the last few are sensitive to outliers adding spurious dimensions to the data or obscuring singularities. Some modifications of approach to outlier detection by principal components analysis are suggested by Hawkins [24] and by Fellegi [17].

Another way in which informal quantitative and graphical procedures may be used to exhibit outliers is to construct reduced univariate measures. Gnanadesikan & Kettenring [20] consider various possible classes of such measures which are all similar in principle to the "distance" measure discussed above. Particularly extreme values of such statistics, possibly demonstrated by graphical display, may reveal outliers of different types. For graphical display of outliers, the "gamma-type probability plots" of ordered values, with appropriately estimated shape parameters, are also a useful approximate procedure and have been widely considered.

We have already noted the way in which outliers may affect, and be revealed by, the correlation structure in the data. Some proposals for identifying multivariate outliers specifically consider this matter. Gnanadesikan & Kettenring [20] suggest that we examine the product–moment correlation coefficients $r_{-j}(s, t)$ relating to the sth and tth marginal samples after the omission of the single observation $\mathbf{x}_j$. As we vary j we can examine, for any choice of s and t, the way in which the correlation changes – substantial variations reflecting possible outliers. Devlin et al. [14] make use of the *influence function* to investigate how outliers affect correlation estimates in bivariate data ($p = 2$). Influence functions of other statistics (apart from the correlation coefficient) have also been proposed as a basis for detecting outliers.

We noted earlier the characterization of multivariate outliers suggested by Rohlf [29] – that they are separated from other observations "by distinct gaps". Rohlf has used this idea to develop a *gap test* for multivariate outliers based on minimum spanning trees (*see* **Graphical Displays**). He argues that a single

isolated point will be connected to only one other point in the minimum spanning tree by a relatively large distance, and that *at least one* edge connection from a cluster of outliers must also be relatively large. Accordingly, an informal gap test for outliers is proposed based on this principle.

This article can only briefly review the very wide range of concepts and methods for multivariate outliers. Barnett & Lewis [7, Chapter 7] provide the entrée to more detailed study.

Multivariate Survival Analysis

Multivariate survival analysis deals with methods designed for the study of correlated failure time observations taken on a single individual or a group of individuals. Examples of applications include epidemiologic studies on the familial tendency in chronic disease incidence, follow-up studies of recurrent diseases (*see* **Repeated Events**), litter-matched carcinogenicity experiments on animals (*see* **Tumor Incidence Experiments**), or **clinical trials** on paired human organs.

Extensions of both non and semiparametric methods of univariate survival analysis to the multivariate setting have turned out to be quite difficult and resulted in many different approaches. In general, the analysis of multivariate failure time data requires a rigorous specification of both censoring mechanisms and timescales on which failure time observations are recorded. Multivariate censoring arises when failure time observations are registered on several different time clocks. This is common to familial studies where life lengths or age at the onset of a disease are measured on a different timescale for each member of the family. Moreover, each family member may be subject to his/her own censoring mechanism. So-called univariate censoring may arise when serial observations are taken on a single individual. These may be, for example, times of successive episodes of asthmatic attacks or times of the onset of specific stages of a nonrecurrent disease. The univariate censoring model applies also to many twin studies and matched-pair experiments. Finally, the occurrence of a single event may be recorded on several timescales. Examples are provided by **staggered entry** models where of interest are both the calendar time of entry into a clinical trial and the duration of the subsequent time period on trial.

From a more mathematical point of view, both univariate censoring models and models involving multiple time measurements of a single event can be formulated usually within the classical marked **point process** framework of survival analysis [4]. However, the martingale-based methods for the derivation of estimates and their large-sample properties are, in general, insufficient in this setting and are replaced by methods related to empirical processes techniques. These methods also apply to models involving multiple clock experiments. Such experiments can only seldom be defined using marked point processes in real time because concepts such as "past–present–future" do not have a clear-cut interpretation in the case of multiparameter processes.

Nonparametric Estimation

Survival function estimation is the center-point of nonparametric approaches towards the analysis of multivariate failure time data. From a practical point of view, multivariate survival functions are seldom of interest on their own; however, they play an important role as an auxiliary tool in other inferential problems. Examples of applications include **density estimation** in **graphical displays** of data, regression analyses with uncensored or censored covariates, estimation of dependence parameters, **goodness-of-fit** tests, and so forth.

In the special univariate case, estimation of the unknown survival function S of a possibly censored failure time T is usually based on the Kaplan–Meier estimate. The choice of this estimator can be justified by both **nonparametric maximum likelihood** and self-consistency principles [20, 30]. In addition, the estimate is the sample analog of the **product-integral** representation of survival functions in terms of cumulative hazards [23]. The latter concept does not have a unique extension to multivariate distributions, whereas both maximum likelihood and self-consistency principles do not lead, in general, to unique and consistent estimates of the multivariate survival functions in the presence of censoring [47, 53]. As a result, there are many different approaches to this estimation problem.

Here, we assume first that the multivariate vector of interest is of the form $(T, \mathbf{Z})$ where T is a univariate failure time subject to censoring and $\mathbf{Z}$ is a vector of uncensored covariates. In this case, nonparametric estimation methods usually aim to recover the parameters of the conditional survival function,

$$S(t|z) = P(T > t|\mathbf{Z} = z) = \pi_{[0,t]}(1 - A(\mathrm{d}u|z)), \tag{1}$$

where $A(t|z)$ is the cumulative hazard function of the conditional distribution of the failure time T given the covariate $\mathbf{Z} = z$. Under identifiability

assumptions such as the conditional independence of the failure time T and censoring time $\tilde{T}$ given the covariate $\mathbf{Z}$, estimation methods are often based on Beran's [5] conditional **Nelson–Aalen** and **Kaplan–Meier** estimates. The conditional Nelson–Aalen estimate assumes the form

$$\hat{A}(t|z) = \int_{[0,t]} \frac{\sum_{i=1}^{n} W_i(z) N_i(\mathrm{d}u)}{\sum_{i=1}^{n} W_i(z) Y_i(u)},$$

where $(N_i, Y_i), i = 1, \ldots, n$, are counting and risk processes $N_i(t) = I(T_i \leq t \wedge \tilde{T}_i)$ and $Y_i(t) = I(T_i \wedge \tilde{T}_i \geq t)$ associated with a sample of n individuals under study, and $W_i(z), i = 1, \ldots, n$, are weights dependent only on their covariates $\mathbf{Z}_1, \ldots, \mathbf{Z}_n$. The conditional Kaplan–Meier estimate is obtained by substituting this estimate into the right-hand side of (1). A general counting process formulation of **nonparametric regression** allows one also to accommodate intensity models with time-dependent covariates or recurrent failure time events. In both settings, different choices of the weights $W_i(z)$ lead to different types of nonparametric regression estimates. Examples include regressogram, kernel, and nearest neighbor estimates. Under regularity conditions, these estimates are uniformly consistent and asymptotically Gaussian at a rate dependent on the choice of the smoother [13, 35].

Under suitable identifiability conditions, the conditional Kaplan–Meier estimate remains consistent when covariates are subject to censoring and provides a convenient tool in the estimation of the joint distribution function of failure time vectors $\mathbf{T} = (T_1, \ldots, T_m)$ subject to multivariate censoring. In what follows we consider the simplest bivariate censoring model and assume that the observable data are of the form $(X_1, X_2, \delta_1, \delta_2)$ where $X_l = T_l \wedge \tilde{T}_l$, $\delta_l = I(T_l \leq \tilde{T}_l)$ and $T = (T_1, T_2)$, $\tilde{T} = (\tilde{T}_1, \tilde{T}_2)$ are independent failure and censoring variables.

As an ad hoc modification of Efron's self-consistency algorithm, Pruitt [47] proposed to consider the sample analog of the identity

$$F(t_1, t_2) = \sum_{i,j=0,1} F_{ij}(t_1, t_2),$$

where $F(t_1, t_2) = P(T_1 \leq t_1, T_2 \leq t_2)$ and $F_{ij}(t_1, t_2) = P(T_1 \leq t_1, T_2 \leq t_2, \delta_1 = i, \delta_2 = j)$. Independence of the failure and censoring times implies

$$\begin{aligned} F(t_1, t_2) = &\int_{[0,t_1]\times[0,t_2]} P(T_1 \leq t_1, \\ &T_2 \leq t_2 | T_1 > u, T_2 > v) \\ &\times \mathrm{E}N_{00}(\mathrm{d}u, \mathrm{d}v) + \mathrm{E}N_{11}(t_1, t_2) \\ &+ \int_{[0,t_1]\times[0,t_2]} \frac{P(v < T_2 \leq t_2 | T_1 = u)}{P(T_2 > v | T_1 = u)} \\ &\times \mathrm{E}N_{10}(\mathrm{d}u, \mathrm{d}v) \\ &+ \int_{[0,t_1]\times[0,t_2]} \frac{P(u < T_1 \leq t_1 | T_2 = v)}{P(T_1 > u | T_2 = v)} \\ &\times \mathrm{E}N_{01}(\mathrm{d}u, \mathrm{d}v), \end{aligned} \tag{2}$$

where $N_{ij}(t_1, t_2) = I(X_1 \leq t_1, X_2 \leq t_2, \delta_1 = i, \delta_2 = j)$. Pruitt's estimate of the distribution function F is the solution to the sample counterpart of this equation obtained by replacing the expected processes $\mathrm{E}N_{ij}(t_1, t_2)$ by their empirical counterparts and by approximating the subdistribution functions $P(v < T_j \leq t_j | T_{3-j} = u)$ using the conditional Kaplan–Meier estimate. In special cases, such as the censoring of only one component of the vector $\mathbf{T}$ or univariate censoring of ordered failure times $T_1 < T_2$, the solution of (2) has an explicit form and the corresponding estimates assume the form of averaged conditional Kaplan–Meier estimates. In the first of these two cases the estimate is also fully efficient [1]. The consistency and asymptotic normality of Pruitt's estimate in the presence of bivariate censoring is shown by van der Laan [55] who also provides a fully efficient survival function estimate designed for data subject to bivariate censoring [56].

There are several alternative estimators based on ad hoc representations of the survival function of the failure times (T_1, T_2) in terms of the subdistribution functions of the observable data. Such estimates are useful in that they are very simple to implement in practice. In particular, they do not rely on smoothing techniques and therefore can be applied towards analysis of data sets of small or moderate sample sizes. One possible choice corresponds to the sample analog of the identity $S(t_1, t_2) = S_1(t_1) S_2(t_2) M(t_1, t_2)$, where S_l are the marginal survival functions and

$$M(t_1, t_2) = \exp \int_{[0,t_1]\times[0,t_2]} \mathrm{d} \log F. \tag{3}$$

The estimate of the bivariate survival function is obtained by replacing the unknown marginals by

their respective Kaplan–Meier estimators, whereas the function M is approximated by

$$\widehat{M}(t_1, t_2) = \prod_{u_j \le t_j} \prod_{\alpha} \left\{ \sum_{i=1}^{n} \prod_{l \in \alpha} [Y_{il}(u_l) - N_{il}(\Delta u_l)] \prod_{l \notin \alpha} Y_{il}(u_l) \right\}^{(-1)^{|\alpha|}},$$

where $|\alpha|$ is the cardinality of a set $\alpha \subseteq \{1, 2\}$ and $(N_{il}, Y_{il}), l = 1, 2, i = 1, \ldots, n$, are the marginal counting and risk processes associated with an independent identically distributed (iid) sample of censored failure times [14]. Alternatively, (3) is the unique solution of the Volterra integral equation:

$$M(t_1, t_2) = 1 + \int_{[0,t_1]\times[0,t_2]} M(u_1-, u_2-) B(\mathrm{d}u_1, \mathrm{d}u_2), \quad (4)$$

where B is a standardized version of the covariance of the marginal martingales, $M_{il} = N_{il} - \int_0 Y_{il}\, \mathrm{d}A_l$, $A_l(\mathrm{d}t) = -S_l(\mathrm{d}t)/S_l(t-), l = 1, 2$. An estimate of this covariance function is given by Prentice & Cai [46] who further propose to recover the function M by the solution to the sample analog of (4). In practice, the two estimates are in close numerical agreement and are both consistent and asymptotically Gaussian in the presence of bivariate censoring. References [8], [15], [18], [22], [24], [58], and [60] discuss the asymptotic properties of these estimates, extensions to multivariate data and also provide applications to regression analyses and testing dependencies. Other examples of survival function estimates designed for multivariate censored data are given in [9], [10], [54], [7], and [53]. Pruitt [49] provides a useful overview of the small sample properties of some of these estimates along with software available through statlib at the Carnegie Mellon University. Some care has to be taken in the use of these estimates, however, as they may define signed measures and may fail to be consistent in the presence of more complex censoring mechanisms [19, 45, 48, 53].

Nonparametric Testing

Testing independence, k sample homogeneity, and symmetry are examples of common testing problems involving multivariate data. In the case of bivariate data, nonparametric tests for independence are often based on **rank correlation** statistics such as logrank and Spearman rank correlation or Kendall's τ. Examples of censored data analogs of these tests are given in [6], [11], [12], and [39]. In particular, given an iid sample $(X_{i1}, X_{i2}, \delta_{i1}, \delta_{i2}), i = 1, \ldots, n$, of the observed withdrawal times and censoring indicators, Oakes' [39] analog of Kendall's τ test rests on a comparison of the number of pairs of observations known to correspond to concordant and discordant failure times:

$$\hat{\tau} = \frac{2}{n(n-1)} \sum_{i<j} a_1(i, j) a_2(i, j),$$

where the score $a_l(i, j), l = 1, 2$, assumes values $\delta_{il}, 0$ and $-\delta_{jl}$ if sign $(X_{il} - X_{jl}) = 1, 0$ and -1, respectively. The logrank (or Savage scores) correlation test is given by

$$R_n = \frac{1}{n} \sum_{i=1}^{n} [\hat{A}_1(X_{i1}) - \delta_{i1}][\hat{A}_2(X_{i2}) - \delta_{i2}],$$

where $\hat{A}_l, l = 1, 2$, are Nelson–Aalen estimates of the marginal cumulative hazard functions. Standardized versions of these statistics are asymptotically mean zero normal and provide consistent tests against alternatives of signed dependence. In the case of uncensored data, under alternatives remote to independence, rank correlation statistics and Kendall's τ statistic also provide consistent estimates of common nonparametric association measures. However, this does not carry over to censored data. In the case of both uncensored and censored data, multivariate extensions of Kendall's test and rank correlation tests are not uniquely defined. Some examples are given in [2] and [18] (*see* **Multivariate Median and Rank Sum Tests**).

Omnibus Kolmogorov–Smirnov type tests for independence are due to Pons & de Turckheim [44]. In the bivariate case, such tests can be based on statistics

$$U_n = \sup_{t_1 \le \tau_1, t_2 \le \tau_2} \sqrt{n} |\hat{S}(t_1, t_2) - \hat{S}_1(t_1) \hat{S}_2(t_2)|,$$

where $\hat{S}_i, i = 1, 2$, are the marginal Kaplan–Meier estimates, and $\hat{S}$ is an estimate of the joint survival function of the underlying failure times. Alternatively, such tests can also be based on the supremum norm statistic comparing estimates of bivariate and

marginal cumulative hazards. Critical values of the tests are obtained based the bootstrap approximation to the null distribution of U_n. Bootstrap methods apply also to other testing problems involving multivariate data such as k sample homogeneity or symmetry tests [50].

Rank tests designed for these problems are discussed in [3], [16], [17], [41], [58], and [61], among others. In particular, symmetry tests arise in matched-pair experiments and are often based on paired or signed rank tests. In the case of uncensored data, paired rank tests (or conditional rank tests) are scores tests derived from the conditional likelihood of ranks given the observed paired ranks [52]. Evaluation of the scores of such tests and derivation of both finite sample and asymptotic properties are, in general, quite difficult; however, special choices such as the paired Wilcoxon and logrank tests gained some popularity due to their good performance as compared with other symmetry tests. Wilcoxon signed-rank tests derive their form from the marginal likelihood of signed ranks in the log-linear model $\log T_{2i} = \log T_{1i} + \theta + \varepsilon_i$, where θ is an unknown shift parameter and ε_i is an error term with a known symmetric distribution. Special cases include the sign, and signed Wilcoxon and **normal scores** tests. Their censored data analogs are limited to models involving univariate censoring. The paper [17] provides a comparison of the **asymptotic relative efficiency** of the two classes of symmetry tests.

Regression Models

Regression analysis of multivariate data is often based on **random effects** (or **frailty**) models. The idea of the use of frailty models is due to Vaupel et al. [57] who introduced this concept to model heterogeneity in univariate survival models. In the multivariate setting, frailty models are used to induce dependence among failure times by way of a random effect accounting for possible genetic, environmental and other factors linking the marginal failure processes.

The simplest random effects models for multivariate data are derived under the assumption that m individuals, such as family members, share a common unobserved factor W. Here, W is a nonnegative random variable such that, conditionally on W and the vector of observable covariates $\mathbf{Z} = (\mathbf{Z}_1, \ldots, \mathbf{Z}_m)$, the failure times $(\mathbf{T}_1, \ldots, \mathbf{T}_m)$ of the m individuals are independent random variables with hazard functions

$$\alpha_i(t|\mathbf{Z}, W) = W\alpha_{0i}(t)\exp(\beta_i^{\mathrm{T}}\mathbf{Z}_i) \quad i = 1, \ldots, m. \tag{5}$$

The conditional survival function of the failure times $\mathbf{T} = (T_1, \ldots, T_m)$ given the covariates $\mathbf{Z}$ is

$$S(t_1, \ldots, t_m|\mathbf{Z}) = \int \exp\left[-w\sum_{i=1}^{m}\exp(\beta_i^{\mathrm{T}}\mathbf{Z}_i)\int_0^{t_i}\alpha_{0i}(u)\,\mathrm{d}u\right] \times F_W(\mathrm{d}w),$$

where F_W is the distribution of the frailty variable W. Typically, this distribution belongs to some known parametric family such as the family of gamma, positive stable, **inverse Gaussian distribution** and **lognormal distribution** [40, 26, 34]. Apart from the conditional independence assumption, the model (5) stipulates that, conditionally on W, components of the vector $\mathbf{T}$ follow the proportional hazard model. However, with the exception of Hougaard's positive stable frailty model, averaging over W leads to models with marginals that do not satisfy the proportional hazard model assumption. Different choices of the frailty distribution give rise also to different types of dependence among the marginal failure times. More flexible frailty models allowing for several types of random effects and different degrees of association among the components of the vector $\mathbf{T} = (T_1, \ldots, T_m)$, can be obtained by assuming that W is a vector or matrix of correlated variables. Examples of such models were provided by Yashin et al. [62] and McGilchrist [34].

Inference methods in these models are quite difficult. A frequent approach rests on **nonparametric maximum likelihood** and **EM algorithm** [38]; however, only partial results covering the gamma and correlated frailty models are available at the present time [36, 37, 42, 43] and much attention is paid to alternate approaches to regression analysis of multivariate data. In particular, in the case of litter-matched experiments. Holt & Prentice [28] propose the model (5) with systematic rather than random effects. The paper [25] provides a detailed derivation of the properties of the Cox and maximum likelihood estimates in this model. Another common choice corresponds to the so-called "marginal

approach" (*see* **Marginal Models for Multivariate Survival Data**). Instead of modeling the conditional distribution of T_j, $j = 1, \ldots, m$, given a frailty variable, it imposes semiparametric assumptions on the marginal distribution of T_js and leaves the joint dependence structure among the components of the vector $(T_1, \ldots, T_m)$ unspecified. Under suitable identifiability assumptions, the unknown parameters of marginals can be estimated by modifying estimation procedures developed for univariate regression analyses. Wei et al. [59] and Lin & Wei [32] provide the joint asymptotic structure of the estimates in multivariate models with marginals satisfying the Cox proportional hazard and accelerated failure time model assumptions. The marginal approach can further be strengthened by assuming that the failure time data follow a multivariate **copula** model. In the absence of covariates, these are multivariate models in which the joint survival function S of the vector $\mathbf{T} = (T_1, \ldots, T_m)$ is of the form $S = C_\theta(S_1, \ldots, S_m)$, where S_l are the marginal survival functions and $\{C_\theta : \theta \in \Theta\}$ is a parametric family of distribution functions on the unit cube with uniform marginals [21, 27]. The parameter θ accounts for the joint dependence among the marginal failure times. In these models, the dependence parameter and the parameters of the marginals can be based on a two-stage estimation process: the parameters of the marginals are first estimated as in univariate analyses, the resulting estimates are next used to construct a **pseudo-likelihood** for the unknown dependence parameter θ [27, 31, 51]. Although the resulting estimates are inefficient, this estimation approach is relatively easy to implement and has a good practical performance. Other examples of semiparametric models that can be used in the analysis of multivariate failure time data are surveyed in [26] and [33].

Multivariate *t* Distribution

Student's *t* distributions on $\mathbb{R}^1$ arise through the use of Studentized statistics in normal-theory sampling models. Multivariate versions on $\mathbb{R}^k$ typically derive through Studentization from **multivariate normal** models through an impressive array of methods employed in the analysis of biomedical and other data. Properties of these procedures in turn rest on those of the corresponding joint distributions, and their implementation requires the availability of special aid tables or their software equivalents. On occasion, multivariate t distributions themselves serve to model the errors of a random experiment, offering greater flexibility and heavier tails than multivariate normal models.

There are two basic types of t distributions on $\mathbb{R}^k$. Type I distributions emerge on scaling each component of a random normal vector by a single random scalar. Type II distributions entail separate scalings by elements of a further random vector, itself having a joint distribution on $\mathbb{R}^k$. Details are supplied subsequently. Excellent references are [5, Chapter 27] and [8, Chapter 9].

There is by now a considerable literature pertaining to multivariate t distributions on $\mathbb{R}^k$, mostly of type I. This literature may be categorized roughly as follows for brevity. Broad topics include: (i) basic multidimensional t distributions and their properties; (ii) computations for and approximations to these distributions; and (iii) special aid tables to support their many applications. Their methodological origins encompass: (iv) **multiple comparisons** for means, including Dunnett's [2] pairwise comparison of treatments with a control; (v) **simultaneous confidence** bounds for location parameters; (vi) ranking and selection problems; (vii) **Bayesian** analyses; (viii) the analysis of repeated measurements (*see* **Longitudinal Data Analysis, Overview**); (ix) **prediction** intervals in regression; (x) **diagnostics** for **outliers**; (xi) topics in **estimation**; and (xii) as primary models for error distributions arising in multilinear models as noted. A lengthy and detailed reference list is omitted here; access is readily available through searching electronic databases such as the *Current Index to Statistics*.

In what follows $\mathbb{R}^k$ denotes Euclidean k-dimensional space; abbreviations include *pdf* and *cdf* for probability density and cumulative distribution functions, respectively; and $\mathcal{L}(\mathbf{X})$ designates the law of distribution of $\mathbf{X} = (X_1, \ldots, X_k)' \in \mathbb{R}^k$. In particular, $\mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ denotes the multivariate normal distribution on $\mathbb{R}^k$ having the mean $\boldsymbol{\mu} \in \mathbb{R}^k$ and the positive-definite $(k \times k)$ dispersion **covariance matrix** $\mathrm{V}(\mathbf{X}) = \boldsymbol{\Sigma} = (\sigma_{ij})$; and $\chi^2(\nu)$ identifies the central **chi-square distribution** having ν **degrees of freedom**.

Type I Distributions on $\mathbb{R}^k$

Basic Properties

Suppose that the distribution of $\mathbf{X} \in \mathbb{R}^k$ is given by $\mathcal{L}(\mathbf{X}) = \mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\sigma}^2\boldsymbol{\Sigma})$ and that $\mathcal{L}(\nu S^2/\sigma^2) = \chi^2(\nu)$ independently of $\mathbf{X}$. In practice, S^2 is typically an error mean square from an **analysis of variance** based on ν degrees of freedom. Then, with $\{T_i = X_i/S; 1 \le i \le k\}$, their joint distribution is a type I t distribution on $\mathbb{R}^k$, to be designated as $\mathcal{L}(T_1, \ldots, T_k) = t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$. Its pdf takes the form

$$f(\mathbf{t}) = C(k, \nu)\left[\frac{1 + (\mathbf{t} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{t} - \boldsymbol{\mu})}{\nu}\right]^{-(\nu+k)/2}, \tag{1}$$

where $C(k, \nu) = \Gamma[(\nu + k)/2]/(\pi\nu)^{k/2}\Gamma(\nu/2)|\boldsymbol{\Sigma}|^{1/2}$. Here $\boldsymbol{\mu}$ is the center of symmetry, $\boldsymbol{\Sigma}$ is the matrix of scale parameters, and ν is the number of degrees of freedom. The distribution is said to be *central* whenever $\boldsymbol{\mu} = \mathbf{0}$, and to be *noncentral* otherwise. The first two moments when defined are $\mathrm{E}(\mathbf{T}) = \boldsymbol{\mu}$ for $\nu > 1$, and $\mathrm{var}(\mathbf{T}) = [\nu/(\nu - 2)]\boldsymbol{\Sigma}$ for $\nu > 2$. For arbitrary $\boldsymbol{\Sigma}$, the one-dimensional marginal distributions are scaled t distributions on $\mathbb{R}^1$. However, if $\boldsymbol{\Sigma}$ is replaced by a positive-definite correlation matrix $\mathbf{R} = [\rho_{ij}]$, then each marginal is a Student's t distribution on $\mathbb{R}^1$, central or noncentral as appropriate, having ν degrees of freedom. These k-dimensional distributions are elliptically contoured from expression (1), and the case $\nu = 1$ yields elliptical **Cauchy** distributions on $\mathbb{R}^k$.

Joint marginal and conditional distributions of $t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$ emerge as follows. Partition $\mathbf{T} = [\mathbf{T}_1', \mathbf{T}_2']'$, $\boldsymbol{\mu} = [\boldsymbol{\mu}_1', \boldsymbol{\mu}_2']'$, and $\boldsymbol{\Sigma} = [\Sigma_{ij}]$ conformably, with $\mathbf{T}_1 \in \mathbb{R}^r$ and $\mathbf{T}_2 \in \mathbb{R}^t$ such that $r +$

$t = k$. Since $\mathcal{L}(\mathbf{T})$ is elliptical, it follows from the theory of elliptical distributions [1] that the joint marginal distribution of $\mathbf{T}_1$ is $\mathcal{L}(\mathbf{T}_1) = t_r(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_{11}, \nu)$, and similarly for $\mathbf{T}_2$. In like manner, the conditional distributions $\mathcal{L}(\mathbf{T}_1|\mathbf{t}_2)$ are elliptical on $\mathbb{R}^r$, having the linear **regression** functions $\boldsymbol{\mu}_{11.2} = \boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}(\mathbf{t}_2 - \boldsymbol{\mu}_2)$ and scale parameters $\kappa(\mathbf{t}_2)\boldsymbol{\Sigma}_{11.2}$ with $\boldsymbol{\Sigma}_{11.2} = (\boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21})$, where $\kappa(\mathbf{t}_2)$ depends on the conditioning value $\mathbf{t}_2$. These properties hold even without moments, where now $\boldsymbol{\mu}_{11.2}$ represents the center of symmetry and $\boldsymbol{\Sigma}_{11.2}$ the matrix of scale parameters.

Probability Inequalities

Basic inequalities for these distributions are essential. In practice, there is an excess of parameters for $t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$, even in the central case with $\boldsymbol{\mu} = \mathbf{0}$, since $(\boldsymbol{\Sigma}, \nu)$ consist of $[k(k+1)+2]/2$ distinct parameters. Owing to limitations of available tables, access to probability inequalities enables the user to employ approximate values from existing tables giving bounds on the required probabilities. In this spirit, we summarize some useful inequalities as follows. Basic references are [7, Chapter 3] and [8, Chapter 9], together with extensive reference lists.

In what follows, $\boldsymbol{\Sigma} = [\sigma_{ij}]$ designates any positive-definite $(k \times k)$ matrix, whereas $\mathbf{R} = [\rho_{ij}]$ denotes a positive-definite correlation matrix. An equicorrelation matrix is denoted by $\boldsymbol{\Xi}(\rho) = [(1-\rho)\mathbf{I}_k + \rho\mathbf{1}_k\mathbf{1}_k']$ for $\{-(k-1)^{-1} < \rho < 1\}$. With these conventions in place, let $P_{\boldsymbol{\Sigma}}(\cdot; \nu)$ be the probability measure for $\mathcal{L}(T_1, \ldots, T_k) = t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$; let $F_{\boldsymbol{\Sigma}}(t_1, \ldots, t_k; \nu)$ be its cdf; and let $\overline{F}_{\boldsymbol{\Sigma}}(t_1, \ldots, t_k) = P_{\boldsymbol{\Sigma}}(T_1 > t_1, \ldots, T_k > t_k; \nu)$. Furthermore, let $F_{\mathbf{D}}(t_1, \ldots, t_k)$ be the cdf of $t_k(\boldsymbol{\mu}, \mathbf{D}, \nu)$, with $\mathbf{D} = \text{diag}(\sigma_{11}, \ldots, \sigma_{kk})$, and similarly for $\overline{F}_D(t_1, \ldots, t_k)$. Finally, identify $G_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k; \nu) = P_{\boldsymbol{\Sigma}}(|T_1| \le a_1, \ldots, |T_k| \le a_k; \nu)$ for the case $\mathcal{L}(\mathbf{T}) = t_k(\mathbf{0}, \boldsymbol{\Sigma}, \nu)$, and similarly $G_D(a_1, \ldots, a_k; \nu)$, with $\mathbf{D} = \text{diag}(\sigma_{11}, \ldots, \sigma_{kk})$ as before. Basic probability inequalities may be summarized as follows.

Property 1. If $\mathcal{L}(\mathbf{T}) = t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$, then for fixed but arbitrary $\{a_1, \ldots, a_k\}$ and ν, the function $F_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k; \nu)$ is increasing in each σ_{ij} for all $i \neq j$, while other values are held fixed.

Property 2. Suppose that $\mathcal{L}(\mathbf{T}) = t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$. If $\sigma_{ij} \ge 0$ for all $i \neq j$, then $F_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k) \ge F_{\mathbf{D}}(a_1, \ldots, a_k) \ge \prod_{i=1}^k F_i(a_i)$ holds for each fixed $\{a_1, \ldots, a_k\}$, where $F_i(\cdot)$ is the marginal cdf of T_i.

Property 3. Suppose that $\mathcal{L}(\mathbf{T}) = t_k(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$. If $\sigma_{ij} \ge 0$ for all $i \neq j$, then $\overline{F}_{\boldsymbol{\Sigma}}(a_1, \ldots, a_k) \ge \overline{F}_{\mathbf{D}}(a_1, \ldots, a_k) \ge \prod_{i=1}^k [1 - F_i(a_i)]$ for arbitrarily fixed $\{a_1, \ldots, a_k\}$.

Property 4. Suppose that $\mathcal{L}(\mathbf{T}) = t_k(\mathbf{0}, \boldsymbol{\Sigma}, \nu)$. Then $G_{\boldsymbol{\Sigma}}(c_1, \ldots, c_k) \ge G_{\mathbf{D}}(c_1, \ldots, c_k) \ge \prod_{i=1}^k G_i(c_i)$ for each fixed set $\{c_1, \ldots, c_k\}$ of positive constants, where $G_i(\cdot)$ is the marginal cdf of $|T_i|$.

Property 5. Suppose that $\mathcal{L}(\mathbf{T}) = t_k[\mathbf{0}, \boldsymbol{\Xi}(\rho), \nu]$. Then for each fixed $a > 0$ and for all real numbers $\{c_1, \ldots, c_k\}$ such that $c_1 + \cdots + c_k = 0$, $P_\rho(|\sum_{i=1}^k c_i T_i| \le a)$ is an increasing function of ρ.

Type II Distributions on $\mathbb{R}^k$

Basic Structure

Type II t distributions on $\mathbb{R}^k$ have origins essentially as follows. Suppose that $\mathcal{L}(\mathbf{X}) = \text{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. Independently of $\mathbf{X}$, let $\nu\mathbf{S} = \nu[S_{ij}]$, of order $(k \times k)$, have a central **Wishart distribution** $W_k(\nu, \boldsymbol{\Xi})$ having ν degrees of freedom and the matrix $\boldsymbol{\Xi}$ of scale parameters, such that diagonal elements of $\boldsymbol{\Sigma}$ and $\boldsymbol{\Xi}$ are the same. If we let $\{T_i = X_i/S_i; 1 \le i \le k\}$, with $\{S_i^2 = S_{ii}; 1 \le i \le k\}$ as the diagonal elements of $\mathbf{S}$, then $\mathcal{L}(T_1, \ldots, T_k)$ is said to have a type II t distribution on $\mathbb{R}^k$.

Expressions for pdfs of such distributions are not available in closed form. Nonetheless, probability inequalities for such distributions are known under special structure for dependencies among the elements of $\mathbf{X}$ and of $\mathbf{S}$. An example follows.

Probability Inequalities

Suppose that $\mathcal{L}(\mathbf{X}) = \text{N}_k(\boldsymbol{\mu}, \mathbf{R})$, its correlation matrix $\mathbf{R} = [\rho_{ij}]$ having the structure $\{\rho_{ij} = \kappa_i\kappa_j\omega_{ij}; i \neq j\}$, such that $\{|\kappa_i| \le 1; 1 \le i \le k\}$, where $\boldsymbol{\Omega} = [\omega_{ij}]$ is a positive-definite correlation matrix. Furthermore, let $\mathcal{L}(\nu\mathbf{S}) = W_k(\nu, \boldsymbol{\Lambda})$ independently of $\mathbf{X}$, such that $\boldsymbol{\Lambda} = [\lambda_{ij}]$ is a correlation matrix with structure $\{\lambda_{ij} = \lambda_i\lambda_j; i \neq j\}$, for some $\{\lambda_1, \ldots, \lambda_k\}$.

Let $\{T_i = X_i/S_i; 1 \le i \le k\}$, with $\{S_i^2 = S_{ii}; 1 \le i \le k\}$, and denote the cdf $G_k(c_1, \ldots, c_k) = \Pr(|T_1| \le c_1, \ldots, |T_k| \le c_k)$. With these conventions, the following monotone properties of $G_k(c_1, \ldots, c_k)$ apply, as shown in [7, Theorem 3.1.2].

Property 6. For each fixed set of positive numbers $\{c_1, \ldots, c_k\}$, the function $G_k(c_1, \ldots, c_k)$ is: (i) strictly increasing in each $\kappa_i \in [0, 1]$ with other parameters held fixed; (ii) strictly decreasing in each $\kappa_i \in [-1, 0]$ with other parameters held fixed; and (iii) strictly increasing in each $|\lambda_i|$ with other parameters held fixed.

Peakedness Ordering

The comparative concentration of probabilities is an essential concept for distributions on $\mathbb{R}^k$. Following Sherman [6], the probability measure $\mu(\cdot)$ is said to be *more peaked about* $\mathbf{0} \in \mathbb{R}^k$ than $\nu(\cdot)$ if and only if $\mu(A) \ge \nu(A)$ for every set A in the class $\mathbf{C}_k$ comprising the compact convex subsets of $\mathbb{R}^k$ that are symmetric under reflection about $\mathbf{0} \in \mathbb{R}^k$, i.e. $\mathbf{x} \in A$ implies $-\mathbf{x} \in A$. For two type I t distributions $t_k(\mathbf{0}, \boldsymbol{\Sigma}, \nu)$ and $t_k(\mathbf{0}, \boldsymbol{\Omega}, \nu)$ on $\mathbb{R}^k$ having ordered scale matrices, the following inequality applies. Sufficiency is shown in [3], and necessity in [4].

Property 7. Let $t_k(\mathbf{0}, \boldsymbol{\Sigma}, \nu)$ and $t_k(\mathbf{0}, \boldsymbol{\Omega}, \nu)$ be type I multivariate t distributions on $\mathbb{R}^k$ having ordered scale matrices such that $\boldsymbol{\Omega} - \boldsymbol{\Sigma}$ is positive-semidefinite, and let $P_{\boldsymbol{\Sigma}}(\cdot; \nu)$ and $P_{\boldsymbol{\Omega}}(\cdot; \nu)$ be their corresponding probability measures. Then $P_{\boldsymbol{\Sigma}}(\cdot; \nu)$ is more concentrated about $\mathbf{0}$ than $P_{\boldsymbol{\Omega}}(\cdot; \nu)$ in the sense that $P_{\boldsymbol{\Sigma}}(A; \nu) \ge P_{\boldsymbol{\Omega}}(A; \nu)$ for every set A in the class $\mathbf{C}_k$.

Multivariate Techniques, Robustness

Many statistical techniques are based on assumptions about either the form or the structure of the data to which they are to be applied. This is as much the case in **multivariate analysis** as it is in other branches of statistics. For example, a **hypothesis test** about a population mean vector may assume normality of the sampled data (an assumption about the *form* of the data), while a comparison between the mean vectors of two populations may additionally require equality of the population dispersion matrices (an assumption about the data *structure*). In practical applications it is accepted that such assumptions will at best only be approximations to the truth, but the hope is that the validity and outcome of the technique will be largely unaffected within the sort of range of departures from these assumptions that might reasonably be encountered for real data.

In the *Dictionary of Statistical Terms* [17], a statistical procedure is described in broad terms as being *robust* if it is "not very sensitive to departure from the assumptions on which it depends". The **robustness** of a technique is thus, loosely, the extent to which it is unaffected by such departures, so that a study of the robustness of standard techniques is important from the point of view of practical statistics. In the univariate situation such study is generally restricted to inferential techniques arising from either hypothesis testing or **estimation** (whether point or interval). A theoretical distinction that is sometimes made in these studies is one between *criterion* robustness and *inference* robustness: the former is when the behavior of any criterion on which the inference depends (e.g. a particular test statistic or estimator) is largely unaffected by departures from assumptions, so that by implication the resulting inferences are also unchanged; in the latter case, the behavior of the criterion may be subject to appreciable changes under departures from assumptions but the resulting inferences are nevertheless unaffected. However, in practical terms this distinction is rather academic – the practitioner merely wants to know whether a technique is robust or not, and if not then what are the main areas of sensitivity.

In the multivariate case interest has again mainly focused on inferential techniques, particularly on hypothesis testing. However, the issue is now wider, as descriptive techniques such as canonical variate analysis (*see* **Canonical Correlation**) and modeling techniques such as **factor analysis** also invoke assumptions about the data, and thus have to be examined for robustness. We therefore consider three broad areas: inference, ordination and classification, and latent variable models, and give an overview of the robustness of the main techniques encountered under each of them. We should be clear at the outset about our frame of reference. We are here concerned only with the robustness of *standard* multivariate techniques to departures from those assumptions on which they are founded, and our aim is to give a general overview rather than to discuss the many detailed points that have been raised in the literature. What we are *not* concerned with is consideration of any specifically robust procedures, by which is meant procedures that remain unaffected by **outliers** or other data contaminants. This is a different aspect of robustness to the one given above, and such procedures are considered elsewhere in these volumes.

Inference

Most standard multivariate inferential procedures are concerned either with statements about the mean vector and/or the dispersion matrix of a single **multivariate normal distribution**, or with the comparison of these parameters across several multivariate normal populations. Moreover, there are now many special estimators of these parameters that are designed to be robust with respect either to outlying observations or to non-normality, so we will not explicitly consider estimation here. However, most extant tests of hypotheses about these parameters are based on the assumption of normality and (for multiple-population comparisons) equality of dispersion matrices, so we focus in this section on the robustness of these tests. It is convenient to subdivide the discussion into single-population and multiple-population tests, and within this subdivision to consider tests of means and tests of dispersion matrices separately.

For single-population tests of the mean vector, **Hotelling's T^2** is the most common normal-based test statistic. There have been various **simulation** studies of the performance of this test statistic (e.g. [4, 7, 16], and [24]). The consensus view is that the test is

more sensitive to **skewness** than to **kurtosis** of the underlying distribution: it is reasonably robust with regard to the nominal significance level (*see* **Level of a Test**) when the underlying distribution is symmetrical, but the actual significance level is greater than the nominal level for skew distributions, and the discrepancy increases both with increasing skewness and with number of variables p.

Single-population tests of dispersion matrices, by contrast, are more sensitive to kurtosis than to skewness in the parent population [19]. There are various standard hypotheses about dispersion matrices, but probably the most common is for independence (either mutual or blockwise). Reassuringly, the study by Pillai & Hsu [21] shows that none of the usual test statistics is seriously affected if departures from normality are only slight.

Turning to multiple-population tests, it is convenient to consider tests of equality of dispersion matrices first (as tests of equality of means usually make this prior assumption as well). Here, unfortunately, the situation is *not* very promising. The standard test for equality of a set of dispersion matrices is the **likelihood ratio test** and its associated approximations [22, p. 449], and available studies (e.g. [10], [15], and [20]) demonstrate its extreme nonrobustness to non-normality. In particular, it is very sensitive to kurtosis, and a significant value of the test statistic could be due equally to kurtosis as to departures from the null hypothesis. Indeed, Layard [15] goes so far as to say that its usefulness is suspect.

Turning finally to tests of equality of a set of g population means, we encounter the most complicated setup of those considered in this Section. Essentially we are in the realms of one-way **multivariate analysis of variance** (MANOVA), in which we assume that individual observations come from multivariate normal distributions having possibly different means but a common dispersion matrix. The complicating feature is that there are now several "standard" test statistics for the null hypothesis (each one sensitive to a different form of departure from the null hypothesis). The likelihood ratio statistic is commonly known as **Wilks' lambda** (λ), the **union–intersection principle** yields **Roy's maximum root**, $\phi_{\max}$, and the two other most common statistics are the **Lawley–Hotelling trace** T_g^2, and the **Pillai trace** V. (All these statistics reduce to the same quantity, Hotelling's generalized T^2, in the case of $g = 2$ populations.)

One of the earliest studies of these statistics was that by Ito & Schull [11], who demonstrated that when the sample sizes are the same from each population then moderate heterogeneity of dispersion matrices does not affect T_g^2 seriously, but when there is inequality in sample sizes then both the significance level and power of T_g^2 can be affected seriously. Analytical investigations of the effect of non-normality on λ and $\phi_{\max}$ were conducted by Davis [5, 6]. Broadly speaking, both statistics are reasonably robust to non-normality providing that the number of residual **degrees of freedom** is moderate to large, but if the underlying populations have large skewness or kurtosis then the effects on the true significance level can be large when there are fewer than about 30 residual degrees of freedom. Generally, effects on significance level for excess skewness are opposite to those for excess kurtosis, while each effect is itself reversed as sample sizes become more unbalanced. The widest comparison of all four statistics was in the 1974 **Monte Carlo** study by Olson [20], although he only considered the case of equal sample sizes from all populations. His conclusions were that kurtosis affects significance levels only mildly, the powers of all tests suffer under kurtosis, and inequality of dispersion matrices is the most serious violation. The worst statistic of the four in these respects is $\phi_{\max}$ (not surprisingly, as it is based on just a single extreme eigenvalue), while the best is Pillai's V. Moreover, robustness generally improves as either the number of groups g or the number of variables p is *reduced* (so, including variables "for the sake of it" is not to be recommended!).

Ordination and Classification

Ordination is the geometrical representation of multivariate samples as points in a low-dimensional space, while classification is the process of allocating individuals in multivariate samples to distinct populations. Often, prior ordination of multivariate data will facilitate subsequent classification. Most ordination techniques are purely descriptive and do not rely on any assumptions about the data, so there is no need to study their robustness. However, a genuine concern is the effect that outliers, contaminations of various types, or perturbations of the data might have on the results of the analysis, and some techniques have been

subjected to scrutiny with this in mind. Sibson [23] has quantified the effect that perturbations of the input dissimilarities might have on a metric scaling representation of the data. This quantification is given in terms of the **Procrustes** statistic between the original and perturbed configurations of points. Langron & Collins [14] have provided a similar quantification for the results of generalized Procrustes analysis, while Jackson [12, pp. 365–369] surveys the methods that have been developed to combat the effects of outliers on **principal components analysis**.

The one ordination technique which *does* make an explicit assumption about the data is canonical variate analysis, in which multivariate observations taken from g separate populations are represented geometrically by points in space in such a way that the ratio of between-population to within-population scatter is maximized (thereby highlighting population differences). This technique assumes a common dispersion structure across populations, and so is closely related to one-way multivariate analysis of variance. Robustness considerations associated with hypothesis testing in the latter situation have already been discussed above, but also of relevance is the robustness or otherwise of the ordination of the populations in the space of the canonical variates. Unfortunately, very little appears to have been done on this aspect. Campbell [3] offers some heuristic approaches for examining the effect of within-population heterogeneity in specific practical cases, but all that can be said in general is that standard canonical variate analysis will give increasingly misleading results as the population dispersion matrices become more disparate [18, p. 194].

By contrast to ordination, the area of discrimination and **classification** has received considerable attention with regard to robustness. The primary focus has been on the case of two groups, and specifically on the linear discriminant function (*see* **Discriminant Analysis, Linear**). This function was first derived in 1936 by Fisher [8] from the point of view of discriminating between two populations. Its derivation in this context was simply as the linear combination of variables that maximizes the ratio of squared difference of sample means to pooled within-sample variance, without recourse to any assumptions about the form or structure of the data. In this (discrimination) usage, therefore, the function is reasonably robust to a variety of data types. However, the function also arises as the optimal function for allocating future individuals to one of two multivariate normal populations that have equal dispersion matrices, where optimality is judged in terms of the expected cost incurred by misclassification of future individuals [25]. If the restriction to equal dispersion matrices is relaxed, but the assumption of normality is retained, then the optimal function becomes a quadratic discriminant function. These two functions are used very often in practice and so have been subjected to many robustness studies, in which the effects of departures from normality and from equality of population dispersion matrices have been examined. The criterion on which this examination is based is usually the error rate incurred in the classification of future individuals (*see* **Misclassification Error**). There are many complicated technical issues involved in some of these studies, and space limitations preclude any detailed discussion of them here; for an excellent summary survey see [18, pp. 152–161]. However, some very broad conclusions that may be drawn are that: both functions will perform very poorly if the data are continuous but non-normal with heavy tails and large skewness, while the quadratic function may still perform reasonably well if the distributions are symmetric even through heavy-tailed; the linear function will perform reasonable well on **binary data** (scored 0 and 1) providing that the true log **likelihood ratio** increases as the number of subjects who score 1 increases, but not otherwise; and the allocatory performance of the linear function with mixtures of discrete and continuous variables depends upon the similarity of the correlation patterns among the continuous variables in the two groups, being good when the similarity is high and poor when the similarity is low.

Latent Variable Models

A popular technique for the analysis of covariance structure, particularly in the social sciences, is factor analysis. This technique had been used since the early part of the twentieth century, but computational and theoretical advances in the 1960s and early 1970s by Jöreskog and co-workers not only greatly popularized its use but also led to developments in more general covariance structure analysis. The whole area now comprises a series of techniques that can be categorized under the heading of **structural equation models** [2]. All these techniques rest on the assumption of underlying sets of latent variables for the

explanation of observed covariances among a set of manifest variables. Models of varying levels of complexity can be built and analyzed with the aid of such software packages as **LISREL** (an acronym for "linear structural relationships", developed by Jöreskog & Sörbom [13]) or EQS (denoting "structural equations", developed by Bentler [1]). The fitting of these models is achieved by optimizing one of a number of available "fit functions" which measure the discrepancy between data and model. While some of these functions are fairly general ones, others have been derived from distributional assumptions about the data. In particular, the "default" choice of many researchers is the function resulting from **maximum likelihood** assuming normality of manifest variables, so again a study of robustness is an important consideration.

As in discrimination and classification, effects of non-normality on the results of the maximum-likelihood technique can be divided up according as the manifest variables are continuous but non-normal, categorical (and hence non-normal), or a mixture of the two types. For continuous non-normal variables, Bollen [2, p. 418] summarizes the available studies by saying that violation of normality does not generally affect the **bias** or **consistency** of estimates, but excessive kurtosis usually eliminates asymptotic **efficiency** and makes the estimated asymptotic covariance matrix and the chi-square **goodness-of-fit** test potentially inaccurate. In the case of discrete or categorical variables, the evidence from available studies [2, p. 435] suggests that not much distortion will occur on using the maximum likelihood procedure if the skewnesses and kurtoses of the variables are close to normal distribution values, but the chi-square goodness-of-fit statistic tends to be too big if the variables are highly skewed. However, as yet there has been little investigation in this area (and virtually nothing in the case of mixed continuous/categorical data), so these results can only be considered to be preliminary ones.

Finally, Henly [9] reports a large-scale Monte Carlo investigation of the robustness of a range of estimators to misspecification of the fit function. As well as concluding that robustness of the maximum likelihood and the normal theory generalized least squares estimators cannot be taken for granted, she provides a comprehensive survey and reference list of previous work in this area.

In summary, therefore, across all the different areas the broad concerns are the effects that departures from normality and/or equal dispersion matrices have on the standard techniques, in particular on type I error (*see* **Level of a Test**) and **power**. As a single overall conclusion it is probably fair to say that departures from normality are relatively unimportant providing that the true distribution is approximately symmetric with kurtosis near the normal value, but lack of equality of dispersion matrices can have much more serious consequences for those techniques that are aimed at analyzing grouped data.

Multivariate Weibull Distribution

Weibull distributions on $\mathbb{R}^1$ have wide usage in modeling cumulative damage, fatigue, life lengths, and as tolerance distributions for quantal responses. These distributions figure prominently in **survival analysis** as models for survival distributions (*see* **Parametric Models in Survival Analysis**). Applications in the biomedical sciences include survival analysis, cumulative damage to the liver and other organs, systems reliability for pacemakers and prosthetic devices in biomedical engineering, and life lengths of surgical repairs and organ duration including transplants. The typical cumulative distribution function (*cdf*) is $F(x) = 1 - \exp(-\lambda x^{\alpha})$, with λ and α as the scale and shape parameters, respectively. The *reliability function* $\overline{F}(x)$, also called the *survival function* $S(x)$, is given by $\overline{F}(x) = 1 - F(x) = \Pr(X > x) = S(x)$. The *failure rate function*, also known as the *intensity function*, the **hazard rate** *function*, and the force of mortality *function*, is given by $r(x) = f(x)/\overline{F}(x)$, with $f(x)$ as the probability density function (*pdf*) of the distribution (*see* **Survival Distributions and Their Characteristics**). In what follows $\mathcal{L}(X) = W(\lambda, \alpha)$ designates the Weibull model on $\mathbb{R}^1$, with $\mathcal{L}(X)$ as its law of distribution, and *iid* refers to independent and identically distributed **random variables**. Weibull distributions on $\mathbb{R}^n$ encompass joint distributions exhibiting essential Weibull characteristics. Since the distribution of $X^{1/\alpha}$ is Weibull on $\mathbb{R}^1$ whenever X has an exponential distribution, multivariate Weibull distributions associate in a natural way with multivariate exponential distributions of various types. Details follow.

A characteristic property of the one-dimensional Weibull family is its closure under the operation of taking minima. Specifically, if $\{X_1, \ldots, X_n\}$ are iid random variables on $[0, \infty)$, and if $Y = \min\{X_1, \ldots, X_n\}$, then $\mathcal{L}(Y)$ is Weibull on $\mathbb{R}^1$ if and only if each $\mathcal{L}(X_i)$ is Weibull on $\mathbb{R}^1$ for $1 \le i \le n$. See Dubey [6] for further details. For additional characterizations let $\mathcal{L}(X)$ be **exponential** with unit mean, and let Z have a stable distribution on $\mathbb{R}^1$ with index α, independently of X. Then the Weibull distribution, $\mathcal{L}(T) = W(1, \alpha)$, can be characterized in terms of X as $\mathcal{L}(T) = \mathcal{L}(X^{1/\alpha})$ as noted, and in terms of (X, Z) as $\mathcal{L}(T) = \mathcal{L}(XZ^{-1})$; see [21] and [22].

On $\mathbb{R}^n$ let $\overline{F}(t_1, \ldots, t_n) = \Pr(T_1 > t_1, \ldots, T_n > t_n)$ be the joint survival function of the positive random variables $[T_1, \ldots, T_n]$. Basic properties of $\overline{F}(s, t)$ for $n = 2$, with obvious extensions, are as follows. The marginal survival function for S is given by $\overline{F}(s, 0)$, for $U = \min\{S, T\}$ is $\overline{F}(u, u)$, and for $V = \min\{aS, bT\}$ is $\overline{F}(av, bv)$ under arbitrary scaling. Let $R(\mathbf{t}) = -\log \overline{F}(\mathbf{t})$. Then the *hazard gradient* is the vector $\mathbf{r}(\mathbf{t}) = [\partial R(\mathbf{t})/\partial t_1, \ldots, \partial R(\mathbf{t})/\partial t_n] = [r_1(\mathbf{t}), \ldots, r_n(\mathbf{t})]$ when defined. These have been studied in Johnson & Kotz [11] and in Shaked [20], where bounds are provided, and elsewhere.

The foregoing facts are central to the study of multivariate distributions exhibiting Weibull characteristics. Many multivariate distributions have Weibull marginals; five classes may be identified here as follows:

C1. $[T_1, \ldots, T_n]$ are independent such that $\{\mathcal{L}(T_i) = W(\lambda_i, \alpha); 1 \le i \le n\}$.

C2. $[T_1, \ldots, T_n]$ are generated as $\{T_i = \min(X_J; i \in J); 1 \le i \le n\}$. Here, $\mathcal{J}$ is a class of nonempty subsets of $\{1, 2, \ldots, n\}$ such that for each i, $i \in J$ for some $J \in \mathcal{J}$, whereas $\{X_J; J \in \mathcal{J}\}$, are independent random variables having distributions $\{W(\lambda_J; \alpha), J \in \mathcal{J}\}$.

C3. For arbitrary positive constants $\{a_1, \ldots, a_n\}$, $U = \min\{a_1 X_1, \ldots, a_n X_n\}$ has a Weibull distribution $\boldsymbol{W(\lambda(\mathbf{a}), \alpha)}$ on $\mathbb{R}^1$ for some $\lambda(\mathbf{a}) = \lambda(a_1, \ldots, a_n) > 0$ and $\alpha > 0$.

C4. $[T_1, \ldots, T_n]$ have a joint distribution with Weibull minima such that $U_s = \min\{T_i; i \in S\}$ has a Weibull distribution $W(\lambda_s, \alpha)$ on $\mathbb{R}^1$ for some $\lambda_s > 0$, for every nonempty subset S of $\{1, 2, \ldots, n\}$.

C5. $[T_1, \ldots, T_n]$ have a joint distribution with arbitrary Weibull marginals $\{\mathcal{L}(T_i) = W(\lambda_i, \alpha_i); 1 \le i \le n\}$, on $\mathbb{R}^1$.

Class C2 comprises joint distributions of minima of overlapping subsets of independent Weibull variates, as in [5] and [14]. Related work by Shaked [20] considers minima over sets of random size.

Examples of **bivariate distributions** in these classes are known. Consider the typical function $\overline{F}(t_1, t_2) = \exp\{-[\lambda_1 c_1^{\alpha} t_1^{\alpha} + \lambda_2 c_2^{\alpha} t_2^{\alpha} + \lambda_{12} \max(c_1^{\alpha} t_1^{\alpha}, c_2^{\alpha} t_2^{\alpha})]\}$ on the positive quadrant, such that $\alpha > 0, c_1 > 0, c_2 > 0, \lambda_1 > 0, \lambda_2 > 0,$ and $\lambda_{12} \ge 0$.

If $c_1 \neq c_2$ and $\lambda_{12} > 0$, then this distribution belongs to class C3. Furthermore, consider functions of the type $\overline{F}(t_1, t_2) = \exp\{-[\lambda_1 t_1^{\alpha_1} + \lambda_2 t_2^{\alpha_2} + \lambda_{12} \max(t_1^{\alpha_1}, t_2^{\alpha_2})]\}$ such that $\alpha_1 > 0, \alpha_2 > 0, \lambda_1 > 0, \lambda_2 > 0$, and $\lambda_{12} \geq 0$. If $\alpha_1 \neq \alpha_2$, then this distribution belongs to class C5. If $\alpha_1 = \alpha_2 = \alpha$ and $\lambda_{12} > 0$, then this distribution belongs to class C2. The typical marginal distribution in the class C4 takes the form $\Pr[\min_{i \in S}(T_i) > t] = \exp(-\lambda_S t^{\alpha})$ for some $\lambda_S > 0$. For further reference see Lee [13].

A subclass of C5, due to Marshall & Olkin [17], is generated as $[T_1, \ldots, T_n] = [X_1^{1/\alpha_1}, \ldots, X_n^{1/\alpha_n}]$, where $[X_1, \ldots, X_n]$ follow the multivariate exponential distribution of those authors (*see* **Multivariate Outliers**). The typical survival function takes the form

$$\overline{F}(\mathbf{t}) = \exp\left[\sum_J \lambda_J \max_{i \in J}(\mathbf{t}_i^{\alpha})\right]$$

with $\alpha > 0$ and $\lambda_J > 0$ for $J \in \mathcal{J}$, where sets J are elements of the class $\mathcal{J}$ consisting of nonempty subsets of $\{1, \ldots, n\}$, such that, for each i, it is true that $i \in J$ for some $J \in \mathcal{J}$. For extensions see Arnold [1]. Weibull distributions of these types are studied extensively in [19].

Lee [13] considered distributions of the foregoing types and proposed the classification scheme adopted here. He further established that the inclusion relations C1 $\subset$ C2 $\subset$ C3 $\subset$ C4 $\subset$ C5 are strict.

Distributions on $\mathbb{R}^n$ are said to have the *increasing failure rate average (IFRA)* property whenever $\mathrm{E}[h(T_1, \ldots, T_n)] \leq \{\mathrm{E}[h^{\gamma}(T_1/\gamma, \ldots, T_n/\gamma)]\}^{1/\gamma}$ for every nonnegative continuous nondecreasing function $h(\cdot)$ and for all $0 < \gamma \leq 1$. Block & Savits [2] show that the Weibull distributions on $\mathbb{R}^n$ of Marshall & Olkin [17], and distributions in the class C2, are all IFRA for the cases $\alpha_i \geq 1$, $1 \leq i \leq n$, and $\alpha \geq 1$, respectively. Related developments pertaining to multivariate hazard rates and their applications are undertaken by Johnson & Kotz [11].

Krishnaiah [12] generalized from Weibull distributions for the case $n = 2$ on taking $[T_1, T_2] = [X_1^{1/\alpha_1}, X_2^{1/\alpha_2}]$ such that $[X_1, X_2]$ follow a bivariate **gamma distribution**. Maxim et al.. [18] considered the choice of optimal designs under multivariate Weibull sensitivity models. Connections are known between particular multivariate Weibull distributions and the multivariate **extreme-value** distributions of Gumbel [7]; see also Johnson & Kotz [10, p. 249 ff].

More recent studies are germane. Repeated failure time measurements are modeled in [3] using conditionally independent Weibull failure times $W(\lambda, \alpha)$, whereas α is then assigned a gamma distribution over subjects. The unconditional mixture on $\mathbb{R}^n$ is a multivariate Burr distribution (see [10, p. 288 ff.]). If, instead, α is given a stable distribution as in [4], then the resulting mixture is genuinely multivariate Weibull having Weibull marginals. See also [8, 9, 15], and [16], where related matters and further mixtures are treated. The univariate Weibull distribution is often employed in discussions of **accelerated life** testing and failure models. Parallel developments are reported in [15] for the class of multivariate Weibull distributions as treated in [8].

D.R. JENSEN

Mutagenicity Study

In many laboratory experiments, data are analyzed via various statistical approaches, each depending on the nature of the endpoint and aspects of the particular assay under study [39]. Among major endpoints of interest, damage to genetic components such as DNA is of increasing interest. Mutation induction, or *mutagenicity*, and other forms of genotoxicity represent fruitful areas of study, particularly as continuing biotechnological advances allow for more precise genetic study.

Mutagenicity is perhaps the most varied of any toxicological endpoint, since the potential mechanisms of genetic damage are so numerous. Indeed, there exist well over 100 different genotoxicological assays, employing all sorts of animal and microbial systems [18, 50]. Statistical themes associated with mutagenicity experiments include proper identification of the **sampling distribution** [24, 31, 40], construction of appropriate biomathematical models to characterize **dose response** and other features of genetic damage [2, 3, 17, 22, 30], **sample size determination** [7, 30, 35, 42], and the selection of statistical approaches associated with these models and methods [28]. A basic introduction to these issues is given in the compilation by Kirkland [21]. Here, attention will be directed at some of the basic issues of dose–response analysis encountered in mutagenesis experiments.

Microbial Systems in Environmental Mutagenesis: The *Salmonella* Assay

Perhaps the most well known of all modern mutagenicity assays is the Ames/*Salmonella* microsome assay [33], employing the bacteria *Salmonella typhimurium* to identify damage to DNA after exposure to toxic agents. The assay is based on strains of the bacterium unable to synthesize histidine, an amino acid required for growth. This production deficiency can be reversed into a production capability via point mutations at selected sites on the bacterial genome. DNA damage is indicated by mutation of the bacteria from histidine-dependency to a self-sustaining state. Thus, the mutated cells can grow in a microenvironment (such as a Petri plate) containing only minimal amounts of histidine; greater mutant yield at higher exposures to the environmental chemical suggests that mutagenesis increases with increasing dose. Observational accuracy of the assay is enhanced by use of a selective medium for the growth environment, so that only mutant colonies grow after exposure to the environmental toxin.

The observations in such a microbial assay are the mutated colony counts, Y_{ij}, for the jth replicate plate at the ith dose ($i = 1, \ldots, T; j = 1, \ldots, R_i$). Commonly, the number of replicate plates is taken to be constant, e.g. $R_i = 3$, for all i. (Table 1 presents an example of data from a *Salmonella* assay, using the chemical agent 1,3-butadiene.) A natural candidate for the sampling distribution of Y_{ij} is the **Poisson distribution** for count variables. Indeed, many processes that drive the Poisson sampling assumption are active with the colony count data seen here. These include:

1. The microbes' responses are independent.
2. Each locally organized group of microbes experiences the same environment (ignoring controlled variables such as dose).
3. The plated number of microbes is large, say 10^8.
4. The probability that a plated microbe gives rise to a visible mutant colony is small, between 10^{-5} and 10^{-9} [30].

A fifth assumption crucial to adoption of the Poisson distribution, however, is that both the environment and the number of microbes plated should remain relatively stable across replicate plates (within a dose group). If this is not the case, extra-Poisson variability results, and one is forced to model or otherwise account for the consequent **overdispersion** in Y_{ij}.

Table 1 *Salmonella* mutagenicity results for 1,3-butadiene in strain TA1535

Dose (ppm)	Mutants per plate, Y_{ij}			Average plate count, $\overline{Y}_i$
0.000	20	31	27	26.0
0.002	100	92	89	93.7
0.007	147	123	178	149.3
0.014	216	170	181	189.0
0.020	176	154	183	171.0
0.030	154	153	149	152.0

Testing for Extra-Poisson Variability

Testing for extra-Poisson variability is critical when analyzing count data from mutagenicity experiments. Standard trend tests for Poisson-distributed counts (see Trend Tests for Counts and Proportions) become too sensitive in the presence of overdispersion, increasing type I error rates above the nominally specified α level [38]. Thus, the data analyst must be aware of the nature and level of any overdispersion in the data before selecting a test for dose response.

Extra-Poisson variability in a set of ostensibly homogeneous observations is most easily assessed by a variance-to-mean comparison. The test employs Fisher's dispersion statistic [14, 15]:

$$X_i^2 = \sum_{i=1}^{T} \frac{(Y_{ij} - \overline{Y}_i)^2}{\overline{Y}_i}, \qquad (1)$$

where $\overline{Y}_i$ is the ith dose sample mean ($i = 1, \ldots, T$) (*see* **Poisson Distribution**). Asymptotically, X_i^2 is distributed as $\chi^2(R_i - 1)$, (i.e. with $R_i - 1$ degrees of freedom), hence $X_i^2 > \chi^2_{1-\alpha}(R_i - 1)$ implies significant extra-Poisson variability. This test is $C(\alpha)$-optimal against the **negative binomial distribution** [35], a standard alternative to the Poisson model. To extend (1) to multiple test groups, simply aggregate the individual X_i^2 statistics into a sum of per-dose contributions [28]: $X^2 = \sum_{i=1}^{T} X_i^2$. Asymptotically, X^2 is distributed as $\chi^2\left(\sum_{i=1}^{T} R_i - T\right)$. (A slightly more powerful test of extra-Poisson variability may be constructed using the similar statistic $C^2 = \sum_{i=1}^{T} \sum_{j=1}^{R_i} (Y_{ij} - \overline{Y}_i)^2 / \overline{Y}$, where $\overline{Y} = \sum_{i=1}^{T} R_i Y_i / \sum_{i=1}^{T} R_i$. The null reference distribution of C^2 is complex, however, and hence somewhat difficult to apply in practice [11].) Dean [13] discusses additional extensions to more complex regression settings; see also [20].

A common application of these tests is to large, controlled databases where similar controlled trials and replicate data are available. Margolin et al. [30] reported on such data, demonstrating that the Poisson model generally is inadequate to describe statistical variability when analyzing *Salmonella* mutagenicity experiments. Further research has suggested that *Salmonella* data often exhibit extra-Poisson variability, and that the parent distribution of the data is better described by a negative binomial distribution [11, 28, 30]. Other publications indicate, however, that the Poisson model can be acceptable in select instances [8], particularly for test data obtained by imposing strict protocol adherence and by harvesting all the data on the same day [16, 26]. Given these conflicting considerations, testing for extra-Poisson variability via X^2 is necessary in practice.

Trend Tests for Dose Response

For mutagenicity experiments where no extra-Poisson variability is evidenced, the well-known Cochran–Armitage trend test for dose response may be employed. Under Poisson sampling, the test is known to be optimal against any monotone dose–response function [32, 48]. Given the observed counts, Y_{ij} ($j = 1, \ldots, R_i; i = 1, \ldots, T$), and denoting x_i as some increasing score (dose, log dose, etc.) associated with treatment level i, the test statistic is

$$Z_{\mathrm{CA}} = \frac{\sum_{i=1}^{T} x_i \left[\left(\sum_{j=1}^{R_i} Y_{ij} \right) - R_i \overline{Y} \right]}{(\overline{Y} S_x^2)^{1/2}}, \qquad (2)$$

in which $S_x^2 = \sum_{i=1}^{T} R_i (x_i - \overline{x})^2$ and $\overline{x} = \sum_{i=1}^{T} R_i x_i / \sum_{i=1}^{T} R_i$. Asymptotically, Z_{CA} is distributed as standard normal, and significant dose response is suggested when Z_{CA} is larger than an appropriate upper-α quantile, $z_{1-\alpha}$.

If the response is overdispersed and the Poisson model is invalid, a form of Cochran–Armitage trend test may still be constructed. Under a negative binomial parent model, one simply replaces $(\overline{Y} S_x^2)^{1/2}$ in (2) with an updated estimator based on estimating the negative binomial variance [28]. The result is

$$Z_{\mathrm{NB}} = \frac{\sum_{i=1}^{T} x_i \left[\left(\sum_{j=1}^{R_i} Y_{ij} \right) - R_i \overline{Y} \right]}{[\overline{Y}(1 + \hat{\delta}\overline{Y}) S_x^2]^{1/2}}. \qquad (3)$$

The dispersion estimator, $\hat{\delta}$, is calculated by the **method of moments**, **maximum likelihood** (ML), or maximum quasi-likelihood [10, 36, 49]. For ML estimation, differentiating the log likelihood function

with respect to δ achieves a nonlinear equation,

$$\psi\left(\frac{1}{\delta}\right)\sum_{i=1}^{T} R_i + \sum_{i=1}^{T}\sum_{j=1}^{R_i}\left[\ln(1+\delta\overline{Y}_i) - \psi\left(Y_{ij}+\frac{1}{\delta}\right)\right] = 0, \qquad (4)$$

the solution of which provides $\hat{\delta}_{\mathrm{ML}}$. In (4), $\psi(\cdot)$ is the digamma function, which is available from tables [1] or computer algorithms [5]. Once calculated, $\hat{\delta}_{\mathrm{ML}}$ is substituted for $\hat{\delta}$ in (3). As above, significant dose response is suggested when Z_{NB} is larger than a standard normal quantile, $z_{1-\alpha}$.

When the parent distribution of the data is not known or indeterminate, it is possible to construct a generalized score statistic (*see* **Likelihood**) for testing trend producing a statistic recommended by Astuti and Yanagawa [4]

$$\mathrm{Z_{GCA}} = \frac{\sum_{i=1}^{T} R_i(x_i-\overline{x})\overline{Y}_i}{\sqrt{\sum_{i=1}^{T}(x_i-\overline{x})^2\sum_{j=1}^{R_i}(Y_{ij}-\overline{Y})^2}}, \qquad (5)$$

where $\overline{x}$, $\overline{Y}_i$, and $\overline{Y}$, are defined as above. In large samples, $\mathrm{Z_{GCA}}$, is distributed approximately as standard normal; thus we reject $\mathrm{H_0}$ in favor of an increasing (decreasing) trend in the mean response when $\mathrm{Z_{GCA}}$ is greater (less) than or equal to $z_{1-\alpha}(-z_{1-\alpha}$. (Two-sided testing is also possible.) This is similar to the basic statistics in (2) or (3); the major difference is that the terms estimating the Poisson or negative binomial variances are replaced by the more robust empirical variance estimate $\sum_{j=1}^{R_i}(Y_{ij}-\overline{Y})^2$.

Trend Test Under Nonmonotone Dose Response

An important, additional feature illustrated by the data in Table 1 is a curious downturn in the response at higher doses. This form of nonmonotone dose response is common in the *Salmonella* assay, and is observed with other mutagenesis assays, including data for chromosomal damage in yeast (*Saccharomyces cerevisiae*) or mold (*Aspergillus nidulans*) [37, 42], *in vitro* cell transformation data, or *in vitro* chromosome aberration data with human lymphocytes [43].

In *Salmonella*, the downturn phenomenon is driven by a number of possible mechanisms, the most common of which is a consequence of the experimental scheme employed to identify the mutational events. Since mutagenesis is identified by growth on a selective medium, any other mechanism that hinders growth will compete with the desired outcome. Thus, for example, high exposures of the toxic agent can lead to cell death or perhaps chemical/threshold induced increases in DNA repair. These factors conspire to *reduce* the yield of mutated cells by killing or neutralizing the microbes before mutations can be observed. The result is a downturn at the higher doses, i.e. an *umbrella response* [25]. As might be expected, simple tests for monotone trend such as Z_{CA}, Z_{NB}, or Z_{GCA} can exhibit large losses in **power** to detect any increase in dose response in the presence of a downturn [12], and suitable alternatives must be employed.

Nonlinear biomathematical and empirical models for this downturn phenomenon are available, which, when coupled with the negative binomial sampling model on the Y_{ij}s, involve fairly advanced statistical methodology [9, 23, 30]. A simple alternative is to identify statistically the point of maximal departure from background mutation levels, and then test for increasing trend up to that point. A number of different procedures have been suggested for such an approach [6, 46], the majority of which analyze the **ranks** of the observations by nonparametric techniques [37].

For example, a nonparametric approach developed by Simpson & Margolin [46] estimates recursively the point of maximal response (the *umbrella point*), and then tests for a significant increase in dose response up to that point. One begins by calculating a series of two-sample **Mann–Whitney** statistics [27], W_i, comparing the ith dose group with – collectively – all preceding dose groups, starting at $i = T$ and working backwards. That is, W_T tests whether the response information at $i = T$ departs significantly above the pooled response information at $i = 1, \ldots, T-1$. If so, an estimate, $\mathbf{h}$, of the umbrella index is $\mathbf{h} = T$. If not, one discards the information at $i = T$, and repeats the process at $i = T-1$. In this way, the test employs the values of $W_i (i = T, T-1, \ldots, 2)$ to estimate the umbrella index via recursive pretesting. In effect, it selects

this estimate as the largest dose index, $\mathbf{h}$, such that $W_{\mathbf{h}}$ is larger than a specified critical value $c_{\mathbf{h}}$; i.e. $\mathbf{h} = \max\{i \in \{2, \ldots, T\} : W_i > c_i\}$, where $c_2 = 0$ and $c_i = c_i(\mathbf{q})(i = 3, \ldots, T)$ is the $\mathbf{q}$-quantile of the distribution of W_i under the null hypothesis of no dose response. The tuning parameter $\mathbf{q} \in (0, 1)$ must be prespecified, and is usually set at, or near, $\mathbf{q} = 0.5$ [37, 47].

Once the umbrella index, $\mathbf{h}$, is estimated, the recursive procedure calculates the conditional Jonckheere–Terpstra trend statistic $U_{\mathbf{h}} = W_1 + \cdots + W_{\mathbf{h}}$ [19], and an increasing dose response is suggested when $U_{\mathbf{h}}$ is larger than the $(1 - \pi)$-quantile of the distribution of U_i under the null hypothesis of no differences among the doses $(i = 2, \ldots, T)$, for $0 < \pi < 1$. For fixed $\mathbf{q}$ and prespecified significance level α, a conservative choice for π is given as $\pi = \alpha(1 - \mathbf{q})/(1 - \mathbf{q}^{T-1})$ [46]. A computing algorithm for these calculations is described in [45], and extensions and other research issues involved with rank-based testing for *Salmonella* data are discussed in [44].

Example: 1,3-Butadiene

Consider the example of the airborne toxin 1,3-butadiene, the data for which appear in Table 1. These values represent a *Salmonella* mutagenic response after gaseous exposure to the chemical, where an increase in the number of observed colonies suggests a mutagenic effect.

Begin by testing whether the data exhibit any overdispersion relative to the Poisson sampling model. Employing the aggregated dispersion statistic using (1) to the data in Table 1 gives $X^2 = 22.134$ on 12 df ($P = 0.004$). Strong departure from Poisson variability is evidenced. If the negative binomial sampling model were considered as an adequate replacement to the Poisson for these data, then a trend test for increasing dose response based on (3) gives $Z_{\mathrm{NB}} = 1.285$, with one-sided $P = 0.099$. Marginal suggestion of an increasing trend is given.

For these data, however, a downturn in the dose response is evident. This could affect the trend test's ability to identify properly a positive dose response. Application of the recursive test for an umbrella response is therefore appropriate: setting the tuning parameter to $\mathbf{q} = 0.5$, the umbrella index is estimated as $\mathbf{h} = 6$, with a corresponding rank-based trend statistic given by $U_6 = 105.5$. Rejection occurs at significance levels as low as $\alpha = 0.005$, providing strong evidence of a positive dose response for these mutagenicity data.

WALTER W. PIEGORSCH

Mutation

Most of the time when chromosomes duplicate, the deoxyribonucleic acid (**DNA**) is faithfully copied. Rarely, however, mutation occurs, i.e. there is a change due to an error in the copying process, leading to a mutant allele (*see* **Gene**). There are different kinds of mutations, depending on which base-pair in a DNA sequence is miscopied, such as missense mutations that change an amino acid in a protein and nonsense mutations that result in the formation of an incomplete protein. Whereas nonsense mutations usually lead to lack of biologic activity, and hence have a large effect, missense mutations can vary in effect from none to serious disease. The word mutation is now often used to mean a mutant allele, especially if the allele is rare and has a deleterious effect, in contrast to a **polymorphism**. But all polymorphisms can be assumed to have arisen by mutation, making evolution possible.

ROBERT C. ELSTON

National Center for Health Statistics (NCHS)

The National Center for Health Statistics (NCHS) is the principal health statistics agency of the US, with responsibility for designing and maintaining a variety of general-purpose descriptive health surveys on a continuous basis and disseminating these data for widespread use (*see* **Surveys, Health and Morbidity**). The NCHS came into being in 1960 through the combining of the National Health Survey and the National Office of Vital Statistics. The principal health surveys conducted by the NCHS include **population-based** surveys (the National Health Interview Survey and the National Health and Nutrition Examination Survey); record-based surveys (the National Health Care Surveys); facility-based surveys (the Master Facility Inventory and the National Nursing Home Survey); and the Cooperative National Vital Statistics System covering births, deaths, fetal deaths, marriages, and divorces (*see* **Vital Statistics, Overview**).

History

The National Vital Statistics System of the US achieved essentially complete coverage for births and deaths in 1933. The collection and archiving of vital records are the responsibilities of each of the states and territories. The federal system is a cooperative program between each of the registration areas and the NCHS (and its predecessor agencies). In coordination with the Association for Vital Records and Health Statistics, which represents the registrars of each of the states, NCHS periodically revises the model certificates for registration of vital events, identifies the data items to be reported to NCHS for national tabulation, and specifies quality criteria for the accuracy, completeness, and timeliness of reporting vital events.

Drawing on the experience of such surveys as the nationwide health survey of 1935–1936 done under the auspices of the Work Projects Administration (WPA) and local health surveys conducted in Hagerstown and Baltimore, Maryland, which showed that interview-based health surveys were feasible, and encouraged by recent advances in population sampling and statistical methods developed by the US Bureau of the Census, the newly created US National Committee of Vital and Health Statistics issued a report calling for the development of a National Morbidity Survey. Largely in response to this report, Congress passed the National Health Survey Act in 1956. The first component of the National Health Survey to be implemented was the National Health Interview Survey which went into the field in July 1957, and has been conducted continuously since then. The second component, the National Health Examination Survey (subsequently to become the National Health and Nutrition Examination Survey when a major nutrition component was added in 1971) was initiated in 1960 and has been conducted periodically seven times with plans for initiating it as a continuously ongoing survey in 1998. The third component was the Health Records Survey which began in 1963 with the creation of a National Master Facility Inventory (NMFI) designed as a comprehensive file of inpatient facilities in the US. Drawing a sample of hospitals from the NMFI, the National Hospital Discharge Survey began in 1965 and has been conducted continuously since. Additional subcomponents of the renamed National Health Care Survey were added over the years including the National Ambulatory Medical Care Survey, the National Survey of Ambulatory Surgery, the National Hospital Ambulatory Medical Care Survey, and the National Home and Hospice Care Survey. The National Nursing Home Survey has been conducted intermittently since 1973 and is based more on characteristics of facilities than on individual patient records.

The NCHS has been based in a number of agencies since its inception, but since 1987 it has been a component of the **Centers for Disease Control (CDC)** of the Department of Health and Human Services with most of its staff of about 500 persons located in Hyattsville, Maryland.

Survey Programs of the National Center for Health Statistics

The National Health Interview Survey

The National Health Interview Survey (NHIS) is a continuous **cross-sectional** survey of the noninstitutionalized, civilian population of the US designed to produce national data on the incidence of acute illnesses and injuries, prevalence of chronic

conditions and impairments, extent of disabilities, utilization of health care services (*see* **Health Care Utilization Data**), and, on a periodic basis, information on other health-related topics such as health insurance coverage, knowledge and attitudes about HIV/**AIDS**, use of medical devices, immunization status of children, and indicators of progress toward achieving the objectives set in *Healthy People 2000: National Health Promotion and Disease Prevention Objectives*. The sampling plan follows a **multistage sampling** design such that the sample scheduled each week is representative of the **target population** and the weekly samples can be cumulated over time. For the years 1985–1994 a typical NHIS sample consisted of 198 primary sampling units (counties or metropolitan statistical areas) with approximately 7500 segments (defined to contain an expected eight households each) yielding about 59 000 assigned households, of which about 15% were vacant or out of scope. The expected final sample of about 49 000 households comprised a **probability sample** of about 125 000 persons. The annual response rates for the core survey have been between 94% and 98% over the years, with somewhat lower response rates for the special topic areas.

The data are collected through personal household interviews conducted by interviewers employed and trained by the Bureau of the Census according to procedures specified by the NCHS. The questionnaires are developed in conjunction with statisticians and experts in cognitive psychology. Extensive pretesting and field trials are conducted before the survey goes into each annual cycle. All members of the household aged 17 and older are invited to participate and to respond for themselves. For children and for persons not at home, information is provided by a proxy (an adult resident of the household). For some topics, a random subsample of household members is selected and special techniques have been developed for eliciting confidential information on sensitive topics in the household setting. The NHIS often serves as a **sampling frame** for follow-on studies and special callbacks will be made to household members selected for such studies (*see* **Call-backs and Mail-backs in Sample Surveys**). These targeted population studies have included the Longitudinal Study on Aging, the Teenage Attitudes and Practices Survey, the Access to Care Followup Study, and the Disability Followup Survey.

The National Health and Nutrition Examination Survey

Through the National Health and Nutrition Examination Surveys, the NCHS provides estimates of the **prevalence** of selected diseases and conditions, normative distributions for a variety of physiologic, anthropomorphic, and nutritional measures, and assessments of exposures to environmental hazards such as lead and pesticides. Seven health examination surveys were conducted by the NCHS between 1960 and 1995. With the addition of the specific mandate to monitor the nutritional status of the US in 1970, the three Health Examination Surveys conducted in the 1960s were followed by the first National Health and Nutrition Examination Survey (NHANES I) in 1970–1973, NHANES II in 1976–1980, and NHANES III in 1988–1994. The surveys were designed to obtain nationally representative information on the health and nutritional status of the population using interviews, physical examinations, and standardized clinical and laboratory tests. This information is of two kinds: prevalence data of selected diseases and health conditions; and normative population data on the distribution of such measurements as height, weight, blood pressure, visual and auditory acuity, and a variety of blood chemistries such as cholesterol levels, vitamin levels, and metabolites of pesticides and other environmental exposures. The several surveys have targeted different age segments of the population, with the latest survey covering the entire noninstitutionalized US population aged two months or older. A special Hispanic Health and Nutrition Examination Survey (HHANES) was conducted in 1983–1984 covering three areas with high concentrations of Hispanic Americans: Mexican Americans in the Southwest; Cubans in Miami (Dade County), Florida; and Puerto Ricans in the New York City area. Oversampling has been used in other surveys to obtain more precise estimates for selected subgroups of the population. In NHANES III, black and Mexican Americans, as well as children and older persons were oversampled.

The sample design of NHANES III employed a **stratified** multistage probability sample of counties, blocks, and persons randomly selected from households. The periods 1988–1991 and 1991–1994 each constituted national samples of the US population. Eighty-one counties were selected from 26 states from which approximately 40 000 persons of all races

were selected and about 30 000 agreed to participate in the medical examination. The examinations are conducted in specially designed mobile examination centers that provide a standardized environment for obtaining the measurements and biologic samples. Some of the 30 topics investigated in the NHANES III were: high blood pressure, high blood cholesterol, obesity, passive smoking, lung disease, osteoporosis, HIV, hepatitis, *Helicobacter pylori*, immunization status, diabetes, allergies, growth and development, blood lead, anemia, food sufficiency, dietary intake including fats, antioxidants, and nutritional blood measures.

NHANES I Epidemiologic Followup Study

The NHANES I Epidemiologic Followup Study (NHEFS) is a national longitudinal study designed to investigate the relationships between clinical, nutritional, and behavioral factors assessed at baseline NHANES I, and subsequent morbidity, mortality, and institutionalization. The NHEFS population includes the 14 407 participants who were 25–74 years of age when first examined in NHANES I (1971–1975). NHEFS provides data on mortality, morbidity, and hospital utilization as well as changes in risk factors, functional limitation, and institutionalization between NHANES I and the follow-up recontacts. The first wave (1982–1984) of data collection was conducted for all members of the NHEFS cohort. Continued follow-ups of the NHEFS population were conducted in 1986, 1987, and 1992.

National Survey of Family Growth

The National Survey of Family Growth monitors childbearing practices and reproductive health through periodic household interview surveys of a national sample of women aged 15–44. The survey provides data on contraception, infertility, use of family planning and infertility services, sexual activity, family formation, family size and related aspects of maternal and child health. Conducted periodically since 1973, the survey was conducted most recently in 1995.

The National Health Care Survey

The National Health Care Survey (NHCS), originally consisting of four discrete record-based surveys, is now an integrated survey of a wide variety of health care providers. The NHCS was built upon the following four continuing surveys: the National Hospital Discharge Survey, the National Ambulatory Medical Care Survey, the National Nursing Home Survey, and the National Health Provider Inventory (formerly the National Master Facility Inventory). The new surveys include the National Survey of Ambulatory Surgery, the National Hospital Ambulatory Medical Care Survey, and the National Home and Hospice Care Survey.

National Hospital Discharge Survey

The National Hospital Discharge Survey (NHDS) is the principal source of information on inpatient utilization of nonfederal short-stay hospitals. It includes data on diagnoses, procedures, length of stay, expected source of payment, and patterns of use of care in hospitals, and on the size, location, and ownership of hospitals, but does not include individual identifiers for patients. Conducted annually since 1965, the NHDS currently is based on data abstracted from a sample of approximately 274 000 patient records from a sample of 525 hospitals from a universe of about 8000 short stay hospitals. Only hospitals with six or more beds and an average length of stay for all patients of less than 30 days are included in the sample.

National Ambulatory Medical Care Survey

The National Ambulatory Medical Care Survey (NAMCS) provides statistics on the characteristics of patients and services provided by office-based physicians. The sample consists of 40 000 visits from approximately 3000 physicians drawn from a sampling frame of licensed physicians in office-based, patient care practices compiled from files maintained by the American Medical Association and the American Osteopathic Association. Data collection is carried out by the participating physicians using a form that takes only one or two minutes to complete. Up to 10 patient visits per physician are reported each day during about a one-week period. The sampling rate and duration depend on the number of patients the physician expects to see. The data collected for each patient visit include information on the patient's symptoms, diagnostic procedures, physician's diagnoses, and medications ordered or provided, as well

as patient management and planned future treatment. The NAMCS has been conducted annually from 1974 to 1981, in 1985, and annually since 1989.

National Survey of Ambulatory Surgery

The National Survey of Ambulatory Surgery (NSAS) provides information on the use of free-standing and hospital-based ambulatory surgery centers in the US. Although most surgery is still performed on an inpatient basis, advances in medical technology have enabled a wide variety of surgical and diagnostic treatments now to be performed in an ambulatory setting. The NSAS, which began in April 1994, provides detailed data on this expanding area of health care. Information collected includes patient characteristics, diagnoses, surgical and diagnostic procedures, and administrative information such as patient disposition and expected sources of payment.

National Hospital Ambulatory Medical Care Survey

The National Hospital Ambulatory Medical Care Survey produces statistics that are representative of the experience of the US population receiving health care in hospital emergency departments and outpatient departments. This hospital-based survey, which is based on abstracts from medical records, provides information similar to that collected in the office-based ambulatory survey: demographic characteristics of patients, patients' complaints, physicians' diagnoses, diagnostic/screening services, procedures, medications, disposition, types of health care professional seen, expected sources of payment, and causes of injury where applicable. Data collection began in 1992 with an annual sample of 70 000 visits to 440 hospitals.

National Nursing Home Survey

The National Nursing Home Survey is based on self-administered questionnaires and interviews with administrators and staff in a sample of about 1500 long-term care facilities. Information is obtained on both the providers of services and on the nursing home patients. Data about the facilities include characteristics such as size, ownership, Medicare/Medicaid certification, occupancy, days of care provided, and expenses. For patients, data are obtained on demographic characteristics, health status, and services received. The survey has been conducted periodically since 1963, most recently in 1995.

National Nursing Home Survey Followup

The National Nursing Home Survey Followup is a longitudinal study that follows the cohort of surviving current residents and discharged residents sampled from the 1985 National Nursing Home Survey. Its primary purpose is to provide data on the flow of persons in and out of long-term care facilities and hospitals. The National Nursing Home Survey Followup provides data on the subjects' vital status, living arrangements, nursing home stays, hospital stays, and sources of payment for stays. The study population consisted of approximately 6600 subjects with follow-up conducted at two-year intervals using **computer-assisted telephone interviews**.

National Home and Hospice Care Survey

The National Home and Hospice Care Survey provides data on home health agencies and hospices and their current patients and discharges. This survey was instituted in 1992, in response to the rapid growth in the number of these agencies throughout the US. The annual survey is based on personal interviews with administrators and staff of approximately 1500 sample agencies. Information is obtained on diagnoses, types and length of services provided, number of visits, patient charges, health status, and reason for discharge.

National Health Provider Inventory

The National Health Provider Inventory (NHPI) is a comprehensive national listing of nursing homes, residential care facilities, hospices, and home health agencies. The NHPI serves as a sampling frame for several sample surveys. In addition, it is an important source of national statistics on the number, type, and geographical distribution of health providers in the US. Conducted periodically since 1963 under different survey titles – National Master Facility Inventory, 1971–1976; Inventory of Long-Term Care Places, 1986 – it was conducted in its

present form in 1991. The NHPI provides names and addresses of almost 56 000 facilities, including more than 7800 home health agencies and hospices, more than 15 500 nursing homes, and more than 31 000 board and care homes. Information about such items as type of facility, ownership, size, location, and resident characteristics is collected from questionnaires sent directly to agencies and facilities.

National Vital Statistics System

The National Vital Statistics System is responsible for US official vital statistics. The registration of vital events – births, deaths, marriages, divorces, fetal deaths, and induced terminations of pregnancy – is the responsibility of each of the states and is carried out under the civil registration laws of each state. However, standard forms for the collection of the data, model procedures for the uniform registration of the events, and standards for quality and timeliness of the statistical reports of events are developed and recommended for state use through cooperative activities of the states and the NCHS. The NCHS shares the costs incurred by the states in providing vital statistics data for national use. It produces annual data for the US and for states, counties, and other local areas, and monthly provisional data for the US and each state. Typically, the record of each event is filed by the responsible party (physician, hospital, or funeral director) with the local registrar of the town, city, or county where the event occurs. The local registrar inspects the report for completeness and accuracy, retains a local copy, and sends the original to the state health department. The state vital records office maintains permanent archives of the records, processes the statistical information, and provides summaries for state and local use. A uniform data set from the individual records is transmitted electronically to the NCHS for compilation into national statistical files. Two principal sets of reports are prepared from these data: monthly provisional estimates assembled on a "current flow" basis and final annual national vital statistics volumes. Before 1997, the provisional mortality data had been based on a 10% sample of deaths, but since then all records received have been incorporated into the provisional reports. The contents and quality standards for the uniform data set are reviewed approximately every 10 years. Rigorous security controls have been instituted to ensure the confidentiality of the records and prevent inadvertent identification of individuals. The annual volumes provide detailed tabulations of a wide variety of characteristics of the approximately 4 000 000 births, 2 100 000 deaths, and 70 000 fetal deaths that occur in the US and of the 2 300 000 marriages and 1 200 000 divorces.

The NCHS linked files of live birth and infant death records are research files for exploring the complex relationships between infant death and risk factors present at birth. The linked files include information from the birth certificate such as birth weight, mother's age, and prenatal care, linked to information from the death certificate for the same infant, such as cause of death and age at death (*see* **Record Linkage**). The files are birth cohort linked files. They are based on deaths under one year of age to all infants born in a calendar year. Each file contains approximately 40 000 linked records. The first annual national linked file was for the 1983 cohort under a pilot project. Beginning with the birth cohort of 1987, linked files are part of the National Vital Statistics System.

National Death Index

Working with state offices, NCHS established the National Death Index (NDI), a central computerized index of death record information, in 1979 as a resource to aid epidemiologists and other health and medical investigators in determining whether persons in their studies have died and, if so, to provide the names of the states in which those deaths occurred, the dates of death, and the corresponding death certificate numbers. The NDI is available to investigators solely for statistical purposes in biomedical research and is not accessible for legal, administrative, or genealogic purposes.

National Maternal and Infant Health Survey

The National Maternal and Infant Health Survey (NMIHS) collects data to study factors related to poor pregnancy outcomes, including low birth weight, stillbirth, infant illness, and infant death. The NMIHS is a followback survey of informants named on vital records. The 1988 survey was based

on 10 000 live births, 4000 fetal deaths, and 6000 infant deaths and was the first national survey that included data on those three pregnancy outcomes simultaneously. National Natality Surveys had been conducted in 1963, 1964–1966, 1968–1969, 1972, and 1980. A National Fetal Mortality Survey was done in 1980, and a National Infant Mortality Survey was conducted in 1964–1966. A 1991 longitudinal follow-up to the NMIHS was conducted to obtain additional information about respondents from the 1988 survey. The NMIHS provides data on socioeconomic and demographic characteristics of mothers, prenatal care, pregnancy history, occupational background, health status of mother and infant, and types and sources of medical care received.

National Mortality Followback Survey

Data on characteristics of deceased persons are provided in the National Mortality Followback Survey. The survey is based on questionnaires sent to informants listed on the death certificates to obtain additional data on socioeconomic characteristics of deceased persons, use of and payment for hospitals and institutional care during the last year of life, and factors related to health status. The 1986 survey was a national sample of approximately 1% of US resident deaths of persons 25 years of age and over. The survey was conducted annually from 1961 to 1968 and in 1986. The most recent survey was initiated in 1993 and is the first survey to collect information from medical examiners and coroners for external causes of death.

Data Dissemination

The dissemination of its vital and health statistics, of summary reports, and of research findings is an essential part of the mission of NCHS. Historically, published reports have been the principal modes of dissemination, but with advancing technologies, electronic products are becoming more common.

Principal Publications

Vital Statistics of the United States has been published annually since 1937. It contains the final summaries of mortality and natality data in extensive demographic and geographic detail. Marriage and divorce data have also been available since 1946.

Monthly Vital Statistics Reports are based on monthly and cumulative data on vital events.

The *Vital and Health Statistics* series (the "Rainbow Series") contains detailed reports of the background, methodology, analytical studies, and tabulations from the various NCHS data collection programs. Each program has its own series with a distinctively colored cover.

Advance Data from Vital and Health Statistics are summary reports that provide the first release of data from the various surveys.

Health, United States is a comprehensive annual report from the Secretary of Health and Human Services to the President and Congress describing the nation's health.

Electronic Products

Data are disseminated in great detail through a variety of electronic products. As technology progresses, the specific types of product have varied. Public-use data tapes had been a dominant form for sharing micro-level files with researchers. These data are now released in cartridge format and on CD-ROMs. Diskettes are available with detailed tables from a variety of surveys. Most recently, the NCHS Home Page (`http://www.cdc.gov/nchswww/nchshome.htm`) has been established to provide instantaneous access to a range of statistical information about health status (*see* **Quality of Life and Health Status**) and use of health services in the US.

MANNING FEINLEIB

National Institutes of Health (NIH)

The National Institutes of Health (NIH), which began as a one-room Laboratory of Hygiene in 1887, today is one of the world's foremost biomedical research centers, and the federal focal point for biomedical research in the US. The goal of NIH research is to acquire new knowledge to help prevent, detect, diagnose, and treat disease and disability, from the rarest genetic disorder to the common cold. NIH works toward achieving its mission by: conducting research in its own laboratories (Intramural Research Programs); supporting the research of nonfederal scientists in universities, medical schools, hospitals, and research institutions throughout the country and abroad (Extramural Research Programs); helping in the training of research investigators; and fostering communication of biomedical information.

The NIH is one of eleven health agencies of the United States Department of Health and Human Services and consists of 27 separate institutes and centers (see Table 1). From a budget of about $300 in 1887, the NIH budget has grown to over $27 billion in 2003, (according to "The National Institutes of Health," a public information brochure published by the NIH.) Biostatistics and biostatisticians have played, and continue to play, an important role in the Intramural and Extramural Research Programs at the NIH.

Biostatistics first appeared as a recognized discipline at the National Institutes of Health in the years 1946–1948. The Division of Statistical Methods in the US Public Health Service was established with **Harold Dorn** as its first Head to support the research of the then new NIH.

The degree of formal statistical training of his first recruits (**Jerry Cornfield**, **Sam Greenhouse**, Jack Lieberman, **Nathan Mantel**, and **Marvin Schneiderman**) varied, but their experience in the applications of statistics to problems of biology and medicine was minimal [12, 13]. Within a few years, **Sid Cutler, Max Halperin**, Bill Haenszel, Harold Kahn, Sam

Marcus, Felix Moore, and others rounded out the cadre of statisticians. Morton Kramer headed a statistics group at the separate National Institute of Mental Health.

Harold Dorn (NIH tenure 1946–1963) was the initial force in the recruitment and the building of a biostatistical presence at NIH (Figure 1). Jerry Cornfield (NIH tenure 1947–1967), hired by Dorn, is characterized by many as a leader who created the theoretical foundation for extensive methodological research in epidemiology and **clinical trials** (Figure 2), and whose forceful influence with physicians and epidemiologists enhanced the prestige of biostatistics at NIH. Unfortunately, both suffered relatively early and untimely deaths.

Many biostatisticians who stayed at NIH for much of their careers tended to move around to different institutes. The initial group of Harold Dorn, Marvin Schneiderman, Jerome Cornfield, Jacob Leiberman, Nathan Mantel, and Samuel Greenhouse arrived in about 1946 (Figure 3). The first "splitting off" of the individuals came in about 1948, when Max Halperin also arrived (Figure 4). A more detailed listing of the comings and goings of the early arrivals is given in Table 2.

Figure 1 Harold Dorn (*ca.* 1950)

Figure 2 Jerry Cornfield (1974)

In 1948 both the statistical group and the NIH were quite small. In the next decade the NIH grew tremendously, as did the numbers and international reputation of its statisticians. Several papers explore the environment conducive to scientific collaboration at NIH in the early decades [1–4, 6–11, 14], indicating that NIH stands as a model emulated throughout the US and the world for the interface of statistics and medicine. At one point in the 1960s there was concern about the absence of intermediate level statisticians to take over in the future and the impact on recruiting younger statisticians that this absence would have. This concern arose after statisticians who would have been very successful in serving as leaders in the future, individuals such as Seymour Geisser and Marvin Zelen, left the NIH for universities.

The medical leaders at NIH have been strong supporters of biostatisticians over the years, and biostatistics as a discipline has flourished. Indeed, for more than 50 years NIH has been home to many of the most influential biostatisticians and the most

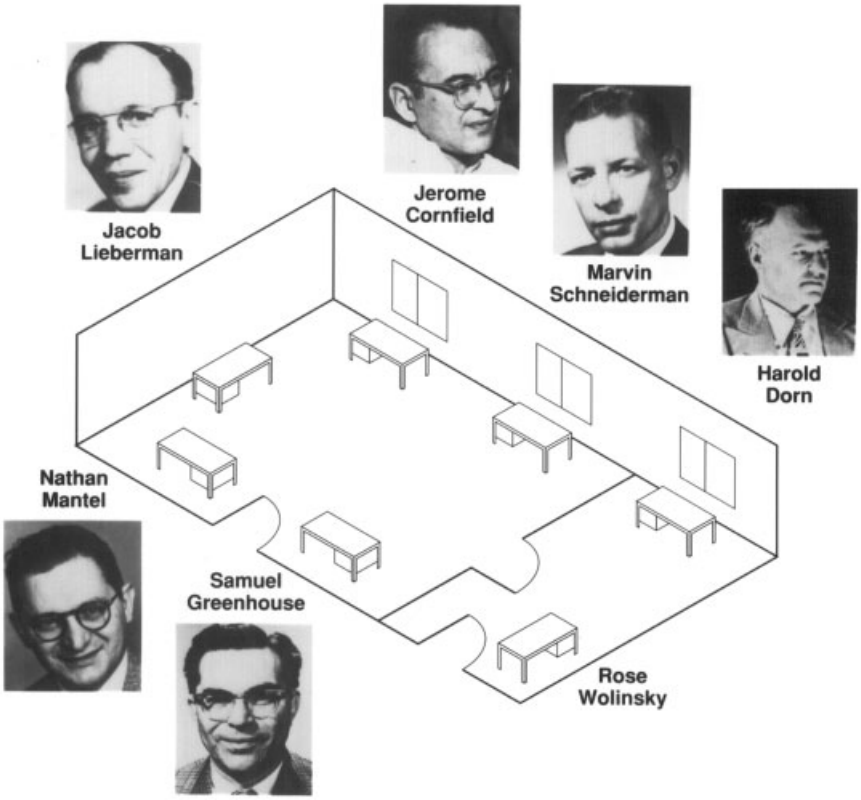

Figure 3 US Public Health Service, Division of Statistical Methods, 1947

important developments in the design and analysis of biomedical experiments. The statistical foundations for epidemiologic **case–control studies**, the use of **regression** models for identification of high-risk individuals, and key methodology for the conduct of modern clinical trials all originated with NIH statisticians.

NIH has also played a major role in the training of biostatisticians. In 2004, 16 US universities offer doctoral training programs (27 separate programs) with funding from 10 NIH institutes.

In celebration of 50 years of biometry at the NIH, a conference was held in January 1993 to acknowledge and review contributions of those pioneers who laid the foundation in the 1940s and continued, through their contributions, persuasiveness, and perseverance, to foster the strong presence of biostatistics at NIH that exists today [5].

Biostatistics, representing the science of the design of biomedical experiments (*see* **Experimental Design**) and the analysis of quantitative data, is more important today than ever. The goal of biostatisticians at the NIH today is to continue to provide statistical insight and rigor to NIH investigations. At the 1993 conference celebrating 50 years of biostatistics at NIH, the diversity and depth of the ongoing biostatistical collaboration was demonstrated by the range of topics presented. Some examples are: **time series** for modeling counts from a relapsing–remitting disease (P.S. Albert); a comparison of **likelihood**-based and marginal **generalized estimating equation** methods for analyzing repeated **ordered categorical** responses with *missing data* (S.D. Mark, M.H. Gail); the utility of large-simple trials in the evaluation of **AIDS** treatment strategies (S. Ellenberg); mixed effects regression models for studying the natural history of prostate disease (J.D. Pearson); partial **questionnaire design** for case–control studies (S. Wacholder); stochastic curtailment (*see* **Data**

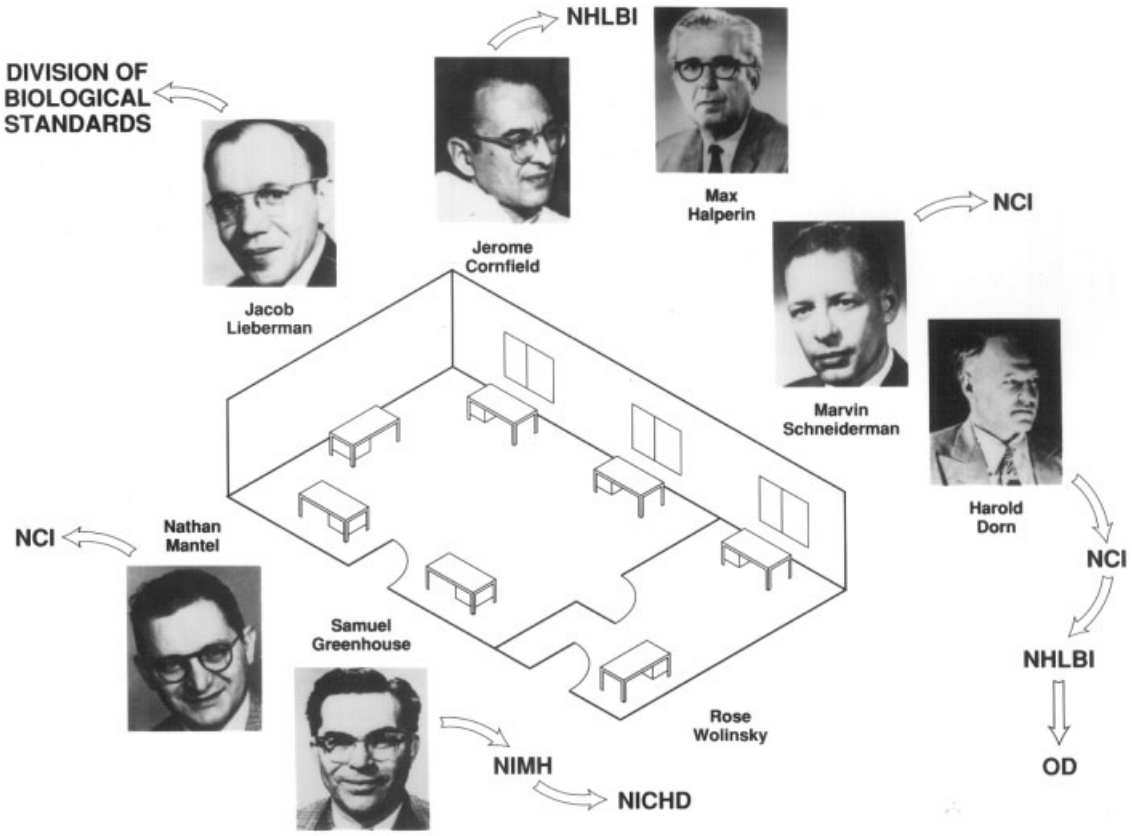

Figure 4 The methodologic "big bang"

and Safety Monitoring) and conditional **power** in matched case–control studies (S. Hunsberger); and a comparison of tumor incidence analyses applicable in single-sacrifice animal experiments [5].

The ongoing collaborations among those interested in developing and applying new statistical methods and those interested in solving biomedical problems account for the continued vitality of biostatistics at NIH.

JONAS H. ELLENBERG & DENNIS O. DIXON

National Surgical Adjuvant Breast and Bowel Project

During the second half of the twentieth century, the scientific method, a process by which hypotheses generated from laboratory and clinical investigation are tested in **randomized** clinical trials, began to be more frequently used. This seminal advance, which marked the transition from anecdotalism and inductivism to science, has accounted for most of the progress that has been made in the management of breast cancer for the past 50 years.

During that time I was fortunate to have been associated with the National Surgical Adjuvant Breast and Bowel Project (NSABP), a cooperative group that I viewed as an extension of my laboratory and that conducted what is now known as translational research. The findings from large randomized clinical trials carried out by my NSABP colleagues and I have, in large part, been responsible for several paradigm shifts that have occurred in the management of breast cancer during the last half century. This overview provides an account of the origin and early years of the NSABP, a description of the major findings obtained from NSABP breast cancer trials involving more than 50 000 women, and a commentary about the accomplishments of the group.

The Origin and Early Trials of the NSABP (1957–1970)

The NSABP grew out of the Surgical Adjuvant Chemotherapy Projects, a program sponsored by the National Institutes of Health (NIH) Cancer Chemotherapy National Service Center (CCNSC) to test the effectiveness of various anticancer drugs used with cancer surgery. The rationale for the project was based on clinical and laboratory findings obtained during the 1950s which suggested that systemic agents administered during and shortly after "curative" operations could improve the outcome of cancer patients. There was evidence that tumor cells were dislodged into the blood during surgery, thus making the procedure less effective; that the growth of cancer cells injected into the blood of animals could be impaired by chemotherapy; and that thiotepa (TSPA) and several other agents might be effective in destroying such cells in humans.

In the spring of 1957, 23 surgeons were invited by Dr I.S. Ravdin, chairman of the CCNSC Clinical Studies Panel, to attend a meeting at Stone House on the NIH campus to discuss the creation of the Surgical Adjuvant Chemotherapy Breast Project (later known as the NSABP), which had as its goal the conduct of clinical trials. Each of the surgeons who participated in that project agreed to abide by specific criteria for the inclusion of patients that had been outlined in a predefined **protocol** and to adhere to strict randomization procedures that divided the patients into treatment and control groups. Randomization was planned to prevent bias in selecting patients for a particular treatment. There were also plans for centralized data collection, evaluation, and review of pathologic material, as well as a program for long-range follow-up. The willingness among this group of surgeons to follow a predefined protocol represented a radical departure from conventional practice and set the stage for the more sophisticated protocols that would subsequently be designed by the NSABP.

Early in 1964 an executive committee was formed to coordinate and direct the study and to provide more effective liaison among project participants. I was co-chairman of the group and was subsequently appointed chairman and principal investigator of the Surgical Adjuvant Chemotherapy Breast Project on 9 May 1967. For the next three years the operations and statistical centers of the group remained at Roswell Park Cancer Institute in Buffalo, New York, while I interacted with them from Pittsburgh.

The first Surgical Adjuvant Chemotherapy Breast Project trial, called Phase I (a term that should not be confused with the current definition of a Phase I trial), compared the outcome of patients treated by radical mastectomy with or without the administration of TSPA. That study accrued 826 eligible patients between April 1958 and October 1961, a remarkable achievement at the time. The results of the Phase I study, which subsequently became known as NSABP B-01, provided the first evidence that the use of chemotherapy could alter the natural history of some patients and demonstrated, for the first time, that the outcome of patients with one to three positive axillary nodes was different from that of patients with four or more positive nodes [10, 12]. However, because so few patients seemed to benefit from

the chemotherapy and because it resulted in toxicity, surgeons were reluctant to accept the use of that treatment modality. When patient entry into the Phase I program was completed, a new study, Phase II, was initiated. Its objective was to evaluate the worth of 5-fluorouracil (5-FU), as compared with TSPA, and the value of postoperative radiotherapy and prophylactic oophorectomy. Findings from the Phase II trial demonstrated no advantage from the use of 5-FU over TSPA and showed that the toxicity resulting from the 5-FU regimen was actually of greater magnitude.

In 1961, as part of the Phase II study, a randomized trial (NSABP B-02) was begun to resolve the uncertainties about the worth of administering postoperative radiation therapy as an adjunct to radical mastectomy. Through five years of follow-up [11], the data failed to confirm conclusions derived from anecdotal information that had been obtained from the use of similar radiation techniques that had indicated an improvement in survival. Our findings resulted in great controversy. It is interesting to note that, 40 years later, uncertainty still exists with regard to the worth of using postoperative radiation therapy to improve survival outcome.

Because uncertainty also existed at that time with regard to the use of prophylactic oophorectomy as an adjunct to radical mastectomy, in 1961 the NSABP initiated the B-03 study, a randomized clinical trial that was designed to evaluate that treatment regimen in premenopausal breast cancer patients. Preliminary findings from B-03 demonstrated no difference in either recurrence or survival data among patients who had been treated by either oophorectomy, TSPA, or placebo [34]. Accruing patients to the study was difficult because there was a lack of appreciation of the urgency for resolving that question – a situation that was to prevail for the next 30 years. B-03, as well as the trial to evaluate postoperative radiation therapy, was never updated because, after the NSABP relocated to Pittsburgh, the data that had been stored at Roswell Park were never made available.

The Phase I and Phase II studies related patient outcome to the location of breast tumors. At that time, it was widely believed that patients with tumors in the inner quadrants of the breast had a poorer prognosis than did those with lesions in the outer quadrants. An evaluation of more than 1000 patients in the Phase I and Phase II studies demonstrated that the location of a tumor was unrelated to prognosis and, thus, led us to conclude that there was no justification for selecting specific surgical or radiation therapy approaches for treatment based upon tumor location. Other information from the patients entered into those trials demonstrated that the larger the tumor the more likely that axillary nodes would be positive, that more nodes would be involved, and that patient outcome would be poorer. This led to the conclusion that, in itself, size was not necessarily related to "earliness" or "lateness" of a tumor and was not as consequential as other tumor and/or host factors that determine the development of metastases. We also correlated recurrence and survival rates with number of lymph nodes examined in surgical specimens. Results indicated that examination of a greater number of nodes in a specimen was no more meaningful in determining prognosis than examination of only a few. Those findings are still relevant to current arguments about the management of axillary nodes in breast cancer patients.

The interval between 1957 and 1969 marked a learning period in the conduct of clinical trials, especially with regard to experimental design. In retrospect, the early trials of the Surgical Adjuvant Chemotherapy Breast Project were too complicated and represented a desire on the part of investigators to answer too many questions at once. This circumstance led to my view that clinical trials should be kept simple and that only a few questions should be answered in any single study. Although the overall results of those trials were disappointing, they were the first to demonstrate that cooperative studies using adjuvant therapy could be effectively conducted among large groups of investigators nationwide.

In addition to marking the rise in the use of the clinical trials mechanism for evaluating adjuvant therapy in the treatment of operable breast cancer, the interval between 1957 and 1969 was noteworthy because of the amount of information that was made available for augmenting existing biologic hypotheses and for generating new ones. The period was particularly significant because it marked my introduction to the clinical trials process, which, in turn, stimulated my interest in tumor metastases. During the late 1950s and 1960s, my laboratory associates and I published our findings in more than 50 scientific papers. The information from our studies led me to formulate an alternative hypothesis that became the basis for a new generation of NSABP clinical trials.

Paradigm Shifts

A New Surgical Paradigm

If any scientific basis existed for the disagreement that persisted for several decades about the operative management of breast cancer, then it related to differences in perception about the biology of the disease, particularly in terms of tumor spread. Two divergent hypotheses were at the center of the variance in opinion. One, the concept formulated by William S. Halsted at the end of the nineteenth century, gave rise to the paradigm that governed the surgical management of breast cancer for most of the twentieth century. The Halstedian paradigm was based on an anatomic and mechanistic perception of tumor spread that was in keeping with the understanding of the biology of tumor metastases at the time [5]. The tenets of this hypothesis gave rise to an anatomic basis for cancer surgery in which the Halsted radical mastectomy, characterized by *en bloc* dissection, became the hallmark of a surgical approach that emphasized that curability could more effectively be achieved as a result of more expansive, meticulously performed surgical procedures. The use of radiation therapy after surgery was governed by the same principles.

The alternative hypothesis, which I synthesized nearly 25 years ago, contended that cancer is a systemic disease that involves a complex spectrum of host–tumor interrelations and that variations in local–regional therapy are unlikely to substantially affect survival [6]. That premise was formulated from a series of laboratory and clinical investigations that my associates and I carried out from 1958 to 1970 to obtain a better understanding of the biology of metastases. All our findings had the same characteristic, i.e. they did not conform to the concepts that served as the basis for the principles of the Halstedian hypothesis but, rather, provided a matrix for the formulation of an alternative thesis. That hypothesis, which we developed in 1968, is biologic rather than anatomic and mechanistic in concept, and its components are completely antithetical to those of Halsted's thesis. Consequently, we hypothesized that variations in the local–regional treatment of breast cancer, i.e. different surgical regimens, were unlikely to affect patient outcome. Thus, in August 1971 we implemented the first of two clinical trials designed to test the validity of the principles upon which our alternative hypothesis was based. In that study, approximately 1700 women [14] without clinical evidence of axillary node involvement were randomized among three treatment regimens: (1) radical mastectomy; (2) total (simple) mastectomy with local–regional irradiation, but no axillary dissection; or (3) total mastectomy and removal of axillary nodes only if they later became clinically positive.

The significant aspect of the B-04 study was that 40% of the patients with clinically negative nodes treated by radical mastectomy were found to have histologically positive nodes. Thus, about 40% of the patients in the groups treated by total mastectomy alone had positive axillary nodes that were left unremoved. Despite this therapeutic nonconformity, no significant difference in overall treatment failure, distant metastasis, or overall survival has been noted among the three groups through more than 20 years of follow-up [33]. The negation of the primacy of radical mastectomy and the principles upon which it was based eliminated most of the biologic considerations that might have contraindicated the performance of breast-conserving operations. Consequently, in 1976 we instituted a second trial, NSABP B-06, to re-evaluate the principles of our hypothesis and, at the same time, to appraise the worth of lumpectomy plus axillary dissection for the surgical management of breast cancer.

In the B-06 study, women with breast tumors of less than or equal to 4 cm in size were randomly assigned to one of three treatment groups: (1) total mastectomy, (2) lumpectomy, or (3) lumpectomy followed by breast irradiation. The lumpectomy removed enough tissue to ensure that the margins of resected specimens were free from tumor. Women in all treatment groups had an axillary dissection, and those with positive nodes received chemotherapy. In almost 2000 women through at least 12 years of follow-up, results (first reported in 1985 [15]) demonstrated the efficacy of lumpectomy and radiation therapy for the treatment of breast cancer [22]. There continues to be no significant difference in either distant distant disease-free survival (DDFS) or overall survival among the three treatment groups. Of most importance is the observation that no difference in DDFS or overall survival has yet occurred despite the fact that the total mastectomy group (by virtue of breast removal) had no breast tumor recurrence, that lumpectomy patients who received radiation therapy had an ipsilateral tumor recurrence rate of 10%, and that patients treated with lumpectomy alone demonstrated a tumor

recurrence rate of 40%. Aside from indicating the efficacy of breast conservation, the findings from B-06, just as did those from B-04, repudiated Halstedian principles of breast cancer management and provided support for our alternative hypothesis. Moreover, they indicated that a large proportion of women with breast cancer could be treated with breast conservation.

In the years between the initiation of the B-04 study and the report of findings from B-06, i.e. from 1971 to 1985, a radical shift occurred in the treatment of primary breast cancer. Most significantly, the events described led to emancipation from conventional thinking about breast cancer and its treatment and set the stage for new scenarios that were to occur in rapid succession. In a sequence that represented an orderly scientific process, one paradigm governing breast cancer management was replaced by another. As a result, Halstedian principles of cancer surgery must now be viewed as nothing more than historical "milestones" against which cancer progress can be measured, and the Halstedian paradigm must now be permitted to assume its proper place in the annals of surgical history.

The Systemic Therapy Paradigm

After a hiatus of almost a decade, the NSABP launched a new trial to evaluate adjuvant therapy. Not until the early 1970s, after Skipper and his associates defined the concept of a growth fraction in a tumor cell population and provided an array of tumor growth kinetic principles that were instrumental in formulating a hypothesis that postulated the value of adjuvant chemotherapy, did such a trial become supportable [35, 36]. The NSABP initiated the B-05 trial to evaluate adjuvant therapy and to test that hypothesis in 1972. In that study, L-phenylalanine mustard (L-PAM) was administered after radical mastectomy to patients with positive axillary nodes. The results, reported in 1975, were the first (subsequent to our 1958 trial) to demonstrate that systemic adjuvant therapy could alter the natural history of certain cohorts of patients with primary breast cancer [13]. Within a short time, that conclusion was confirmed by findings from a study by other investigators in which cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) was used [1].

In general, postoperative chemotherapy for the treatment of node-positive, premenopausal women (less than 50 years of age) has been widely accepted. Of particular importance in the treatment of such women was the report of findings from NSABP B-15, which demonstrated that patients treated with doxorubicin (Adriamycin) and cyclophosphamide (AC) over 63 days had the same outcome as those who received six months of conventional CMF administered on each of 84 days [18]. In 1984 the NSABP implemented B-16, a trial designed to determine whether tamoxifen plus chemotherapy (AC) was more effective than tamoxifen alone in improving the Disease-free Survival (DFS), DDFS, and overall survival of node-positive, tamoxifen-responsive patients aged 50 years and older. Results from almost 1200 eligible patients provided the first definitive information to demonstrate a greater benefit from tamoxifen plus AC than from tamoxifen alone [19]. Moreover, our studies had failed to demonstrate an unfavorable interaction between chemotherapy and tamoxifen when that regimen was administered simultaneously to tamoxifen-responsive patients. As a result of the findings from the B-15 and B-16 studies, we concluded that AC therapy given over 63 days produced results comparable with those from CMF therapy given over 154 days. We also recommended that node-positive patients aged 50 years and older should receive tamoxifen in addition to chemotherapy.

In the late 1980s it was hypothesized that failure to achieve a greater therapeutic effect from the use of systemic therapy was due to inadequate drug administration. It was considered that a higher dose intensity, i.e. amount of drug administered per unit of time, would result in a better outcome. On the basis of this consideration, we implemented NSABP B-22, a study in node-positive patients that involved manipulating the total dose and intensity of cyclophosphamide in an AC combination. We reported [25] no significant difference in DFS among the treatment groups. Results from a companion study (NSABP B-25), in which the intensity and total dose of cyclophosphamide were increased to levels beyond that in B-22, showed that an even greater drug intensity and/or cumulative dose than was administered in B-22 failed to demonstrate a benefit beyond that obtained using the "standard" dose and intensity of the drug. Failure to note a difference in outcome among the groups was unrelated to either differences in amount and intensity of cyclophosphamide or to dose delays and intervals between courses of therapy. We concluded that, until

there was more information about the worth of more intensive high-dose therapy, increasing the total dose of cyclophosphamide was inappropriate in the treatment of women with primary breast cancer.

At an NIH Consensus Conference held in 1985, it was decided that a lack of information precluded recommending therapy other than surgery for breast cancer patients with negative axillary nodes [3]. Findings from four NSABP randomized clinical trials involving more than 8000 patients subsequently indicated the propriety of using systemic therapy to treat such women. Two of the studies, NSABP B-13 and B-19, were conducted to evaluate the worth of adjuvant chemotherapy in patients with estrogen-receptor (ER)-negative tumors.

In B-13, 760 women were randomly assigned to either methotrexate (M) and sequentially administered fluorouracil (F) (M→F) followed by leucovorin, or to surgery and no chemotherapy [16, 23]. In B-19, a total of 1095 women with the same eligibility requirements were randomly assigned to receive either M→F or cyclophosphamide (C) together with MF (CMF) as conventionally used [23]. The aim of the B-19 trial was to determine if the alkylating agent cyclophosphamide contributed an additional benefit when used in a chemotherapeutic regimen. Data from both studies led us to conclude that M→F and CMF were effective for women with ER-negative tumors and negative axillary nodes. In the younger age group, treatment with CMF clearly resulted in a better DFS and survival; in the older age group, a benefit from both regimens was apparent, although it was less clear which regimen was most effective. Because severe toxicity was less frequent after M→F therapy, that regimen was recommended for older women with associated medical problems that might preclude the use of more toxic agents.

Two additional trials, B-14 and B-20, were conducted by the NSABP in patients with ER-positive tumors. The aim of B-14, a randomized, double-blind, placebo-controlled trial initiated in 1982, was to determine the effectiveness of adjuvant therapy with tamoxifen in patients with negative axillary nodes [17]. That study, which involved more than 2800 randomized and 1200 registered tamoxifen-treated patients, has, arguably, provided some of the most compelling information that has been gathered during the past decade. Through 10 years of follow-up, a significant advantage was observed in DFS and survival among tamoxifen-treated women 49 years of age or younger and 50 years old or older [24]. Tamoxifen therapy was also associated with a significant reduction in the incidence of contralateral breast cancer, a finding that led us subsequently to consider the use of that drug for the prevention of breast cancer. No additional benefit, however, was observed from tamoxifen administration beyond five years.

Before the B-14 findings became available, however, we concluded that the degree of benefit achieved with tamoxifen in this patient population was unlikely to be sufficiently great to eliminate the need for other trials to test potentially more effective regimens. As a result of that consideration, we implemented NSABP B-20, a study that involved more than 2300 women and was aimed at testing the hypothesis that the addition of either M→F or CMF to tamoxifen (MFT, CMFT) would result in a greater benefit than that which could be achieved with tamoxifen alone [26]. In that trial, chemotherapy plus tamoxifen resulted in significantly better DFS and survival than that observed with tamoxifen alone [26]. When compared with tamoxifen alone, MFT and CMFT reduced both the rate of ipsilateral breast tumor recurrence (IBTR) after lumpectomy and the rate of recurrence at other local, regional, and distant sites. Of particular significance was the observation that the rate of treatment failure was reduced after the administration of both types of chemotherapy, regardless of the size of a patient's tumor, the degree of tumor ER positivity, progesterone-receptor (PgR) level, or age. In addition, we failed to identify any subgroup of patients who did not benefit from chemotherapy.

Because the B-14 findings showed that tamoxifen significantly reduced the rate of treatment failure at local and distant sites, the rate of tumors in the contralateral breast, and the incidence of IBTR, and because all subgroups of patients benefited and the benefits were attained with a relatively low incidence of undesirable side-effects, we concluded that tamoxifen was justified for women who met the eligibility criteria of the study participants. Also, when analyses of the B-20 study failed to identify a subgroup of women with ER-positive tumors and negative nodes who failed to benefit from either MFT or CMFT, we concluded that women similar to those in the trial might be considered candidates for chemotherapy plus tamoxifen. However, because patients with small (1 cm or less), mammographically identified lesions were rarely enrolled in the B-14

and B-20 studies, no information was obtained to indicate whether or not such women "should receive tamoxifen or tamoxifen and chemotherapy".

The findings from the four studies conducted in axillary node-negative patients raised several issues. They demonstrated that, after surgery alone, the overall prognosis of such patients was sufficiently poor to warrant the use of systemic therapy. In fact, the prognosis of some of those women was worse than that of women with positive nodes. That situation prevails in women with ER-negative as well as in women with ER-positive tumors. Although some patients in the four studies did not need systemic therapy, many women derived substantial benefit from it. Findings from appropriate statistical analyses that we conducted in search of inconsistencies in treatment effect among node-negative patients in our studies failed to identify subgroups of women with either ER-negative or ER-positive tumors who did not achieve some benefit from systemic adjuvant therapy, i.e. chemotherapy in the former and tamoxifen plus chemotherapy in the latter. However, as has previously been mentioned, definitive information about the propriety of using tamoxifen and/or chemotherapy for the management of patients with tumors of 1.0 cm or less in size is not yet available.

Consequently, when asked the question, Should *all* patients with negative nodes and ER-positive tumors be treated with tamoxifen plus chemotherapy?, we are unable to provide as precise an answer as we would like, despite the extent and credibility of our findings. Certainly, there are patients who either will not benefit from or will not need such therapy. Because other investigators have also been unable to identify these women with precision, we have taken the position that, until markers are found that will be able to do so with greater certainty than now exists, patients who have been judged to be candidates for such therapy should not be denied the chance to receive it so that they may experience the benefit that has been demonstrated.

In a recent attempt to identify subpopulations of node-negative women with ER-positive tumors who might require more aggressive forms of therapy and to distinguish them from women for whom such therapy is unnecessary, we assessed the outcomes, through 10 years of follow-up, of more than 4000 node-negative patients in B-14 who received either placebo or tamoxifen, taking into account their age at surgery, ER status, PgR status, tumor size, tumor S-phase fraction, and tumor nuclear grade [2]. Tumor size and S-phase were viewed as continuous variables [2]. Perhaps the most significant of the findings from that study was the observation of an extreme heterogeneity of outcomes among a population that has, until recently, been considered to have a favorable prognosis. For example, the 10-year DFS for 35-year-old women in the B-14 trial varied from about 80% to less than 40%, depending upon the interaction of the various prognostic variables being assessed. Thus, a group of node-negative patients who received tamoxifen or placebo consisted of women who displayed myriad heterogeneous outcomes. These observations indicate that more aggressive therapy is warranted for some, but not all, patients in the node-negative, ER-positive population. Before a specific therapeutic regimen is prescribed, however, each patient's prognosis must first be determined as accurately as is currently possible.

The remarkably low incidence of IBTR observed in all of the node-negative and node-positive studies following lumpectomy, breast irradiation, and systemic therapy has further justified the use of breast-conserving surgery for most women. Those findings support the author's long-held contention that the effect of local–regional therapy, i.e. surgery and radiation therapy, should no longer be considered independent of the effect of systemic therapy. Thus, the two separate and independent paradigms that governed the management of breast cancer, one that related to the management of local and regional disease by surgery and radiation therapy and the other that involved governing the treatment of micrometastatic disease, have merged into a single, interdependent paradigm.

The Preoperative Chemotherapy Paradigm

Hypotheses formulated from biologic and clinical information obtained during the 1980s led us to initiate NSABP B-18, the first randomized clinical trial (involving more than 1500 women) that was designed to evaluate the role of preoperative chemotherapy in the treatment of primary operable breast cancer [27, 28]. Although the use of such therapy failed to improve the overall benefit beyond that of patients who were randomly assigned to receive the same therapy postoperatively, the findings demonstrated that preoperative chemotherapy could be used

without fear of decreasing the DFS or survival of patients who received it. The most compelling findings were those that demonstrated that women whose tumors displayed a clinical and pathological complete response as the result of preoperative therapy had a more favorable outcome than did women whose tumors displayed either a clinical complete response or a clinical partial response. Thus, we concluded that the response of a breast tumor to preoperative chemotherapy could serve as a surrogate or intermediate end point for determining the response of micrometastases to systemic therapy. Because breast tumor response could be determined within weeks after preoperative chemotherapy was administered, it became possible to predict a patient's outcome and then to provide her with information so that she and her physician could consider other treatment strategies without having to postpone therapy until a treatment failure occurred.

Another finding of particular importance demonstrated that the downstaging of large tumors after the use of preoperative chemotherapy permitted more patients to be treated with lumpectomies. As a consequence, I have proposed that women with tumors judged by surgeons to be too large for lumpectomies, or women whose surgeons are ambivalent about performing that procedure, should initially have the option of receiving preoperative chemotherapy to determine whether the primary tumor sufficiently decreases in size so that lumpectomy and radiation therapy, rather than mastectomy, can be carried out in an attempt to enhance quality of life without increasing the risk for distant disease. Finally, the finding that preoperative chemotherapy downstages axillary lymph node status, i.e. converts nodal status from positive to negative, must be taken into account before a decision with regard to the management of axillary nodes can be made.

Whether or not preoperative chemotherapy is sufficiently important to replace postoperative systemic therapy remains to be seen. At least at this time, there is justification to suggest its use in certain circumstances.

The Breast Cancer Prevention Paradigm

The concept that tamoxifen could be used to prevent breast cancer had its origins in the late 1970s and 1980s, when the drug was shown to be of value in a variety of laboratory and clinical settings. Particularly germane to the concept of breast cancer prevention was tamoxifen's demonstrated ability to reduce the incidence of contralateral breast cancer [9]. To test that thesis, in 1992 the NSABP implemented the P-1 trial [8, 29]. In that study, women at increased risk for invasive breast cancer were randomly assigned to receive either placebo or tamoxifen for five years. The study findings demonstrated that tamoxifen decreased the overall risk of invasive and noninvasive breast cancer by 50%, a reduction that occurred in various age groups and categories of risk. The incidence of ER-positive tumors (but not of ER-negative tumors) was also reduced. The findings obtained in women who had a history of lobular carcinoma *in situ* (LCIS) or atypical hyperplasia – pathological entities considered to increase the risk of invasive breast cancer – were of particular importance, as they not only provided the only quantitative information available from a clinical trial to indicate the magnitude of their risk, but also demonstrated that the risk could be substantially reduced by tamoxifen administration. These findings are particularly relevant to those that were recently obtained from our studies in which strategies for the treatment of ductal carcinoma *in situ* (DCIS) were evaluated.

In 1985, because of uncertainty regarding the management of DCIS, we initiated B-17, the first randomized clinical trial to test the hypothesis that the treatment of localized DCIS by lumpectomy with tumor-free specimen margins followed by radiation therapy was more effective than was lumpectomy alone in preventing the subsequent occurrence of invasive tumor in the ipsilateral breast [20]. The 1993 report of our findings supported that hypothesis and demonstrated that postoperative breast irradiation markedly reduced the subsequent occurrence of invasive ipsilateral breast tumors. When the outcome of patients was examined relative to a wide array of pathologic and mammographic characteristics, we failed to find a discriminant that identified any group of DCIS patients who did not benefit from postoperative radiation therapy.

Because our previous trials and the studies of other investigators had demonstrated a benefit from tamoxifen administration in a variety of settings, it was considered that the drug might interfere with either the development of a primary invasive cancer from its start, or with the progression of residual DCIS to invasive cancer in women with a history of DCIS.

Consequently, in 1991 we initiated a second randomized clinical trial, NSABP B-24, to test the hypothesis that treatment with postoperative radiation therapy and tamoxifen would be more effective in patients who had had DCIS removed either with or without tumor-free specimen margins than would radiation therapy alone in preventing invasive and noninvasive cancers in the ipsilateral and contralateral breast [30]. The results of that study demonstrated that the risk of ipsilateral breast cancer was lower in women treated with tamoxifen, regardless of whether specimen margins were tumor free and regardless of whether DCIS was associated with comedonecrosis. Because the benefit from tamoxifen was due to a decrease in the rate of ipsilateral, contralateral, and metastatic invasive breast cancers, it seemed reasonable to conclude that focusing only on the frequency with which ipsilateral breast tumors occurred was too limited and that an assessment of the effect of treatment on all the sites combined seemed more appropriate. Finally, because women in the P-1 trial who had a history of LCIS or atypical hyperplasia were thought to be at sufficiently high risk of developing an invasive cancer to warrant being considered candidates for tamoxifen administration, it seemed reasonable to recommend that women with DCIS should also be considered candidates for tamoxifen, since they are at an even greater risk for developing invasive disease, even after they have been treated with radiation therapy.

There has often been more of an emphasis on the adverse effects of tamoxifen than on the benefits resulting from its use. Findings from the NSABP P-1 and B-24 trials, as well as the results of other NSABP studies that have evaluated tamoxifen, have failed to justify concerns about quality-of-life issues, liver damage, hepatoma, retinal toxicity, and cancers at other sites [4, 31, 32]. The excess risk of endometrial cancer [7, 21] and of vascular-related events such as stroke, deep-vein thrombosis, and pulmonary embolism that were observed in the tamoxifen group, as compared with those in the placebo group in these studies, has caused the most concern. In the P-1 study, less than 1 woman per 100 (0.7%) in the tamoxifen group developed endometrial cancer over a five-year period. All such cancers were International Federation of Gynecology and Obstetrics (FIGO) stage 1, and no deaths from endometrial cancer have, to date, been reported. The undesirable vascular events in the tamoxifen group in excess of those in the placebo group over a five-year period were few: 0.2%–0.3% of women experienced a stroke, approximately 0.2% had a pulmonary embolism, and between 0.2% and 0.3% exhibited deep-vein thrombosis. Those events occurred less frequently in women 49 years of age or younger and were slightly more frequent in women 50 years of age or older, being approximately 1% for endometrial cancer and less than 1% for each of the vascular-related events over five years. In view of the relatively few side-effects that resulted from tamoxifen administration, we concluded that its use as a breast cancer preventive agent may be appropriate in many women at increased risk for the disease.

Summary and Comments

This article has provided an overview of some of the more important accomplishments achieved by the NSABP during the past four decades. Subsequent to each of the advances that I have noted, the same paradoxical situation occurred that has relevance for the conduct of future breast cancer research. Because the extent of the unknown is often recognized only as knowledge expands, it is not surprising that, after each demonstration of a therapeutic advance in breast cancer management, issues arise that cannot immediately be resolved. That consequence of accomplishment has, all too often, resulted in confusion and in pessimism about the meaning of the results obtained. Thus, uncertainty arises with regard to the clinical application of the findings. As a result, success may now create more havoc than does failure. This circumstance is, indeed, unfortunate because those putative uncertainties do not detract from either the credibility or the importance of the findings that gave rise to them. It is, indeed, rare, if not impossible, for a single study to provide enough information to eliminate all uncertainties associated with positive achievement. In essence, every answer generates a whole set of new questions.

With the demonstration of the worth of systemic adjuvant therapy for the treatment of invasive breast cancer, postoperative breast irradiation after lumpectomy for the treatment of DCIS, and tamoxifen for reducing the incidence of invasive and noninvasive breast cancer in women at increased risk for the disease, the same questions have arisen. They relate to who will benefit from treatment and who will not;

who will not need the therapy because they will never demonstrate a treatment failure; how much of a benefit is worthwhile; and whether or not the toxicity and mortality encountered justify its administration. Despite these uncertainties, the use of adjuvant therapy is considered to be a major advance in the treatment of breast cancer. Similarly, the use of breast irradiation following lumpectomy for the treatment of both invasive and noninvasive breast cancer has been a major advance in the local–regional treatment of that disease despite the questions that have arisen. Also, the use of tamoxifen to obtund, and perhaps prevent, the development of a phenotypically expressed cancer before its diagnosis denotes a similar advance. Nevertheless, research directed toward identifying cohorts of patients who either do or do not benefit from those therapies that demonstrate an overall advantage must be vigorously pursued because such information will permit more precisely identifying patients according to their need for and response to therapy.

In conclusion, I believe that the continued use of the scientific process is imperative if progress is to continue in breast cancer research and treatment. Although critics of the clinical trials mechanism are numerous and their objections variable, e.g. that such trials take too long, are too cumbersome, are too costly, and are in need of replacement by other mechanisms, until other alternatives become available, such studies continue to provide the most appropriate way of obtaining the kind of information necessary for verifying hypotheses and for evaluating therapies. It is unfortunate that many critics of clinical trials do not participate in them, do not understand the complexities and diligence necessary in their conduct to obtain credible data, and would prefer to continue to believe in the worth of retrospective information for therapeutic decision-making. On the other hand, there is little disagreement that there is a need for some clinical trials to be made simpler, that they be subject to fewer, less rigid rules and regulations, and that the media look upon them more favorably so as to eliminate the fear created by negative publicity, which inhibits patients from participating in them. Finally, the contributions made by the NSABP during the past 40 years to advance the treatment of breast cancer could not have occurred without the cooperation of more than a hundred thousand physicians, biostatisticians, nurses, administrative and support staff, technicians, and, above all, the patients, who participated in approximately 30 major NSABP clinical trials. Their passion in carrying out this effort against a single disease is, in itself, a unique undertaking in medical history.

BERNARD FISHER

Natural History Study of Prognosis

Prognosis is defined as a forecast as to the probable outcome of an attack of disease; the prospect as to recovery from a disease as indicated by the nature and symptoms of the case [10]. In the context of research, it is a prediction of the future course of a disease following its onset. The natural history of a disease is the evolution of a disease in the absence of medical intervention [14]. Today, however, this definition may be too narrow for many diseases in which there are widely accepted treatments that are offered universally. For example, if a patient is diagnosed with severe diabetes, insulin may be prescribed. The description of disease course would include the influence of the insulin, since few patients would continue without medical intervention. Accordingly, we use the term *clinical course* to describe the natural history of a disease that has been affected by medical intervention. In this discussion the use of the term *natural history* may also, include clinical course.

The term prognosis implies an outcome. Natural history studies of prognosis are studies in which the course of a disease is observed over time as outcomes such as death, relapse of a tumor, or acquisition of AIDS following HIV-1 infection. **Rates,** such as percent of patients recurring within five years or a 10 year survival rate, are used to summarize these outcomes [16]. While a rate is a simple description of the outcome in a natural history study of prognosis, it can sometimes mask different processes. For example, in a study of cutaneous malignant melanoma, approximately one-quarter of the Stage I patients had a prophylactic lymph node dissection. The authors found that while this procedure was associated with an early survival advantage, this advantage was not sustained over a longer follow-up period. Thus, a conclusion based on five years of follow-up, as opposed to 10 years, would have been erroneous [33].

Sometimes we express outcomes as technical results, e.g. percent change in tumor size, or whether coronary dilatations exceed the diameter of normal adjacent segments by 1.5 times [2], or specific values of laboratory markers like CD4 T-cell counts [31]. While a laboratory marker is a more easily measured outcome than an outcome such as "pain", and one that lends itself more readily to rigorous statistical analysis, either type is relevant only if it is truly prognostic and related to the clinical outcomes.

It is important to distinguish between the concepts of **risk** and prognosis. Risk is related to the likelihood of getting a disease, while prognosis is about the progress and outcome of the disease, once it has been acquired. Similarly, risk factors are those characteristics that increase the probability of getting the disease, while **prognostic factors** are those variables associated with different possible outcomes of the disease, or time to an outcome, once the disease is present. Of course, some variables may be both a risk factor and a prognostic factor for the same disease. Variables that have both risk and prognostic roles may work in opposite directions. For example, men are more likely than women to develop coronary disease in middle age (risk), and also are more likely to die from it if they get it (prognosis) [29]. Conversely, younger women are less at risk of getting breast cancer, but once diagnosed with breast cancer, young age is associated with worse prognosis [24].

This article discusses design considerations for studies of prognosis, as well as analytical approaches.

Design Considerations

Design considerations in natural history studies of prognosis include the definition and selection of the population and samples to be studied, the definition of time zero, the definitions of outcomes, and potential sources of **bias**. We described definitions of outcomes. The following describes these other design issues.

Cohort Studies

The usual design for a natural history study of prognosis would be a **cohort study** [25]. In a cohort study we follow a subject population over time, during which periodic assessments or observations are scheduled and the occurrence of predefined outcomes in the cohort is recorded. The cohort can be prospectively or retrospectively sampled. A retrospective cohort might include all the patients presenting at a hospital within a period of time with a specific diagnosis or set of symptoms (*see* **Cohort Study, Historical**). We assemble the cohort via a medical record review. For example, in a retrospective study

of the natural history of ductal adenocarcinoma of the pancreas in patients under 40 years old, all patients seen at the Mayo Clinic from 1970 to 1985 were reviewed [21].

A prospective cohort study utilizes an inception cohort, i.e. a group of subjects assembled near the onset ("inception") of disease. This cohort typically cannot be gathered at a single point in time because the screening and recruitment process requires some time. Studies of this type typically are designed to have a recruitment or accrual period when the cohort is identified, and a specified follow-up period after the last subject has been entered into the cohort. Thus, the length of follow-up may vary by patient, depending on their early vs. late recruitment. In a study of the long-term prognosis of lupus nephritis, an inception cohort of 87 patients at Montreal's General Hospital and Children's Hospital seen between 1967 and 1983 was studied. The inception point was the day of first renal biopsy [17]. While prospective studies clearly are less susceptible to **selection bias, retrospective studies** provide preliminary answers more quickly and at a relatively low cost. Researchers use retrospective cohort study results to plan a prospective study more effectively.

Bias

There are many types of biases that can occur in natural history studies of prognosis and that effect the conclusions. The most frequent are sampling or selection bias, **length bias,** and dropout bias.

Sampling or selection bias results, also known as assembly bias, results from the method by which patients are sampled or selected to be in the study [25]. This type of bias may occur, for example, when the selected cases are not representative of the diseased population, or when the groups of patients differ in terms of the extent of disease under study. For example, in a study of infective endocarditis, it was shown that the clinical spectrum of the disease could be distorted by referral patterns when a community cohort in Minnesota was compared with a Mayo Clinic cohort [39]. In general, natural history studies of prognosis based only on patients in academic institutions (or tertiary care centers) tend to suggest poorer prognosis, unless the disease is treated only at academic institutions. This is because subjects may be referred to these centers only after treatment efforts at the community level have failed. In cancer studies conducted at tertiary care cancer research centers, which tend to receive higher proportions of more advanced cases, the natural history prognostic estimates appear worse than those derived from a representative sample of patients at all stages of the disease. This is analogous to the susceptibility bias that is present in cohort studies performed to estimate the risk of acquiring disease based on exposure [14].

Length bias occurs in several ways. An example is the natural history estimate of the **latent period** from HIV infection to the onset of AIDS. Early studies of HIV-infected cohorts estimated that this interval was at least four years, on the basis of **surveillance** data from the **Centers for Disease Control** [7]. Researchers continuously updated these estimates to a current estimate of eight years or more on the basis of cohorts from the US, Canada, Australia, and the Netherlands [40]. Patients with shorter latency presented earlier with the disease and affected the estimate. Another form of length bias combined with selection bias occurs when a cohort is not assembled at the inception of disease, but is selected on the basis of availability of patients (e.g. accepting patients at different stages of the disease), and information is collected after the inception of each subject's disease. In this case the cohort includes only those subjects who are available for study, and thus may not include patients with the same time disease-inception in whom a failure event (death, relapse) has already occurred. This introduces length bias into the estimates of time to progression within the natural history of disease if the analysis does not take this into account [6].

In dropout bias the patients who drop out of a study or are lost to follow-up may be different from the patients remaining in the study. Since the study conclusions are based only on available data, if the dropout pattern is not random, then this introduces a form of selection bias. In addition to aggressive retention and follow-up of subjects, a carefully designed observation schedule is helpful in assessing the magnitude of the problem due to dropout (*see* **Bias, Overview**).

Definition of Time Zero

For a cohort study to be meaningful, a well-defined time zero should be defined for the disease of interest. We define time zero as the time of onset of the first or specified symptoms or the date of diagnosis. For

diseases in which **screening** is routinely performed, such as certain screening tests for newborns, this definition is easy. In other cases, such as breast cancer, this determination is less clear; the point of inception might be based on a routine mammogram, on the discovery of a lump during self-examination test, or the onset of symptoms. The importance of an unambiguous definition for time zero in a natural history study of prognosis cannot be overemphasized. The goal of describing the time course until outcome events occur will be thwarted in the absence of an unambiguous starting point.

In summary, the design of natural history studies of prognosis must include a carefully defined cohort, appropriate selection and assembly procedures, and clearly defined starting points (time zero), follow-up procedures, and unambiguous definitions of outcome.

Analysis Approaches

Dichotomous Outcomes and Logistic Regression

The choice of appropriate analysis tools depends on the type of outcome that the study is describing. In the first step of analysis in a natural history study of prognosis we estimate the rate or percentage of those who had a given outcome, e.g. the percentage who died. At the next step we relate the percentage outcome to prognostic factors. In the simplest case there is a single, dichotomous prognostic factor. In a study of severe cardiac events such as death and myocardial infarction, researchers assessed the prognostic value of dipyridamole first-pass radionuclide ventriculography using a **Fisher's exact test** [3]. A **chi-square** is also typically used.

When there are several prognostic variables, epidemiologists typically use logistic regression to analyze further the natural history of prognosis. In **logistic regression** we define a dichotomous outcome variable Y, such as alive at the end of three years ($Y = 0$) or died within the first three years since time zero ($Y = 1$). We model the outcome variable as a function of the prognostic variables or **explanatory variables** [19]. The prognostic variables can be dichotomous, such as sex, continuous, such as age, or categorical, such as race. In a cohort study examining the prognostic value of ultrasound findings at birth in predicting disabling cerebral palsy, both dichotomous variables, such as presence of ultrasound findings, and continuous variables, such as gestation age at birth, were explored [38]. In this study the logistic regression modeling showed that certain ultrasound findings (parenchymal echodensities/lucencies) were strongly prognostic (**odds ratio** of 15) of disabling cerebral palsy, even after accounting for well-known prognostic factors such as gestation age and birth weight.

The relationship between variables can also be studied using a regression tree (*see* **Tree-structured Statistical Methods**). In a study on the impact of disease activity on long-term prognosis of lupus nephritis, the researchers used a regression tree technique which gave easily interpretable and useful results [17].

Survival Analysis

By far the most popular analysis tool in natural history studies of prognosis is **survival analysis** [9]. In this approach we assemble a cohort at a particular time zero in the course of disease, and follow the subjects until either the outcome occurs (called "failure"), or a prespecified point for the end of the study is reached. This prespecified time point can be a total follow-up time or a total number of observed failures. A description of the natural history of the group is given by a **Kaplan–Meier** curve or a product–limit estimator (*see* **Life Table**) [22]. This curve gives the estimated survival experience of the study subjects as a function of time. Sometimes, patients exit the study before the failure event occurred, owing to loss to follow-up, patient withdrawal from the study, or other reasons. The observations on these patients are defined as **censored**, and the calculation adjusts for these. The estimation of the survival probabilities at each point in time provides a description of the overall prognosis of the disease in question. The outcome variable is, therefore, the time until an event occurs.

In the next step, specific prognostic factors for the disease are examined. For example, in a study of risk **stratification** and prognosis of patients with recent onset of angina, the researchers examined whether a positive thallium stress test and the number of clinical risk characteristics as well as the number of involved arteries were prognostic predictors of future medical events [4]. The analytical tools used to examine the effect of a single prognostic factor on survival are the Mantel–Cox test, **logrank test**, the Wilcoxon–Gehan test or the Peto test [28]. These tests examine whether a dichotomous or categorical

factor is significantly associated with better or worse prognosis of the disease, depending on the value of this factor. The tests differ primarily in the weight that they place on observations at the early vs. later part of the Kaplan–Meier curve.

When there is interest in the joint effect of several factors on survival or when a factor is continuous and there is no desire to categorize it (and hence lose some information), the most popular analytical tool is the **Cox regression model**, which is **semiparametric**. The Cox model is a regression model proposed for survival distributions in which the time to failure is related to the prognostic factors and it allows the introduction of the censored observations into the model [8].

The typical use of the Cox model is in the context of a **proportional hazards** model. A proportional hazards model possesses the property that different individuals have **hazards** that are proportional to one another over time, depending on the values of the fixed **covariates**. A typical example of the use of a Cox model is in the study of unknown primary carcinomas [1]. The fixed covariates used were pathology subtype (adenocarcinoma, neuroendocrine carcinoma), number of sites (1, 2, 3+), gender, and involved organ site.

Other covariates included in a Cox model may be time-varying covariates (*see* **Time-dependent Covariate**). When the covariates are time-varying, the hazards are no longer proportional with respect to the time-varying covariate, since the value of the covariate may change over time. Thus, there is no meaning to the concept of proportional hazards. Time-varying covariates may be very important in understanding the natural history of prognosis. CD4 T-cell counts are typical time-varying covariates for understanding the natural history of HIV infection [15].

In addition to the Cox nonparametric approach to survival analysis, there are **parametric survival models**, including, in particular, **accelerated survival models** that serve well for natural history studies of prognosis. An example is a study based on the **Framingham** Heart Study data which used a **Weibull distribution** based accelerated failure time model to model the time to angina pectoris when there is **interval censoring** [36].

The development of martingale theory and **counting processes** gave researchers many more opportunities to expand and allow for more complex survival models [13]. These models allow for **multivariate survival** outcomes and flexibility in modeling, resulting in better understanding of the natural history of complex diseases such as **AIDS** [5]. In this study both seroconversion time and progression to AIDS were studied. The counting processes models also allow for approaches such as modeling time-varying effects using **spline functions** to examine, for example, whether tumor necrosis is a prognostic factor for early recurrence and death in lymph-node-positive breast cancer [16]. The issue here was that the effect of tumor necrosis appeared to be changing with time, and the spline modeling enabled the researchers to provide a better description of the prognosis of these patients than more traditional survival analysis approaches.

Longitudinal Data Analysis

Another way to study the natural history of prognosis in terms of data analysis is to use models for the analysis of **longitudinal data**. This approach is useful especially when the interest is not necessarily in the presence/absence of an outcome, but rather in the changes in a parameter over time. The parameter may be the lung function of cystic fibrosis patients, or a molecular biomarker called prostate specific antigen (PSA) in the study of the natural history of prostate disease [37]. The longitudinal model in this example estimates the natural history of the biomarker both as a function of time (or age) and as a function of other prognostic factors, such as age at diagnosis, or presence of cancer (as a time-varying parameter). In a study of this type the subjects are measured repeatedly over time. In natural history studies of prognosis, which are based on a cohort of subjects, there are frequently unequal intervals between follow-up visits of different patients and unequal numbers of measurements for different patients. In this situation an appropriate approach is a mixed effects model or **random effects** model [26, 27]. This approach models the change in a parameter across time, using the repeated measurements and modeling the **correlation** between the measurements of an individual. For example, in a study of neurodevelopment in children who were perinatally infected with HIV, the number of measurements ranged from two to nine and the timing was different between children [35].

The mixed effects model assumes a linear relationship between the outcome variable and

the explanatory variables. Moreover, it assumes a **normal distribution** for the error of the so-called individual random effects. The **generalized estimating equations** approach (GEE) relaxes these assumptions and generalizes the model to dichotomous and other outcome variables [30]. Both of these methods have received considerable attention in the last decade, with much research devoted to expanding these methods. As the methods are developed and become more accessible, they may be better suited for application in natural history studies. In a study relating the outcome of poor visual acuity to the genetic type of retinas pigmentia, the GEE approach was used to combine correlated data of two eyes per individual [23] (*see* **Correlated Binary Data**).

Combining Data from Several Studies

There are several indirect approaches to natural history studies of prognosis that are based on existing data and previous studies. One approach takes the raw data from several studies with similarly defined populations, and combines the data for an overall natural history study. In a study addressing the prognostic variables for survival in hepatocellular carcinoma, data on patients from three consecutive clinical trials conducted by the Eastern Cooperative Oncology Group were combined and a Cox proportional hazards model fit to the combined data set [11]. The study is a natural history study because none of the therapeutic approaches worked, and ignoring the treatment or allowing the treatment to be a covariate did not change results. The definition of the patient population was identical in all studies, and thus the homogeneity of the combined study population was established and generalizability was possible (*see* **Validity and Generalizability in Epidemiologic Studies**). Combining the studies increased substantially the **power** to detect significance of prognostic factors for survival.

Another approach to combining data from several studies is **meta-analysis** [20]. In meta-analysis one combines the results from several studies, either by summarizing all of the studies that meet certain criteria, such as in a study of inconsistent prognoses of post-acute myocardial infarction [32], or by actual data synthesis. An example of the latter is a study of prognosis and outcomes of patients with community-acquired pneumonia where **odds ratios**, rate differences, and **confidence intervals** were calculated as well as overall mortality and the relationship with prognostic factors [12].

Multiple Outcomes

Sometimes a natural history study can have multiple outcomes. This can be true for all types of analysis approaches. It can occur in the context of logistic regression where there are two or more dichotomous outcomes that can be observed, or multivariate survival variables that are observed. One example is time to metastases of breast cancer at various sites as multiple outcomes. This problem can be dealt with both as a **competing risks** problem in the context of a Cox model, or in a generalization of joint outcomes [41].

Conclusion

The choice of analytical approach depends on many factors related to the design of the study and the definition of outcomes. Sometimes more than one approach is applied to the same data and conclusions are compared [34]. For example, consistency may be a problem when there are **missing data** [18]. The use of more than one analytical approach helps to understand better the natural history of prognosis and prevents erroneous conclusions.

AVITAL CNAAN

Negative Binomial Distribution

The negative binomial distribution has been used in biostatistical literature since Student [31]. He proposed that the error in counting red blood cells using the hemocytometric camera follows that distribution. The method consists of stretching a few drops of blood on a special slide that has a camera with a grid superimposed. After some chemical treatment to preserve the material and to color the blood cells, the specimen is read on a microscope. The reader counts the number of red blood cells in a fixed number of quadrats (say 100). From that, given a proportionality constant, the total number of red blood cells of the donor is estimated.

This first application is emblematic, because the negative binomial was proposed as an alternative to the **Poisson distribution** for modeling counts when data show a certain degree of extra-Poisson variation (*see* **Overdispersion**). In this application, this extra variation is due to the fact that the intensity rate is not homogeneous, since the blood is not uniformly spread on the slide.

The Negative Binomial Distribution

Definition

The distribution is obtained from the expansion of $(Q - P)^{-R}$, where $Q - P = 1$ and $P > 0$, similarly to a derivation for the **binomial distribution**. The probability mass function equals

$$\Pr(y) = \frac{(R + y - 1)!}{y!(R - 1)!} \left(\frac{P}{Q}\right)^y \left(1 - \frac{P}{Q}\right)^R \quad (1)$$

and is defined for nonnegative integer values y. The value R need not be an integer, but when it is, this is known as the *Pascal distribution*. The mean is RP and the variance is RPQ. Therefore, the variance exceeds the mean, and the distribution shows greater tail probabilities than the Poisson. The probabilities can be calculated from the binomial distribution, observing that [16]

$$\frac{(R + y - 1)!}{(y)!(R - 1)!} \left(\frac{P}{Q}\right)^y \left(1 - \frac{P}{Q}\right)^R = \frac{R}{R + y} \frac{(R + y)!}{(y)!(R)!} \left(\frac{P}{Q}\right)^y \left(1 - \frac{P}{Q}\right)^R. \quad (2)$$

Example The observed number of accidents at work during a five-week period are reported in Table 1; the fitted negative binomial and Poisson expected counts [17] are also shown. The negative binomial distribution has higher probability for the zero count and has a longer right-hand tail than the Poisson distribution with the same expected value (*see* **Accident Proneness**).

Derivation A

The negative binomial distribution can be derived in two ways.

Suppose that we are interested in the number of trials (say N) until R successes have occurred, when the probability of success is p for each trial. Then the probability distribution of N is

$$\Pr(N = y + R) = \frac{(R + y - 1)!}{y!(R - 1)!} p^R (1 - p)^y \quad (3)$$

for the reparameterization $P = (1 - p)/p$. This distribution is also called the *binomial waiting-time distribution* and, in the special case $R = 1$, it is the **geometric distribution**, the discrete analogue of the exponential distribution (*see* **Parametric Models in Survival Analysis**).

Table 1 Negative binomial and Poisson expected frequencies for observed counts of work accidents during a five-week period

y_i	f_i	Negative binomial	Poisson
0	447	442	406
1	132	140	189
2	42	45	45
3	21	14	7
4	3	5	1
≥5	2	2	0.1

Reproduced from [17] by permission of the Royal Statistical Society

Example In the *surveillance* of rare health events, such as congenital birth defects, the probability that a birth has a malformed baby can be modeled as a function of the number of nonmalformed babies born since the previous malformation occurred (negative binomial with $R = 1$). This approach is used in the SETS scheme [7].

Derivation B

Suppose that a heterogeneous Poisson process generates the observed counts. This could be modeled as a mixture of Poisson distributions, the expected value μ of which is the realization of a **gamma distribution** with density

$$\Pr(\mu) = [\nu^\kappa \Gamma(\kappa)]^{-1} \mu^{\kappa-1} \exp\left(-\frac{\mu}{\nu}\right), \qquad (4)$$

with $\kappa > 0$ and $\nu > 0$. Then

$$\begin{aligned}\Pr(y) &= \int_0^\infty \left[\frac{\mu^y \exp^{-\mu}}{y!}\right] [\nu^\kappa \Gamma(\kappa)]^{-1} \mu^{\kappa-1} \\ &\quad \times \exp\left(-\frac{\mu}{\nu}\right) \mathrm{d}\mu \\ &= [\nu^\kappa \Gamma(\kappa) y!]^{-1} \int_0^\infty \{\mu^{y+\kappa-1} \\ &\quad \times \exp[-\mu(\nu^{-1}+1)] \,\mathrm{d}\mu\} \\ &= \frac{(y+\kappa-1)!}{y!(\kappa-1)!} \left(\frac{\nu}{\nu+1}\right)^y \left(\frac{1}{\nu+1}\right)^\kappa, \qquad (5)\end{aligned}$$

which is negative binomial with parameters $\{\kappa, \nu\}$ (where $R = \kappa$ and $P = \nu$). This mixture could arise (factorizing $\mu = \theta t$) either by varying the *rate* θ of occurrence of the events for constant time span (t) or the population at risk for each observation, or by varying t. We cannot distinguish between these two mechanisms from the data, and usually one of the two sources of heterogeneity is controlled by the study design.

Example: Varying rates. The observed regional variation of the rate of surgical interventions can be split into a component reflecting the underlying rate variability among areas, service availability, physicians practice styles, etc. which can be modeled by the gamma density, and a random Poisson component [13].

Example: Varying population-time. In counting the number of larvae caught in a trap, the total catch is the sum of the larvae that emerged from distinct egg masses, the number M of which is unknown. The negative binomial distribution arises as a Poisson stopped sum of a logarithmic series variable [30].

Estimation of Parameters

Method of Moments

The **method of moments** [19] is the simplest way to obtain estimates of the parameters of the negative binomial. The method equates the population parameters to their sample counterparts (the mean to the sample mean and the variance to the sample variance) and then solves for the parameter estimates

$$\hat{P} = \frac{s^2}{\overline{y} - 1}, \qquad (6)$$

$$\hat{R} = \frac{\overline{y}^2}{(s^2 - \overline{y})}, \qquad (7)$$

where $\overline{y}$ and s^2 are the sample mean and variance of the observed counts. This method could give negative values if $s^2 < \overline{y}$. A different approach uses the observed proportion of zero counts, p_0 [3]:

$$\hat{R}\hat{P} = \overline{y}, \qquad (8)$$

$$p_0 = (1 + \hat{P})^{-\hat{R}}. \qquad (9)$$

This method can be used if $\overline{y} > -\log p_0$.

Iterative methods of moments were used by Scheaffer & Leavenworth [28] and Clayton & Kaldor [9]. The first used a normal approximation for a transformation introduced by Anscombe [3] based on $\sinh^{-1}$ to develop a new formula based on the variance of the transformed variable. The second, given initial estimates, is based on estimates of the parameters of the Poisson distributions. From their mean and variance, one updates the estimates of the negative binomial parameters, and repeats until convergence. A further refinement is to equate the Pearson χ^2 to its expected value, instead of using the variance (see also [23]). In most circumstances the method of moments works well. However, a warning has been posed when the mean is small and the sample size does not exceed 20 [8].

Maximum Likelihood

Maximum likelihood (ML) estimation was discussed by Fisher [15], who gave formulas for the case of moderately small sample sizes. The ML estimator is indeterminate when $s^2 < \overline{y}$, and Anscombe [4] comments that the ML estimator does not have a distribution, since there is a nonzero probability of observing a data set with sample variance less than the sample mean. A useful reparameterization is $\alpha = 1/\kappa$, which yields the Poisson distribution as $\alpha \to 0$; the parameter α is called the dispersion parameter, because the negative binomial variance is $V(y) = \mu + \alpha\mu^2$ [27]. To facilitate the specification of a linear model for the mean value, the other parameter is assumed to be the mean $\mu = \nu/\alpha$. The negative binomial density becomes

$$P(y) = \frac{(y + \alpha^{-1} + 1)!}{y!(\alpha^{-1})!} \left(\frac{\alpha\mu}{1+\alpha\mu}\right)^y \left(\frac{1}{1+\alpha\mu}\right)^{1/\alpha}. \tag{10}$$

When μ is assumed as the parameter of the Poisson likelihood the gamma prior has only one parameter. Maximum likelihood estimates can be obtained using the Newton–Raphson method [21] (*see* **Optimization and Nonlinear Equations**). This method produces biased results in small sample sizes, and the distribution of $\hat{\alpha}$ is discrete in those cases. It is recommended, therefore, to utilize other methods, such as those listed below.

Conditional Maximum Likelihood

The conditional maximum likelihood estimator for the dispersion parameter of the negative binomial distribution was first proposed by Kalbfleisch & Sprott [20] and evaluated by Anraku & Yanagimoto [2]. The negative binomial likelihood can be factored into two terms: the first term allows the estimation of μ, and the second term allows the estimation of the dispersion parameter given μ. The relationship between the conditional (CL) and the unconditional ML estimator (UL) is

$$\frac{1}{2}\frac{\overline{y}}{1+\alpha\overline{y}} < CL - UL < \frac{\overline{y}}{1+\alpha\overline{y}}. \tag{11}$$

The UL estimator is smaller than the CL, for any sample. Simulation studies seems to support CL against ML. It should be noticed that both estimators are defined only for $s^2 > \overline{y}$.

Maximum Extended Quasi-likelihood

Extended quasi-likelihood was proposed by Nelder & Pregibon [26] in the context of the **generalized linear model**. Clark & Perry [8] considered it for the estimation of the dispersion parameter of the negative binomial distribution. One of the merits of this approach (see [24]) is the ability to handle overdispersed as well as *underdispersed* data (*see* **Overdispersion**). The extended quasi-likelihood for the negative binomial distribution is

$$\begin{aligned} l(\mu_i, \alpha) = {} & y_i \ln\left(\frac{\mu_i}{y_i}\right) - \frac{1+\alpha y_i}{\alpha}\ln\left(\frac{1+\alpha\mu_i}{1+\alpha y_i}\right) \\ & - \frac{1}{2}\ln(2\pi) - \ln(1+\alpha y_i) - \frac{1}{2}\ln\left(y_i + \frac{1}{6}\right) \\ & - \frac{1}{2}\ln\left(1+\frac{\alpha}{6}\right) + \frac{1}{2}\ln\left(\alpha y_i + 1 + \frac{\alpha}{6}\right), \end{aligned} \tag{12}$$

and α is estimated by maximizing this. A simulation study of Piegorsch [27] ended by concluding that "it is more prudent to recommend general use of the maximum *quasi*-likelihood approach as long as the sample size is adequate (above 20), and α is not very small".

Regression Models with Random Effects

Random Intercept Model

Suppose that y_i follows the Poisson distribution with expected value $\mu_i = \exp(\mathbf{x}_i\boldsymbol{\beta} + u_i)t_i$. The term u_i is a random intercept that can be modeled by assuming that $\exp(u_i)$ follows a gamma density with mean 1 and variance α ([21]; see also [5]). This is consistent with the interpretation of u_i as a random noise with expected value zero.

Example In a paper by Zeger & Edelstein [32], y_i denoted the number of deaths in village i with t_i person-years at risk, $\mathbf{x}_i$ was a vector of predictor variables, and u_i was a random effect for the effects of baseline health status on mortality. The model allowed the underlying mortality rate to vary from village to village.

Extensions

First, an important extension allows the dispersion parameter to vary as a function of covariates, such as by letting $\log \alpha_i = \mathbf{z}_i \boldsymbol{\gamma}$. Using this approach, Manton et al. [22] analyzed the geographic distribution of age-specific lung cancer rates among North Carolina counties using a model with scale parameter varying by age group and shape parameter by birth cohort.

Secondly, in longitudinal studies a series of measurements $\mathbf{y}_i$ is recorded for the ith subject. When the responses are counts, the negative binomial model allows subject-specific covariates and random terms for each subject. In most cases, however, we have to cope with time-varying covariates. Morton [25] adapts the negative binomial model by proposing that the conditional variance take the form $V(y_{ij}|u_i) = \phi\mu_{ij}$, obtaining the estimates of β, α, and ϕ using a quasi-likelihood approach.

The reader familiar with generalized linear models (GLMs) will be aware that taking $\log \mu_i$ as a linear function of the covariates and incorporating random terms results in a noncanonical link, so that standard errors are only asymptotically equivalent to those obtained from a GLM extended quasi-likelihood model with canonical link $\log[\mu/(\mu + \alpha)]$. Models with random effects on the same scale as the fixed effects can be more attractive [6], while other methods avoid the specification of the form of the mixing distribution (see [18] and [1] for an extension to the general **exponential family**).

Empirical Bayes Estimates

Suppose that we want to estimate the rate of a certain disease by areas within a country. Given $\{y_i\}$, the observed event counts, and $\{E_i\}$, the expected counts for the areas given some standard reference rates, the maximum likelihood estimator for θ_i is $r_i = y_i/E_i$, while the empirical Bayesian estimator for θ_i is the mean of the posterior density $f(\theta_i|y_i)$ [14],

$$f(\theta_i|y_i) = \frac{f(y_i|E_i\theta_i)\, f(\theta_i|\kappa, \nu)\, \mathrm{d}\theta_i}{\int f(y_i|E_i\theta_i)\, f(\theta_i|\kappa, \nu)\, \mathrm{d}\theta_i}, \qquad (13)$$

which is gamma $[y_i + \kappa, \nu/(\nu E_i + 1)]$ with mean $\hat{\theta}_i = (y_i + \kappa)/(E_i + \nu^{-1})$. The parameters κ and ν can be estimated from the marginal distribution $\int f(y_i|\theta_i)\, f(\theta_i)\, \mathrm{d}\theta_i$, which is the negative binomial distribution.

Example The empirical Bayes estimator (ebmr) of the rate ratios for lip cancer of 56 Scottish counties is reported by Clayton & Kaldor [9]. The ebmr values are shrunk toward the mean, and nonzero estimates are produced even for areas with observed zero counts. The degree of shrinkage is proportional to the variance of the gamma density and, for a given area, to the amount of population at risk (i.e. the E_i) (*see* **Shrinkage Estimation**).

Test of Overdispersion for Count Data

A *score* test with one degree of freedom (*see* **Likelihood**), based on the negative binomial variance, uses the statistic

$$T_1^2 = \frac{\left[\sum_i^n (y_i - \hat{\mu}_i)^2 - (1 - h_i)\hat{\mu}_i\right]^2}{2\sum_i^n \hat{\mu}_i^2}, \qquad (14)$$

where $\hat{\mu}_i$ is the expected value and h_i is the diagonal element of the hat matrix derived from fitting a regression model to the observed counts [11, 12]. Under a quasi-likelihood approach, the statistic is

$$T_2^2 = \frac{1}{2n}\left[\sum_i^n \frac{(y_i - \hat{\mu}_i)^2 - (1 - h_i)\hat{\mu}_i}{\hat{\mu}_i}\right]^2. \qquad (15)$$

The first test is an extension of the Fisher dispersion test (*see* **Poisson Distribution**) to the general case of regression models (see also [10]).

Conclusions

The interest in the negative binomial distribution arises from the frequency of occurrence in fieldwork of count data with over- or underdispersion with respect to the Poisson variance. Regression models can be built and maximum likelihood or extended maximum quasi-likelihood estimates of the mean and dispersion parameters can be obtained. Currently, some software provides commands for negative binomial regression analyses (see `glm`, `nbreg`, and `gnbreg` in *Stata* [29]).

Applications can be found in **geographical analysis**, in experimental designs, in epidemiology for the analysis of cohort studies, and in **longitudinal data analysis**. In most of these cases, the negative binomial distribution is considered as an alternative to the Poisson. The assumption of a specific form for the density of random terms, using a scale different from that of the fixed effects, limits the popularity of such modeling.
