ANNIBALE BIGGERI

Nelson–Aalen Estimator

The Nelson–Aalen estimator is a nonparametric estimator which may be used to estimate the cumulative hazard rate function from censored survival data (*see* **Survival Distributions and Their Characteristics**). Since no distributional assumptions are needed, one important use of the estimator is to check graphically the fit of parametric models, and this is the reason why it was originally introduced by Nelson [10, 11]. Independently of Nelson, Altshuler [2] derived the same estimator in the context of **competing risks** animal experiments. Later, by adopting a counting process formulation, Aalen [1] extended its use beyond the survival data and competing risks setups, and studied its small and large sample properties using martingale methods. The estimator is nowadays denoted the Nelson–Aalen estimator, although other names (the Nelson estimator, the Altshuler estimator, the Aalen–Nelson estimator, the empirical cumulative hazard estimator) are sometimes used as well. Below we present a number of situations where the Nelson–Aalen estimator may be applied and exemplify its use in one particular case. Furthermore, we indicate how counting processes provide a framework which allows for a unified treatment of all these diverse situations, and we summarize the most important properties of the Nelson–Aalen estimator. A detailed account is given in [3, Section IV.1].

Survival Data

Consider first the survival data situation, where we want to study the time to death (or some other event) for a homogeneous population with hazard rate function $\alpha(t)$ and cumulative hazard rate function $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$. Assume that we have a sample of n individuals from this population. Our observation of the survival times for these individuals will typically be subject to right censoring, meaning that for some individuals we only know that their true survival times exceed certain censoring times. The censoring is assumed to be independent in the sense that the additional knowledge of censorings before any time t does not alter the risk of failure at t (*see* **Censored Data**). We denote by $t_1 < t_2 < \cdots$ the times when deaths are observed and let d_j be the number of individuals who die at t_j.

The Nelson–Aalen estimator for the cumulative hazard rate function then takes the form

$$\widehat{A}(t) = \sum_{t_j \le t} \frac{d_j}{r_j}, \tag{1}$$

where r_j is the number of individuals at risk (i.e. alive and not censored) just prior to time t_j. Thus the Nelson–Aalen estimator is an increasing right-continuous step function with increments d_j/r_j at the observed failure times. The variance of the Nelson–Aalen estimator may be estimated by

$$\widehat{\sigma}^2(t) = \sum_{t_j \le t} \frac{(r_j - d_j)d_j}{(r_j - 1)r_j^2}. \tag{2}$$

It may be shown (see below) that the Nelson–Aalen estimator (1) as well as the variance estimator (2) are almost unbiased. In large samples the Nelson–Aalen estimator, evaluated at a given time t, is approximately normally distributed, so a standard $100(1-\alpha)\%$ confidence interval for $A(t)$ takes the form

$$\widehat{A}(t) \pm z_{1-\alpha/2}\widehat{\sigma}(t), \tag{3}$$

with $z_{1-\alpha/2}$ the $1-\alpha/2$ fractile of the standard normal distribution. The approximation to the normal distribution is improved by using a log transform giving the confidence interval

$$\widehat{A}(t) \exp\left[\pm z_{1-\alpha/2}\frac{\widehat{\sigma}(t)}{\widehat{A}(t)}\right]. \tag{4}$$

This interval is satisfactory for quite small sample sizes [5].

Right censoring is not the only kind of data incompleteness in survival analysis. Often, e.g. in epidemiological applications, individuals are not followed from time zero (in the relevant time scale, typically age), but only from a later entry time (conditional on survival until this entry time). Thus, in addition to right censoring, the survival data are subject to left truncation. For such data we may still use the Nelson–Aalen estimator (1) and estimate its variance by (2). The number at risk, r_j, now is the number of individuals who have entered the study before time t_j and are still in the study just prior to t_j. For left-truncated data the numbers at risk, r_j, may be low for small values of t_j. This will result in estimates $\widehat{A}(t)$ which have large sampling errors. But because the increments of the Nelson–Aalen estimator are

uncorrelated (see below), the uncertainty induced for small time values has no influence on the increment $\widehat{A}(t) - \widehat{A}(s)$ of the Nelson–Aalen estimator over a later time interval $(s, t]$. An estimator for the variance of this increment is $\widehat{\sigma}^2(t) - \widehat{\sigma}^2(s)$.

Quite often we want to estimate the survival distribution function $S(t) = \exp[-A(t)]$, representing the probability that an individual will be alive at time t. This may be done from right-censored and/or left-truncated survival data by the **Kaplan–Meier estimator**. The relation $A(t) = -\ln S(t)$ suggests that the cumulative hazard rate function alternatively may be estimated as minus the logarithm of the Kaplan–Meier estimator. Even though this estimator numerically will be close to the Nelson–Aalen estimator, the latter is the canonical one from a theoretical point of view. Furthermore, the Nelson–Aalen estimator may be used in a number of different situations (see below) while the alternative estimator applies only to the survival data situation.

An Illustration

To give an illustration of the Nelson–Aalen estimator we use data from a randomized clinical trial for patients with histologically verified liver cirrhosis. Patients were recruited from several hospitals in Copenhagen between 1962 and 1969 and were followed until death, lost to follow-up or until the closing date of the study, October 1, 1974. The time variable of interest is time since entry into the study. Patients are right censored if alive on October 1, 1974, or if lost to follow-up before that date.

We consider only the 138 placebo-treated male patients. Their median age at entry was 57 years, while the lower and upper quartiles were 51 and 66 years, respectively. Of the 138 patients, 88 died during the study. The Nelson–Aalen estimate for these patients is shown in Figure 1 with 95% confidence intervals computed according to (4). Even though the cumulative hazard rate function provides a useful summary measure (e.g. [6, Section 2.3]), it is usually the hazard rate function itself which is the entity of real interest. So when interpreting the estimate in Figure 1, we mainly focus on the "slope" of the curve. The estimate of the cumulative hazard rate function is steeper for the first 9–10 months after randomization than at later times. Therefore we have evidence that the risk of dying for these patients is highest just after randomization. (This may, at least in part, be due to heterogeneity which is not accounted for in our simple analysis.) The hazard rate function is approximately 0.3 per year for the first 9–10 months and slightly below 0.2 per year thereafter when estimated as the average slope of the curve over the relevant time periods. More formal procedures for smoothing the Nelson–Aalen estimate in order to obtain an estimate for the hazard rate function itself are available but will not be considered here (*see* **Smoothing Hazard Rates**). A further discussion and analysis of the cirrhosis data is given in [12]. The data were also used for illustrative purposes in [3].

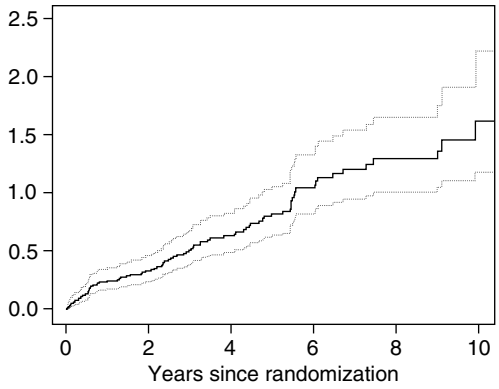

Figure 1 Nelson–Aalen estimate of the cumulative hazard rate function for death for 138 placebo-treated male patients with liver cirrhosis, with 95% log-transformed confidence intervals

Multi-state Models and Recurrent Events

The survival analysis setup considered above may be generalized in two directions. More than one type of event may be considered for each individual under study, and/or the event in question may happen more than once for each individual. Examples of the first type are competing risks with two or more causes of death and the Markov illness–death model with the states "healthy", "diseased", and "dead" (*see* **Counting Process Methods in Survival Analysis**). More generally, we may consider any **Markov process** with a finite number of states which may be used to model the life history of an individual. An example of the second type is an inhomogeneous **Poisson process** with intensity $\alpha(t)$ modeling the occurrence of some recurrent event like episodes of

angina pectoris in patients with coronary heart disease or infections in AIDS patients. For both of these two types of situations we observe the times when events occur for a number of individuals (modeled as iid copies of the relevant process) who need not all be observed over the same interval of time. The Nelson–Aalen estimator may then be applied to estimate cumulative intensities.

To be specific, consider a finite-state Markov process with transition intensities $\alpha_{gh}(t)$ for $g \neq h$. Focusing on fixed g and h in what follows, we drop the subscripts and write just $\alpha(t)$ for the $g \to h$ transition intensity. Furthermore, we denote by $t_1 < t_2 < \cdots$ the times when transitions from g to h are observed. Let d_j be the number of individuals who experience a $g \to h$ transition at t_j, and write r_j for the number of individuals in state g (i.e. at risk for a $g \to h$ transition) just prior to time t_j. Then the cumulative $g \to h$ transition intensity $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$ may be estimated by (1) and its variance by (2). Similarly, the integrated intensity of an inhomogeneous Poisson process may be estimated with the t_js denoting the times of observed events, and the d_js and r_js being the corresponding numbers of events and numbers at risk, respectively. An illustration of the use of the Nelson–Aalen estimator to estimate integrated Markov transition intensities is given by Keiding & Andersen [9].

Two Other Applications

For the situations considered so far, (1) and (2) apply with r_j the number at risk at t_j for the event in question. The use of the Nelson–Aalen estimator is, however, not restricted to such situations. We mention here two other applications and return to a general discussion below.

Relative Mortality

Our first example considers right-censored and/or left-truncated survival data, but they no longer come from a homogeneous population. Rather, we assume that the hazard rate function of the ith individual may be written as the product $\alpha(t)\mu_i(t)$, where $\alpha(t)$ is a relative mortality common to all individuals and $\mu_i(t)$ is the hazard rate function at time t for a person from an external standard population corresponding to the ith individual (e.g. of the same sex and age as individual i). Typically the $\mu_i(t)$ will be known from published life tables for the general population. In this situation the Nelson–Aalen estimator may be used to estimate the cumulative relative mortality $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$. All that is required is that r_j in (1) be taken to denote the sum of the external rates $\mu_i(t_j)$ for all individuals at risk just prior to t_j. An illustration of this use of the Nelson-Aalen estimator is provided by Breslow & Day [7, Chapter 5].

An Epidemic Model

A simple model for the spread of an infectious disease in a community is the following (*see* **Epidemic Models, Stochastic**). At the start of the epidemic, i.e. at time $t = 0$, some individuals make contact with individuals from elsewhere and are thereby infected with the disease. There are no further infections from outside the community during the course of the epidemic. Let $S(t)$ and $I(t)$ denote the number of susceptibles and infectives, respectively, just prior to time t. Assuming random mixing, the infection intensity in the community at time t becomes $\alpha(t)S(t)I(t)$, where $\alpha(t)$ is the infection rate per possible contact. We denote by $0 < t_1 < t_2 < \cdots$ the times when individuals are infected and let d_j denote the number infected at t_j. Then the cumulative infection rate, $A(t) = \int_0^t \alpha(s)\,\mathrm{d}s$, may be estimated by the Nelson–Aalen estimator (1) where now $r_j = S(t_j)I(t_j)$; see Becker [4, Section 7.6] for an illustration.

Counting Process Formulation and Small Sample Properties

In general we consider the occurrences of some events of interest (e.g. deaths, occurrences of a disease, infections), and denote by $0 < t_1 < t_2 < \cdots$ the times when an event is observed. We assume that two or more events cannot occur at the same time, so that there are no tied observations. (The handling of ties is discussed briefly below.) Then the process $N(t)$ counting the number of observed events in the time interval $[0, t]$ is a (univariate) counting process. The behavior of $N(t)$ is governed by its intensity process $\lambda(t)$ given heuristically by

$$\lambda(t)\,\mathrm{d}t = \Pr(\text{event occurs in } [t, t + \mathrm{d}t) | \mathcal{F}_{t-}).$$

Here $\mathcal{F}_{t-}$ represents all the information available to the researcher just before time t. The counting process satisfies Aalen's multiplicative intensity model if we may write its intensity process as

$$\lambda(t) = \alpha(t)Y(t), \tag{5}$$

for some unknown function $\alpha(t)$ and some observable process $Y(t)$ whose value at time t is known just prior to t. All the situations considered above give counting processes which fulfill (5). Survival data from a homogeneous population, finite-state Markov processes, and the inhomogeneous Poisson process, all give a $Y(t)$ process which is the number at risk just prior to time t. For the model for relative mortality, $Y(t)$ is the sum of the $\mu_i(t)$ for those at risk just before t, while for the epidemic model, $Y(t) = S(t)I(t)$. The common structure of all these models when formulated as counting processes is the reason why the Nelson–Aalen estimator may be applied to all these diverse problems.

In fact, the counting process formulation provides a framework which makes it simple to study the statistical properties of the Nelson–Aalen estimator. We briefly indicate a few main steps and refer to [3, Section IV.1.1] for a thorough treatment. First, we note that, with $r_j = Y(t_j)$, we may write the Nelson–Aalen estimator (1) as

$$\widehat{A}(t) = \int_0^t \frac{J(s)}{Y(s)}\,\mathrm{d}N(s), \tag{6}$$

where $J(s) = I(Y(s) > 0)$ and 0/0 is interpreted as 0. Then using (5), (6), and the decomposition $N(t) = \int_0^t \lambda(s)\,\mathrm{d}s + M(t)$ of a counting process into a sum of its integrated intensity process and a local square integrable martingale $M(t)$, we obtain

$$\widehat{A}(t) = A^*(t) + M^*(t). \tag{7}$$

Here $A^*(t) = \int_0^t J(s)\alpha(s)\,\mathrm{d}s$ is almost the same as $A(t)$ when there is only a small probability that $Y(s) = 0$ for some $s \le t$, while $M^*(t) = \int_0^t [J(s)/Y(s)]\,\mathrm{d}M(s)$ is a stochastic integral and as such is a local square integrable martingale. Relation (7) is the key to studying the statistical properties of the Nelson–Aalen estimator. Since $M^*(t)$ has expected value zero for any given t, we have $\mathrm{E}\widehat{A}(t) = \mathrm{E}A^*(t)$, so the Nelson–Aalen estimator is almost unbiased. Furthermore, an unbiased estimator for the variance of $M^*(t)$ is its optional variation process $\int_0^t [J(s)/Y(s)^2]\,\mathrm{d}N(s)$. Thus the variance estimator (2) is almost unbiased when there are no ties. Finally, a martingale has uncorrelated increments, and by (7) this is (almost) the case for the Nelson–Aalen estimator as well.

In the presence of ties, i.e. when the number of events d_j at t_j exceeds one, the process $N(t)$ counting occurrences of events in $[0, t]$ may have jumps of size two or larger and is therefore no longer a counting process. Often, however, we may write $N(t) = \sum_{i=1}^n N_i(t)$, where $N_i(t)$ is a counting process registering the events for individual i. If we consider a homogeneous population where the rates of occurrence of the events are the same for all individuals, we may adopt the discrete extension of the model described in [3, pp. 180–181]. For this extended model, the arguments of [8, pp. 94–96], apply, to show that the variance estimator (2) is almost unbiased also in the presence of ties. This justifies the use of the tie-corrected estimator (2) for all situations considered above, except for the model with relative mortality and the epidemic model. Within the framework of the extended model the Nelson–Aalen estimator is a **nonparametric maximum likelihood** estimator; see [3, Section IV.1.5] for details and further discussion.

Weak Convergence and Confidence Bands

By (7) the martingale central limit theorem may be used to prove that, considered as a stochastic process, the Nelson–Aalen estimator (properly normalized) converges weakly to a mean zero Gaussian martingale. In particular, for a fixed t it is asymptotically normally distributed, a fact that was used in connection with the confidence intervals (3) and (4). The weak convergence result also makes it possible to derive confidence bands for A, i.e. limits which contain $A(t)$ for all t in an interval $[\tau_1, \tau_2]$ with a prespecified probability.

One important class of such confidence bands are the equal precision bands. The standard and log-transformed equal precision bands are obtained by replacing $z_{1-\alpha/2}$ in (3) and (4) by $d_{1-\alpha}$, the $1-\alpha$ fractile in the distribution of the supremum of the absolute value of a standardized Brownian bridge (over a certain time interval). This fractile may be found (approximately) by solving (with respect to d)

the nonlinear equation

$$\frac{4\phi(d)}{d} + 2\phi(d)\left(d - \frac{1}{d}\right)\ln\left[\frac{\widehat{\sigma}(\tau_2)}{\widehat{\sigma}(\tau_1)}\right] = \alpha,$$

where $\phi(d)$ is the standard normal density function. The equal precision bands require $\widehat{\sigma}(\tau_1) > 0$, so they cannot be extended all the way down to $t = 0$. Typically, one will also omit the largest values of t. The standard equal precision band has poor small sample properties, so even with sample sizes in the hundreds the use of the log transformed confidence band is recommended [5]. As an illustration we use once more the liver cirrhosis example. Considering the interval from 4 months (1/3 year) to 8 years, we have $\widehat{\sigma}(1/3) = 0.027$ and $\widehat{\sigma}(8) = 0.163$, so that $d_{0.95} = 2.99$. Therefore the 95% log transformed equal precision band for the cumulative hazard rate function between 4 months and 8 years may be obtained from (4) by using the fractile 2.99 instead of the value 1.96 used for the pointwise confidence intervals in Figure 1. A detailed study of the weak convergence of the Nelson–Aalen estimator and the derivation of confidence bands are provided by [3, Section IV.1.2-3]. Here another class of confidence bands, the Hall–Wellner bands, is also discussed.

We finally note that **semi-Markov processes** (or Markov **renewal processes**), where the transition intensities (only) depend on the sojourn times in the states, do not give rise to counting processes which fulfill the multiplicative intensity model (5). Thus the results outlined above do not immediately extend to such models. However, it turns out that enough of the above structure is preserved to be able to define Nelson–Aalen estimators also for such semi-Markov processes and to derive identical asymptotic results for these as for the case of Markov processes; see [3, Section X.1] for a discussion and further references.

ØRNULF BORGAN

Nephrology

Nephrology is defined as the scientific study and treatment of the kidney and its diseases. Acute renal failure usually occurs in previously normal kidneys, often after a major injury or surgery, and typically the patient's renal function returns to normal after a short period. Chronic renal failure, which is usually associated with kidney disease, results in the irreversible deterioration of kidney function. When the condition becomes terminal the patient is said to have end-stage renal failure (ESRF). Two forms of renal replacement therapy are available for patients with ESRF; renal dialysis and **transplantation**.

Dialysis partially cleans the blood of toxic waste products normally excreted by the kidney. Hemodialysis and continuous ambulatory peritoneal dialysis (CAPD) are the most common treatment methods. Other kidney functions are supplemented by drugs. Transplantation is the preferred treatment for most patients as it replaces all functions of the kidney, but the main bar to expanding this is the worldwide shortage of donor organs.

The clinical challenge in the management of dialysis patients is the dialysis prescription. Inadequate dialysis can lead to toxin build-up, anemia, infection, nutritional problems and an increased risk of mortality. For the transplant recipient, rejection and infection are the primary complications.

Renal Disease Registers

Several regional, national, and international registries collecting data on ESRF patients have been established worldwide (*see* **Disease Registers**). The range of data collected extends to patient demography and treatment modality, acceptance rates (**incidence**) and patient stock levels (**prevalence**), patient outcome and co-morbidity factors, dialysis duration and adequacy and treatment center parameters (structure, staffing, etc.). The reports prepared by the Registries [1] indicate the areas of key interest and the statistical techniques applied.

Excepting for the registries in the US, Holland, Finland, and Germany (under development), participation is voluntary. Return rates for the first established European Dialysis and Transplant Association–European Renal Association (EDTA–ERA) registry have been particularly poor in recent years (less than 50% for some countries) but other registries claim high compliance rates of over 90% [1]. Similar registries exist in the transplant arena in the US, UK, Europe, and elsewhere [14]. These databases tend to be less ambitious, having implemented the concept of a core database of key readily available data items. For specific additional studies, more detailed information is then collected from co-opted centers for a limited time.

In addition to these registries of observational data, there have been a number of **clinical trials** in nephrology, of which the National Cooperative Dialysis Study (see, for example, Laird et al. [6]) is probably the most comprehensive.

Nephrology Journals

A number of journals publish articles on the study and treatment of renal disease in the clinical and laboratory setting. Many papers include reference to, and use of, statistical methods, although often the content is quite low. Use of the t, Wilcoxon, and χ^2 tests and analysis of variance are widely reported, as are Kaplan–Meier and Cox survival analyses. Most authors quote the package used but few comment on the analysis method chosen or its limitations, and even fewer acknowledge statistical advice. Generally, the statistical content is higher in the transplantation journals and in *Kidney 1International*.

Patient Survival Under Alternative Treatment Modalities

Choosing an Appropriate Start Point and Study Cohort

For many patients, the onset of ESRF can only be defined retrospectively as the long-term prognosis may be uncertain when regular dialysis first begins, so the start point is often set at 90 or 120 days after the start of dialysis. Also, several patients will change dialysis modality in the first months of treatment. Similarly, when comparing patients' survival prospects under dialysis and transplantation, setting the start point as the date of listing for transplant excludes the potential bias of including patients unsuitable for transplantation.

Modeling Treatment Changes

Several authors have avoided the issue of patients changing treatment by censoring (*see* **Censored Data**) when a change occurs. To minimize the effect of possible nonindependent censoring, the survival time is censored at the point of change, but a death within the following two months is considered a death on the previous modality (unless the death is unrelated to treatment) (see, for example, Nelson et al. [12]). Similarly, transplantees are censored at the date of grafting, as the chance of a patient receiving a kidney is governed by donor availability and not by dialysis mode or duration.

This is inadequate when the total survival experience under alternative treatments is of interest (*see* **Survival Analysis, Overview**). For a transplantee, for example, it is necessary to account for the time the patient survived on dialysis prior to receiving a graft. The **Cox regression model** with **time-dependent covariates** can be used for inference about **relative risks** in this situation.

In its simplest form (with a single treatment change), the model would be

$$h_i(t) = h_0(t) \times \exp[\mathbf{z}_i'\beta + I_i(t)\gamma], \qquad (1)$$

where $h_0(t)$ is the baseline **hazard**, $\mathbf{z}_i$ is the $p \times 1$ vector of fixed covariates, and $I_i(t) = 0$ if patient i has not changed treatment at time t, 1 otherwise, with $\beta_1, \ldots, \beta_p$, γ the regression coefficients to be estimated.

For a patient changing between dialysis treatments, this model may not be unreasonable, but for a change from dialysis to transplantation, model (1) is not entirely appropriate as it assumes the transplantation hazard remains constant. It is well recognized that the hazard after transplantation is not constant over time, and that the initial postoperative period has the greatest hazard. An extension to (1) that would allow for transient effects would be to include multiple indicators to reflect the clinically relevant cutpoints, t_1, t_2, and t_3, say, namely

$$\begin{aligned} h_i(t) = h_0(t) \times \exp[\mathbf{z}_i'\beta &+ I_i(0 \le t - t_i^* < t_1)\gamma_1 \\ &+ I_i(t_1 \le t - t_i^* < t_2)\gamma_2 \\ &+ I_i(t_2 \le t - t_i^* < t_3)\gamma_3], \end{aligned} \qquad (2)$$

where t_i^* is the time from entry to the study to transplant.

The effects would then be modeled by way of the step function. An alternative approach for exploring transient hazard effects is to assume the hazard after transplant has an exponential decay (*see* **Parametric Models in Survival Analysis**), namely

$$\begin{aligned} h_i(t) = h_0(t) &\times I_i(t) \\ &\times \exp\{\beta_0 + \beta_1 \exp[-\gamma(t - t_i^*)]\}. \end{aligned} \qquad (3)$$

Other covariates can be controlled for by **stratification**. Mauger et al. [10] have developed this further to estimate the times at which the hazard and survival curves for dialysis patients awaiting transplantation cross the transplant hazard and survival curves.

Inherent in models (1) and (2) is the assumption that the relative risks, $\beta_1, \ldots, \beta_p$, do not change over time. Various studies have shown that the risks attributable to human leukocyte antigen (HLA) mismatching for transplant survival are transient. For further exploration of issues surrounding the analysis of transplant outcome per se, *see* **Transplantation**.

Occurrence of Repeated Events

Repeated events, usually of an adverse nature, arise in many clinical settings, including nephrology. For example, infections in the peritoneal cavity and at the point of insertion of the catheter are common complications that hamper significantly the success of CAPD as a treatment. Statistical models have been developed to understand better the etiology and incidence of infection in these patients. Infection occurrence can be recorded in one of two ways:

1. Number of infections, x_i, say, over follow-up time T_i.

In this situation, a **Poisson process** for counts is appropriate, and both **fixed effects** and **random effects** models have been explored. Vonesh [15] fitted a mixed effect **gamma** Poisson **multiplicative model** for modeling individual peritonitis infection rates, namely

$$\lambda(\mathbf{z}_i) = \lambda_i \exp(\mathbf{z}_i'\beta), \qquad (4)$$

with

$$\lambda_i \sim \Gamma(\alpha, \gamma), \qquad (5)$$

and compared the results with a fixed effects model with $\lambda_i = \lambda_0$ for all i. The conclusions were similar,

but the mixed model, by giving less weight to the few high-risk cases, provided a better fit and more realistic **standard errors**.

2. Distinct recurrence times, t_{ij}, $j = 1, \ldots, n_i$, where n_i is the number of infections occurring in follow-up time T_i.

When distinct times to infection are available, survival models with covariates can be applied. Common approaches when repeated event times are recorded are either to reduce the data to counts and fit **Poisson regression** models as described above, or, if the first event is of greatest clinical significance and the number of repeated events small, to consider time to the first occurrence and discard second and subsequent events.

Hierarchical models with **frailty** allow full use of the data and have been used to evaluate the relative risks for repeat infections at the catheter insertion with censoring. McGilchrist & Aisbett [11] assumed the recurrence times were independent and suggested fitting a multiplicative Cox model of the form:

$$h_i(t) = h_0(t) \times f_i \exp(\mathbf{z}_i' \beta), \tag{6}$$

where f_i is the frailty term and

$$\ln(f_i) \sim \mathrm{N}(0, \sigma^2). \tag{7}$$

If independence between the repeated infections is not assumed, then more complex models are required and Lindsey [7] has explored how this can be achieved through **counting processes** and the use of **loglinear models**.

Repeated Measurements

In many clinical trials and studies in nephrology, outcome takes the form of repeated measures of a (continuous) biochemical response recorded over the treatment period. For example, in a trial to compare the biocompatibility and functionality of alternative dialysis membranes, white blood cell (WBC) counts were recorded before dialysis and at 15, 60, 120, and 210 minutes after the start of dialysis. Many authors have considered the issues associated with the analysis of serial measurements in the context of clinical research (e.g. Matthews et al. [9]). Some of the simplest approaches are to choose an appropriate summary measure such as the area under the curve, value at a fixed time or when the response reaches a peak, rate of increase/decrease (slope) for each patient, and use **analysis of variance** to compare treatment effects. If the response relative to a pretreatment baseline is appropriate, **analysis of covariance** can be used.

However, if interest lies in evolution of the response, and patient **covariates** are also appropriate, this simple approach will be inadequate and more complex models that allow for within individual **correlation** are required. Linear models with fixed and random effects and **time series** models for characterizing the covariance structure are alternate approaches that have received considerable attention in the literature. Rochon [13] uses data from a trial to evaluate the efficacy of erythropoietin for treating anemia in patients with ESRF to illustrate the use of **ARMA** covariance models with time dependence in the covariance matrix. In the trial, patients were allocated at random (*see* **Randomization**) to receive one of three drug doses and hemoglobin measurements were measured weekly for 26 weeks to ensure target levels were reached. Observations were relatively stable at the beginning of the study, but became more variable towards the end, so that the usual ARMA assumption of constant **variances** and covariances over time was not entirely appropriate and a model allowing for heteroscedasticity (*see* **Scedasticity**) was fitted.

Biomedical Time Series – Patient Monitoring

Biomedical time series also arise in the routine ongoing monitoring of both dialysis and transplant patients. The function of a transplanted kidney is monitored regularly for signs of rejection, while patients on long-term dialysis are routinely tested for high levels of toxic waste and low levels of other blood constituents, such as WBC.

Physiological variation gives rise to typically noisy series that are subject to different types of abrupt change. For example, the WBC count will rise temporarily following the administration of steroids, and to assess accurately the underlying level, these values need to be filtered out. Similarly, a functioning kidney may exhibit alternating periods of improvement and deterioration, some of which may be self-correcting, others which may require medical intervention. Thus, the simple cumulative sum

(CUSUM) procedure is not suitable as there is a need to detect both the occurrence and form of each change.

The multiprocess Kalman filter methodology was developed by Gordon & Smith [5] specifically to analyze these renal monitoring series. An appropriate form of model for the series is selected [an AR(1) for the WBC data], which can be expressed in the general form:

$$y_t = \mathbf{H}_t\theta_t + \delta y_t^{(j)}, \tag{8}$$

$$\theta_t = \mathbf{G}_t\theta_{t-1} + \delta\theta_t^{(j)}, \tag{9}$$

where y_t is the reading at time t, θ_t is a vector of parameters, $\mathbf{H}_t$ and $\mathbf{G}_t$ are known regression and transition matrices, and j represents one of four possible states – stable state, impulse (temporary perturbation), change of level, and transient (temporary perturbation). The components $\delta y_t^{(j)}$ and $\delta\theta_t^{(j)}$ are assumed **normally distributed**:

$$\delta y_t^{(j)} \sim \mathrm{N}(0, \lambda^{-1}R_y^{(j)}) \quad \text{and} \quad \delta\theta_t^{(j)} \sim \mathrm{N}(0, \lambda^{-1}\mathbf{R}_\theta^{(j)}), \tag{10}$$

where the elements of R_y and $\mathbf{R}_\theta$ are chosen to reflect the different states. The quantities of interest and of greatest clinical importance are the associated probabilities that a change of level is obtained at time t given $y_1, \ldots, y_t$, and that a change of level occurred at time t given $y_1, \ldots, y_{t+1}$.

Institutional Comparisons

Comparison of institutional success rates has received considerable attention in nephrology, particularly in the transplantation arena. Of particular interest is the work of Gilks [4]. He proposed a hierarchical Bayes model for distinguishing between systematic and random variation in center success rates and showed for a study of UK transplant center success rates from 1978 to 1984 that the phenomenon of persistent center variability in raw success rates to suggest institutional variation was an illusion.

Missing Data

Random missing values occur (*see* **Missing Data**), especially in multicenter registries, because data may be unavailable at some units and from patient migration to other cities and missed appointments. Informative missing values arise particularly in studies that involve monitoring renal function. Typically, patients who show a more rapid decline in function are those more likely to terminate the study early and this tends to occur particularly among patients enrolling with poor function.

Clinical Trials

There are numerous examples in the literature of **clinical trials** in nephrology. The use of randomized controlled trials and **factorial designs** and **crossover designs** have proved particularly popular. These designs are appropriate as the majority of trial "treatments" are not expected to cure or permanently alter the state of the patient.

Examples of recent trials that have presented particular statistical challenges, although not unique to nephrology, include the treatment of side effects of renal dialysis (multivariate repeated measurements evaluated using **Bayesian methods**) [3], and complications arising from long-term dialysis (**paired comparisons** with a "no preference" option in the analysis of pain) [8].

Future Developments

The examples we have considered here were chosen to illustrate the range of statistical methods that have found application in nephrology in recent years. While not unique to nephrology, many of the more complex models described are examples of the application of recent statistical advances and methodological developments. The computational aspects of fitting these models are necessarily complex and further evaluation of the performance of the **algorithms** used for estimating the model parameters, and of the properties of the estimates obtained, are likely to be an area of continuing research.

Extensions to the Cox model by way of assessing the model through the use of various diagnostics such as martingale residuals (*see* **Counting Process Methods in Survival Analysis**), estimated **explained variation**, and assessing a model's predictive ability though **cross-validation** are just some developments that could have application in nephrology studies. A

recently proposed **nonparametric method** for estimating relationships between covariates and hazard rates that relaxes the assumption that covariate effects are linear and additive on the log hazard [2] may also be relevant.

While the survival of the patient is the primary outcome, there is increasing interest in the development of **co-morbid** conditions among renal patients, such as heart disease and malignancy (in transplant recipients). Further developments are needed to study these **competing risks** better and to assess the influence of a patient's treatment history, and factors specific to different "treatment" episodes, on their future status.

With the increasing computer power and the continuing development of renal disease databases there is potential for greater use of **simulation**, not only in resource planning and allocation but also in assessing the validity and **robustness** of model estimates. The problem of missing values, particularly in large multicenter databases, is likely to be a continuing one and awareness of the effect and handling of all types of missing values is an area for further study.

Network Sampling

Conventional sampling and network sampling differ with regard to the number of different selection units at which the same population element is countable in the survey. Conventional sampling postulates that every population element is uniquely linked to one and only one selection unit at which it is enumerable in the survey. Network sampling is not subject to this restriction. The network sampling paradigm indicates that every population element belongs to a network of selection units at which it is countable and the network sizes may vary, including possibly null networks without any selection units. Conventional sampling may be viewed as a special case of network sampling in which every population element is linked to a network, and each network contains one and only one selection unit.

Flexibility with respect to network sizes provides network sampling with design alternatives that may be superior to those based on conventional sampling. Network sampling is sometimes preferable when multiple selection units seem to be inextricably linked to the same population elements. However, network sampling may be fostered as a design strategy to improve survey efficiency whether or not multiple selection units are inextricably linked to the same population elements.

Historical Perspective

Network sampling is a relatively new kind of sample design that emerged in the early 1960s in response to an **estimation** problem involving a sample survey of medical providers [7] designed to estimate the **prevalence** of cystic fibrosis, a relatively rare and often lethal genetic disease of children. In the survey, medical providers reported each individual they had treated for the disease. The estimation problem arose because in designing the survey it had been implicitly assumed that each patient had been treated by only one medical source. The survey designers did not realize that it was common practice for the same patient to be treated by multiple medical sources during the course of the disease. The mistake became apparent when multiple medical providers in the survey reported the same patients. If not adjusted, the conventional estimation procedure would have counted the same patients as many times as reported by different medical sources and the estimate would have been **biased**. The conventional procedure would have been biased even if duplicate reports of the same patients had not been counted.

Birnbaum & Sirken [1] derived three **unbiased** estimators for network sampling which addressed the effects of multiple reporting on the sample selection probabilities. Their estimators differ from one another with respect to kinds of information required about network sizes of population elements that are counted in the sample survey.

Initially, network sampling was applied only in surveys for which multiple selection units appeared to be inextricably linked to the same population elements. Many were establishment surveys which, like the cystic fibrosis survey, involved estimating population **prevalence** rates based on counts of individuals having transactions with establishments whose constituents overlap. For example, Laska et al. [9], estimated the number of different individuals receiving mental health clinic care in a sample survey of the patients of several mental health clinics with overlapping clients (see also [18]). Establishment surveys are not the only venues in which network sampling is applied when multiple selection units are inextricably linked to the same population elements. Levy & Sirken [13] applied network sampling in estimating the number of defective statistical statements in texts of technical publications on the basis of number of defective statements that straddle sampled lines of text. Faulkenberry & Garoui [6] and Hendricks et al. [8] applied network sampling in agricultural surveys to estimate the number of farms that overlapped sampled area land segments.

It was not until the 1970s that network sampling was applied as a deliberate strategy to foster design efficiency. This development occurred after Sirken [19] demonstrated that fostering network sampling could substantially increase survey yields and decrease sampling errors, particularly in population surveys of relatively rare events. He proposed fostering network sampling in household surveys by linking individuals to households of relatives and others with whom they had well-defined relationships and who could serve as good proxy respondents. Network sampling based on kinship relationships was applied

in several health surveys, including diabetes prevalence surveys [30], cancer prevalence surveys [4, 5], surveys of births and marriages [15], surveys of recent decedents [17], and surveys of the Jewish population [26].

Subsequently, it became apparent that network sampling had potential for reducing **measurement errors** as well as sampling errors. For example, network sampling using kinship counting rules was applied in a post-enumeration population survey to improve estimates of **census** population undercoverage [14, 30], and network sampling based on friendship counting rules was applied in drug use surveys to improve the quality of response on sensitive questions [16]. More recently, Sirken et al. [31] demonstrated the utility of fostering network sampling in **population-based** establishment surveys of disease prevalence which link individuals having multiple transactions with the same establishments. Population-based establishment surveys are particularly applicable when free-standing establishment frames with good measures of establishment size are not available.

Since Birnbaum & Sirken [1] first proposed several network sampling estimators, the theory of network sampling has been extended in several directions. Sirken & Nathan [28] developed several "hybrid" network estimators based on combinations of counting rules. Network sampling theory has been extended to ratio estimation [27] (*see* **Ratio and Regression Estimates**), and to complex types of sampling, including **stratified sampling** [10, 20], **cluster sampling** [11], and **multistage sampling** [31]. Also, relationships between network sampling and other sample designs involving multiple linkages of selection units to the same population elements have been investigated. For example, Casady & Sirken [2] compared stratified network sampling and multiple frame sampling estimators; Sirken [23, 24] and Casady et al. [3] derived several unbiased network estimators for dual system sampling, and Sudman et al. [32] discuss conventional sampling, network sampling, and **capture–recapture** sampling as alternative design strategies for sampling rare and elusive populations. Sampling textbooks by Levy & Lemeshow [12] and by Thompson [33] give special attention to network sampling and other sampling strategies involving multiple linkages for sampling rare and elusive populations.

Sample Design Strategies

Surveys are complex measurement instruments involving multiple interdependent design features, each feature usually having several options, and each option having its respective cost, error, and other survey effects. Designing surveys involves selecting an options set that contains one option for each design feature, and the goal is to select the optimum option set which has the greatest overall utility in meeting the survey objectives.

In addition to the sample selection procedure (i.e. stratified, cluster, multistage sampling, etc.) three survey design features are key to network sampling designs and are particularly important in understanding the survey circumstances that favor network sampling [22].

1. *Counting rules* link population elements to selection units at which they are eligible to be enumerated in the survey.
2. *Estimators* are algebraic **algorithms** for counting and weighting the population elements enumerated in the sample survey to estimate population parameters.
3. *Respondent rules* specify the sources that are eligible to provide information about population elements that are enumerated in the survey.

Each of these design features and some of their respective options are discussed in the next section, and their design effects in terms of sampling errors, measurement biases, and survey costs are discussed in the final section.

Survey Design Features

Counting Rules

Counting rules specify conditions for linking population elements to selection units at which they are eligible to be counted in the survey [22]. Groupings of selection units that are linked to the same population elements are called *networks*, and groupings of population elements that are linked to the same selection units are called *clusters*.

A requirement of conventional sampling is that the conditions specified by counting rules have the property of linking each population element to a network that contains one and only one selection

unit at which it is countable in the survey. Counting rules satisfying this condition are called *conventional counting rules*. *De facto* and *de jure* residence rules in household surveys are examples of conventional counting rules. The *de facto* rule links individuals to the households at which they happen to be located. The *de jure* rule links individuals to their legal places of residence.

Network sampling permits multiple linkages of selection units to the same population element. Counting rules of this type are called *network counting rules*. Network counting rules in household surveys typically link individuals to households of kinfolk or others (such as friends or neighbors) with whom they have close social relationships. Frequently, the rules also link individuals to their own households so that individuals without any relationships to others will not be missed in the survey.

In the following example, we compare effects of a conventional and two network counting rules on the formation of networks and clusters:

1. *Conventional rule*. Individuals are uniquely linked to their own households.
2. *Sibling rule*. Individuals are linked to households of their siblings.
3. *Conventional/sibling rule*. Individuals are linked to their own and their siblings' households.

Assume a census of diabetes prevalence is conducted on a fictional population of seven individuals residing in four households. Table 1 shows the within-household and between-household relationships of these individuals. Note that the three sons of the head of household A are siblings to one another.

Table 2 compares the effects of the counting rules on the formation of clusters. It lists the individuals that are countable at every household by each of the three rules. At household A, for example, three individuals are countable (A_1, A_2, and A_3) by the conventional rule, two individuals are countable (B_1 and C_1) by the sibling rule, and five individuals are countable (A_1, A_2, A_3, B_1 and C_1) by the conventional/sibling rule.

Table 3 compares the counting rules' effects on the formation of networks. It lists the households at which the seven individuals are countable by each counting rule. For example, B_1 is countable at one household (B) by the conventional counting rule, at two households (A and C) by the sibling counting rule, and at three households (A, B, and C) by the conventional/sibling counting rule. On the other hand, A_1 is countable once (household A) by the conventional and by the conventional/sibling rule but is missed by the sibling rule.

Continuing with this example, to estimate diabetes prevalence requires knowing which of the seven

Table 1 Fictional population of households and individuals

Households	Individuals	Within-household relationship	Relationship to head of household A
A	A_1	Head	Self
	A_2	Wife	Wife
	A_3	Son	Son
B	B_1	Head	Son
C	C_1	Head	Son
	C_2	Wife	Daughter in law
D	D_1	Head	Unrelated

Table 2 Effects of three counting rules on the formation of clusters

Household	Conventional rule	Sibling rule	Sibling/conventional rule
A	A_1, A_2, A_3	B_1, C_1	A_1, A_2, A_3, B_1, C_1
B	B_1	A_3, C_1	A_3, B_1, C_1
C	C_1, C_2	A_3, B_1	A_3, B_1, C_1, C_2
D	D_1	–	D_1

Table 3 Effects of three counting rules on the formation of networks

Individuals	Conventional rule	Sibling rule	Conventional sibling rule
A_1	A	–	A
A_2	A	–	A
A_3	A	B, C	A, B, C
B_1	B	A, C	A, B, C
C_1	C	A, B	A, B, C
C_2	C	–	C
D_1	D	–	D

individuals were diabetic. This information would be obtained by enumerating all individuals that are countable at every household (Table 2). Summing the unweighted numbers of individuals that are diabetics is an unbiased estimation procedure for the conventional counting rule because that rule counts each individual once and only once. However, this would be a biased estimation procedure for either of the network counting rules. The sibling rule is biased because it counts three individuals (A_3, B_1, and C_1) twice and fails to count any of the other four individuals. It is a biased estimation procedure for the conventional/sibling rule because three individuals (A_1, B_1, and C_1) are each counted three times.

In this example the conventional estimation procedure would be unbiased for the conventional/sibling counting rule if duplicate enumerations were eliminated for individuals counted multiple times. In some sample surveys, however, eliminating duplicate enumerations is not a sufficient condition for unbiasedness.

Survey Estimators

Two network estimators (multiplicity A and B) and a conventional estimator are compared, assuming **simple random sampling** of selection units to estimate N, the population prevalence of a **binomial** variable. Both network estimators are weighted sums of population elements that are countable at sample selection units in compliance with the counting rule adopted in the survey. The estimators differ, however, with respect to the ways they count the population elements, and the network information they use to determine the network weights.

The first multiplicity estimator (N_a) counts the same population element every time it is countable at the same or different sample selection units, and weights the element by the ratio of the number of times it is countable at the sample selection unit to the number of times it is countable at all selection units. The second multiplicity estimator (N_b) counts the same population element at most once at any sample selection unit and weights the countable elements by the inverse of the number of selection units in its network. For example, in a household survey using a conventional/sibling counting rule in which two siblings that were enumerated in a sample household have three other siblings living in another household, each of the two siblings at the sample household would get a weight of two-fifths based on the multiplicity A estimator, and a weight of one-half based on the multiplicity B estimator. Both network estimators are unbiased if every population element is linked to at least one selection unit by the counting rule. The multiplicity A estimator is one of the three unbiased network estimators originally proposed by Birnbaum & Sirken [1].

The conventional estimator (N_c) is an unweighted sum of the population units that are countable at sample selection units in compliance with the conventional counting rule.

Assume a population of N elements $I = \{I_1, \ldots, I_\alpha, \ldots, I_N\}$ with a specified attribute, and a **sampling frame**, $H = \{H_1, \ldots, H_i, \ldots, H_L\}$, containing L selection units households. Denote the links between elements and units by the indicator variable:

$$\delta_{\alpha,i} = \begin{cases} 1, & \text{if } I_\alpha \text{ is linked to } H_i, \\ & \alpha = 1, \ldots, N; i = 1, \ldots, L, \\ 0, & \text{otherwise} \end{cases}$$

The general form of the network estimator based on a sample of l selection units is

$$\hat{N} = \frac{L}{l} \sum_i^l \lambda_i,$$

where $\lambda_i = \sum_\alpha W_{\alpha i} \delta_{\alpha i}$ is the weighted sum of the population elements countable at $H_i, i = 1, \ldots, L$, and $W_{\alpha i}$ is the network weight assigned to I_α, $i = 1, \ldots, N$, when I_α is counted at $H_i, i = 1, \ldots, L$. The network estimator is unbiased if and only if

$$\sum_i W_{\alpha i} \delta_{\alpha i} = 1, \quad \alpha = 1, \ldots, N.$$

The multiplicity estimator $\hat{N}_a$ assigns the network weights

$$W_{\alpha i} = \frac{S_{\alpha i}}{S_\alpha}, \quad \alpha = 1, \ldots, N, i = 1, \ldots, L,$$

where $S_{\alpha i}$ is the number of times I_α is linked to H_i, $i = 1, \ldots, L$, and $S_\alpha = \sum_i^L S_{\alpha i}$ is the number of times I_α is linked to all L selection units.

The multiplicity estimator $\hat{N}_b$ assigns the network weights

$$W_{\alpha i} = \frac{1}{S_\alpha^*}, \quad \alpha = 1, \ldots, N; \quad i = 1, \ldots, L,$$

where $S_\alpha^* = \sum_i^L \delta_{\alpha i}$ is the number of different H_i, $i = 1, \ldots L$, to which I_α is linked.

The conventional estimator is a special case of the network estimator in which $S_\alpha = 1$, $\alpha = 1, \ldots, N$, and thus $W_{\alpha i} = 1$, $\alpha = 1, \ldots, N$; $i = 1, \ldots, L$.

It is noteworthy that the multiplicity estimators $\hat{N}_a$ and $\hat{N}_b$ require the network weights for the I_α that are enumerated at sample selection units and not at any others. Hence, it is often feasible and cost-effective to collect the information needed to calculate the weights from the selection units at which the population elements are enumerable or possibly from other information sources that are identified by the sample selection units.

Respondent Rules

Essentially, three kinds of information are collected for individuals enumerated in population surveys that are based on network sampling:

1. *Eligibility information* identifies the individuals that are countable at sample addresses in compliance with network counting rules.
2. *Topic information* calibrates countable individuals on survey topic related variables.
3. *Network information* is used to determine network weights.

For example, a diabetes prevalence survey based on the conventional/sibling rule and the multiplicity A estimator or the multiplicity B estimator would collect the following kinds of information at sample households:

1. Eligibility information – listing of resident individuals and their nonresident siblings that are countable at the household.
2. Topic information – identifies the countable individuals that have diabetes.
3. Network information – for each countable diabetic, determines either the number of his or her siblings for multiplicity estimator B (in this instance self-evident from the eligibility information) or the number of different households in which the diabetic and siblings reside for multiplicity estimator A.

Most population surveys based on network sampling collect all three types of information from the sample households at which individuals are counted. (The individual himself and/or other sample household residents may be specified as eligible within-household respondents.) Otherwise, sample households may identify other sources, such as *de jure* residences of individuals who are not residents of sample households; or the information could be obtained from multiple sources with eligibility information being ascertained at sample households, and topic and network information being obtained from *de jure* residences.

Nonhouseholds are also potential information sources. Population-based establishment surveys are notable examples of network sample surveys in which establishments are the principal sources of information about individuals enumerated in household sample surveys. Population-based establishment surveys use network counting rules such as the following: "individuals with diabetes are countable at every household whose residents were treated by the same medical providers". Suppose, for example, there are two individuals living in different households that are being treated by the same medical provider and one of the households is selected in the sample and the other is not. The population survey determines that a resident at the sample household has diabetes, and then obtains from that household the name and address of his or her medical provider. A follow-up survey is conducted with that provider who provides information about all diabetics in his practice, which in this example would be two diabetics. The network weight assigned by network estimators A and B to each diabetic would be equal to one-half.

Survey Design Effects

Sampling Errors

Assuming simple random sampling of l of L selection units with replacement, the sampling **variance** of the network estimator of N is

$$\text{var}(\hat{N}) = \frac{1}{l}\text{var}(N),$$

where

$$\text{var}(N) = \frac{1}{L}\sum_{i}^{L}(\lambda_i - \overline{\lambda})^2$$

and

$$\overline{\lambda} = \frac{1}{L}\sum_{i}^{L}\lambda_i = \frac{1}{L}\sum_{i}^{L}\sum_{\alpha}^{N} W_{\alpha i}\delta_{\alpha i} = \frac{N}{L}.$$

Clearly, the ideal network counting rules and weights would have $\lambda_i = \overline{\lambda}$, $i = 1, \ldots, L$, and $\text{var}(\lambda) = 0$. This would occur if, for example, the network counting rule linked every population element to all L selection units, that is, $S_\alpha = N$, $\alpha = 1, 2, \ldots, N$, an arrangement quite unlikely to be practicable.

Sirken [21] decomposed the variance of the multiplicity B estimator into components having interpretations that are useful for guiding the selections of counting rules and network weights:

$$\text{var}(\hat{N}_\text{b}) = \frac{1}{l}\left\{\sum_{\alpha=1}^{N}\frac{1}{L}\sum_{\beta\neq\alpha}^{N}\frac{\delta_{\alpha i}\delta_{\beta i}}{S_\alpha S_\beta} + \hat{\lambda}\frac{\text{var}(\gamma)}{\text{E}(\gamma)} + \overline{\lambda}[\text{E}(\gamma) - 1] + \overline{\lambda}(1 - \overline{\lambda})\right\}$$

where

$$\gamma_{\alpha i} = \frac{\delta_{\alpha i}}{S_\alpha}, \quad \alpha = 1, \ldots, N; i = 1, \ldots, L,$$

$$\text{E}(\gamma) = \frac{N}{R},$$

$$\text{var}(\gamma) = \frac{1}{R}\sum_{\alpha}^{N}\frac{1}{S_\alpha} - \left(\frac{N}{R}\right)^2,$$

and

$$R = \sum_{\alpha}^{N}\sum_{i}^{L}\delta_{\alpha i} = \sum_{\alpha=1}^{N} S_\alpha$$

is the total number of links between selection units and population elements.

The fourth term of $\text{var}(\hat{N}_\text{b})$ is independent of network counting rules and weights, depending only on the population parameter $\overline{\lambda}$. Ignoring the first three terms and $\text{var}(\hat{N}_\text{b})$ becomes $\text{var}(\hat{N}_\text{c})$.

Network counting rules and weights affect the first term and network counting rules affect the second and third terms.

The first term is nonnegative, and measures heaping of population elements within selection units. It is equal to zero if none of the population elements is linked to more than one selection unit. The second term is also nonnegative. It is a measure of network size variability, and it equals zero if and only if $S_\alpha = S$, $\alpha = 1, \ldots, N$. The third term is nonpositive, and is a measure of clustering of population elements within networks that equals zero if and only if $s = 1$, $\alpha = 1, \ldots, N$.

In summary, it is desirable from the viewpoint of sample error effects to select network counting rules and weights that minimize heaping of population elements within selection units, maximize **clustering** of selection units within networks, and minimize network size variability.

Though network sampling typically yields more population elements, it is not necessarily more design-effective than conventional sampling. Thus, the sampling error of neither $\hat{N}_\text{a}$ nor $\hat{N}_\text{b}$ is necessarily less than that of $(\hat{N}_\text{c})$. Nor for that matter are the sampling errors of one network estimator more design-effective than the other. However, assuming that none of the elements is linked to more than one selection unit, which is a very strong assumption most likely to be approximated when $\overline{\lambda} = N/L$ is small,

$$\text{var}(\hat{N}_\text{b}) \leq \text{var}(\hat{N}_\text{a}) \leq \text{var}(\hat{N}_\text{c}),$$

where

$$\text{var}(\hat{N}_\text{c}) = \frac{1}{l}\overline{\lambda}(1 - \overline{\lambda}),$$

$$\text{var}(\hat{N}_\text{a}) = \frac{1}{l}\overline{\lambda}\left[\frac{1}{l}\sum_{i}^{L}\sum_{\alpha}^{N}\left(\frac{S_{\alpha i}}{S_\alpha}\right)^2 - \overline{\lambda}\right],$$

and

$$\text{var}(\hat{N}_\text{b}) = \frac{1}{l}\overline{\lambda}\left[\frac{1}{L}\sum_{\alpha}^{N}\frac{1}{S_\alpha^*} - \overline{\lambda}\right].$$

It is apparent that

$$\text{var}(\hat{N}_\text{a}) = \text{var}(\hat{N}_\text{b})$$

if and only if

$$S_{\alpha i} = \frac{S_\alpha}{S_\alpha^*}, \quad \alpha = 1, \ldots, N,$$

which implies that I_α is linked the same number of times to each of the S_α^* selection units in its network. Also

$$\text{var}(\hat{N}_\text{c}) = \text{var}(\hat{N}_\text{b})$$

if and only if

$$S_\alpha^* = 1(\alpha = 1, \ldots, N).$$

Under the conditions stated above, the **design effect** (DE) of network sampling compared to conventional sampling is

$$DE = \frac{\text{var}(\hat{N}_\text{b})}{\text{var}(\hat{N}_\text{c})} = \frac{h - \overline{\lambda}}{1 - \overline{\lambda}},$$

where

$$h = \frac{1}{N} \sum_\alpha^N \frac{1}{S_\alpha^*}$$

is the inverse of the harmonic mean of S_α. If $\overline{\lambda}$ is small, then the design effect is approximately

$$DE = h.$$

Measurement Biases

The major sources of survey measurement bias are coverage, **nonresponse**, and response errors. Coverage errors occur if population elements are erroneously counted when they are unlinked to selection units, or missed when linked population elements are not counted. Nonresponse errors occur when information is not obtained for linked elements, and response errors occur when invalid information is obtained for linked elements. It is noteworthy that network estimators are subject to response errors in network information as well as response errors in survey information.

Network sampling can be an effective design strategy for handling measurement biases especially when conventional sampling is predisposed to large measurement biases, such as when conventional counting rules fail to link population elements to any selection units (e.g. incomplete sampling frames) and/or link elements to units that fail to report them in the survey.

For example, survey experiments demonstrated the efficacy of network sampling in overcoming measurement biases associated with estimating the number of deaths in conventional household surveys of population change. These surveys adopt counting rules that link living persons to their *de jure* residences, and deceased persons to their terminal *de jure* residences. Royston et al. [17] demonstrated that population change survey estimates of the numbers of deaths are subject to measurements biases due to lack of coverage of deaths occurring in nursing homes and other institutional establishments, and due to underreporting of noninstitutional deaths.

Household sample survey experiments conducted in North Carolina [29] compared the effectiveness of network and conventional sampling to estimate N, the number of North Carolinians that died during a calendar period. The experiment tested three counting rules:

Rule 1. Decedents are linked to their terminal households of residence.

Rule 2. Decedents are linked to residences of surviving spouses, siblings and children residing in counties that were decedents' terminal residences.

Rule 3. Decedents are linked by rules 1 and 2.

Rule 1 implies conventional sampling and rules 2 and 3 imply network sampling. The experiment compared the coverage and response biases and the total undercounts of deaths associated with the three counting rules.

The findings of the experiment are summarized in Table 4 for decedents in the age range 65–84. Undercoverage bias represents the fraction of N deaths unlinked to any households, and underreporting bias represents the fraction of linked deaths that are unreported in the survey. The total undercount of decedents is

$$\text{total undercount} = (1 - g) + g(1 - f),$$

where g is undercount bias and f is underreporting bias.

Total percentage undercounts are substantially less for network sampling than for conventional

Table 4 Comparison of three counting rules

Counting rule	Total undercount	Undercoverage bias	Underreporting bias
1	0.29	0.22	0.09
2	0.22	0.16	0.07
3	0.15	0.06	0.07

sampling. The undercounts are about a half and a third smaller for rules 2 and 3 respectively than for rule 1. Most of the undercount differences are accounted for by differences in the undercoverage rate, but underreporting bias was also less for network sampling.

Rule 1 failed to cover any of the institutional deaths representing about 29% of North Carolina deaths in this age group. On the other hand, rule 3 covered about two-thirds of the institutional deaths because they were survived by relatives residing in the decedents' county of terminal residences. Rule 2 missed about 16% of all deaths that were not survived by relatives residing in the decedents' counties of terminal residence.

About 7% of all deaths were unreported by households eligible to report them by rules 2 and 3, and 9% by rule 1. Nearly all the unreported deaths occurred at terminal decedent residences without any surviving relatives when the survey was conducted. This is not a particularly surprising finding after one realizes that the event of death itself often precipitates household dissolution and dislocation.

In this example, sampling error effects as well as the measurement biases favor network sampling. The sample design effect of rule 3 compared with rule 1 is substantially less than one, implying that network sampling would attain equivalent precision comparable with conventional sampling with a substantially smaller sample size.

Survey Costs

Since the yields are greater and the interviews are longer, data collection costs are greater for surveys based on network sampling than for those based on conventional sampling. Consequently, to be cost-effective, network sampling must be more efficient than conventional sampling, a necessity most likely to be realized when conventional sampling is subject to large sampling and/or measurement errors.

Assume a sampling frame of L households containing N individuals with a specified attribute. A network sample survey is conducted to estimate N based on a simple random sample of l households. A simplified version of the expected field costs model proposed by Sirken [25] is

$$C = lc,$$

where the unit cost is

$$c = c_1 + \overline{\lambda}\overline{s}c_2$$

in which c_1 is the expected cost of contacting a household, c_2 the expected cost of enumerating an individual linked to a household, $\overline{\lambda} = N|L$, and $\overline{s} = (1/N)\sum_i^N S_\alpha$.

What gains in data quality would be required to overcome the lower field costs of conventional sampling? Assuming measurement biases are a standoff, and that none of the elements is linked to more than one selection unit, network sampling is a cost-effective design alternative to traditional sampling when the following inequality is satisfied:

$$\overline{s} < 1 - (1 - \overline{\lambda})(1 - \theta),$$

where θ is ratio of conventional sampling and network sampling unit field costs. If $\overline{\lambda}/\theta$ is small, network sampling enhances design efficiency whenever $\overline{s} < \theta$.

Values of the parameters $\overline{s}$ and θ vary depending on the particular set of network sampling options that is selected for the counting rule, the estimator, and the respondent rule. For example, the parametric values would be different for an option set comprising the sibling counting rule, the multiplicity A estimator, and a household respondent rule allowing proxy respondents than they would be for an option set comprising the conventional/sibling rule, the multiplicity B estimator, and a self-respondent rule disallowing any proxy respondents. The optimum network sampling design option set represents that particular option set from among all feasible network sampling option sets for which the $\overline{s}$ is smallest relative to its θ. Unless $\overline{s} > \theta$ for the optimum network sampling option set, network sampling would be more cost-effective than conventional sampling.

MONROE SIRKEN

Neural Network

Modern regression and classification techniques (*see* **Classification, Overview**) have seen a rapid development over the last 15 years. We hear of names such as smoothers (*see* **Nonparametric Regression**), **projection pursuit**, **additive model**, CART (*see* **Tree-structured Statistical Methods**), MARS, belief networks, and many more, each designed to accommodate some of the deficiencies of our more traditional linear-model-based regression techniques. *Neural networks* appeared in the early 1980s and their coming established a new and popular branch of applied statistical modeling, practiced mainly in the computer science and engineering community. Neural network models tend to be far more ambitious than traditional statistical models, and more successful on large-scale problems. The initial response from the statistics community was either rejection or heavy skepticism. At the time of this writing neural networks have flourished for 13 years, and are used successfully in a large variety of applications including face recognition, handwriting and speech recognition, stock market prediction, medical diagnosis (*see* **Computer-aided Diagnosis**), system control, and genetic modeling.

While neural networks probably get more attention than they deserve in the scientific community at large, they in turn get less attention than they deserve from statisticians. This article gives an overview of the technology, and attempts to place it in the broad context of flexible regression and classification. Along with these models comes a lot of new, redefined, and often attractive terminology, which we emphasize in the text in *italics*.

Figure 1 depicts a neural network with three predictors or *inputs*, a single hidden layer of four hidden units, and an output layer of two responses or *output* units.

If we denote the vector of p inputs by $\mathbf{x}$, and the vector of K outputs by $\mathbf{y}$, then this model can be written more traditionally as

$$z_j = \sigma(\alpha_{j0} + \alpha_j^{\mathrm{T}}\mathbf{x}), \quad j = 1, \ldots, m = 4,$$
$$\hat{y}_k = f_k(\beta_{k0} + \beta_k^{\mathrm{T}}\mathbf{z}), \quad k = 1, \ldots, K = 2 \quad (1)$$

1. The *activation function* σ is used to introduce a nonlinearity at the hidden layer, and is often taken to be the sigmoid $\sigma(z) = 1/(1 + \mathrm{e}^{-z})$.

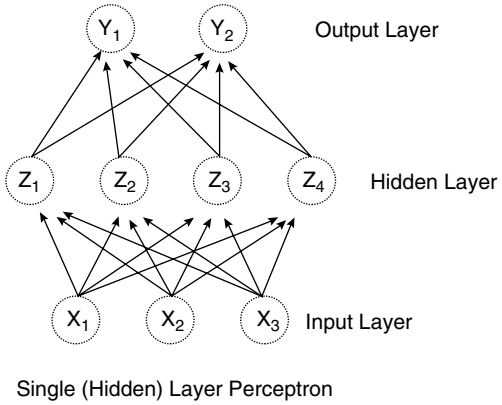

Figure 1 A network diagram represents a neural network model with three inputs (predictors), four hidden units, and two outputs (responses). This configuration is often referred to as a single layer perceptron

2. The parameters α_{jl} and β_{kj} are known as *weights*, and define linear combinations of the input vector $\mathbf{x}$ and hidden unit output vector $\mathbf{z}$, respectively.
3. The intercepts α_{j0} and β_{k0} are known as *biases*.
4. The function f_k permits a final transformation of the output, and the typical choices are:
   (i) $f_k(v) = v$: identity, suitable for regression with quantitative responses;
   (ii) $f_k(v) = 1/[1 + \exp(-v)]$: inverse logit, suitable when responses should lie in [0, 1] (as in two-class nonparametric **logistic regression** problems);
   (iii) $f_k(\mathbf{v}) = \mathrm{e}^{v_k} / \sum_{l=1}^{K} \mathrm{e}^{v_l}$: inverse multiple logit, used for k-class classification. Note here that each f_k requires the entire vector of outputs $\mathbf{v}$.

Neural networks can have more than one hidden layer of units. A *multilayer perceptron* (MLP) simply repeats the hidden layer several times, creating even more complex models. In what follows we focus on the *single layer perceptron* (SLP).

Each hidden unit can be thought of as a nonlinear basis function which creates a new derived variable z_j from a linear combination of the inputs. The responses are then regressed on these transformed data z_j either linearly or via logistic regression. When the model is *learned* or fit to the data, an optimal set of basis functions is learned at the same time.

Early *perceptron* models used *hard or binary thresholding* functions $\sigma(z) = 1(z > 0)$ at the hidden units, with strong neurophysiological implications–the hidden unit (neuron) either fires or does not in response to its inputs. This biological interpretation is not taken too seriously today, and soft threshold functions such as the sigmoid permit differentiation and smoother learning algorithms.

Versions of neural networks look like familiar statistical models:

1. linear regression, when $\sigma(z) = z$, as long as $m \geq p$;
2. logistic regression with two or more classes; again, $\sigma(z) = z$ and the appropriate versions of f_k are used;
3. series and basis expansion models, where we regress the response on a few appropriately placed basis functions.

In addition, there are interesting comparisons with the *projection pursuit* model [3]:

$$\hat{y}_k = \sum_{j=1}^{m} f_{kj}(\alpha_{kj}^{\mathrm{T}}\mathbf{x}),$$

where the functions f_{kj} and the directions α_{kj} are fit simultaneously. The projection pursuit model typically invests many parameters on each function f_{kj} for a given direction α_{kj}, while the neural network can be seen to use exactly two.

Learning Neural Network Models

The computational paradigm central to most neural network systems is *backpropagation*, which is essentially gradient descent using the chain rule plus a few bells and whistles.

Suppose we use least squares on a sample of *training data* to learn the parameters or *weights* in (1):

$$R(\alpha, \beta) = \sum_{i=1}^{N}\sum_{k=1}^{K}(y_k^i - \hat{y}_k^i)^2,$$

a criterion nonlinear in the parameters. Since we anticipate using gradient descent algorithms, we require derivatives. All the derivatives will be sums over the N observations, and we display only the ith component (denoted by superscript i):

$$\frac{\partial R^i}{\partial \beta_{kj}} = -2(y_k^i - \hat{y}_k^i) f_k'(\beta_k^{\mathrm{T}}\mathbf{z}^i) z_j^i,$$

$$\frac{\partial R^i}{\partial \alpha_{jl}} = -\sum_{k=1}^{K} 2(y_k^i - \hat{y}_k^i) f_k'(\beta_k^{\mathrm{T}}\mathbf{z}^i)\beta_{kj}\sigma'(\alpha_j^{\mathrm{T}}\mathbf{x}^i) x_l^i.$$

Given these derivatives, a gradient update at the $(r+1)$th iteration has the form

$$\beta_{kj}^{(r+1)} \leftarrow \beta_{kj}^{(r)} - \gamma_r \sum_{i=1}^{N} \frac{\partial R^i}{\partial \beta_{kj}^{(r)}},$$

$$\alpha_{jl}^{(r+1)} \leftarrow \alpha_{jl}^{(r)} - \gamma_r \sum_{i=1}^{N} \frac{\partial R^i}{\partial \alpha_{jl}^{(r)}},$$

where γ_r is the *learning rate* which can change with iteration number r. The standard initialization is to use *random* (Gaussian) starting values for the parameters.

On-line learning refers to a similar gradient descent algorithm, but where we take a separate gradient step in response to each observation one at a time (as opposed to the *batch* mode as presented). The algorithm then has two distinct phases of operation in response to each new training pair $(\mathbf{x}^i, \mathbf{y}^i)$:

1. the *feed-forward* phase, in which $\mathbf{x}^i$ is filtered up through the network to produce a prediction $\hat{\mathbf{y}}^i$:
2. the *backpropagation* phase in which the error $(\mathbf{y}^i - \hat{\mathbf{y}}^i)$ is filtered back and apportioned to each of the coefficients, which are modified in turn in a small way to reduce such a future error.

There are many different variants of this basic approach – some examples are:

1. Batch algorithms typically use second derivative information as well as gradients.
2. On-line algorithms are useful for very large datasets, since changes are made continuously without having to cycle through the entire training data set. The name *on-line* refers to their use in dynamical systems which respond continuously to a changing environment.

3. When the responses are categorical, a different criterion such as likelihood can be used for fitting, but the basic algorithm is the same.

Neural network models are typically overparameterized, often with more parameters than observations. Furthermore, the parameters are intrinsically aliased – in fact, the model is perfectly symmetrical with respect to the hidden units. The symmetry is resolved by using random starting values, similar in flavor to the fitting of mixture models. Although the overparameterization can be controlled somewhat by restricting the number of hidden units, other strategies for regularization are popular, as follows.

Early Stopping. Gradient descent will converge slowly to a local minimum, which in a saturated model will fit the training data perfectly. If an independent validation set is available, then one can monitor the performance of the model on this validation set after each one or set of updates. The usual bias-variance tradeoffs will cause this validation error to eventually increase as the training error approaches zero, and will provide an optimal place to stop.

Weight Decay. Similar to **ridge regression**, various proposals exist for shrinking the weights towards zero (*see* **Shrinkage**). As a simple example, consider adding a penalty of the form $\lambda(\sum \alpha_{kj}^2 + \sum \beta_{jl}^2)$ to the criterion R. This introduces a hyperparameter λ, which shrinks between the unrestricted model ($\lambda = 0$) and the constant model ($\lambda = \infty$). This approach is similar in flavor to cubic smoothing splines (*see* **Spline Function**) [4]. A large basis of cubic splines is created, with a knot at each data point, but then the large number of coefficients is fit subject to the rather stringent smoothness constraints of the derived function.

Model Averaging. Even when the model is not overfit, the criterion R has multiple minima, and the random starting weights will lead to one. One can restart the algorithm many times, and then combine the solutions in some way. Simple averaging works well; [5] proposes an approximate form of Bayesian posterior averaging.

Discussion

The *field* of neural networks is large, and there are many large and important conferences each year, which at their inception in the mid-1980s were devoted to various aspects of the model described in this chapter. The annual NIPS Neural Information Processing Conference in Denver, Colorado is one such venue. The mid-1990s versions of these conferences would be more aptly described as applied statistics than neural networks. Neural network models tend to be currently viewed as one of a number of flexible regression models.

There have been many ingenious modifications and restrictions to the neural network model to broaden its range of applications. Two examples are *bottleneck* networks for nonlinear principal components (the inputs are also the outputs), and networks with duplicated weights to mimic autoregressive models.

While this field is strongly application driven, some interesting theory has been produced [1]. For example, neural networks are *universal approximators* – given enough parameters they can approximate smooth functions arbitrarily well.

This author has seen many examples of inappropriate use of neural network models. For example, their use is unlikely to be appropriate in small biostatistical binary regression problems, where the primary goal is to understand the effect of the inputs on the event represented by the binary response. The converse problem, of course, abounds as well. How often do we struggle to fit large traditional parametric models to huge datasets with our inappropriate software. When prediction is a goal, the *black box* neural network model will often deliver close to the best fit with very few tears.

There are many commercial software packages available for fitting neural networks, and many free packages as well. An SAS (*see* **Software, Biostatistical**) module exists, and functions for S-PLUS (*see* **S-PLUS and S**) contributed by B.D. Ripley are available from the Statlib archive `http://lib.stat.cmu/S`. For statisticians interested in reading more about neural networks, I strongly recommend the books by Bishop [2] and Ripley [5]. Both of these synthesize the vast neural network literature, contain key references, and use a style and language familiar to statisticians.

TREVOR HASTIE

Neurology

Neurology is the specialty of medicine which deals with the structure and function of the nervous system, and with its diseases. Although the word "neurology" was introduced as long ago as 1681, this specialty of medicine was closely allied with **psychiatry** until the early decades of the twentieth century – both being concerned with "nerve" disorders. Their proximity is still apparent today within conjoint areas such as neuropsychiatry. The main neurological disorders (approximate point **prevalence** per 100 000) are migraine (20 000), **stroke** (500), **epilepsy** (500), Parkinson's disease (200), cerebral palsy (60), multiple sclerosis (50), and primary brain tumours (50); others, such as syringomyelia (chronic progressive disease of the spinal cord), Huntington's chorea (a hereditary, chronic muscular twitching), polymyositis (simultaneous inflammation of many muscles), muscular dystrophy (progressive wasting and atrophy of muscles), and motor neurone disease (degeneration of motor neurones) are much rarer (each <10 per 100 000); the most interesting biostatistically are stroke and epilepsy.

ANTHONY L. JOHNSON

Neuropathology

Neuropathology is the study of the nature, causes, structure, and function of nervous system diseases. This broad area of medicine includes pathology of cerebrovascular disease (**stroke**, hypoxia, ischemia, aneurysms, hemorrhage), neurodegenerative diseases and dementia, craniocerebral trauma, neurometabolic and demyelinating disorders, as well as many other related topics covered in a standard reference text on the subject such as *Greenfield's Neuropathology* [3]; see also [4]. Complementary aspects of neuropathology have from its beginning been the topographical, anatomical emphasis of the French school and the cellular emphasis on pathogenesis of the German school. Modern technology is helping to integrate these two aspects of the field. Biostatistical methods and applications in neuropathology are as broad as the field itself, ranging from **simple linear regression** models to detailed histological **image analyses**. The most important elements in the nervous system are neurons, their bodies (somata), branches (dendrites) and firing channels (axons), and the central questions of neuropathology are concerned with how these most complex cells in our bodies grow, degenerate, and die by natural aging or disease processes. From a biostatistical perspective, image analysis perhaps serves best to orient one's thinking about a field whose main aim is to help clinical and basic scientists recognize the cellular features of central nervous system diseases and whose central tool remains the light microscope. By special staining techniques one is able in microscopic neuropathologic image analysis to observe complex alterations of neurons, glia and astrocytes, degenerative-reductive changes such as axonal demyelination, and productive-accumulative changes such as neurofibrillary tangles and senile plaques seen in Alzheimer's dementia.

For instance, it is well known that neurons may aggregate in functionally significant ways to form discrete layers within the cerebral cortex of macrocolumnar arrays of neurons that occur vertically across the individual layers [8], and hence it is conceivable that a disorder like schizophrenia, involving disturbances in several key corticolimbic brain areas [1], might involve unusual arrangements of neurons [2] arising from specific neurodevelopmental disturbances [11, 12, 15]. Although schizophrenia is also known currently to be a neurochemical disorder involving dysfunction of glutamatergic circuitry [9], biostatistical image analysis has helped demonstrate significant *post mortem* differences in the arrangements of pyramidal neurons in layer IV of the cingulate cortex for normal control, schizoaffective and schizophrenic subjects [5]. Employing a second-moment estimator for stationary **point processes** [10] and a modified **bootstrap** procedure for statistical **inference**, a **stereological** analysis of these spatial point patterns showed not only that the psychotic subjects had fewer pyramidal neurons per cubic micrometer in this brain region but also that these cells tended to be more regularly spaced (nonoverlapping) for these subjects. This finding suggested that there may be increased inhibitory distances among these neurons, and, therefore, that there may be a relative expansion of the neuropil surrounding these cells. Since the neuropil is the site where most neural connections are found, this finding implied further that the pyramidal neurons of the cingulate cortex in schizophrenics may be engaging in more synaptic connections than those of normal individuals.

Neuropathology also uses macroscopic imaging modalities such as computed tomography and magnetic resonance imaging for studies of brain structure, and functional magnetic resonance imaging and single photon emission computed tomography for studies of brain function, to provide data for detailed yet lower resolution analyses. Volumetric studies by computed tomography and magnetic resonance imaging help quantify both **cross-sectional** and **longitudinal** changes in sizes and shapes of various brain structures over time for the same individual or cohorts of individuals. The growing literature on differences between normal aging, Alzheimer's dementia, and vascular dementia provide a further example of the biostatistics of neuropathology. For instance, a lack of neuroimaging data may have contributed to an underrecognition of mixed Alzheimer's and vascular dementia cases in community-based studies [6, 14]. An analysis of computed tomography brain scans from histopathologically confirmed Alzheimer's dementia cases [7] reported a 10-fold increase in the yearly rate of medial temporal lobe atrophy relative to losses experienced by **control** subjects, from 1.5% per year to 15.1% per year. This excessive atrophy was evidence for a neuropathological cascade process and not a simple acceleration of the normal aging process, and was

confirmed through use of stereological techniques that compared regional patterns of neuronal cell loss in the hippocampus related to normal aging to that associated with Alzheimer's dementia [13], providing additional information on neurodegenerative processes involved.

These two brief examples of current neuropathology research have been included here, and many more could have been cited, to demonstrate to the reader that new technologies such as those involved in microscopic cellular imaging and macroscopic structural and functional brain imaging enable neuroscientists to ask and to answer entirely new quantitative questions regarding the neuropathology of the developing brain, the mature brain, and the aging brain. It is anticipated that, by further evolution, the predominantly qualitative findings of the past will continue to be enlarged, discarded and refined through the kinds of detailed quantitative result provided by biostatistical analyses.

NICHOLAS LANGE

Neyman, Jerzy

Born: April 16, 1894, in Bendery, Russia.
Died: August 5, 1981, in Berkeley, California, USA.

Reproduced by permission of the Royal Statistical Society

Jerzy Neyman, one of the principal architects of modern statistics, was Director of the Statistical Laboratory, University of California, Berkeley. He was born into a Polish family in Bendery, and died in Berkeley at the age of 87. With Neyman's passing, history has closed a chapter on the early development of this important scientific field.

At the time of his birth, there was no Poland as a nation. The "Poland proper" had been divided among Germany, Austria, and Russia. Neyman's father was a lawyer. When Neyman was 12 years old, his father died of a heart attack. His caring mother moved her family to Kharkov, where he attended school and college. Although he was born a Pole, Neyman spoke Russian almost as early as he spoke Polish. At an early age, he could also speak Ukrainian, German, French, and Latin fluently. Upon his graduation from high school, through his mother's arrangement, he joined a student group making a journey to see Europe outside Russia. Before entering the college in Kharkov, he decided to study mathematics instead of pursuing his father's profession. He received his mother's support and encouragement. "She had respect for intellectual activity", Neyman fondly recalled to Constance Reid in the late 1970s. (Reid published her book entitled *Neyman – From Life* in 1982 [33].) In 1921, after a Polish–Soviet peace treaty, Neyman was sent to Poland in a repatriation of prisoners of war program between the two countries. Thus Neyman saw his fatherland Poland for the first time when he was 27 years old!

Neyman's interest in mathematics was reinforced when he studied with the Russian probabilist S.N. Bernstein at the University of Kharkov. When he read Henri Lebesgue's *Leçons sur l'intégration et la recherche des functions primitives*, Neyman was fascinated by sets, measure, and integration. During his college days he had proved five theorems on the Lebesgue integral on his own. His article entitled "Sur une théorème metrique concernant les ensembles fermés", published in 1923 [9], was one of his early research papers in pure mathematics. His candidate thesis at the University of Kharkov (1916) was on the integral of Lebesgue. In 1917, Neyman returned to the university for a postgraduate study. In the following year he was a *docent* at the Institute of Technology, Kharkov. At the University of Warsaw, Neyman studied mathematics with Waclaw Sierpinski. He earned the Doctor of Philosophy degree from the University of Warsaw in 1924. The oral examination consisted of *Rigorosum Major* in mathematics and *Rigorosum Minor* in philosophy. No one knew more statistics than Neyman to examine him on the subject.

In the little spare time that he had during his student days, Neyman was heavily involved in teaching to earn a living. He also gave supplementary lectures for professors at the university, and taught mathematics and statistics to college students.

Neyman first heard of **Karl Pearson** from his reading of Pearson's book. *The Grammar of Science* [32]. Apparently, he was influenced by Pearson's philosophical views expressed in the book.

Neyman's contact with statistics occurred early in his academic career. It appears that he had studied applications of mathematical statistics with Bernstein at the University of Kharkov. But he learned most statistics through his work on his own, especially in agricultural experimentation. He had held a position of "senior statistical assistant" at the National Agricultural Institute in Bydgoszcz, Poland, in 1921, and he was a special lecturer at the Central College of Agriculture in Warsaw in 1922.

In the fall of 1925, Sierpinski and Kazimierz Bassalik, the director of the National Agricultural Institute, were awarded a Polish Government Fellowship for Neyman to study mathematical statistics with Karl Pearson in London. Neyman was well prepared in mathematics and in statistics. While in London, Neyman and a young man about his own age, Pearson's son, **Egon S. Pearson**, became good friends.

During the academic year 1926–27, Neyman was on a Rockefeller fellowship to study pure mathematics in Paris. He attended lectures given by Emile Borel at the University of Paris and also lectures by Lebesgue and Jacques Hadamard at the Collège de France. In addition, he had some of his own notes read at these institutes. Quite possibly, the year of studying mathematics in Paris had prepared him well for his joint endeavor with Egon Pearson in the development of statistical theory in the years to come.

Neyman and Pearson's joint work formally started in the spring of 1927, when Pearson visited Neyman in Paris. While there are no records of what transpired during the ten days during which they worked together, they must have laid out plans for their future joint project. At the end of the 1926–27 academic year, Neyman went back to Poland, and in 1928 he became head of the Biometric Laboratory at the Nencki Institute in Warsaw. He carried out his joint work with Pearson mostly through correspondence between Warsaw and London. Between 1928 and 1934, they published seven of their 10 most important papers on the theory of testing statistical hypotheses [20–26] (*see* **Hypothesis Testing**).

In developing their theory, Neyman and Pearson recognized the need to include **alternative hypotheses**; and they perceived the errors in testing hypotheses concerning unknown population values based on sample observations which are subject to variation. They called the error of rejecting a true hypothesis the first kind of error, and the error of accepting a false hypothesis the second kind of error. They placed the importance on the probability of rejecting a hypothesis when it is false. They called this probability the **power** of a test. They proposed a term "**critical region**" to denote a set of sample statistic values leading to the rejection of the hypothesis being tested. The "size" of a critical region is the probability of making the first kind of error, which they called the level of significance.

They called an hypothesis which completely specifies a probability distribution a simple hypothesis. An hypothesis which is not a simple hypothesis is a composite hypothesis. An hypothesis concerning the **mean** of a **normal distribution** with a known **standard deviation**, for example, is a simple hypothesis. The hypothesis is a composite hypothesis if the standard deviation is unknown.

It is now difficult for us to imagine how one could perform a statistical test without these concepts. But the Neyman–Pearson theory was a considerable departure from traditional hypothesis testing at the time. They were severely criticized for their new theory by the leading authorities of the field, especially by **R.A. Fisher**.

Neyman and Pearson used conceptual mathematics and logical reasoning to develop the theory of hypothesis testing. They emphasized "the importance of placing in a logical sequence the stages of reasoning in the solution of ... inference". In their initial papers [20, 21], it seems that they were leading the reader, step by step, in their development of the theory. They relied on the concept of the **likelihood ratio** in testing hypotheses concerning parameters in known probability distributions; and they elucidated their ideas further with specific examples and numerical computations.

After they had laid a solid mathematical foundation for their theory, they applied it to the problem of two samples [22], and to the problem of k samples [24]. In one of their joint papers [26], they used the likelihood ratio to establish an objective criterion for determining the best (in the sense of power of test) critical regions for testing a simple hypothesis and a composite hypothesis. That was a high point of their accomplishments. The landscape of statistical hypothesis testing would no longer be the same.

In 1934, Neyman joined the faculty of E.S. Pearson's Department of Applied Statistics at University College London. Between 1934 and 1938 they published only three more joint papers on testing hypotheses [27, 28], possibly because of Pearson's involvement in administrative responsibilities. Neyman, however, was still very productive during that period. From time to time, Neyman published many papers on hypothesis testing on his own; but most of the fundamental work was contained in his joint publications with Pearson.

When he was still in Poland, Neyman had developed the idea of **confidence interval** estimation. He

even gave his lectures on confidence interval estimation rather than hypothesis testing in his class at University College London in 1934. He published his work in 1937 [10]. At that time, many statisticians confused the confidence interval with the **fiducial** interval, a concept developed by Fisher. That confusion was soon dispelled by Fisher himself [3]. Neyman clarified the difference between the two in his *Lectures and Conferences* [11].

To put it in very simple terms, the difference between confidence interval and fiducial interval lies in the assumption regarding the population value being estimated. Consider a sample of size n and mean $\overline{X}$ from a normal distribution with an unknown mean u and unit **variance**. The basic quantity for estimating u is the product $n^{1/2}(\overline{X} - u)$. According to the confidence interval theory, the product $n^{1/2}(\overline{X} - u)$ is subject to variation, because the sample mean $\overline{X}$ is a random variable. For a given probability, say 0.95, $\Pr\{\overline{X} - 1.96/\sqrt{n} < u < \overline{X} + 1.96/\sqrt{n}\} = 0.95$. After a sample is taken and the sample mean (say $\overline{X}_0$) is determined, the product becomes $n^{1/2}(\overline{X}_0 - u)$, which is not subject to variation. The interval $\{\overline{X}_0 - 1.96/\sqrt{n},\ \overline{X}_0 + 1.96/\sqrt{n}\}$ becomes a confidence interval, and 0.95 becomes the corresponding confidence coefficient. In the fiducial interval argument, there is a range of values of u, each of which could have generated the sample mean $\overline{X}_0$. For a given probability 0.95, one can find two values of u depending on $\overline{X}_0$, say $u' < u''$, such that fiducial $\Pr\{u' < u < u''|\overline{X}_0\} = 0.95$. The interval (u', u'') is the fiducial interval and 0.95 is the fiducial probability.

In addition to the theory of statistical inference, Neyman made contributions to many other branches of statistics, such as the design of agricultural experimentation (in 1923, 1925, and 1935), the theory of sampling (in 1925, 1938 and 1939), a class of **"contagious" distributions** (1939), and others. He even used the "storks bring babies" example to show how to avoid reaching a wrong conclusion by misusing a **correlation** between variables, the so-called spurious correlation [11].

Neyman's work on applications of statistical methods in practical problems was very extensive. He considered practical problems as a source of inspiration for theoretical statisticians. His publications related to **biostatistics** and health include: virulent bacteria and disease (with R. Iwaskiewicz [5]); recovery and relapse of cancer patients (with E. Fix [4]); accident proneness (with G.E. Bates [1]); a **stochastic** model of an epidemic (with E.L. Scott [30]) (*see* **Epidemic Models, Stochastic**); multiphasic **screening** and diagnosis (with M.F. Collen et al. [2]); health-pollution (in 1972); a view of biometry [15]; energy crisis, pollution, and health (in 1975); environmental pollution and public health [17] (*see* **Environmental Epidemiology**); some problems of biometry deserving particular attention (with R. Bartoszynski et al. [18]); **radiation**-related public health studies (in 1980); probability models in medicine and biology [19]; and on understanding the mechanism of radiation effects (with P.S. Puri [29]).

There was an interesting feature in Neyman's approach to practical problems. He had the ability to visualize the phenomena behind the data and a model of the mechanism that creates the phenomena. He would express the model in mathematical terms to produce new probability distributions, or new stochastic models. Only then would he find appropriate statistical methods with which to analyze the data on hand [7].

Neyman devoted a considerable amount of time and effort to three major projects of research. The first was his joint studies of galaxies with E.L. Scott and C.D. Shane. Over a span of 25 years, Neyman published 24 papers on the subject. He reported their work on the spatial distribution of galaxies (in 1953, with Scott and Shane), on the problem of expansion of clusters of galaxies (in 1954, with Scott), on the statistical approach to the problems of cosmology (in 1958, with Scott), and on the relation of galaxies in clusters in the presence of instability and absorption (in 1961, with Scott).

In a separate effort, Neyman organized and edited the volume *The Heritage of Copernicus* [16] for the National Academy of Sciences, to commemorate the 500th anniversary of the birth of the great Polish astronomer.

The second major project was on cloud seeding and weather modification, jointly with Scott. This project covered a period of over 20 years from the early 1950s to 1980, and was reported in 26 publications. In this project, Neyman had the opportunity to witness several cloud seeding experiments, and to evaluate the designs and the outcomes. Their conclusion was as follows: "Methods of evaluation of the effects of cloud seeding proposed by commercial

operators could not be considered scientific. After a few years and a few experiments nothing remarkable could be asserted" [6].

His third project was on cancer and carcinogenesis, but on a much smaller scale than the other two. This was also a joint effort with Scott. There were two theories regarding the formation of cancerous clones available to them: the one-stage mutation theory and the two-stage mutation theory. According to the one-stage mutation theory, the growth of a clone of abnormal cells is from a single mutant cell; while according to the two-stage theory, a second mutation is necessary in order to produce a cancer clone. Their main objective was to construct stochastic models that would best describe the process of formation of cancerous clones [31] (*see* **Dose–Response Models in Risk Analysis**).

In the spring of 1937, Neyman delivered a series of lectures on mathematical statistics and probability at the Graduate School in the US Department of Agriculture in Washington, DC. That was the first time that the American statistical public had the opportunity to hear statistical theory from Neyman in person. The lecture notes were subsequently published in 1937 [11], and revised and expanded in 1952 [14], under the title *Lectures and Conferences on Mathematical Statistics and Probability*. Among the reviews of the 1937 book, there was one written by William Feller, published in *Zentralblatt*, which reads in part as follows:

> The point of departure for the author is always actual practical problem, and he never loses sight of the applications. At the same time his goal is always a truly rigorous mathematical theory. He appears to insist on absolute conceptual clarity and rigor, not only as a sound foundation, but also because it is really useful and necessary, particularly where the practical problem goes beyond the mathematical aspect. . ..

Feller's words should apply equally well to Neyman's other publications.

In 1938, Neyman accepted a mathematics professorship from the University of California at Berkeley, and he established the Statistical Laboratory, with himself as the director. That was the beginning of one of the preeminent statistical centers in the world. In 1955, Neyman established the Department of Statistics. He retained the title Director of the Statistical Laboratory.

Neyman was a very dynamic person, full of ideas and energy. Soon after the Statistical Laboratory was established and the teaching program was in good order, he began to plan a symposium of mathematical statistics and probability "to mark the end of the war and to stimulate the return to theoretical research". The symposium had the participation of leading authorities in theoretical probability and in mathematical statistics, as well as those in applied fields. The *Proceedings* of the symposium, edited by Neyman [13], were published in 1949 to "stimulate research and foster cooperation between the experimenter and the statistician".

The success of the symposium prompted Neyman to plan a series of symposia, once every five years. The number of participants and the coverage grew from one symposium to the next. The Sixth Berkeley Symposium, held in three different periods in 1970 and 1971, was attended by 240 leading authors in 33 subject areas in the theory of probability, in mathematical statistics, and in scientific fields using applications of statistics. The *Proceedings*, edited by LeCam et al. [8], were published in 1972, in six volumes and 3397 pages – a gigantic undertaking!

These symposia supplemented the teaching programs and research activities normally carried out in universities and other academic institutions. They also had a great deal of influence on the attitude of the theoretical statisticians and research scientists, making them recognize the need for and the advantage of applications of statistics.

During the 40 years during which he was in Berkeley, Neyman had students coming from all over the world to attend his lectures and to learn the proper way of conducting research. Neyman was a generous man. He helped students financially in any way he could. He recommended students for the university scholarships and he secured Federal grants for the support of both students and the faculty. At times, when he could not obtain the funds that he needed to support students from any other sources, Neyman took the money out of his own pocket!

Neyman was a member of the National Academy of Sciences, the American Academy of Arts and Sciences, the Royal Swedish Academy, and the National Academy of Poland. He was a fellow of the Royal Society of London, and he was honorary president of the **International Statistical Institute**.

Neyman used to say: "Statistics is the servant to all sciences". In many ways, Neyman had expanded the domain and improved the quality of the service.

CHIN LONG CHIANG

Neyman–Pearson Lemma

In the mid-1920s, **Jerzy Neyman** and **Egon S. Pearson** set out to elaborate a theory of testing statistical hypotheses (*see* **Hypothesis Testing**). This resulted in the publication of two papers [3] in 1928. They proposed as a *principle* the use of **likelihood ratio tests**. Suppose that the observable random vector possesses, with respect to some measure μ, a density $f(x, \theta)$ that depends on a parameter $\theta \in \Theta$. One hypothesis specifies that $\theta \in \mathrm{H}_1$, while the alternative specifies that $\theta \in \mathrm{H}_2$, where the H_i are subsets of Θ. Neyman & Pearson proposed to reject H_1 if the ratio $r(x) = \sup[f(x, \theta); \theta \in \mathrm{H}_2] / \sup[f(x, \theta); \in \mathrm{H}_1]$ exceeds a specified value c determined to insure that the probabilities of rejection of H_1 if true do not exceed a specified limit.

They showed that many of the tests then in use could be derived from that principle. They also introduced the concept of **power** of a test, the probability for $\theta \in \mathrm{H}_2$ that H_1 be rejected.

This, however, was a *principle*. It needed a mathematical justification. To describe the justification with a simple notation, we shall use test functions instead of "critical regions". A test function ϕ is a measurable function defined on the sample and such that $0 \leq \phi \leq 1$. If the measures are noted $P_\theta, \theta \in \Theta$, the power of ϕ at θ is $\int \phi \, \mathrm{d}P_\theta$. Critical regions correspond to functions ϕ that take only values zero or one, being one in the critical region.

The Neyman–Pearson lemma [4] initially covered only the case in which each H_i is reduced to a single point θ_i. It then says the following.

Lemma. Let $r(x) = f(x, \theta_2)/f(x, \theta_1)$ and let ϕ be such that $\phi(x) = 0$ if $r(x) < c$ and $\phi(x) = 1$ if $r(x) > c$. Then, for any other test function ψ such that $\int \psi \, \mathrm{d}P_{\theta_1} \leq \int \phi \, \mathrm{d}P_{\theta_1}$, one has $\int \psi \, \mathrm{d}P_{\theta_2} \leq \int \phi \, \mathrm{d}P_{\theta_2}$.

This lemma allowed Neyman & Pearson [5, 6] to solve the problem of selection of critical regions and justify their likelihood ratio principle in many problems where there exist *uniformly most powerful tests*. That includes the case in which the parameter θ is real and the densities form a family with monotone likelihood ratios (e.g. exponential families) if the hypotheses are of the form $\{\theta \leq a_1\}$ against $\{\theta > a_2\}$. The case of two-sided hypotheses of the kind $\{\theta = 0\}$ against $\{\theta; |\theta| > a_2\}$ was not covered. Neyman & Pearson introduced for such cases a concept of **unbiasedness**; requiring, for instance, that the derivative of the power function vanish at $\theta = 0$.

This led Neyman & Pearson to consider problems of the following type. Given a finite set of functions f_i, $i = 1, 2, \ldots, m+1$, and constants c_i, find test functions ϕ such that $\int \phi f_i \, \mathrm{d}\mu = c_i, i = 1, \ldots, m$, and such that $\int \phi f_{m+1} \, \mathrm{d}\mu$ be maximized. The method of Lagrange multipliers suggests the introduction of positive constants $k_i, i = 1, \ldots, m$, and the sum $s(x) = \sum_{i=1}^{m} k_i f_i$. One then takes $\phi = 0$ where $f_{m+1} < s$ and $\phi = 1$ where $f_{m+1} > s$. For a precise statement, see, for instance, [2, p. 96].

With the advent of Wald's Theory of statistical decision functions [7] (*see* **Decision Theory**), such problems were essentially subsumed under the following general theorem.
If the family of measures $\{P_\theta\}$ is dominated, then all admissible tests are either Bayes solutions or limits of them.

Another more recent form of a Neyman–Pearson lemma is that given by Huber & Strassen [1]. These authors consider sets $\mathrm{H}_i = \{P; P \leq v_i\}$ where the v_i are Choquet capacities alternating of order two, that is such that $v(A \cup B) + v(A \cap B) \leq v(A) + v(B)$. They show that in this case there exist least informative pairs (P_1, P_2) with $P_i \in \mathrm{H}_i$ and that the likelihood ratios of these pairs provide the optimal tests between the H_i.

L.M. LE CAM

Nightingale, Florence

Born: May 12, 1820, in Florence, Italy.
Died: August 13, 1910, in London, UK.

Florence Nightingale was the second daughter of Fanny and William Nightingale. The Nightingales were a wealthy family and had two large country houses, one in Derbyshire and the other near Romsey in Hampshire, as well as rooms in Mayfair, London. Florence and her elder sister, Parthenope, were educated at home, initially by a governess and later also by their father who was a graduate of Trinity College, Cambridge. Their education was classical and included only basic mathematics.

Florence was fascinated by numbers and in 1840 announced her wish for further tuition in mathematics. This request met with family disapproval, particularly from her mother who thought this unnecessary study for a girl, who should by now be forming social ambitions. Florence won the support of her Aunt Mai, who managed to persuade Florence's father to allow the tuition, and for a few weeks Florence was tutored by James Sylvester [2]. It is not clear when she was introduced to statistics, but she used to study the blue books and statistics on public health and hospitals in the early hours of the morning [1]. Thus she was familiar with the problems of hospital administration well before her thoughts turned to **nursing**.

Florence believed that God had called her to do something, but did not know what. She was discontented with life and with herself. She seemed to gain most satisfaction from helping the poor and sick living near her family's Derbyshire home. Sometime in 1844 the realization came to her that her vocation lay in hospitals among the sick, but, anticipating family disapproval, it was not until December 1845 that she proposed her plan to go to Salisbury Infirmary to work as a nurse. The scheme was totally opposed by her parents. Florence was not to be deterred, and in 1851 persuaded her family to allow her to undertake a course of training at Kaiserswerth in Germany. She finally managed to convince her family that she should be allowed to practice nursing and in 1853 took a position as superintendent of an Institution for Sick Gentlewomen in Distressed Circumstances in Harley Street, London.

Once the Institution was running smoothly, Florence started visiting other hospitals to collect facts to establish the case for reforming conditions for hospital nurses. As her reputation grew, doctors contacted her, asking her to recommend nurses. Florence recognized the need for a training school capable of producing a supply of respectable, reliable and qualified nurses. She established such a school in 1860.

In 1853 the Crimean War began; the initial battles were horrific in terms of casualties. There were few facilities for the sick and wounded, and the problem was compounded by a cholera epidemic. Sidney Herbert was the Secretary of State for War responsible for the treatment of the sick and wounded. He was also a friend of Florence and knew of her work in the Harley Street Institution. He wrote to her inviting her to lead, with the government's sanction and at the government's expense, a party of nurses to Scutari to work in the British Army hospital.

The party of 38 nurses arrived at Scutari on November 4, 1854. The first hurdle to overcome was to be accepted by the Army medical department, which had declared itself against the introduction of women as nurses for soldiers. By the end of November there were 8000 men in the hospitals and the conditions were terrible, and so the Army medical authorities grudgingly had to accept all offers of help. All the administrative systems of the hospital had collapsed, and slowly Florence got her way. Sanitary improvements, cleaner surroundings and an improved diet were rewarded with a massive decrease in the

death rate. Woodham-Smith [7] provides a detailed account of Florence's time in Scutari.

Florence returned to England in July 1856 a national hero, and the position of the nursing profession had now been established. Florence was determined to reform the British Army. In 1857, largely through her efforts, a Royal Commission was set up to investigate the disasters of the Crimean War. Since women were not allowed to serve as members of the Commission or to testify, Florence wrote and compiled facts about the war and sent them to the Commission. She worked with **William Farr** on compiling the data she had collected in Scutari and devised some novel **graphical displays**, most notably her coxcomb [2, 6], to help convey her message. Her work was published in 1858 [3].

On December 21, 1858, Florence was elected a Fellow of the Statistical Society of London (now the **Royal Statistical Society**); she was one of the first female fellows of the society. She became an honorary member of the **American Statistical Association** in 1874.

Soon after her return from Scutari, Florence became reclusive and only saw people by appointment, usually at her home in South Street, Mayfair. She was a prolific writer, and in 1859 published her famous work *Notes on Nursing – What It Is And What It Is Not*. The book was very popular and was expanded and republished in 1860 [4]. It has sold millions of copies all over the world.

In 1859 she began her campaign for uniform hospital statistics. She devised a disease classification system and some model forms for the collection of the data. Again she worked with William Farr on this project. In 1860 this work was presented at the International Statistical Congress, held in London [5]. For a short time London hospitals made returns on these model forms, the data being published in the *Journal of the Statistical Society*. **Adolphe Quetelet** attended the congress, where Florence and he first met. She was fascinated by his statistical work, which had a great influence on her thinking [1].

In 1860 Florence established the Nightingale Training School for nurses at St Thomas's Hospital, London. This was financed by the Nightingale Fund established from donations made in recognition of her work in Scutari. It became the model for schools of nursing everywhere.

Florence's work in the mid-1860s was dominated by the contributions she made to sanitary improvements in India, both for the Army in India and the people of India. In 1907 she became the first woman to be awarded the Order of Merit. Three years later she died peacefully at the age of 90.

NICOLA J. CRICHTON

Noise and White Noise

Noise is familiar to us as an *unmusical* sound or, technically speaking, *interference* in a communication channel. The effect of *snow* on a television set is a form of visual noise. In communication engineering, noise arises from all the uncontrolled sources of fluctuations of voltage, current, thermal agitation of electrons in resistors, etc. Shannon [6] depicted a communication system schematically as in Figure 1. Any difference between the message at source and at destination could be attributable to inherent disturbances, or noise, in any, or all, of the activities indicated. Engineers spend much time and effort to control and reduce the noise in a system.

In statistical methods such as regression analysis, noise is the random sampling component and the "message or signal" the underlying model. Most time series are subject to noise, usually represented as a stochastic element in an appropriate model description. A typical problem is to estimate $X(t + \Delta)$ for positive, negative or zero Δ, from an observed process $\{Y(t)$; where t is a real value$\}$ with assumed model $Y(t) = X(t) + Z(t)$, where $Z(t)$ is the *noise* component. Barahona & Poon [1] give details of methods that can be used to distinguish deterministic chaos from random noise in short time series.

To allow the investigator to identify the underlying model or signal from the collection of noisy observations, he or she needs to determine the nature and structure of the noise. There is a range of tools available to analyze noise in time series data; see, for example, [5]. The **fast Fourier transform (FFT)**, introduced by Cooley & Tukey [4], can be used to estimate the power spectra of noise (*see* **ARMA and ARIMA Models**). Computer software is also available to fit autoregressive moving-average models to the noise process, using the analysis of autocorrelation and partial autocorrelation functions [3, 5].

White Noise

Biostatistical time series data often occur as sequences of observations equally spaced in time, and can therefore be analyzed using discrete-time models [2, 3, 5]. If $\{Z_t\}$ is a set of random

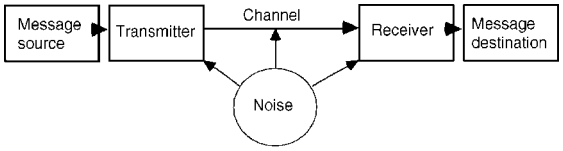

Figure 1 Main components of a communication system, indicating where noise can affect the message sent

variables with $\mathrm{E}(Z_t) = \mu_t$, and autocovariance function (*see* **Autocorrelation Function**) $\gamma_{t,s} = \mathrm{cov}\{Z_t, Z_s\} = \mathrm{E}[\{Z_t - \mu_t\}\{Z_s - \mu_s\}]$, then the stochastic process is said to be **stationary** if $\mu_t = \mu$ and $\gamma_{t,s} = \gamma(|t - s|)$. In many applications the noise process is assumed stationary and ergodic, i.e. its parameters can be estimated from a single realization of the process.

White noise, in discrete time, is simply the name given to a stochastic process $\{Z_t\}$ with $\mathrm{E}(Z_t) = 0$, and

$$\gamma_{t,s} = \begin{cases} \sigma^2, & t = s, \\ 0, & t \neq s. \end{cases}$$

Such a process has a constant spectral density. Autoregressive moving-average processes are derived from discrete-time white noise. The step from discrete to continuous time is not easy and involves an understanding of the Wiener process [2].

CLIVE J. LAWRENCE

Nominal Data

Nominal data arise from a specific type of *measurement*. As defined by the psychologist S.S. Stevens [9], measurement is the assignment of numbers to entities according to some rule. Close examination of such rules allows us to classify the various types of measurements into a small set of possibilities. Measurements are, of course, taken for many different reasons to answer many different questions, usually (but not always) on experimental units or subjects or on observational units. Measurements produce data which take on values along some **measurement scale**. The measurement type(s) of data to be analyzed dictates the analyses that yield justifiable, and meaningful interpretations.

Stevens classified measurement scales into four types:

1. nominal;
2. ordinal;
3. interval;
4. ratio.

Nominal measurements give rise to a measurement scale which classifies entities by labeled categories. The categories are unordered. All we can state when comparing measurements on different entities is that they are equal or unequal. There is no particular mathematical significance given to the labeled categories themselves. The scale produces labels to be attached to the entities so that the entities can be classified into (usually) a discrete number of categories (hence, statisticians often view nominal measurements simply as producing unordered categorical data).

Ordinal and interval measurements produce scales on which measurements can be ranked (ordinal), or scale values on which arithmetic can be defined (interval). Letter grades given to students on an examination, or preoperative condition scores of patients (poor, fair, good, and so forth) follow ordinal scales; temperature measured in Fahrenheit or centigrade falls on an interval scale (the absence of an absolute zero-point is noteworthy for interval scales). Lastly, ratio measurements have all the features of interval measurements, with the additional property that levels on the scale may be expressed as ratios. Zero-points are well-defined (as in the case of the Kelvin temperature scale). A very good, and lengthy, discussion of measurement theory can be found in Krantz et al. [5], Suppes et al. [10], and, especially, Luce et al. [6] and a nice summary is given in Wallsten [11].

Ordinal measurements are usually categorical in nature, and can be studied with **ordered categorical data** techniques. Statisticians often assume that measurements on interval and ratio scales can be modeled as continuous random variables. One can of course use techniques for nominal data to analyze ordinal measurements, but not ordinal techniques for nominal data. It clearly is best to match the level of measurement with the analytic techniques used.

A good example of a nominal measurement scale is gender, measured on people – two categories, which clearly cannot be ordered in a meaningful way. A nominal scale can have any number of levels – assume that the number of levels is I. Other examples include race, religion, and, of course, the outcome of a possibly fatal disease (alive or dead). Other examples of nominal data, as well as a little more on the measurement aspects of nominal scales, can be found in [7]. Nominal data are common in all areas of science, and the techniques for their analyses have expanded greatly since the 1960s. There is a large variety of such techniques – any of the tools of **categorical data analysis** are appropriate, as long as categories are not assumed to be ordered. Here, we briefly mention these techniques.

We assume that interest is on a set of experimental units, or some observational subjects (people or otherwise). Let this set be of size N. For simplicity, we also assume that this set of units arises from a simple random sample, and that we are taking measurements on $S \geq 1$ nominal scales. Responses given by the units are unknown, and are governed by some statistical mechanism (more on this below), so that the nominal scales may be termed *nominal variables*. Analytic techniques, whether they be data analytic or statistical, depend on the number of variables under study, and hence, the discussion here is divided into the three possibilities: univariate, bivariate, and multivariate.

Univariate Techniques

For the analysis of a single nominal variable, we record the frequencies of units falling into the I

categories. These frequencies can be displayed graphically, in a variety of different ways. When $I = 2$, these **binary data** are often assumed to arise from Bernoulli random variables, so that statistical techniques based on the **binomial distribution** are usually appropriate when studying the frequencies. We usually use 0 and 1 to code the two categories. If interest is not on the frequencies, but on how many subjects must be sampled before the frequencies attain certain values, then the **negative binomial distribution** may be appropriate. For these probability models, we let p be the probability that a unit takes on the value 1, or falls into the "second" category. Frequently, interest centers on the odds of a measurement of 1 vs. a measurement of 0, which equals $p/(1-p)$. The logarithm of this **odds ratio** is often termed a *logit*, and is a useful transformation of binary data.

For $I > 2$ categories, or **polytomous data**, we define p_i as the probability of falling into the ith category. The I frequencies can be displayed using many graphical techniques (*see* **Exploratory Data Analysis**). Relevant probability distributions include the polytomous generalization of the binomial, the **multinomial distribution**, and occasionally, the **Poisson distribution** (which arises naturally from the stochastic **Poisson process** by counting how many events occur in some fixed interval of time, for example).

Statistical inference centers on learning about the unknown parameters of these distributions. Often, one might hypothesize models for such parameters; for example, one could test for equal probabilities ($p_1 = p_2 = \cdots = p_I = 1/I$). A variety of logits could be calculated and studied. These hypotheses are often modeled loglinearly by postulating that the logarithms of the probabilities (another useful theoretic transformation) are linear functions of various parameters (*see* **Loglinear Model**). More sophisticated forms of **generalized linear model** arise by relaxing distributional and scale assumptions concerning the response variable. The standard, albeit asymptotic for large N, approach to such testing is via *chi-square tests*. Other approaches are possible, including the use of other distributions (such as the **beta-binomial distribution**).

If some of the $\{p_i\}$ are zero, some of the categories must have zero frequencies regardless of the magnitude of N. Such categories are called structural zeros, and inferential procedures must take them into account.

Bivariate Techniques

Assume that one has a pair of nominal variables, one with I_1 categories, and the second with I_2 categories. We record the frequencies of the units falling into the $I_1 I_2$ categories of the cross classification of the two variables. These frequencies are arrayed into a two-dimensional **contingency table**, of size $I_1 \times I_2$. We usually assume that a multinomial distribution with probabilities $\{p_{ij}\}$, or a set of multinomial distributions (one for each row of the table, for example), generated these data.

Hypotheses about the probabilities are usually translated into loglinear models. Maximum likelihood estimates of model parameters often have closed form solutions, although iterative algorithms (such as **iterative proportional fitting**) can almost always be used.

Without question, the most common hypothesis is independence of the two variables; that is, a test of whether p_{ij} can be factored into the product $p_{i\cdot}p_{\cdot j}$, for all i, j. The study of independence has led to the construction of a wide range of measures of association between two nominal variables; two of the oldest and still most widely used are the **Goodman–Kruskal** indices. Odds ratios can also be used to quantify association.

This very standard hypothesis of independence can be tested in a variety of ways, although the most common is still via Pearson's χ^2 statistic, which for large N, is **chi-square distributed**. Note, however, that **exact tests for categorical data** do indeed exist (which are not asymptotic **likelihood ratio tests**); the most widely used is **Fisher's exact test**.

In the case of square, $I \times I$ tables, a range of special hypotheses arise, including tests of symmetry and **quasi-symmetry** of the table (for example, does $p_{ij} = p_{ji}$?), and the **McNemar test**, which looks at equality of the upper and lower triangles. Such a **square contingency table** is common when the two variables have exactly the same categories (perhaps they are measurements on the same units, separated in time; such as success or failure of some drug at time 1 and time 2). If both variables are binary, we obtain a **two-by-two table**.

Yet another possibility, although one that is used more often when $S > 2$ variables, is a regression approach, using the logit transformation(s) of one of the variables as the response variable. Techniques for such a **logistic regression** are well understood, and

increasingly used. Explanatory variables can be of many types, and allow for a wide range of interactions.

Multivariate Techniques

Lastly, suppose that $S > 2$, so that the contingency table is multiway. Data analytic and statistical techniques are designed to highlight the many interactions that can exist among the variables, and to test for different types of independence. We refer those interested to the article on **Categorical Data Analysis**, or to one of the many textbooks on the subject, especially Agresti [1] and Bishop et al. [3] for the more advanced student, or to the primers by Agresti [2], Wickens [12], and Fienberg [4]. The chapter by Sobel [8] presents a nice overview of multivariate techniques.

Acknowledgments

STANLEY WASSERMAN

Noncentral *t* Distribution

The noncentral t distribution is a two-parameter family with a **unimodal** density having parameters ν (**degrees of freedom**) and δ (noncentrality parameter). Degrees of freedom are usually positive integers, although any positive value is theoretically possible. The noncentrality parameter can take on any real value, although when it equals zero the distribution reduces to a special case; namely, the well known (central) **Student's *t* distribution**.

Suppose that X and Y are stochastically independent **random variables** such that X is **normally distributed** $\mathrm{N}(\delta, 1)$ and Y is central χ^2 with ν degrees of freedom (df). Then the ratio

$$R = \frac{X}{\sqrt{(Y/\nu)}}$$

follows the noncentral t distribution. (If Y is noncentral χ^2, then R has the doubly noncentral t distribution.) The most important application relates to the testing of the **null hypothesis** H_0, that the mean of a normal population with unknown variance equals μ_0. If H_0 is true, the statistic $T = \sqrt{n}(\overline{x} - \mu_0)/s$ follows the central t distribution with $n - 1$ df, but if the mean instead equals μ_1, then T follows the noncentral t distribution with noncentrality parameter $\delta = \sqrt{n}(\mu_1 - \mu_0)/\sigma$. Similarly, for testing the equality of means for two normal populations having common unknown variance, one may construct the statistic $T = \sqrt{[n_1 n_2/(n_1 + n_2)]}(\overline{x}_1 - \overline{x}_2)/s_\mathrm{p}$, where s_p is the pooled standard deviation. Under the null hypothesis, T follows the central t distribution with $n_1 + n_2 - 2$ df, but when the two population means differ by an amount $\Delta = \mu_1 - \mu_2$ the relevant noncentrality parameter is $\delta = \sqrt{[n_1 n_2/(n_1 + n_2)]}\ \Delta/\sigma$. The **power** of either test is expressible with the cumulative distribution function (cdf) of the relevant noncentral t, evaluated at the appropriate critical point(s) of the corresponding central t distribution.

Some moments of the noncentral t are

$$\mathrm{E}(R) = \delta\sqrt{\frac{\nu}{2}}\left[\Gamma\left(\frac{\nu-1}{2}\right)\Big/\Gamma\left(\frac{\nu}{2}\right)\right],$$

$$\mathrm{var}(R) = \frac{\nu}{\nu-2}(1+\delta^2) - [\mathrm{E}(R)]^2,$$

$$\mu_3(R) = \frac{\nu}{\nu-3}\mathrm{E}(R)\left[\frac{3(1+\delta^2)}{(\nu-2)} - 2\delta^2\right] + 2[\mathrm{E}(R)]^3.$$

The noncentral t density can be written as

$$f(\nu, \delta; t) = \frac{\exp(-\delta^2/2)}{\sqrt{(\pi\nu)}}\left[\Gamma\left(\frac{\nu+1}{2}\right)\Big/\Gamma\left(\frac{\nu}{2}\right)\right] \times \left[\frac{\nu}{\nu+t^2}\right]^{(\nu+1)/2} S(\nu, \delta; t),$$

where

$$S(\nu, \delta; t) = \sum_{j=0}^{\infty}\left[\Gamma\left(\frac{\nu+j+1}{2}\right)\Big/\Gamma\left(\frac{\nu+1}{2}\right)j!\right] \times \left[\frac{t\delta\sqrt{2}}{\sqrt{(\nu+t^2)}}\right]^j.$$

Although this series converges rather slowly for large arguments, it satisfies the equation

$$\frac{\mathrm{d}^2 S(t)}{\mathrm{d}t^2} = \left[\frac{\delta^2\nu t}{(\nu+t^2)^2} - \frac{3t}{\nu+t^2}\right]\frac{\mathrm{d}S(t)}{\mathrm{d}t} + \frac{\delta^2\nu^2(\nu+1)}{(\nu+t^2)^3}S(t).$$

This relationship is useful for recasting noncentral t distributions in terms of S-system differential equations, which are used in solving their densities, cdfs, and **quantiles**, as well as **moments** of integer and fractional orders [4].

Alternative expressions for the noncentral t are available; for example,

$$f(\nu, \delta; t) = K\exp\left[-\frac{\nu\delta^2/2}{\nu+t^2}\right]\left(\frac{\nu}{\nu+t^2}\right)^{(\nu+1)/2} \times Hh_\nu\left[-\frac{\delta t}{\sqrt{(\nu+t^2)}}\right],$$

where

$$K = \nu!\left[2^{(\nu-1)/2}\sqrt{(\pi\nu)}\Gamma\left(\frac{\nu}{2}\right)\right]^{-1}$$

and

$$Hh_\nu(x) = \frac{1}{\nu!}\int_0^\infty u^\nu \exp\left[\frac{-(u+x)^2}{2}\right]\mathrm{d}u.$$

For a random sample of size n from an $\mathrm{N}(\mu, \sigma^2)$ population, with $\mu > 0$, the sample coefficient of

variation $s/\overline{x}$ has a distribution related to noncentral t, although the tails of the former map to small values of the latter. More specifically, if R has $\nu = n - 1$ and $\delta = \mu\sqrt{n}/\sigma$, then $\Pr(s/\overline{x} > c) = \Pr(0 \leq R \leq \sqrt{n}/c)$.

Other situations in which noncentral t distributions are relevant include one-sided *tolerance* limits for a normal distribution (*see* **Tolerance Interval**), lot acceptance sampling plans, **confidence** limits on one-sided normal **quantiles** and **binomial** proportions, and one-sided tolerance limits in **linear regression**.

Noncentral t tables have occasionally been published; a fresh and extensive compilation [1] has appeared recently. See also [2] and [3].

Noncompliance, Adjustment for

The randomized **clinical trial** (RCT) is arguably the most important contribution of statistical science to human health. It provides a scientific basis for the **unbiased** evaluation of preventive and therapeutic treatments, not by controlling sources of variation as done in the laboratory, but by balancing them across treatment groups (*see* **Randomized Treatment Assignment**). In the simple RCT design (*see* **Clinical Trials, Overview**), each participant is randomly assigned to one treatment (e.g. placebo; *see* **Blinding or Masking**) or another (active agent) as indicated by the value of $R_i = 0$ or 1. Given his or her random assignment, a patient actually takes either the placebo or active treatment as indicated by $D_i(R_i) = 0$ or 1, and then experiences a health outcome $Y_i[D_i(R_i)] = 0$ or 1, $i = 1, \ldots, n$.

In the ideal trial, 100% of participants comply with the treatment to which they were randomly assigned so that $D_i(R_i) = R_i$. In practice, however, compliance is less than perfect as illustrated in Table 1 with data from the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CPPT) [8, 10, 16]. Of the 337 subjects reported in the table, 123 (36%) fail to reach the (arbitrary) 60% compliance level used for illustration below. Note that the noncompliance (<60%) rates in the placebo ($R = 0$) and cholestyramine ($R = 1$) arms are quite different – $46/172 = 27\%$ and $77/165 = 47\%$, respectively.

Such a RCT is designed to address several questions including:

1. Is there sufficient evidence to reject the **null hypothesis** that the treatment and placebo have the same effect on the health outcome (*see* **Outcome Measures in Clinical Trials**)?
2. What is the average difference in outcome caused by being randomized to the treatment, rather than placebo, group?
3. Among persons who comply with their treatment regimen, what is their average improvement as a result of receiving treatment rather than placebo?

Questions 1 and 2 are typically addressed with an **intention-to-treat (ITT) analysis**, in which the average response is compared across randomization groups ($R = 0$ vs. $R = 1$) without regard to the treatment that was actually received. The target of estimation implicit in the ITT analysis has been called the *programmatic effectiveness* [14], which combines the average therapeutic effect of the treatment and the rate of patient compliance to the treatment regimen. Question 3 focuses upon the therapeutic benefit alone. The average benefit among compliers has been referred to as the *biologic efficacy* [14]. While efficacy is often of scientific interest, the ITT analysis alone is inadequate to estimate it. Compliance information must also obviously be used.

Even when addressing questions 1 and 2, compliance information is relevant. As compliance decreases, effectiveness and the **power** to detect a treatment difference also decrease [5]. Hence, sample sizes must be increased to maintain a desired level of power (*see* **Sample Size Determination for Clinical Trials**). A second design strategy to contend with imperfect compliance is inclusion of a *run-in period* [13] after which persons with poor compliance are dropped from the study. **Randomization** to treatment group occurs at the end

Table 1 Two-by-two-by-two table displaying presence (1) or absence (0) of improvement in cholesterol level by 20 units (Y); treatment group assignment; $R = 0$ for placebo and $R = 1$ for cholestyramine; and compliance level: <60%; ≥60%

		Placebo ($R = 0$)			Treatment ($R = 1$)		
		Compliance			Compliance		
		<60%	≥60%		<60%	≥60%	
Y	0	$m_{00} = 42$	$m_{01} = 98$	$m_{0\cdot} = 140$	$n_{00} = 50$	$n_{01} = 16$	$n_{0\cdot} = 66$
	1	$m_{10} = 4$	$m_{11} = 28$	$m_{1\cdot} = 32$	$n_{10} = 27$	$n_{11} = 72$	$n_{1\cdot} = 99$
		$m_{\cdot 0} = 46$	$m_{\cdot 1} = 126$	$m_{\cdot\cdot} = 172$	$n_{\cdot 0} = 77$	$n_{\cdot 1} = 88$	$n_{\cdot\cdot} = 165$

of the run-in period (*see* **Compliance Assessment in Clinical Trials**).

Compliance is easy to discuss in the abstract, but can be difficult to measure in practice. In many trials, patients are asked to make diary entries of pills taken. Or, in some studies, investigators repeatedly collect patient sera samples from which estimates of drug concentrations are made. In these cases, a longitudinal data set is generated, from which compliance can be inferred using methods such as those discussed by Lim [15] and Kim & Lagakos [12].

Until recently, RCT practitioners were reticent to estimate efficacy using compliance information collected after randomization because substantial **selection biases** can occur. Recently, the method of *instrumental variables*, common in econometrics, has been applied to the RCT to contend with selection bias inherent in estimating efficacy. Because the method leads to the ITT test of the null hypothesis, and to unbiased estimates of efficacy in many situations, they are attractive to many, although certainly not all, statistical scientists. Below, the main ideas of this approach are illustrated using the LRC-CPPT data. Extensions to different kinds of outcomes and compliance measures are then summarized. Connections to instrumental variables methods in econometrics and to Rubin's causal model are important and are discussed in detail by Angrist et al. [2]. One of the more complex models for compliance is presented in Efron & Feldman [8] and in a paper critical of their approach by Albert & DeMets [1].

Adjusting for Compliance to Estimate Efficacy

The ITT estimate of **relative risk** (RR) representing programmatic effectiveness for the LRC-CPPT data in Table 1 is $RR_{\mathrm{ITT}} = (66/165)/(140/172) = 0.49$ with an approximate 95% **confidence interval** (0.40, 0.60). These data provide evidence that assignment to receive cholestyramine reduces the risk of failing to improve the cholesterol level in comparison with a group assigned to receive a placebo. However, only 88 of the 165 participants (53%) in the treatment group actually took more than 60% of their medication. Hence, the relative risk estimate, RR_{ITT}, probably underestimates the biologic impact of treatment, since only about half of the treatment group actually received a substantial fraction of the drug assigned.

The question remains, what is the treatment effect among the subgroup of persons who complied with their treatment assignment? The direct, but naive, way to estimate efficacy from Table 1 is to compare the compliers in the treatment and placebo groups. From Table 1, we have $RR_{\mathrm{E_I}} = (16/88)/(98/126) = 0.23$. Use of this simple estimate raises serious concerns, because it is subject to selection bias. The compliers in the treatment and placebo groups may not be comparable in ways other than their treatment status. There is evidence to this effect – the fraction of compliers in the placebo group is 73% as compared with 53% in the treatment group. Ingesting cholestyramine has been described as similar to eating sand; perhaps the placebo was more tolerable; hence, the compliant subgroups in the two arms are not necessarily comparable. This potential for differential subgroup selection bias is one basis for serious concerns about such efficacy estimates among many clinical trialists [6].

There is, however, another estimate of efficacy that can be useful in some circumstances because it does not suffer from this selection bias. Consider an imaginary, perfect placebo that is identical to the treatment in every possible way except that it has no biologic activity. Further assume that compliance is conditionally independent of the health outcome given treatment assignment; that is, the effect of the treatment (or lack thereof) on the health outcome is not the cause of the differential compliance. Then, in a clinical trial in which participants receive the drug only if they are in the treatment group and comply $[D(1) = 1; D(0) = 0]$, randomization guarantees two conditions:

1. The expected fraction of compliers would be the same in the two treatment groups. The observed fraction in the cholestyramine group (53%) is an unbiased estimate of this common compliance rate.
2. Among the noncompliers, no drug is received (not quite true in the LRC-CPPT example where the compliance level is actually a continuum) so that their expected rate of health outcome would be the same across the two treatment groups.

Under the assumptions above, these two facts allow us to infer the expected entries in the placebo side of Table 1 for an imaginary, perfect placebo. As shown

by Sommer & Zeger [23], m_{10} can be estimated by $m_{..}n_{10}/n_{..}$. That is, the expected rate of successful outcomes in a perfect-placebo, noncompliant subgroup can be estimated by the observed rate in the treatment, noncompliant group. The expected number of successful outcomes in the placebo, compliant subgroup can then be obtained by subtracting the imputed values for the noncompliant group from the marginal totals $m_{0\cdot}$ and $m_{1\cdot}$. This leads to the alternative relative risk estimate [23]:

$$RR_{E_2} = \frac{n_{01}/n_{\cdot 1}}{\hat{m}_{01}/(\hat{m}_{01} + \hat{m}_{11})},$$

where $\hat{m}_{11} = m_{1\cdot} - (m_{..}/n_{..})n_{10}$ and $\hat{m}_{01} = m_{0\cdot} - (m_{..}/n_{..})n_{00}$. For the cholestyramine example, the new estimate of treatment efficacy is $RR_{E_2} = (16/88)/(87.9/91.7) = 0.190$. It is different from the naive estimate RR_{E_1} because it is corrected for the differential compliance rates in the two treatment arms.

RR_{E_2} is a simple example of an *instrumental variables* estimator, commonly used in econometric research [4]. Recent applications of this approach to clinical trials are by Permutt & Hebel [19], Robins [20] and Baker & Lindeman [3]. A detailed discussion of the use of instrumental variables for causal inference (*see* **Causation**) within Rubin's framework is given by Angrist et al. [2].

More Realistic Applications

In an analysis of data from the Multicenter Diltiazem Post-infarction Trial (MDPIT), Oakes et al. [18] include a measure of compliance as a **covariate** in Cox's **proportional hazard's** model [7] to estimate a **relative hazard** parameter for each of three comparisons; treatment vs. placebo for compliers; treatment vs. placebo for noncompliers; and compliers vs. noncompliers among persons allocated to the placebo group. Their treatment vs. placebo comparison among compliers is a **survival analysis** analog of RR_{E_1}. But their analysis also summarizes the evidence about selection bias in the comparison of the noncompliant subgroups and hence is a sensible first step. White & Pocock [24] extend this approach by considering **time-dependent** indicators of compliance.

Robins [20], Robins & Tsiatis [21] and Mark & Robins [17] develop and apply an **accelerated failure-time model** [7] to estimate the causal relative hazard of a treatment taking account of compliance information. Following Rubin's framework for causal inference [11, 22], they assume that each individual can be thought of as having a latent survival time associated with each treatment. The causal effect is defined as the difference in the latent survival times for the treatments being compared. Under the accelerated failure-time model, the effect of treatment is to rescale (make faster or slower) time so that the parameter of interest is the fractional increase in survival for an individual on vs. off treatment. Their use of compliance information is a survival analog of what is done in the simple **binary** case above. The strength of the Robins & Tsiatis method is that, as in the binary case, the test of the null hypothesis of no treatment effect is identical to the ITT test of the same hypothesis. See also Goetghebeur & Lapp [9].

Goetghebeur & Molenberghs [9] have developed this approach for the case of a **binary** response, but with an ordinal measure of compliance, as occurs in the cholestyramine example above. To do so, they make the additional *monotone treatment effect* assumption that, if a failure occurred at a given level of treatment, then it would also have occurred at all lower levels of treatment. This rules out the possibility of drugs being toxic and therefore less effective at higher doses, for example.

Efron & Feldman [8] take account of a continuous measure of compliance with a continuous outcome reduction in serum cholesterol level. Because they are interested in a possible interaction whereby the treatment effect will differ depending on a person's tendency to comply, they must use the observed compliance information in both the treated and control groups. Hence, they do not protect against unequal selection from an imperfect placebo as was done in the binary example above. Instead, they assume that an individual's inherent tendency to comply is measured by their quantile of compliance within their own treatment group. With this assumption, they use both the conditional means and variances of cholesterol change, given the level of compliance, to assess the causal effect of treatment as a function of compliance. This approach is distinct in its assumptions from the others described above. A critique of the Efron & Feldman efficacy estimate is provided by Albert & DeMets [1].

In summary, *programmatic effectiveness* and *biologic efficacy* are both important targets for estimation in clinical trials. The ITT analysis estimates

effectiveness. This article reviews the use of instrumental variable methods as one approach to estimating the efficacy of the treatment among persons who comply. In the case of a binary treatment indicator and binary outcome, this approach leads to an estimator that is not biased by differences between treatment groups in compliance when the differences are due to factors that are conditionally independent of the outcome given the treatment assignment. Hence, they will be useful when the decision to comply does not depend on the outcome being studied. Several extensions to more realistic situations are also summarized.

Nondifferential Error

Suppose a response variable Y has a conditional distribution $F(y|x)$ given a true exposure measurement, $X = x$. Suppose that instead of measuring X, one measures an error-prone version of X, say Z. Then the error process is said to be nondifferential if $F(y|x, z) = F(y|x)$, namely if Y and Z are conditionally independent given X. In usual cases, though not in all cases, the effect of analyzing the model $F(y|x)$ by substituting Z for X will be to **bias** estimates of **exposure effect** toward the **null hypothesis** (*see* **Bias Toward the Null**) when the exposure error is nondifferential. However, if exposure measurements are differential, the bias can be in any direction.

The term nondifferential error can also be applied to errors in the outcome measure, Y. Suppose that one measures the error-prone version W of Y, rather than Y itself. Then the error process is nondifferential if W is conditionally independent of X given Y.

MITCHELL H. GAIL

Non-Fourier Waveforms

While the discrete Fourier transform (DFT) is indispensable for analyzing **stationary** data, whose frequency behavior is fixed over time, we often have data that exhibits periods of high-frequency behavior, which do not extend over the whole time period. The DFT is not necessarily the "best" representation of such data, and we wish to find sets of basis function, which are able to isolate such behavior. Quite recently, there has been much interest in a class of **orthogonal** transforms that give information about the data at different times and scales. The functions that are used to represent the data are no longer the well-known sines and cosines of Fourier theory but are functions that are known as **wavelets**. These wavelets, as the name suggests, are "small" waves, meaning that they are only nonzero in a finite time interval. This compact support is critical for the success of these representations and allows us to study different scale behavior at different times.

A wavelet function, $\psi(\cdot)$, must satisfy two basic properties, namely,

1. The integral of $\psi(\cdot)$ is zero:

$$\int_{-\infty}^{\infty} \psi(t)\,\mathrm{d}t = 0. \tag{1}$$

2. The square of $\psi(\cdot)$ integrates to unity:

$$\int_{-\infty}^{\infty} \psi^2(t)\,\mathrm{d}t = 1. \tag{2}$$

The orthogonal transform associated with wavelets as basis functions is known as the discrete wavelet transform (DWT) and it results in a set of coefficients, which relate to different times and scales. In the same way, that the **fast Fourier transform** (FFT) has revolutionized the implementation of **spectral** methods, there exists a fast method of calculating the coefficients of the DWT, which is in fact computationally even faster than the FFT.

Arguably the oldest wavelet function is named after Haar [2]:

$$\psi(t) \equiv \begin{cases} \dfrac{-1}{\sqrt{2}}, & -1 < t \leq 0; \\ \dfrac{1}{\sqrt{2}}, & 0 < t \leq 1; \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

The Haar wavelet at different scales is shown in Figure 1.

More recently, many other families of wavelets have appeared that have more desirable properties, for example, in terms of their "smoothness", than the Haar wavelet. In particular, a class of wavelets

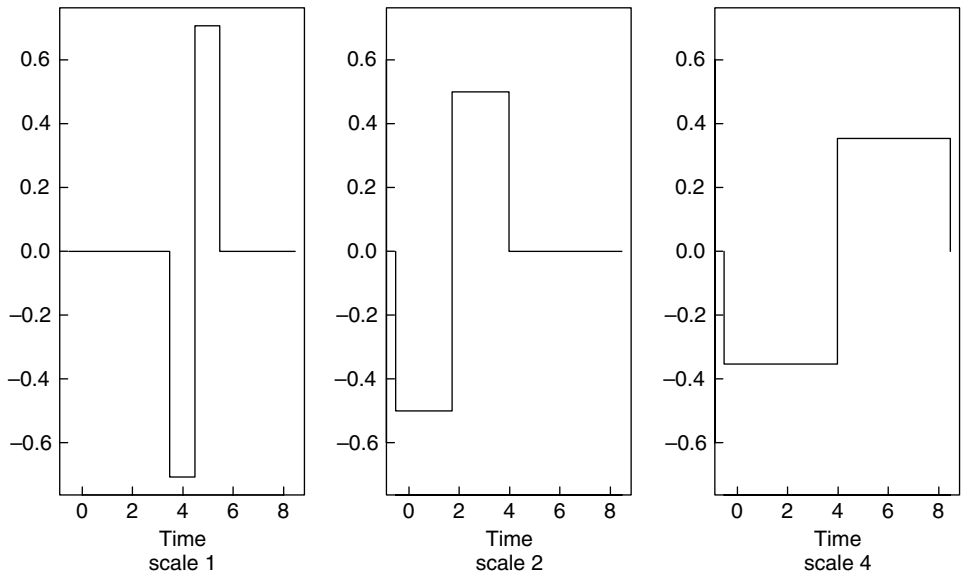

Figure 1 The Haar Wavelet at different scales

introduced by Daubechies [1] have proved popular and gained widespread use.

Given a time domain sequence $\boldsymbol{g} = (g_0, \ldots, g_{N-1})^\top$, the calculation of the N DWT coefficients, $\boldsymbol{w} = (w_0, \ldots, w_{N-1})^\top$ can be written in matrix form as

$$\boldsymbol{w} = \boldsymbol{W}\,\boldsymbol{g}, \tag{4}$$

where $\boldsymbol{W}$ is the $N \times N$ orthogonal wavelet matrix.

For illustrative purposes, when $N = 8$ and using the Haar wavelet, we have

$$\boldsymbol{w} = \begin{bmatrix} w_0 \\ w_1 \\ w_2 \\ w_3 \\ w_4 \\ w_5 \\ w_6 \\ w_7 \end{bmatrix} = \begin{bmatrix} (g_1 - g_0)/\sqrt{2} \\ (g_3 - g_2)/\sqrt{2} \\ (g_5 - g_4)/\sqrt{2} \\ (g_7 - g_6)/\sqrt{2} \\ (g_3 + g_2 - g_1 - g_0)/2 \\ (g_7 + g_6 - g_5 - g_4)/2 \\ (g_7 + \cdots + g_4 - g_3 - \cdots - g_0)/\sqrt{8} \\ (g_7 + \cdots + g_0)/\sqrt{8} \end{bmatrix}. \tag{5}$$

The first four rows of this matrix correspond to unit scale changes (*high-frequency behavior*), the next two rows represent changes on a scale of two, the seventh row represents changes on a scale of four, while the final row represents the average at scale 8 (*low-frequency behavior*). In addition, each of the rows corresponds to different, nonoverlapping, time intervals in the data. For a good introduction to the DWT with direct comparisons to the DFT see [4].

Non-Fourier waveforms find a wealth of applications, particularly in areas where the underlying process has time-varying properties, for example, the study of arrhythmia in electrocardiogram (ECG) data, or denoising medical images (*see* **Clinical Signals**). For some statistical applications of wavelets, see [3].

Nonignorable Dropout in Longitudinal Studies

Most longitudinal studies (*see* **Longitudinal Data Analysis, Overview**) are designed to collect data on every individual in the sample in a planned sequence of observation times. However, longitudinal studies habitually suffer from the problem of attrition; that is, some individuals "drop out" of the study prematurely. For example, suppose for each individual we plan to make a sequence of T observations on outcome variables $Y_1, \ldots, Y_T$. In addition, for each individual we may have a set of fixed covariates, X, and these are assumed to be fully observed. In that case, the term *dropout* refers to the special case where if Y_k is missing, then $Y_{k+1}, \ldots, Y_T$ are also missing. This gives rise to a monotone data pattern (see Figure 1) in contrast to the nonmonotone patterns that arise when data are missing intermittently. Note that intermittent missing data give rise to a considerably larger number of potential missing data patterns but, apart from that, do not raise any further technical considerations. When there is dropout in a longitudinal study, the key issue is whether those who drop out and those who remain in the study differ in any further relevant way. If they do not, then analyses restricted to those remaining in the study yield valid (albeit inefficient) inferences. If they do differ, then such analyses are potentially biased.

In the statistical literature, three different types of dropout have been distinguished [2, 4, 5]: *completely random, random*, and *nonignorable* dropout (see [3] for a more refined classification of dropout). Often the term "informative" dropout is used to refer to nonignorable dropout, e.g [1] (*see* **Diggle–Kenward Model for Dropouts**). To clarify the distinction between these different types of dropout, it is helpful to introduce a dropout indicator variable, D, for each individual. Let $D = k$ if an individual drops out between the $(k-1)$th and kth observation time, and $D = T + 1$ if there is no dropout. That is, when $D = k$ we only observe $Y_1, \ldots, Y_{k-1}$, and the remaining $Y_k, \ldots, Y_T$ are missing. Note, however, that D is recorded for all individuals. With completely random dropout, individuals leave or drop out of the study in a process that is independent of any other observed variables. That is, $\Pr(D = k|X, Y_1, \ldots, Y_T) = \Pr(D = k)$, and the probability of dropout does not depend on an individual's outcomes $Y_1, \ldots, Y_T$. Little [3] distinguishes completely random dropout from *covariate-dependent* dropout. In the latter, $\Pr(D = k|X, Y_1, \ldots, Y_T) = \Pr(D = k|X)$, and the probability of dropout depends on values of the fixed covariates X, but, given X, it is conditionally independent of an individual's outcomes $Y_1, \ldots, Y_T$. Note, however, that if dropout depends on covariates that have not been fully observed or on covariates that have been omitted from the model for the longitudinal outcomes, then dropout is no longer said to be *covariate-dependent*. With random dropout, the process can depend on the outcomes that have been observed in the past, but, given this information, it is conditionally independent of all future (unrecorded) values of the outcome variable following dropout. That is, $\Pr(D = k|X, Y_1, \ldots, Y_T) = \Pr(D = k|X, Y_1, \ldots, Y_{k-1})$, and the probability of dropout depends only on outcomes that have been observed or recorded. Finally, in the case of nonignorable or informative dropout, the dropout process, $\Pr(D = k|X, Y_1, \ldots, Y_T)$, depends on unobserved values of the outcome variable. That is, dropout is said to be nonignorable when the probability of dropout depends on the unrecorded values of the outcome variable that would have been observed had the individual remained in the study.

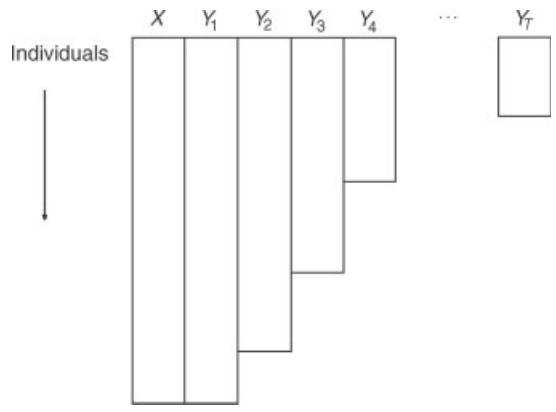

Figure 1 Schematic representation of a monotone data pattern (adapted from Little [3])

Completely random, covariate-dependent, and random dropout are often referred to as being *ignorable* (provided that the parameters of the dropout process are distinct from the parameters of the model for the longitudinal outcomes) [5]. We caution, however, that the use of the term ignorable does not imply that

the individuals with missing data can simply be disregarded. Rather, the term ignorable is used to indicate that it is not necessary to specify an explicit model for dropout in likelihood-based or **Bayesian inference** concerning the parameters in any model for longitudinal outcomes. Ignorable dropout can often be handled using standard statistical software (e.g. BMDP5V or SAS PROC MIXED), where those who drop out are included in the likelihood-based analysis (*see* **Software, Biostatistical**). However, with nonignorable dropout, the dropout mechanism cannot be ignored in likelihood-based or Bayesian inference [4, 5]. With nonignorable dropout, inference is only possible once assumptions are made about the dropout process. Recently, quite a number of methods have been proposed for handling nonignorable dropout, and all of these methods make particular assumptions about the dropout process. A general overview of the statistical literature on methods for modeling dropout can be found in [3]. However, it is worth stressing that, short of tracking down the individuals who have left the study, any assumptions made about the dropout process are not verifiable. Therefore, it is important to assess carefully the sensitivity of inferences to a variety of plausible assumptions concerning the dropout process.

Finally, there are some subtle issues concerning the identifiability of models for nonignorable dropout. That is, for any given set of data, some parameters may not be estimable from the information in the data since the likelihood is exactly the same for a whole range of parameter values. In general, nonignorable dropout models are nonidentifiable unless some arbitrary constraints are imposed on the model.

GARRETT FITZMAURICE

Nonlinear Growth Curve

Traditional growth curve analysis is associated with the monitoring of development of individuals over time. A classic case involves recordings made on a group of children, say, of y (height or weight) at times x (age). For each child the points (x, y) can be plotted to give individual growth curves. Traditionally, again, low-degree polynomials would be fitted to the curves and the resulting parameter estimates used for inferences such as comparisons between different groups of children.

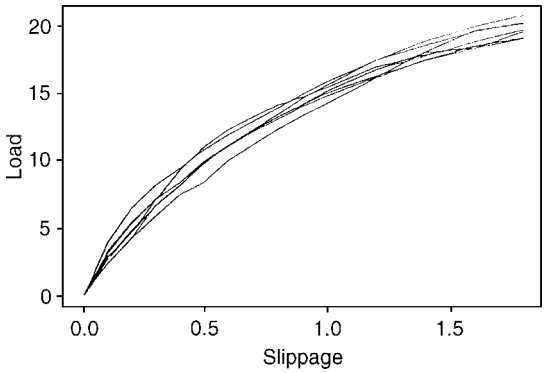

Figure 1 Timber slip under loading: load vs. slippage

Linear Growth Curves

Suppose that the observed value for a particular individual at time x_j is Y_j, $j = 1, \ldots, p$, and that the curve is to be represented as a quadratic (for $p > 3$). Then the statistical model is

$$Y_j = \beta_0 + \beta_1 x_j + \beta_2 x_j^2 + \varepsilon_j,$$

where $\beta = (\beta_0, \beta_1, \beta_2)'$ is the 3×1 vector of regression coefficients and ε_j is the "error" term. As an example, consider the data given in Table 1, plotted in Figure 1. The x values here are the loads required to produce slippage x of a timber specimen in a clamp. There are eight specimens, each producing 15 points on the curve. The eight individual curves in Figure 1 are quite close, and, by eye, it would not be unreasonable to entertain a quadratic fit.

The matrix version of the quadratic model equation is $\mathbf{Y} = \mathbf{X}\beta + \varepsilon$, where $\mathbf{Y}$ is the $p \times 1$ vector with jth component Y_j, ε is $p \times 1$ with components ε_j, and $\mathbf{X}$ is $p \times 3$ with jth row $(1, x_j, x_j^2)$. The simplest assumption for the ε_js, $j = 1, \ldots, p$, is that they all have mean 0, all have the same variance σ^2, and are uncorrelated. In this case, least squares estimates and their standard errors can be obtained for the βs. More formal inferences can be made under the standard additional assumption that the ε_js are normally distributed. More generally, a *multivariate normal distribution* N $(\mathbf{0}, \mathbf{E})$, in which the ε_js may be correlated, will be adopted for ε. Often, a structured form will be adopted for $\mathbf{E}$ depending on a parameter vector τ.

The description above applies to the measurements made on one individual (e.g. timber specimen) only. To extend this to a group of individuals, denote the set of data points for the ith by $\{(x_{ij}, y_{ij}) : j = 1, \ldots, p_i\}$. Here, the individual subscript i is applied to x as well as to y to allow the possibility of different x values between individuals, and to p to allow the possibility of different numbers of measurements between individuals. In addition, the βs will also be enhanced with the subscript i: individuals tend to have different growth parameters. The linear model equation for the ith individual is then

$$Y_{ij} = \beta_{0i} + \beta_{1i} x_{ij} + \beta_{2i} {x_{ij}}^2 + \varepsilon_{ij}, \qquad (1)$$

or, in vector notation, $\mathbf{Y}_i = \mathbf{X}_i \beta_i + \varepsilon_i$.

To perform an analysis on the group as a whole, rather than on individuals separately, the individual

model equations are linked via the parameters β_i. In the simplest case, where the β_is are supposed to differ from one another only by random variation between individuals in a homogeneous population, they can be represented as $\beta + \mathbf{b}_i$, where the $\mathbf{b}_i$s are independent with mean $\mathbf{0}$ and covariance matrix $\mathbf{B}$. The model for $\mathbf{Y}_i$ becomes

$$\mathbf{Y}_i = \mathbf{X}_i\beta + \mathbf{X}_i\mathbf{b}_i + \varepsilon_i.$$

In the more general formulation of Laird & Ware [2], the design matrices multiplying β and $\mathbf{b}_i$ are allowed to differ: thus, the model becomes

$$\mathbf{Y}_i = \mathbf{X}_i\beta + \mathbf{Z}_i\mathbf{b}_i + \varepsilon_i. \tag{2}$$

Nonlinear Models

The elements of the rows of $\mathbf{X}_i$ determine the shape of the fitted curve for individual i. In the quadratic example, row j of $\mathbf{X}_i$ is $(1, x_{ij}, x_{ij}^2)$, the presence of x_{ij}^2 making the curve nonlinear. However, this is not the nonlinearity referred to in the title of this subsection. The general model so far considered is linear in the regression parameter β, whatever the shape of curve determined by the elements of $\mathbf{X}_i$. It is only when parameters occur nonlinearly in the equation that the model is said to be nonlinear.

As an example, consider an exponential regression curve $y = \beta_0 + \beta_1 \exp(-\gamma x)$. Here, the parameters β_0 and β_1 occur linearly, but the parameter γ does not. We assume here that the value of γ is unknown and to be estimated from the data, like β_0 and β_1. Otherwise, γ would just be a known constant and the model would be linear. In the case of timber slippage, there is a well-established empirical law, $y = \alpha[1 - \exp(-\gamma x)]$, of exponential form with the constraint $\beta_1 = -\beta_0 = \alpha$. The exponential regression model for individual i is

$$Y_{ij} = \beta_{0i} + \beta_{1i} \exp(-\gamma_i x_{ij}) + \varepsilon_{ij}, \tag{3}$$

ε_{ij} being the usual zero-mean error term. The (3) model is similar to that of (1), the β parameters appearing linearly, but now with the additional γ parameter appearing nonlinearly. In vector notation this is $\mathbf{Y}_i = \mathbf{X}_i(\gamma_i)\beta_i + \varepsilon_i$, where $\mathbf{X}_i(\gamma_i)$ is $p \times 2$ with jth row $[1, \exp(-\gamma_i x_{ij}]$: the design matrix $\mathbf{X}_i$ now depends on the γ parameter. The more general Laird–Ware form, corresponding to (2), has

$$\mathbf{Y}_i = \mathbf{X}_i(\gamma_i)\beta + \mathbf{Z}_i(\gamma_i)\mathbf{b}_i + \varepsilon_i; \tag{4}$$

here, $\mathbf{Y}_i$ is of length p_i, $i = 1, \ldots, n$, and the error vectors ε_i are taken to be independent with mean $\mathbf{0}$ and covariance matrices $\mathbf{E}_i(\tau)$.

Not all nonlinear models present themselves in the standard form given above. For instance, the Bleasdale–Nelder form $y = (\alpha_1 + \alpha_2 x^{\phi})^{-\kappa}$ ([1], Section 8.1) has no linear parameters. However, it can be reformulated as $\beta(1 + \alpha x^{\phi})^{-\kappa}$, where $\beta = \alpha_1^{-\kappa}$ and $\alpha = \alpha_2/\alpha_1$, which does have a linear parameter.

Nonlinear Parameter Homogeneous Over Individuals

The statistical analysis is much simpler when there is no variation in γ_i over individuals and we consider this case first. Such homogeneity of γ, and of τ in the covariance structure, is tenable when these parameters are somehow more fundamental than the $\mathbf{b}_i$s, i.e. more like constants of nature than the individually varying $\mathbf{b}_i$-characteristics. For instance, in the exponential curve, β_{0i} and β_{1i} are location and scale parameters, respectively, for the measurements on individual i, whereas γ determines the intrinsic shape of the regression curve. The general model, (4), can be written as

$$\mathbf{Y}_i = \mathbf{X}_i(\gamma)\beta + \mathbf{Z}_i(\gamma)\mathbf{b}_i + \varepsilon_i, \tag{5}$$

where now γ has lost its subscript i.

Suppose that the random coefficients $\mathbf{b}_i$ have mean $\mathbf{0}$ and covariance matrix $\mathbf{B}(\tau)$, and that the ε_i and $\mathbf{b}_i$ are all independent. Then the $\mathbf{Y}_i$ are independent $p_i \times 1$ vectors with means and covariance matrices given by

$$\begin{aligned} \mu_i = \mathrm{E}(\mathbf{Y}_i) &= \mathbf{X}_i(\gamma)\beta, \\ \Sigma_i = \mathrm{cov}(\mathbf{Y}_i) &= \mathbf{Z}_i(\gamma)\mathbf{B}(\tau)\mathbf{Z}_i(\gamma)' + \mathbf{E}_i(\tau). \end{aligned} \tag{6}$$

Nonlinear Parameter Randomly Varying Over Individuals

In many circumstances it is necessary to allow for random variation in all the parameters, e.g. when modeling biological data, in view of the large natural variation among living things. Unfortunately, however, allowing the γ_i to vary randomly over individuals introduces a higher level of difficulty.

Referring again to the general model, (4), to calculate μ_i and Σ_i the operations $\mathrm{E}(\cdot)$ and $\mathrm{var}(\cdot)$ must be taken over the joint distribution of $\mathbf{b}_i$ and γ_i now, not just that of $\mathbf{b}_i$ in (6). To evaluate these, some distributional specifications will have to be made for γ_i. This will depend on the context, i.e. on what kind of parameter γ is; for instance, if γ were a rate parameter in an exponential decay model, a distribution on $(0, \infty)$ would be appropriate. In most practical cases **numerical integration** will be needed to evaluate these expectations and covariances.

Normal Likelihood Theory

For the between-individuals model, which describes the distribution of parameters over the population of individuals, suppose that $(\mathbf{b}_i, \gamma_i)$ has a joint probability density $f_{b\gamma}(\mathbf{b}_i, \gamma_i)$. Then, denoting the conditional density of $\mathbf{Y}_i$ given the individual parameters by $f(\mathbf{y}_i|\mathbf{b}_i, \gamma_i)$, the likelihood is $\mathbf{\Pi} f(\mathbf{y}_i)$, where $f(\mathbf{y}_i)$ is the unconditional density of $\mathbf{Y}_i$ obtained by integration over $(\mathbf{b}_i, \gamma_i)$:

$$f(\mathbf{y}_i) = \int f(\mathbf{y}_i|\mathbf{b}_i, \gamma_i) f_{b\gamma}(\mathbf{b}_i, \gamma_i)\, \mathrm{d}\mathbf{b}_i\, \mathrm{d}\gamma_i.$$

The integral is usually intractable for realistic models.

A certain amount of simplification is possible in some cases. If the conditional distribution of $\mathbf{b}_i|\gamma_i$ is taken as normal, so is that of $\mathbf{Y}_i|\gamma_i$. Then the expression for $f(\mathbf{y}_i)$ can be reduced by integrating out $\mathbf{b}_i$:

$$\begin{aligned} f(\mathbf{y}_i) &= \int f(\mathbf{y}_i|\mathbf{b}_i, \gamma_i) f_{b|\gamma}(\mathbf{b}_i|\gamma_i) f_\gamma(\gamma_i)\, \mathrm{d}\mathbf{b}_i\, \mathrm{d}\gamma_i \\ &= \int f(\mathbf{y}_i|\gamma_i) f_\gamma(\gamma_i)\, \mathrm{d}\gamma_i; \end{aligned}$$

here $f(\mathbf{y}_i|\gamma_i)$ is the multivariate normal density with mean $\mathrm{E}(\mathbf{Y}_i|\gamma_i)$ and covariance matrix $\mathrm{cov}(\mathbf{Y}_i|\gamma_i)$, and $f_\gamma(\gamma_i)$ is the marginal density of γ_i in the $(\mathbf{b}_i, \gamma_i)$ distribution. This integral, over γ_i only, is of smaller dimension than the preceding one. If there were no between-individuals variation in γ_i, $f_\gamma(\gamma_i)$ would be concentrated at a single point, say γ, and then the integral would reduce to $f(\mathbf{y}_i|\gamma)$, the density of $\mathrm{N}(\mu_i, \Sigma_i)$ with μ_i and Σ_i given in (6). The assumption of conditional normality of $\mathbf{b}_i$ given γ_i is just a natural extension of the usual assumption of unconditional normality of $\mathbf{b}_i$ given a fixed γ.

In general, $\mathbf{Y}_i$ will not have a normal distribution, even though it is conditionally normal given γ_i. Once $f_\gamma(\gamma_i)$ has been specified, $f(\mathbf{y}_i)$ can be computed by numerical integration, and a likelihood function thus obtained for inference.

Mean Curves

Consider again the exponential model (3), and suppose that $(\beta_{0i}, \beta_{1i}, \gamma_i)$ has mean $(\beta_0, \beta_1, \gamma)$ over the population of individuals. The "mean curve", obtained by inserting these mean parameter values, has the same exponential form. However, the "curve of means", i.e. the curve resulting from taking the expectation of (3) over the joint distribution of $(\beta_{0i}, \beta_{1i}, \gamma_i)$, is not generally of this form. This is because γ_i occurs nonlinearly in the equation: the form of the curve, $\mathrm{E}(Y_{ij})$ vs. x_{ij}, is determined by the form of $\mathrm{E}[\beta_{1i} \exp(-\gamma_i x_{ij})]$.

The curve of means defines average y responses at given x values, whereas the mean curve exhibits the characteristics of individual trajectories such as turning points and asymptotes. In linear models, and more generally in cases where γ_i is homogeneous over individuals, the mean curve and the curve of means coincide.

Further Reading

The literature on nonlinear growth curves is wide and scattered, much of it concerned with numerical approximations to the awkward integrations mentioned above. Some representative works are listed, and further details and examples (including timber slippage) are given, in Hand & Crowder [1, Section 8.4].

Nonlinear Mixed Effects Models for Longitudinal Data

Experimental and observational studies in the medical, biological, and social sciences often result in data collected on specific *subjects* (or, in a more general sense, specific *experimental units*) that can be regarded as a sample drawn from the population of interest. When several observations are collected on each subject, the data are described as *repeated measures*. If the multiple measurements are indexed by the time of the observation, we say they are **longitudinal data**.

In the analysis of such data, we often must account for the variation between the subjects but, in doing so, we are not interested in the change in the response associated with specific subjects as much as we are interested in estimating the overall variation in the response within the population that can be attributed to subject-to-subject differences. *Mixed-effects models* are a flexible and powerful class of statistical models for use with longitudinal data and other types of repeated measures. These models incorporate both **fixed effects**, which we will write as $\boldsymbol{\beta}$, a vector of length p representing parameters associated with the entire population or with certain repeatable levels of experimental factors, and **random effects**, which we will write as $\mathbf{b}_i, i = 1, \ldots, m$, a collection of m vectors of length q that model the variation associated due to subject i in the observed collection of m subjects.

A fundamental difference between the fixed effects, $\boldsymbol{\beta}$, and the random effects, $\mathbf{b}_i$, is that the components of $\boldsymbol{\beta}$ are parameters in the statistical model but the components of $\mathbf{b}_i$ are not. The statistical model incorporates parameters that determine the *distribution* of the random effects. Sometimes these parameters can be expressed as **variance components** in the overall model.

Linear Mixed-effects Models

Laird and Ware [6] formulated a linear mixed-effects model for univariate repeated measures data as

$$\mathbf{y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\mathbf{b}_i + \boldsymbol{\varepsilon}_i, \quad \mathbf{b}_i \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}),$$
$$\boldsymbol{\varepsilon}_i \sim \mathcal{N}(\mathbf{0}, \sigma^2\mathbf{I}), \quad i = 1, \ldots, m,$$
$$\boldsymbol{\varepsilon}_i \perp \boldsymbol{\varepsilon}_j, \quad \mathbf{b}_i \perp \mathbf{b}_j, \quad i \neq j \quad \boldsymbol{\varepsilon}_i \perp \mathbf{b}_j, \quad \forall\, i, j, \tag{1}$$

where $\mathbf{y}_i$ is the vector of length n_i of responses for subject i; $\mathbf{X}_i$ is the $n_i \times p$ model **matrix** for subject i with respect to $\boldsymbol{\beta}$; and $\mathbf{Z}_i$ is the $n_i \times q$ model matrix for subject i and the random effects $\mathbf{b}_i$. The symbol $\perp$ indicates independence of random variables. The columns of the model matrices $\mathbf{X}_i$ and $\mathbf{Z}_i$ are based on any **covariates** that are observed along with the response for subject i.

The data shown in Figure 1 and described in [9, Appendix A.19]. are an example of **growth** *curve* data for which a **linear mixed-effects model** could be appropriate. Here the response is the height and the only covariate measured is the (scaled and centered) age of the boy at each observation. Each boy's height was measured nine times over a fixed range of age but the specific ages of the measurements vary from boy to boy.

In applying model (1) to these data, we may choose just an intercept and an age term for the fixed effects, the model matrix $\mathbf{X}_i$, in which case $\boldsymbol{\beta}$ would be of length 2, or we could use a quadratic model with an intercept, a column of age and a column of age^2 for which $\boldsymbol{\beta}$ would have length 3. The random effects model matrix could be a single column for the intercept, representing a random additive shift in height for each subject, or could have the intercept column and an age column, representing a random shift in the intercept and a random shift in the growth rate.

Nonlinear Mixed-effects Models

Although the linear mixed-effects model (1) is a versatile model, it does not encompass all of the mixed-effects models that are used in biostatistics. In some fields, the experimenters will have externally determined models of the mechanism determining the response as a function of the covariates. For example, it is common in **pharmacokinetics** to use **compartment models** [1, Chapter 5] to predict the subject's serum concentration of a drug as a function of the time since administration of the drug.

The data shown in Figure 2 and described in [9, Appendix A.29] are typical longitudinal data from

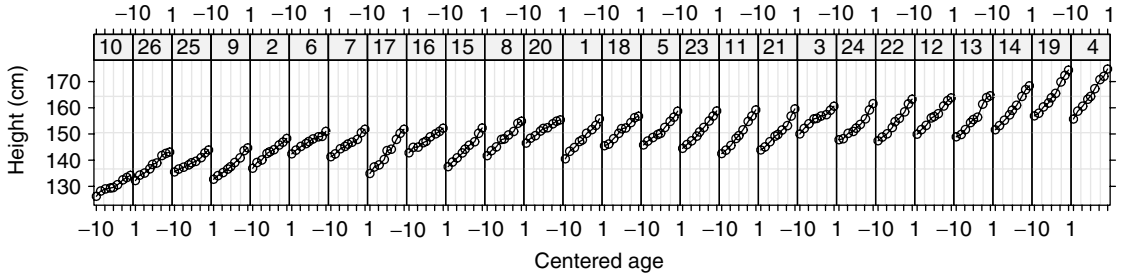

Figure 1 Heights (cm.) of a sample of 26 boys from Oxford, England versus their scaled, centered age

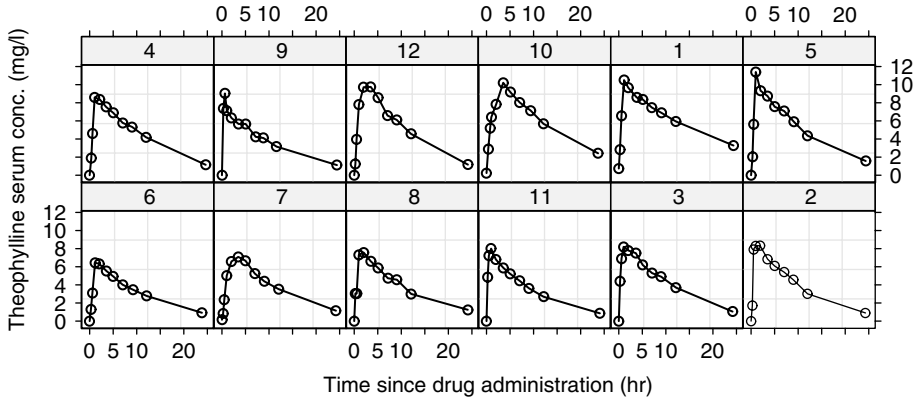

Figure 2 Serum concentration of theophylline (mg/l) versus time since administration of an oral dose of the drug. Each panel shows the concentration profile for one subject

a clinical pharmacokinetic study. The concentration profile for a single subject could be modeled as

$$c_t = \frac{Dk_e k_a}{Cl\,(k_a - k_e)}\left[\exp(-k_e t) - \exp(-k_a t)\right]. \quad (2)$$

where c_t is theophylline concentration in the serum at time t after an initial oral dose of D. The parameters in the model are the *elimination* rate constant k_e, the *absorption* rate constant k_a, and the *clearance* Cl.

The concentration profile (2) reflects many of the properties that we would expect in such data, such as $c_0 = 0$, a predicted concentration of zero at time zero, and $\lim_{t\to\infty} c_t = 0$, complete elimination of the drug after a long period of time.

All three of the parameters k_e, k_a, and Cl occur nonlinearly in (2). The desire to incorporate fixed effects and random effects in a population model based on nonlinear models for pharmacokinetic data motivated early formulations and development of nonlinear mixed-effects models [10]. One form [7] of the statistical model for the jth observation on the ith subject is

$$y_{ij} = f(\boldsymbol{\phi}_{ij}, \mathbf{x}_{ij}) + \varepsilon_{ij}, \quad i = 1, \ldots, m, \quad j = 1, \ldots, n_i, \quad (3)$$

where the underlying model function f depends on a subject-specific parameter, $\boldsymbol{\phi}_{ij}$ and the values of covariates $\mathbf{x}_{ij}$ and is nonlinear in at least one component of $\boldsymbol{\phi}_{ij}$. The random effects and the fixed effects determine the subject-specific parameter through model matrices $\mathbf{A}_{ij}$ and $\mathbf{B}_{ij}$ of suitable dimension as

$$\boldsymbol{\phi}_{ij} = \mathbf{A}_{ij}\boldsymbol{\beta} + \mathbf{B}_{ij}\mathbf{b}_i, \quad i = 1, \ldots, m, \quad j = 1, \ldots, n_i. \quad (4)$$

Using the vector function $\mathbf{f}_i$ with components $\{\mathbf{f}_i(\boldsymbol{\beta}, \mathbf{b}_i)\}_j = f(\boldsymbol{\phi}_{ij}, \mathbf{x}_{ij})$, we can write model as

$$\begin{aligned} &\mathbf{y}_i = \mathbf{f}_i(\boldsymbol{\beta}, \mathbf{b}_i) + \boldsymbol{\varepsilon}_i, \quad \mathbf{b}_i \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}), \\ &\boldsymbol{\varepsilon}_i \sim \mathcal{N}(\mathbf{0}, \sigma^2\mathbf{I}), \quad i = 1, \ldots, m \\ &\boldsymbol{\varepsilon}_i \perp \boldsymbol{\varepsilon}_j, \quad \mathbf{b}_i \perp \mathbf{b}_j, \quad i \neq j \quad \boldsymbol{\varepsilon}_i \perp \mathbf{b}_j, \quad \forall\, i, j. \end{aligned} \tag{5}$$

As in the linear mixed-effects model (1), the fixed effects $\boldsymbol{\beta}$ are common to the entire population and the random effects $\mathbf{b}_i$ are specific to the subject. In this model, the parameter vector for the underlying nonlinear model, $\boldsymbol{\phi}_{ij}$, can depend on both the subject and the observation because the model matrices $\mathbf{A}_{ij}$ and $\mathbf{B}_{ij}$ can depend on the observation j. This allows the model to incorporate **time-dependent covariates**.

The use of the matrices $\mathbf{A}_{ij}$ and $\mathbf{B}_{ij}$ may be confusing. To make this more concrete, let us consider a specific model [9, §8.2] for the theophylline data. The parameters Cl, k_e, and k_a, in (2) must be positive for the model to be physically meaningful so we reexpress (2) in terms of the logarithms of these parameters.

$$\begin{aligned} c_t = \frac{D \exp(lKe + lKa - lCl)}{\exp(lKa) - \exp(lKe)} &\left\{\exp\left[-\exp(lKe)\, t\right]\right. \\ &\left. - \exp\left[-\exp(lKa)\, t\right]\right\}, \end{aligned} \tag{6}$$

where $lCl = \log(Cl)$, $lKe = \log(k_e)$ and $lKa = \log(k_a)$. The subject-specific parameter is $\boldsymbol{\phi}_{ij} = \boldsymbol{\phi}_i = (lCl, lKe, lKa)'$ and the covariate vector for the jth observation on the ith subject is $\mathbf{x}_{ij} = \left(D_i, t_{ij}\right)'$, representing the dose given to subject i and the time of the jth concentration measurement for subject i.

As shown in [9, Section 8.2], a reasonable nonlinear mixed-effects model for these data can be formulated with $\boldsymbol{\beta}$ having the same components as $\boldsymbol{\phi}_i$ and with random effects only for lCl and lKe. That is, $\boldsymbol{\phi}_i$ has length 3 as does $\boldsymbol{\beta}$ while $\mathbf{b}_i$ has length 2. The matrices $\mathbf{A}_{ij} = \mathbf{I}_3$, the 3×3 identity matrix, and $\mathbf{B}_{ij}$, which is the first two columns of $\mathbf{I}_3$, do not change with i or j.

It is possible to use a more general form of the dependence of $\boldsymbol{\phi}_{ij}$ on $\boldsymbol{\beta}$ and $\mathbf{b}_i$ [4, Section 4.2] but the ability to reparameterize the nonlinear model $f(\boldsymbol{\phi}_{ij}, \mathbf{x}_{ij})$ in another set of parameters $\mathbf{g}(\boldsymbol{\phi})$ allows other forms of dependence on $\boldsymbol{\beta}$ and $\mathbf{b}_i$ to be rewritten as (4).

Estimation of Parameters

The parameters in the nonlinear mixed-effects model (5) are $\boldsymbol{\beta}$, the fixed effects, σ^2, the variance of the within-subject random variation, and $\boldsymbol{\theta}$, some set of parameters that determine $\boldsymbol{\Sigma}$, the variance–covariance matrix of the random effects or, equivalently, the set of parameters that determine the relative variance–covariance Σ/σ^2. Although many estimation criteria for these parameters have been proposed [4], the most common is **maximum likelihood**.

To evaluate the **likelihood** function, we must determine the **marginal** density of the $n = \sum_{i=1}^{m} n_i$-dimensional response $\mathbf{y}$ from the model (5)

$$\begin{aligned} L(\boldsymbol{\beta}, \boldsymbol{\theta}, \sigma^2|\mathbf{y}) &= \prod_{i=1}^{M} p(\mathbf{y}_i|\boldsymbol{\beta}, \boldsymbol{\theta}, \sigma^2) \\ &= \prod_{i=1}^{M} \int p(\mathbf{y}_i|\mathbf{b}_i, \boldsymbol{\beta}, \sigma^2)\, p(\mathbf{b}_i|\boldsymbol{\theta}, \sigma^2)\, \mathrm{d}\mathbf{b}_i. \end{aligned} \tag{7}$$

In theory, it is straightforward to define the maximum likelihood estimators $\hat{\boldsymbol{\beta}}$, $\widehat{\sigma^2}$, and $\hat{\boldsymbol{\theta}}$ as the values that optimize (7). In practice, evaluation of the integral in (7) and **optimization** of the resulting likelihood or log-likelihood function is difficult. Software for estimating the parameters in a nonlinear mixed-effects model uses approximations to the integral in (7) or to the likelihood function itself. The nlme package for **S-PLUS** and for **R** [5] uses an approximation to the log-likelihood based on conditional estimates $\hat{\boldsymbol{\beta}}(\boldsymbol{\theta})$ and conditional modes $\hat{\mathbf{b}}_i(\boldsymbol{\theta})$ obtained from a penalized nonlinear **least squares** problem [9, 7] (*see* **Penalized Maximum Likelihood**). PROC NMIXED in SAS uses adaptive Gaussian quadrature [8], which also is based on the conditional modes $\hat{\mathbf{b}}_i(\boldsymbol{\theta})$ of the random effects. The NONMEM program [2, 3] which is widely used in pharmacokinetics, can use different approximations to the log-likelihood including a first-order Taylor expansion of the model function around $\mathbf{0}$, the expected value of the random effects vector $\mathbf{b}$.

This is but a brief introduction to the formulation of nonlinear mixed-effects models and to methods of estimating the parameters in such models. There are, naturally, many other aspects of these models that we

have not discussed but are covered in references such as [4, 9].

Nonlinear Regression

One of the most common situations in statistical analysis is that of data which consist of observed responses Y_i thought to be related to corresponding k-dimensional inputs $\mathbf{x}_i = (x_{i_1}, \ldots, x_{i_k})'$. Nonlinear regression is used when this situation may be represented by the regression equation

$$Y_i = f(\mathbf{x}_i, \boldsymbol{\theta}) + \varepsilon_i, \quad i = 1, \ldots, n, \tag{1}$$

where the form of the **expectation** function f is entirely known except for the parameter vector $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_p)'$ and f is a nonlinear function of $\boldsymbol{\theta}$. In this model, the random variable Y_i, often called the response or dependent variable, represents the response for case i and the variable $\mathbf{x}_i$, usually called the explanatory (*see* **Explanatory Variables**) or independent variable, may represent an experimental setting or predetermined conditions associated with the ith response. A wide variety of assumptions concerning the error terms $\{\varepsilon_i\}$ are possible, but the most frequent one is that they are independent and identically distributed (iid) normal random variables.

Linearity or nonlinearity of a model depends on how the parameters occur in the expectation function, but not on how the explanatory variables do, and a nonlinear regression model is one in which at least one of its parameters appears nonlinearly. For example,

$$f(\mathbf{x}, \boldsymbol{\theta}) = \theta_1 + \theta_2 x_1 + \theta_3 x_2^2 + \theta_4 x_1 x_2$$

is a linear model as the expression is linear in the parameters, whereas

$$f(\mathbf{x}, \boldsymbol{\theta}) = \theta_1 \exp(\theta_2 x) \tag{2}$$

is a nonlinear model, being nonlinear in θ_2. More formally, *nonlinear* means that at least one of the derivatives of the expectation function f with respect to the parameters is a nontrivial function of at least one of those parameters.

Some nonlinear models can be transformed to a linear one by taking a suitable transformation (*see* **Transformations**) of the data. For example, in the model in (2) we can take a log transformation of the response variable, $Y_i^* = \log Y_i$, and setting $\theta_1^* = \log \theta_1$, $\theta_2^* = \theta_2$, we obtain a new expectation function

$$f^*(\mathbf{x}, \boldsymbol{\theta}^*) = \theta_1^* + \theta_2^* x.$$

This model is now linear in its unknown parameters θ_1^* and θ_2^* and therefore we could estimate these parameters using linear regression (*see* **Linear Regression, Simple**) of the logarithm of the data on the explanatory variable $\mathbf{x}_i$. However, assuming that the error in Y_i is additive, the model for Y_i^* is

$$\begin{aligned} Y_i^* &= \theta_1^* + \theta_2^* x_i + \log\left[1 + \frac{\varepsilon_i}{f(\mathbf{x}_i, \boldsymbol{\theta})}\right] \\ &= \theta_1^* + \theta_2^* x_i + \varepsilon_i^*, \end{aligned}$$

and now the variance of the error becomes dependent on x_i through the expectation function $f(\mathbf{x}_i, \boldsymbol{\theta})$. Thus, transforming the data results in a transformation of both the expectation function and the disturbance term, and so the usual assumption of constant variance and normality required for simple linear regression may no longer be valid. This may lead to serious deficiencies in the estimates of $\boldsymbol{\theta}^*$ and hence of $\boldsymbol{\theta}$. The decision whether or not to make a linearizing transformation depends very much on the nature of the errors, and linearization should only be used when the transformed data are adequately described by a model with an additive normal error.

Another type of transformation of a model is a parameter transformation where the parameters of the new model are related to the parameters of the old one by an expression which involves parameters only and not the explanatory variables $\mathbf{x}_i$. For example, consider the following models:

$$Y_i = \theta_1 \frac{x_i}{x_i + \theta_2} + \varepsilon_i$$

and

$$Y_i = \frac{x_i}{\theta_1^* x_i + \theta_2^*} + \varepsilon_i.$$

If we define $\theta_1^* = 1/\theta_1$ and $\theta_2^* = \theta_2/\theta_1$, then the two models (parameterizations) produce identical values of Y_i for the same value of x_i. However, the statistical properties of estimators in one of these models may be much better than in the other, in the sense that the former may have properties closely approaching those of estimators in linear regression models. This is an important feature of nonlinear regression and we give more details regarding this problem in the final section.

If the joint distribution of $\{\varepsilon_i\}$ in the model in (1) is assumed known, then the parameter $\boldsymbol{\theta}$ can be estimated through the use of the **maximum likelihood** method. Under the assumption that the $\{\varepsilon_i\}$

are iid normal random variables with a constant but unknown variance σ^2, the maximum likelihood estimates of $\boldsymbol{\theta}$ are the **least squares** values, which, by definition, minimize the sum of squares

$$S(\boldsymbol{\theta}) = \sum_{i=1}^{n} [Y_i - f(\mathbf{x}_i, \boldsymbol{\theta})]^2$$

over all possible values of $\boldsymbol{\theta}$. Other methods of estimation include a weighted least squares method which allows for variance heterogeneity in the model, robust estimation (*see* **Robust Regression**), which may be considered as an alternative to the least squares method if **outliers** are present in data, and *quasi-likelihood* estimation which does not require the distribution of ε_i to be known explicitly, except for its first two moments. These methods and others, including Bayes estimation (*see* **Bayesian Methods**), are discussed by Bates & Watts [4] and Seber & Wild [18]. In what follows we discuss mainly the least squares method assuming the validity of the assumption of iid normal error.

In contrast to linear models, in nonlinear regression it is not possible to write down an explicit expression for the least squares estimators of the parameters. In addition, the least squares estimators in this case have essentially unknown properties for finite sample sizes. In particular, they are usually neither unbiased, normally distributed, nor *minimum variance estimators* as are those in linear models. The estimators achieve these properties only asymptotically as the sample sizes approach infinity (*see* [11] and **Large-Sample Theory** for a detailed development of asymptotic theory). It is not possible, in general, to present any guidelines as to how large the sample size must be for these asymptotic properties to be closely approximated.

This difference between estimators in linear and nonlinear models should be remembered, since in practice inference regions for nonlinear models are often approximated using linear models. A number of measures and procedures have been developed for studying the behavior of the estimators in nonlinear cases and they provide information on the adequacy of linear approximation inference regions and indicate situations where by changing the parameters a nonlinear model behaves more like a linear model. A brief description of some measures of nonlinearity is given in the final section.

Examples of Applications

An important step in nonlinear regression is the specification of the model, including both the expectation function and the characteristics of the disturbance (*see* **Model, Choice of**). Frequently the expectation function is tentatively suggested by theoretical investigations and the analyst's job is then to find the simplest form of the model and the parameter estimates which provide an adequate fit of the model to the data, subject to the assumptions about the disturbance. However, in many situations, particularly in the biological sciences, the underlying processes are complex and no physically meaningful models for the expectation functions may be advanced. In such cases, the statistician may suggest a model which has the same sort of behavior as the data. In this search, particularly helpful may be the literature, such as the handbook by Ratkowsky [16], which examines commonly used nonlinear regression models.

Nonlinear regression has been applied to a wide range of situations and we now give a selection of examples.

Example 1

Processes producing sigmoidal growth curves are widespread in many fields of study. In medicine, for example, we may be interested in the normal growth of infants (*see* **Growth and Development**) or the growth of a tumor, and the effect of treatments upon such growth. It is usually assumed that the theoretical growth curve belongs to a known parametric family of curves which start at some fixed point and increase their growth rate monotonically to reach an inflection point; after this the growth rate decreases to approach asymptotically some final value. A number of functions have been proposed for modeling such curves (e.g. [18, Chapter 7]), many of which are claimed to have some underlying theoretical basis. In most cases, however, the approach to the analysis of growth data is purely empirical and involves fitting a parametric family of curves to the data. Two examples of growth curves are the Gompertz function

$$f(x, \boldsymbol{\theta}) = \theta_1 \exp[-\exp(\theta_2 - \theta_3 x)]$$

and the logistic function

$$f(x, \boldsymbol{\theta}) = \frac{\theta_1}{1 + \exp(\theta_2 - \theta_3)x}.$$

Usually, the variable x represents time, but similar models occur also in situations when the explanatory variable is an increasing intensity of some other factor, such as the amount of nutrients in a diet and its effect on weight gain.

Example 2

Biological assay (bioassay) is a method for estimating the potency of a drug or material by the study of the reaction caused by its use on experimental subjects. In an indirect assay specified doses are each given to a set of experimental units and the resulting responses are recorded. For quantitative responses the assay can then be analyzed by fitting a nonlinear dose–response regression model to the data. Various functions having different characteristics have been proposed to fit dose–response curves of a generally sigmoidal shape. For example, in radioligand assays (*see* **Radioimmunoassay**), in which potency estimation involves the relation between counts of radioactivity and dose, many researchers have found the regression function to be satisfactorily represented by the four-parameter logistic model (e.g. [10]), which can be written as

$$f(x, \boldsymbol{\theta}) = \theta_1 + \frac{\theta_2}{1 + \exp(\theta_3 - \theta_4 x)},$$

where x is the logarithm of the dose. This representation is only one of many possible parameterizations and, although different parameterizations give the same predicted value of the response for a specified dose, from a statistical perspective they are not all equivalent [17].

Example 3

The forced expiratory volume Y, a measure of how much air a subject can breathe, is widely used epidemiologically for screening against chronic respiratory disease. Cole [7] discusses a nonlinear model relating Y to height ($x_{i,1}$) and age ($x_{i,2}$) of the form

$$Y_i = x_{i,1}^{\theta_1}(\theta_2 + \theta_3 x_{i,2}) + \varepsilon_i.$$

This model appears to be equally suitable for predicting maximum oxygen uptake which is the best-known measure of an individual's capacity to deliver oxygen to, and to use oxygen in, exercising muscle [14]. In this case $x_{i,1}$ denotes the body weight.

Example 4

It is not necessary for the expectation function to be an explicit function of the parameters and the explanatory variables. For example, in an important class of models, known as compartment models, the expected response is given by the solution to a set of linear differential equations. These models are commonly used in **pharmacokinetics**, where the exchange of materials in biological systems is studied. To estimate the parameters in such models several methods can be used. In some cases it is possible to obtain an analytic solution to the system of differential equations and then use the expectation function, corresponding to the compartment for which data are available, in a standard nonlinear estimation program. However, special techniques have been developed which allow one to avoid solving explicitly for the expectation function and its derivatives [5, 13].

In other situations, the expectation function may be the solution to a nonlinear differential equation or a partial differential equation which has no analytic solution. Then the values of the expectation functions must be determined numerically for any given parameter values. In such situations numerical derivatives or derivative-free *optimization* procedures often have to be used to calculate the least squares estimates. Dalgaard & Larsen [8], for example, proposed an **algorithm** for the analysis of data obtained by vitreous fluorophotometry, a method in clinical eye research. The model involves the *diffusion* equation, and the parameters are the diffusion coefficient in the vitreous body of the eye and the permeability of the blood–retinal barrier.

Calculating Parameter Estimates

Most of the methods of estimation in nonlinear regression require an estimator obtained by maximizing or minimizing some objective function of $\boldsymbol{\theta}$, like $S(\boldsymbol{\theta})$ for the least squares estimator. Since these optimization problems can seldom be solved analytically, the optimal value of $\boldsymbol{\theta}$ must be in most cases located by iterative techniques using a computer. One option is to use standard nonlinear optimization algorithms such as modifications of the Newton method or conjugate gradient method, which are widely available in a number of numerical libraries (see, for example, [12] and [18, Chapter 15]). However, when choosing an

algorithm, some understanding of how it works and its limitations may be necessary. Another option is to use specialized software which exploits the particular structure of a nonlinear problem. For least squares, most such methods are based on the Gauss–Newton algorithm, which we now briefly describe.

For a given data set, the values of $\mathbf{x}_i$ are fixed, and as we vary $\boldsymbol{\theta}$ through all possible values, the expectation vectors

$$\begin{aligned}\mathbf{f}(\boldsymbol{\theta}) &:= (f_1(\boldsymbol{\theta}), \ldots, f_n(\boldsymbol{\theta}))' \\ &:= (f(\mathbf{x}_1, \boldsymbol{\theta}), \ldots, f(\mathbf{x}_n, \boldsymbol{\theta}))'\end{aligned}$$

generate a surface in R^n, called the *expectation surface*. The Gauss–Newton algorithm uses a linear approximation to this surface as follows:

1. Near an initial point $f(\boldsymbol{\theta}^{(0)})$ the expectation surface is approximated by its tangent plane.
2. The observation vector $\mathbf{y}$ is projected onto the tangent plane by linear regression to obtain a new parameter vector $\boldsymbol{\theta}^{(1)}$.
3. The tangent plane is calculated at $f(\boldsymbol{\theta}^{(1)})$ and the procedure is continued until either convergence or abnormal termination.

Formally the process can be justified using a Taylor series expansion. Suppose that $\boldsymbol{\theta}^{(0)}$ is an approximation to the least squares estimate $\hat{\boldsymbol{\theta}}$. For $\boldsymbol{\theta}$ close to $\boldsymbol{\theta}^{(0)}$ we have the linear Taylor expansion:

$$f_i(\boldsymbol{\theta}) \approx f_i(\boldsymbol{\theta}^{(0)}) + \sum_{s=1}^{p} \frac{\partial f_i}{\partial \theta_s}(\boldsymbol{\theta}^{(0)})(\theta_s - \theta_s^{(0)}),$$
$$i = 1, \ldots, n,$$

or

$$\mathbf{f}(\boldsymbol{\theta}) \approx \mathbf{f}(\boldsymbol{\theta}^{(0)}) + \mathbf{V}_0(\boldsymbol{\theta} - \boldsymbol{\theta}^{(0)}), \tag{3}$$

where $\mathbf{V}_0 = \mathbf{V}(\boldsymbol{\theta}^{(0)}) = [\partial f_i(\boldsymbol{\theta}^{(0)})/\partial \theta_s]$ is the derivative matrix evaluated at $\boldsymbol{\theta}^{(0)}$. With approximation (3) the original model can be rewritten as follows:

$$\mathbf{Y} - \mathbf{f}(\boldsymbol{\theta}^{(0)}) \approx \mathbf{V}_0\boldsymbol{\beta} + \boldsymbol{\varepsilon},$$

where $\boldsymbol{\beta} = \boldsymbol{\theta} - \boldsymbol{\theta}^{(0)}$ and $\boldsymbol{\varepsilon} = (\varepsilon_1, \ldots, \varepsilon_n)'$. Since this approximation is linear in the parameter $\boldsymbol{\beta}$, we can use linear regression to obtain the least squares estimate of $\boldsymbol{\beta}$:

$$\hat{\boldsymbol{\beta}}^{(0)} = (\mathbf{V}_0'\mathbf{V}_0)^{-1}\mathbf{V}_0'\mathbf{r}^{(0)},$$

where $\mathbf{r}^{(0)} = \mathbf{y} - \mathbf{f}(\boldsymbol{\theta}^{(0)})$ is the residual vector at $\boldsymbol{\theta}^{(0)}$. This suggests that for a given current approximation $\boldsymbol{\theta}^{(0)}$, the next approximation should be

$$\boldsymbol{\theta}^{(1)} = \boldsymbol{\theta}^{(0)} + \hat{\boldsymbol{\beta}}^{(0)}. \tag{4}$$

This provides an iterative scheme for obtaining $\hat{\boldsymbol{\theta}}$ and usually is referred to as the Gauss–Newton method. If the starting value $\boldsymbol{\theta}^{(0)}$ is sufficiently close to a local minimum $\hat{\boldsymbol{\theta}}$, the algorithm will converge. The unmodified algorithm, however, is rarely used in practice. To deal primarily with ill-conditioning of the derivative matrix $\mathbf{V}$, which may cause, for example, the sum of squared residuals at $\boldsymbol{\theta}^{(i+1)}$ to be greater than $\boldsymbol{\theta}^{(i)}$ on the ith iteration, and to avoid having to code and specify the derivatives, modifications to this method, as well as alternative methods, have been suggested. The most common of these modifications are the Hartley and Levenberg–Marquardt algorithms. Another modification, described in [4], forms the basis of the algorithm implemented in S-PLUS (*see* **S-PLUS and S**). When the residuals for the fitted model are large, the above algorithms may converge very slowly or even fail. In such situations two alternative methods can be used: the NL2SOL algorithm and the algorithm due to Gill and Murray (see [18, Chapter 14] for details about these and other methods).

Optimization programs require specification of convergence criteria and initial parameter estimates $\boldsymbol{\theta}^{(0)}$. Obtaining good starting values is essential to guarantee convergence, and many methods for determining them have been proposed (e.g. [15] and [4]). Convergence criteria are often based on the relative change in $S(\boldsymbol{\theta})$ from one iteration to the next or on the relative change in the components of $\boldsymbol{\theta}$. Although they are usually reliable, they are not unambiguous and criteria using different rules have also been proposed [2]. In practice, the concurrent use of several criteria is often recommended.

Confidence Regions and Effects of Nonlinearity

Several methods for determining confidence regions for the parameter $\boldsymbol{\theta}$ (*see* **Estimation**) have been proposed. These include an exact method, usually referred to as the lack-of-fit method, the **likelihood** confidence regions, and linearization confidence

regions (e.g. [11] and [9]). Only the first method gives exact confidence regions, but it is computationally the most difficult. Likelihood regions are generally easier to calculate but are still computationally tedious compared with the linearization method, which is the most commonly used. In this method confidence regions and confidence intervals are obtained using the method of linear regression with the estimated variance–covariance matrix approximated by $(\hat{\mathbf{V}}'\hat{\mathbf{V}})^{-1}s^2$, where $\hat{\mathbf{V}}$ is the derivative matrix calculated at $\hat{\boldsymbol{\theta}}$ and s^2 is the estimate of the residual variance. Unlike the exact and likelihood regions, the linearization region is always ellipsoidal. However, the extent to which such a region approximates the exact region depends on the extent of nonlinearity of the model, and in some cases the discrepancies may be very large.

To provide information on the adequacy of the linear approximation, Beale [6] and Bates & Watts [1, 3, 4] have developed a number of measures of nonlinearity using a geometric approach. For nonlinear models the expectation surface is curved, and this is in marked contrast to the linear models where the expectation surface is always planar. This nonplanarity has been called the *intrinsic nonlinearity*. The term *intrinsic* is suitable, as this nonlinearity becomes determined the moment a model/data set combination has been defined, and it cannot be altered by reparameterization.

The other way in which linear and nonlinear models differ involves the position on the expectation surface of the values having equal increments in $\boldsymbol{\theta}$. For a linear model, points $f(\boldsymbol{\theta})$ representing constant values of $\boldsymbol{\theta}$ are straight, parallel and equally spaced for equal increments of $\boldsymbol{\theta}$, which in general is not true for nonlinear regression models. This nonuniformity of the spacing defines the second component of nonlinearity, termed *parametric effects nonlinearity*. This component depends on how parameters occur in the expectation function and it can be changed by reparameterization.

To quantify the extent of the two components of nonlinearity, Bates & Watts derived curvature measures based on second-order derivatives of the expectation function. As found by these authors, and in subsequent studies, the intrinsic nonlinearity is typically small for most models of practical interest. In contrast, the parametric curvature is usually large enough to affect linear approximation inference regions. However, a large parametric curvature can often be substantially reduced by finding an appropriate reparameterization. At present little guidance is available as to the choice of a reparameterization, although occasionally certain transformations are recommended from practical experience or are suggested by the model itself (e.g. [15–17] for the four-parametric logistic model).

For detailed information about measures of curvature and nonlinearity and their applications in assessing the appropriateness of linear approximations, see [4] and [18].

ADAM W. KOLKIEWICZ

Nonlinear Time Series Analysis

Nonlinear time series analysis is currently a most active area of research in **time series** and dynamical systems literature. This is partly because of the enormous interest in nonlinear dynamical systems, including **chaos**, since the early 1970s. A number of recent textbooks on time series analysis have included some coverage of this important area; see, for example [3] and [5]. For a wider and more in-depth coverage, we refer to [9, 16] and [19]. These cover roughly the work up to the early 1990s. For more recent surveys, we refer to [18] and [20].

Nowadays, the term "nonlinear time series" is used in both the statistical and the dynamical systems literature. Although there is much common ground, the emphases are different, with the former focusing on the randomness generated by a stochastic system/model and the latter on the randomness generated by a purely deterministic system/model. In this article, we shall concentrate on the former, although passing references will be made to the latter where appropriate.

To date, biostatistical applications using the statistical analysis of nonlinear time series include epidemiology (e.g. [21] and [22]) and physiology (e.g. [19]) and others. For similar applications, but using the dynamical systems approach, see, for example [6, 10, 12, 13] and [21].

Why Nonlinearity?

At the simplest level, linearity may be exemplified by the doubling of the deflection of the indicator of the balance if we place two copies of this article instead of one on the balance. Departure from this doubling is often associated with nonlinearity. In fact, it is obvious that we do not expect the balance to keep doubling the deflection of its indicator every time we double the number of copies on it. This simple example illustrates a fundamental fact: in reality, *linearity cannot hold in the large (or globally) although it may hold in the small (or locally)*. For a deeper discussion of the notion of nonlinearity in the context of time series analysis, we refer to, for example, [1, 16], and [19].

In time series analysis, linear methodology culminates in the classic family of autoregressive moving average models (*see* **ARMA and ARIMA Models**) including the vector cases, e.g. [2] and [11]. However, there are many observable phenomena that cannot be explained properly if we restrict ourselves to linear systems/models. The above, rather simple, example of a balance is, in fact, an example of the so-called saturation effect, in that the indicator has only a finite range of deflection. The saturation effect is common to many real systems, since almost all real systems have finite capacity/energy only.

Cycles are another often-observed phenomenon in many time series and these may be due to the bifurcation of a single global linear dynamics into multiple local dynamics. For example, Watier & Richardson [22] have studied the cycles observed in the monthly notifications of *Salmonella typhimurium* in France from January 1978 to December 1988. They have suggested that the increase in the prevalence of some phage types from the cold period to the warm period could alter the epidemiological system from one approximately linear dynamics to another and they have modeled the switching by reference to the notification of seven months previously. They have used the fitted nonlinear time series model (specifically a self-exciting threshold autoregressive model, whose form will be given in the next section) to explain the cycles by showing that, in the absence of the background noise that is modeled as a sequence of independent identically distributed random variables, the nonlinear dynamics of the fitted model generate cycles that bear some resemblance to the observed cycles. As a digression, the Watier–Richardson example also shows a possible intimate connection between nonlinearity (e.g. different dynamics corresponding to different states of the phage types) and nonstationarity (e.g. different dynamics corresponding to different seasons), in some cases (*see* **Stationarity**). We can sometimes put both notions, at least formally, on the same footing by treating time as a covariate/state variable as well.

Returning to our discussion, there are other observable phenomena that can only be explained properly by reference to nonlinear dynamics. These include chaos, synchronization (i.e. how the

frequency of oscillations of a system can get locked into that of an external oscillator), jump phenomenon (i.e. how the amplitude of oscillations of the output signal of a system is affected when we alter the frequency of the input signal), and others; e.g. [19].

Various Approaches to Nonlinear Time Series Modeling

Parametric

There are essentially two major approaches to nonlinear time series modeling in statistical literature; namely, the parametric approach and the nonparametric approach. In the former, several classes were proposed in the late 1970s and the early 1980s. These included the threshold autoregressive models (TAR), the autoregressive models with conditional heteroscedasticity (ARCH), bilinear models (BL), the nonlinear moving average models (NLMA), the polynomial autoregressive models, random coefficient autoregressive models (RAC), and others. Tong [19] has given a fairly comprehensive list of these various parametric models, together with some of their probabilistic structure and statistical estimation. Granger & Terasvïrta [9] and Priestley [16] are also relevant whilst Engle & McFadden [7], Nicholls & Quinn [15] and Rao & Gabr [17] give more details on specific models.

Given the vast number of parametric families of models, it would be impossible to survey them properly in this article. However, in order to give the readers some general flavor, we refer to Watier–Richardson's model mentioned in the last two sections. Let $\{X_t\}$ denote the monthly notifications of cases of *Salmonella typhimurium* in France over the period January 1978 to December 1988. Their fitted model takes the form

$$X_t = 74.84 + 0.378X_{t-1} - 0.367X_{t-4} + 0.341X_{t-12} + \varepsilon_t^{(1)}, \quad (1)$$

if $X_{t-7} \leq 81$, and

$$X_t = -0.392 + 0.658X_{t-1} + 0.314X_{t-11} + \varepsilon_t^{(2)}, \quad (2)$$

if $X_{t-7} > 81$. Here, $\varepsilon_t^{(1)}$ and $\varepsilon_t^{(2)}$ denote two independent sequences of zero-mean, independent and identically distributed random variables (to be referred to as iid), where $\varepsilon_t^{(1)}$ has an estimated standard deviation 32.53 and $\varepsilon_t^{(2)}$ 14.66. Essentially, the nonlinearity is modeled by dividing the state space (i.e. the space of values of X) into two regimes, one corresponding to $X_{t-7} \leq 81$ and the other to $X_{t-7} > 81$, and inside each regime a linear autoregressive model is used. This model is an example of the class of self-exciting threshold autoregressive models; the adjective "self-exciting" refers to the fact that the division is effected by reference to a covariate that happens to be some past value of the response. We have already mentioned some of the properties of this fitted model in the last section.

The threshold models are currently one of the more popular nonlinear time series models in the literature. It is clear that conditional on the past X values up to and including $t-1$, the expectation of X_t is a piecewise linear function of the past X values. The primary, although by no means exclusive, objective of the above model is clearly the general drift of the time series. In econometric literature, often the interest lies not so much in the drift but rather in the diffusion about this drift (e.g. the volatility of the stock market). Translated into statistical language, the focus is then primarily on the conditional variance term. Perhaps for this reason, the class of ARCH models is particularly popular in the econometric literature. In its simplest form, it may be written as

$$X_t = \varepsilon_t \sqrt{V_t}, \quad (3)$$

where $\{\varepsilon_t\}$ are iid and

$$V_t = \gamma + \phi_1 X_{t-1}^2 + \ldots + \phi_q X_{t-q}^2, \quad (4)$$

with $\gamma > 0$, $\phi_i \geq 0$ for all i. Note that $\mathrm{E}[X_t|X_{t-1}, X_{t-2}, \ldots] = 0$ and $\mathrm{var}[X_t|X_{t-1}, X_{t-2}, \ldots] = V_t$.

Once the parametric form of the model is defined, we could then proceed with general statistical inference, including model identification, estimation of parameters and testing of hypotheses (e.g. testing for linearity), and so on. The method of conditional least squares seems to play a particularly important role in many of the studies. By this we mean the minimization, with respect to the unknown parameters, of $\sum\{X_t - \mathrm{E}[X_t|X_{t-1}, \ldots, X_{t-k}]\}^2$, where the summation is over the data set and k is an appropriately chosen order. (See, for example, [19] for details.) We return to the issue of an appropriately chosen order later. All

in all, although a significant number of asymptotic results are now available, there are still many outstanding problems, as we can see from the above references.

Nonparametric

Putting the drift and the diffusion together, we may write down a more general model in the form

$$X_t = f(X_{t-1}, \ldots, X_{t-p}) + \varepsilon_t g(X_{t-1}, \ldots, X_{t-q}), \tag{5}$$

where $\{\varepsilon_t\}$ is the usual iid. This is also called a nonlinear autoregressive model. If we assume that $g(\cdot) \equiv 1$, we have the so-called nonlinear autoregressive model of order p with homogeneous noise. If we assume that f is piecewise linear and g is piecewise constant, then we recover the self-exciting threshold autoregressive model. If we assume that f is identically zero and g is $\sqrt{V_t}$ as in (4), then we recover an ARCH model.

In the nonparametric approach, we do not assume any particular parametric form for f or g. Instead, we typically make only minimal assumptions, such as differentiability. The general idea is that "we let the data tell us what f and g are".

There are numerous ways to estimate f and g and we refer to [18] and [20] for some references. To give some general flavor, we describe briefly the locally polynomial approach, which is one of the currently favored approaches. (For details, see, for example, [8].) Let $p(\cdot)$ denote a probability density function, called the kernel. Consider the following local sum of squares:

$$S(\alpha) = \sum (X_t - \alpha)^2 p\left(\frac{X_{t-1} - x_1}{h}\right), \tag{6}$$

where the summation is taken over $t = 2, \ldots, n$, n being the sample size of the X data and h is a positive real constant, usually called the bandwidth of the kernel $p(\cdot)$. Here, α is treated as an unknown parameter as in the classical regression setup. The major significance of the above sum is its local characteristic: observations far from x_1 are given less weight. Minimizing $S(\alpha)$ with respect to α yields the estimate

$$\hat{\alpha} = \frac{\sum X_t p\left(\frac{X_{t-1} - x_1}{h}\right)}{\sum p\left(\frac{X_{t-1} - x_1}{h}\right)}, \tag{7}$$

which coincides with the Nadaraya–Watson estimate of $\mathrm{E}[X_t | X_{t-1} = x_1]$, i.e. $f(x_1)$. Here, we call it the locally constant estimate of $f(x_1)$. We can generalize it to yield a locally polynomial estimate in an obvious way by replacing α in $S(\alpha)$ by $\sum_{j=0}^{q} \alpha_j (X_{t-1} - x_1)^j$, where q denotes the degree of the local polynomial. We can further generalize to obtain similar estimates of $\mathrm{E}[X_t | X_{t-1} = x_1, \ldots, X_{t-k} = x_k]$, i.e. $f(x_1, \ldots, x_k)$, for $k > 1$. For example, the locally constant estimate of $f(x_1, \ldots, x_k)$ may take the form

$$\hat{f}(x_1, \ldots, x_k) = \frac{\sum_{t=k+1}^{n} X_t p\left(\frac{X_{t-1} - x_1}{h}\right) \ldots p\left(\frac{X_{t-k} - x_k}{h}\right)}{\sum_{t=k+1}^{n} p\left(\frac{X_{t-1} - x_1}{h}\right) \ldots p\left(\frac{X_{t-k} - x_k}{h}\right)}. \tag{8}$$

Here, we have effectively taken the associated k-dimensional kernel $p(u_1, \ldots, u_k)$ as a product of k one-dimensional kernels $p(u_j)$, $j = 1, \ldots, k$. (We have abused the notation of $p(\cdot)$.)

With the above nonparametric tools, many important issues can be addressed. For example, in practice, we often have to determine an appropriate order for a nonlinear autoregressive model even though we do not wish to commit ourselves to any particular parametric form of the autoregression. Let us denote the true order by k_0. To describe one nonparametric solution, let us omit the entry $t = j$ in (8). We have the so-called leave-one-out estimate of $f(x_1, \ldots, x_k)$, say $f_j(x_1, \ldots, x_k)$. Let L denote a fixed positive integer, which is much smaller than n. Minimizing

$$\sum_{j=L+1}^{n} [X_j - \hat{f}_j(X_{j-1}, \ldots, X_{j-k})]^2 \tag{9}$$

with respect to $k = 1, \ldots, L$ gives us an estimate $\hat{k}_{\mathrm{CV}}$ of k_0. It turns out that $\hat{k}_{\mathrm{CV}}$ is a consistent estimate of k_0. Moreover, the sample size requirement

for a "good" performance of $\hat{k}_{\mathrm{CV}}$ is not excessive; see [20].)

Other important issues that have been addressed in the context of nonparametrics include tests for independence, linearity, determinism, initial-value sensitivity, nonlinear forecasting, and others.

Stationarity and Prediction

The problem of obtaining sufficient and necessary conditions for strict stationarity for a nonlinear time series model is much deeper than its linear counterpart. The latter problem has a complete solution. This is far from being the case for the former.

If the model can be recast in the form of a **Markov chain** on a Euclidean space (of suitable dimension), then we can appeal to the extensive literature concerning the ergodicity of such Markov chains. (See, for example, [14].) Chan & Tong [4] were probably the first to point out that there is an intimate connection between strict stationarity and the notion of stability in deterministic difference equations. Specifically, let us consider the following nonlinear difference equation

$$z_t = f(z_{t-1}, \ldots, z_{t-k}). \tag{10}$$

We may think of this as the skeleton of the nonlinear autoregressive model; namely

$$X_t = f(X_{t-1}, \ldots, X_{t-k}) + \varepsilon_t. \tag{11}$$

Now, if $|z_t| \to \infty$ as $t \to \infty$, then we say that the system (10) is unstable. Otherwise, we say that it is stable. In fact, under suitable conditions on f, z_t may converge to a finite limit, say z^*, regardless of the initial value z_0. Chan & Tong [4] have proved that, under mild conditions on the distribution of ε, if the z system has the above properties, then the corresponding nonlinear autoregressive model (11) defines an ergodic Markov chain and hence a strictly stationary time series $\{X_0, X_1, \ldots\}$ if X_0 is endowed with the unique invariant distribution of the ergodic Markov chain.

For a strictly stationary time series $\{X_t\}$ with finite variance, the conditional expectation of X_{t+m}, given observations up to and including t, is the m-step-ahead least square predictor of X_{t+m}. Let us denote this by $\hat{X}_t(m)$. It need not be linear in $X_t, X_{t-1}, \ldots$. If $\{X_t\}$ is, in fact, given by a nonlinear autoregressive model of order k, then $\hat{X}_t(m)$ is a nonlinear function of $X_t, X_{t-1}, \ldots, X_{t-k+1}$ only. Unlike the case with linear Gaussian time series models, (i) $\mathrm{var}(X_{t+m}|X_t, \ldots, X_{t-k+1})$ is a function of $X_t, \ldots, X_{t-k+1}$ and need not be monotonically increasing with respect to m; (ii) if it exists, the conditional probability density function of X_{t+m}, given $X_t, \ldots, X_{t-k+1}$, need not be unimodal.

HOWELL TONG

Nonparametric Maximum Likelihood

Consider estimation of the survival function of a univariate or multivariate time variable T of interest, based on observing n subjects from a particular population (*see* **Survival Distributions and Their Characteristics**). In an early phase of understanding the survival function of T, or equivalently the **hazard** of T, one typically has only limited knowledge about the shape of these quantities. For example, it might be reasonable to assume that the hazard of T is increasing, but all other assumptions are hard to justify. In such situations there is a need for a nonparametric or semiparametric estimation method of the distribution of T (*see* **Semiparametric Regression**). Nonparametric maximum likelihood estimation (NPMLE) has received a lot of attention over the last few decades.

For simplicity, we will assume that the n observations on the subjects are independent and identically distributed (iid). Let $\mathbf{x} = x_1, \ldots, x_n$ represent n iid observations on a random variable X with probability distribution P_{θ_0} indexed by a parameter θ_0 which is known to be an element of a set Θ. The set of possible probability distributions $\{P_\theta : \theta \in \Theta\}$ is called a *model* for the distribution of X. If $\Theta \subset \mathbb{R}^k$, then the model is called *parametric*, and if Θ is infinite dimensional, then the model is often referred to as being *semiparametric*. For semiparametric models the structure $\theta \to P_\theta$ and/or the structure of the set Θ usually imply that the model is still strictly smaller than the set of all possible probability distributions, which explains the name *semiparametric model*. In statistics, an important goal is to find an estimator of θ_0 based on the data $\mathbf{x}$.

A celebrated estimation method is to define a **likelihood** of the data $\mathbf{x}$ as a function of θ and maximize this likelihood over all θ in Θ (*see* **Maximum Likelihood**). This method makes sense in the classical parametric models where there is only one sensible candidate for the likelihood, but in semiparametric models containing both continuous and discrete probability distributions one typically needs a generalization of maximum likelihood estimation. In this article, we will define maximum likelihood estimation, the generalization, provide illustrations, and elaborate on potential problems of maximum likelihood estimation in semiparametric models.

To start with we will assume that the model is dominated by a single measure μ so that standard maximum likelihood estimation (MLE) can be defined. This allows one to identify each probability distribution P_θ with a density p_θ with respect to (wrt) μ. This density p_θ is defined by the property that the probability that $\mathbf{X}$ falls in a set A (under P_θ) is computed by integrating p_θ over the set A wrt μ. If the P_θs are continuous probability distributions on $\mathbb{R}^k$, μ being the Lebesgue measure, then one can choose p_θ to be the classical derivative of the cumulative distribution function corresponding with P_θ (e.g. the normal density). And if the P_θs are discrete probability distributions on a finite set of outcomes, μ being the counting measure on this set, then $p_\theta(w)$ equals the probability that $\mathbf{X} = w$ (e.g. the **binomial distribution**).

The *likelihood* at θ of a given data vector $\mathbf{x}$ is defined as the density of $\mathbf{X}$ evaluated at $\mathbf{x}$ and is thus given by:

$$L_\mu(\theta|\mathbf{x}) = \prod_{i=1}^{n} p_\theta(x_i),$$

where we indexed the likelihood by μ to stress that the likelihood depends on the choice of dominating measure μ. Assume now that for this given data vector $\mathbf{x}$ there exists a $\hat{\theta}$ for which the likelihood $L(\hat{\theta}|\mathbf{x})$ is larger than or equal to the likelihood $L(\theta|\mathbf{x})$ for any $\theta \in \Theta$. Then $\hat{\theta}$ is called the *maximum likelihood estimator* of θ_0 for the model $\{P_\theta : \theta \in \Theta\}$.

Under "regularity" conditions, a maximum likelihood estimator $\hat{\theta}$ of θ is root-n **consistent**, asymptotically normally distributed and **efficient** (see [1]). We consider a classical textbook example of a parametric maximum likelihood estimator.

Example 1

Let $T_1, \ldots, T_n$ be n iid observations of a survival time T of interest which is known to be **exponentially** distributed with parameter $\lambda > 0$; the density of T is given by $f_\lambda(t) = \lambda \exp(-\lambda t)$ and its hazard equals λ and is thus constant. Thus, the likelihood of an observed data vector $\mathbf{t}$ of $\mathbf{T} = (T_1, \ldots, T_n)$ is given by

$$L(\lambda|\mathbf{t}) = \prod_{i=1}^{n} f_\lambda(t_i) = \lambda^n \exp\left(-\lambda \sum_{i=1}^{n} t_i\right).$$

In iid models it is more convenient to maximize the log likelihood, which is here given by

$$\log(L(\lambda|\mathbf{t})) = n\log(\lambda) - \lambda\sum_{i=1}^{n} t_i.$$

Since $\lambda = 0$ is not a maximizer, the maximizer falls in the interior of the parameter space. Thus, the maximum likelihood estimator λ_n solves the score equation:

$$0 = \frac{\mathrm{d}}{\mathrm{d}\lambda}\log[L(\lambda|\mathbf{t})]\bigg|_{\lambda_n} = \frac{n}{\lambda_n} - \sum_{i=1}^{n} t_i.$$

Thus, $\lambda_n = 1/\bar{t}$, $\bar{t}$ being the sample mean of the t_is.

Note that in the definition of a maximum likelihood estimator it is essential that the likelihoods at different elements of the model are comparable. A semiparametric model typically contains both discrete and continuous probability distributions. In this case, the model is often not dominated by a single probability distribution so that we need a generalization of the definition given above. For every pair θ_1, θ_2 one can define the density (likelihood) of P_{θ_1} and of P_{θ_2} wrt $\mu_{\theta_1,\theta_2} \equiv P_{\theta_1} + P_{\theta_2}$, even when P_{θ_1} is discrete and P_{θ_2} is continuous. Now, we will call $\hat{\theta}$ a maximum likelihood estimator of θ_0 if

$$L_{\mu_{\hat{\theta},\theta}}(\hat{\theta}|\mathbf{x}) \geq L_{\mu_{\hat{\theta},\theta}}(\theta|\mathbf{x}), \quad \text{for all } \theta \in \Theta.$$

This definition is due to Kiefer & Wolfowitz [9]. It is easily verified that if the model is dominated by a single measure μ, then the two definitions agree with each other. In the case that the model is semiparametric, the maximum likelihood estimator is called the *nonparametric maximum likelihood estimator*. This name can be misleading since it does *not* mean that no assumptions on the distribution of X have been imposed.

It is typically possible to identify the nonparametric maximum likelihood estimator with a finite dimensional vector so that it can be defined as the maximizer of a real valued functional on a euclidean space. This often allows one to consider the MLE as a vector solution of a set of estimating (score) equations (*see* **Likelihood**). In some semiparametric models these estimating equations can be explicitly solved. In general, numerical iterative subroutines for determining such a maximum or solution of a multivariate estimating equation are available. In some applications specific algorithms might arise naturally.

There exist several examples in the literature where one can explicitly solve for the nonparametric maximum likelihood estimator by deriving a set of score equations. The following example shows how one can obtain score equations via differentiation along one-dimensional submodels (see [5]).

Example 2

Let $T_1, \ldots, T_n$ be n iid copies of a univariate survival time T with cumulative distribution function F, where F is completely unspecified. Let F_n be the empirical cumulative distribution which jumps $1/n$ at each observation. By definition, we have that $\hat{F}$ is a nonparametric maximum likelihood estimator of F if for any distribution F_1:

$$\int \log\left[\frac{\mathrm{d}\hat{F}}{\mathrm{d}(\hat{F}+F_1)}\right]\mathrm{d}F_n \geq \int \log\left[\frac{\mathrm{d}F_1}{\mathrm{d}(\hat{F}+F_1)}\right]\mathrm{d}F_n. \tag{1}$$

Suppose $\hat{F}$ exists. Let μ_n be a dominating measure of $\hat{F}$. Then $\hat{f} \equiv \mathrm{d}\hat{F}/\mathrm{d}\mu_n$ maximizes

$$f \to \int \log(f)\,\mathrm{d}F_n \text{ over all } f = \mathrm{d}F/\mathrm{d}\mu_n, \quad \text{with } F \text{ dominated by } \mu_n. \tag{2}$$

In parametric models we could derive empirical score equations for the maximum likelihood estimator by differentiating the loglikelihood wrt the parameters that indexed the density of T. Differentiation wrt such a one-dimensional parameter means that one moves from p_{θ_n} to some local alternative in the particular direction implied by this parameter. Therefore, in order to imitate this procedure of obtaining score equations in our nonparametric case it is natural to define one-dimensional submodels $\varepsilon \to [1 + \varepsilon h(t)]\hat{f}(t)$ which go through $\hat{f}(t)$ at $\varepsilon = 0$ and where h represents a direction in which we move from $\hat{f}$ to an alternative. This one-dimensional submodel should consist of densities and therefore we need to enforce $\hat{F}h \equiv \int h(t)\,\mathrm{d}\hat{F}(t) = 0$. Thus, we can represent h with $h'(t) - \hat{F}h'$ for any uniformly bounded function h'. We will delete the prime ($'$) and just work with directions $h - \hat{F}h$, h being any uniformly bounded function.

Because $\hat{f}$ maximizes (2) we have that

$$\phi_h(\varepsilon) \equiv \int \log\{\hat{f}_{\varepsilon,h}(t)\}\,\mathrm{d}F_n(t)$$

is maximized at $\varepsilon = 0$, where $\hat{f}_{\varepsilon,h}(t) \equiv \{1 + \varepsilon[h(t) - \hat{F}h]\}\hat{f}(t)$. Consequently, the derivative of the one-dimensional log likelihood $\phi_h(\varepsilon)$ at ε equals zero. Thus

$$\int [h(t) - \hat{F}h]\,\mathrm{d}F_n(t) = 0 \text{ for all uniformly bounded } h,$$

which implies that $\hat{F}h = \int h(t)\,\mathrm{d}F_n(t)$ for all uniformly bounded h. This proves that $\mathrm{d}\hat{F} = \mathrm{d}F_n$. In other words, the maximum likelihood estimator in the completely nonparametric model is given by the empirical cumulative distribution function F_n.

Alternatively, one can view the likelihood as a function of a finite-dimensional vector of parameters and obtain score equations by differentiating wrt these parameters. In the following success story of nonparametric maximum likelihood estimation we present both approaches for obtaining score equations, each of them leading to different insights in the maximum likelihood estimator.

Example 3: Univariate Right-censoring Model

In survival applications T is often either observed or right-**censored** by a censoring variable C. Let the distributions F and G of T and C be completely unspecified and we will assume that C is independent of T. A right-censored observation on T can be represented as

$$Y = [\tilde{T} = T \wedge C, \Delta = I(T \leq C)].$$

In other words, we observe the minimum of failure and censoring and the failure indicator. The density of Y can be represented as

$$p_{F,G}(\tilde{t}, \delta) = \{\mathrm{d}F(\tilde{t})\overline{G}(\tilde{t})\}^{\delta} + \{S(\tilde{t})\,\mathrm{d}G(\tilde{t})\}^{1-\delta}.$$

So the log likelihood is given by:

$$\sum_{i=1}^{n} \log[\mathrm{d}F(\tilde{T}_i)]\Delta_i + \log[S(\tilde{T}_i)](1 - \Delta_i) + \log[\overline{G}(\tilde{T}_i)]\Delta_i + \log[\mathrm{d}G(\tilde{T}_i)](1 - \Delta_i).$$

We are concerned with estimating F. For maximum likelihood estimation we concentrate on maximizing the relevant part of the likelihood wrt F given by

$$\sum_{i=1}^{n} \log[\mathrm{d}F(\tilde{T}_i)]I(\Delta_i = 1) + \log[S(\tilde{T}_i)]I(\Delta_i = 0).$$

One can now obtain a set of score equations by differentiating the log likelihood wrt a class of one-dimensional submodels $\mathrm{d}F_\varepsilon(x) = (1 + \varepsilon h(x))\,\mathrm{d}F_n(x)$, $\int h\,\mathrm{d}F_n = 0$, through the nonparametric maximum likelihood estimator F_n, as in the preceding example. This shows that F_n solves the self-consistency equations (see [4] and [5]):

$$F_n(t) = \frac{1}{n}\sum_{i=1}^{n} E_{F_n}[I(T_i \leq t)|\tilde{T}_i, \Delta_i],$$

which provides an important heuristic interpretation to the estimator, explained in detail in the next example.

The following alternative way of obtaining score equations provides a closed-form solution F_n. First, note that F_n is discrete on the uncensored observations $T_1, \ldots, T_m$. Then we can reparameterize the log likelihood in terms of the jumps $\mathrm{d}\Lambda$ of the hazard at the uncensored observations by substitution of $\mathrm{d}F(\tilde{T}_i) = \mathrm{d}\Lambda(\tilde{T}_i)S(\tilde{T}_i-)$ and $S(\tilde{T}_i) = \prod T_j \leq \tilde{T}_i[1 - \mathrm{d}\Lambda(T_j)]$, where for a $\tilde{T}_i$ with $\Delta_i = 0$ we have $S(\tilde{T}_i) = S(\tilde{T}_i-)$. This shows that the log likelihood can be expressed as

$$\sum_{i=1}^{n} \left\{ \Delta_i \log[\mathrm{d}\Lambda(T_i)] + \sum_{T_j < \tilde{T}_i} \log[1 - \mathrm{d}\Lambda(T_j)] \right\}.$$

Consider this as a function of $(\lambda_1, \ldots, \lambda_m) \equiv [\mathrm{d}\Lambda(T_1), \ldots, \mathrm{d}\Lambda(T_m)]$. Let $\boldsymbol{\lambda}_n = (\lambda_{1n}, \ldots, \lambda_{mn})$ be the maximizer of the log likelihood. Let k_j be the number of uncensored observations at T_j, $j = 1, \ldots, m$, so with continuous data $k_j = 1$. Differentiation of the log likelihood wrt λ_1 at $\boldsymbol{\lambda}_n$ yields

$$0 = \frac{k_1}{\lambda_{1n}} - \frac{1}{1 - \lambda_{1n}}\sum_{i=1}^{n} I(\tilde{T}_i > T_1).$$

Simple algebra yields:

$$\lambda_{1n} = \frac{k_1}{k_1 + \sum_{i=1}^{n} I(\tilde{T}_i > T_1)}.$$

Similarly, differentiation wrt λ_j yields

$$\lambda_{jn} = \frac{k_j}{k_j + \sum_{i=1}^{n} I(\tilde{T}_i > T_j)}, \quad j = 1, \ldots, m.$$

In other words, the jump of Λ_n at T_j is given by the number of uncensored observations at T_j divided by the number of subjects at risk just before T_j. The corresponding estimator F_n of F is the well-known **Kaplan–Meier estimator**.

If the supremum of the likelihood over the model is attained by an element at the boundary of the model, where the boundary is not part of the model, then the maximum likelihood estimator will not exist. For example, if the model for a real-valued random variable X consists of all continuous densities, then the supremum over the likelihood of n iid observations is attained by the empirical probability distribution, which is not an element of the model (see, for example, [12]). However, if we restrict in this iid setting the model to all monotone decreasing (increasing) densities, then the maximum likelihood estimator appears to be a histogram density estimator with variable bandwidth [3, 7]. The latter estimator can be computed as the left derivative of the convex minorant of the empirical cumulative distribution function, which yields an extremely fast algorithm for computing this beautiful maximum likelihood estimator. It should be noted that in these problems where the support of the maximum likelihood estimator is unknown as well, score equations as derived in the preceding example do not uniquely characterize the maximum likelihood estimator (see [8]).

The monotone density model and right-censored data model provide examples for which the maximum likelihood estimator is very sensible. Roughly speaking, it can be shown that if the nonparametric maximum likelihood estimator of a parameter of P_θ is root-n consistent, then it will also be asymptotically efficient (see, for example, [6]). In other words, if it works, then it results in asymptotically optimal estimators of root-n estimable parameters.

The fact that the nonparametric maximum likelihood estimator tries to be efficient at every element in the model is one of the main reasons why it performs poorly in truly high-dimensional models (e.g. involving several covariates). In [10] and [11] it is reasoned that for semiparametric estimation with high-dimensional data structures one should sacrifice the global efficiency and instead search for estimators which are consistent at every element of the model *and* are efficient at a specified subset of the model. By now, their presented method has been used and applied in several high-dimensional censored data models.

This article concludes with an example where the NPMLE is inconsistent, but can be repaired successfully by slightly transforming the data.

Example 4: Bivariate Right censoring

Suppose that we are concerned with estimation of the bivariate lifetime distribution S_0 of a particular population of twins (*see* **Twin Analysis**). Let $T = (T_1, T_2)$ be the corresponding bivariate survival time (*see* **Multivariate Survival Analysis**) of a randomly drawn twin from this population and assume that each twin is subject to right-random censoring by an irrelevant censoring vector $C = (C_1, C_2)$. The iid observations on n twins are now

$$Y_i \equiv (\tilde{T}_i, \Delta_i) \equiv [T_i \wedge C_i, \quad I(T_i \leq C_i)],$$

with components given by:

$$\tilde{T}_{ij} = \min\{T_{ij}, C_{ij}\},$$
$$\Delta_{ij} = I(T_{ij} \leq C_{ij}), \quad j = 1, 2.$$

In other words, for twin 1 we observe the minimum of censoring and survival and we observe if this minimum is the actual survival time of interest, and similarly for twin 2. Each bivariate randomly right-censored observation Y_i tells us that $T_i = (T_{1i}, T_{2i})$ has fallen in a region $B(Y_i)$ in the plane where this region is a dot if both T_{1i} and T_{2i} are observed (uncensored), it is a half-line if only one of the survival times is right censored (singly censored), and it is a right-upper quadrant if both T_{1i} and T_{2i} are right censored (doubly censored). Therefore, the data can be nicely presented as in Figure 1 (disregard the strips, at this stage). If we had observed all $T_i, i = 1, \ldots, n$, then the NPMLE $S_n(t_1, t_2)$ of $S(t_1, t_2)$ would equal the fraction of the T_i which is larger than (t_1, t_2). In other words, we would give each observation T_i weight $1/n$ and sum up the weights of the T_is with $T_i > (t_1, t_2)$.

In general, we can still give all uncensored observations weight $1/n$. An observation Y_i only tells us that $T_i \in B(Y_i)$; so we want to give the mass $1/n$ to $B(Y_i)$ in an appropriate way. Assume that by using the observations in $B(Y_i)$ we are able to obtain a good estimator $P_{F_n^0}(T \in \cdot | T \in B(Y_i))$ of the conditional distribution $P(T \in \cdot | T \in B(Y_i))$ of T_i given that $T_i \in B(Y_i)$. Then a natural thing to do is to redistribute the mass $1/n$ corresponding with the censored

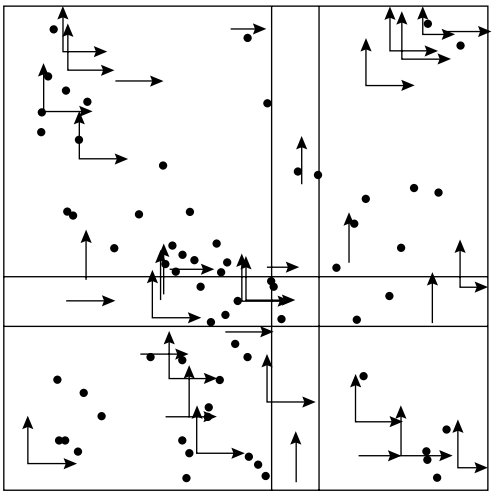

Figure 1 Right-censored bivariate data; • = uncensored, →= censored.

observation Y_i over $B(Y_i)$ as follows (assume for convenience that the estimate is discrete): a point $s > t$ gets the following fraction of the mass $1/n : P_{F_n^0}(T = s|T \in B(Y_i))$. If we do the redistribution for all censored observations, then we obtain a new estimator F_n^1, which might be an improvement.

This suggests the following **algorithm**:

1. Let $\{s_1, \ldots, s_k\}$ be a set of points in the plane which contains all uncensored T_i and it is such that each $B(Y_i)$ (lines and quadrants) contains at least one of these s_is.
2. Give each s_i a weight $f_n^0(s_i) > 0$. $\sum_{i=1}^k f_n^0(s_i) = 1$. Set the count $M = 0$.
3. Compute a new estimator f_n^{M+1}, as follows:

$$f_n^{M+1}(s_i) = \sum_{j=1}^{n} P_{f_n^M}(T = s_i|T \in B(Y_j))\frac{1}{n}, \quad i = 1, \ldots, k. \tag{3}$$

In other words, a point s_i gets from each observation Y_j mass $1/nP_{f_n^M}(T = s_i|T \in B(Y_j))$, which is zero if $s_i \notin B(Y_j)$ and it is 1 if s_i equals the observed T_j.

4. Replace M by $M + 1$ and go to step 3.

This is the **EM algorithm** [2, 14]. f_n^M can be shown to converge to a solution f_n of (3) with $f^M = f^{M+1} = f_n$. Eq. (3) in f_n is the well-known self-consistency equation of Efron [4], which is solved by NPMLE. The latter can be shown as in the univariate right-censoring example by differentiating the log likelihood along one-dimensional submodels.

If an uncensored observation receives mass from a censored observation at step M of the EM algorithm, then this influences the conditional probabilities $P_{f_n^{M+1}}[T = s|T \in B(Y_j)]$ of each region $B(Y_j)$ which contains this uncensored observation. If the underlying F is continuous, then the half-lines $B(Y_j)$ corresponding with singly censored observations will with probability one not contain any uncensored observations. Then the conditional probabilities over lines do not change at a step of the EM algorithm by mass given to the uncensored observations; i.e. a singly censored observation with half-line $B(Y_i)$ does not listen to information given by uncensored observations, but its redistribution over the half-line might change by mass given by doubly censored and other singly censored observations interacting with $B(Y_i)$. Since uncensored observations around a half-line provide a lot of information about the distribution over the half-line, there is no reason to expect good performance of S_n. Indeed, S_n is not consistent for continuous data [13].

Suppose now that the uncensored components of the singly censored observations Y_i are **interval censored** by a lattice partition $A_{k,l} = (u_k, u_{k+1}] \times (v_l, v_{l+1}]$, in the sense that (we do as if) it is only known to lie in $(u_k, u_{k+1}]$ (if T_1 is uncensored) or in $(v_l, v_{l+1}]$ (if T_2 is uncensored) (see Figure 1). In this way we have reduced the original data Y_i by putting an additional slight transformation on top of it, $i = 1, \ldots, n$. The interval-censored singly censored observations tell us that T_i has fallen in a strip around the original singly censored observation, which will contain other uncensored observations, and hence we expect a better result from the EM algorithm. In [15] it is shown that if one reduces the data in this manner, then the NPMLE based on the reduced data is efficient for the reduced data and efficient for the original data if the reduction converges to zero slowly enough when n converges to infinity.

MARK VAN DER LAAN

Nonparametric Methods

Many of the earliest statistical procedures proposed and studied rely on the underlying assumption of distributional normality. How well these procedures operate outside the confines of this normality constraint varies from setting to setting. Although there were a few isolated attempts to create statistical procedures that were valid under less restrictive sets of assumptions that did not include normality, such as the early introduction of the essence of the **sign test** procedure by Arbuthnott [2] in 1710, and the **rank correlation** procedure considered by Spearman [51] in 1904, it is generally agreed that the systematic development of the field of nonparametric statistical **inference** traces its roots to the fundamental papers of Friedman [18], Kendall [31], Kendall & Babington Smith [33], Mann & Whitney [38], and Wilcoxon [58].

The earliest work in nonparametric statistics concentrated heavily on the development of **hypothesis testing** that would be valid over large classes of probability distributions – usually the entire class of continuous distributions, but sometimes with the additional assumption of distributional symmetry. Most of this early work was intuitive by nature and based on the principle of ranking (*see* **Ranks**) to de-emphasize the effect of any possible **outliers** on the conclusions. Point and interval **estimation** expanded out of this hypothesis testing framework as a direct result of centering of the test statistics and test inversion, respectively (*see* **Estimation, Interval**).

Most distribution-free test procedures (and associated confidence intervals) are based on one or more of the following three fundamental properties.

Result 1. Let $Z_1, \ldots, Z_n$ be a **random sample** from some probability distribution and let A be a subset of the common domain for the Zs. If $I(t)$ represents the indicator function for this subset A, then the random variable $V = \sum_{i=1}^{n} I(Z_i)$ has a **binomial distribution** with parameters n and $p = \Pr(Z_i \in A)$.

Result 2. Let $Z_1, \ldots, Z_n$ be a random sample from a continuous distribution with cumulative distribution function (cdf) $F(\cdot)$, and let R_i denote the rank (from least to greatest) of Z_i among the n Zs, for $i = 1, \ldots, n$. Then the vector of ranks $\mathbf{R} = (R_1, \ldots, R_n)$ has a joint distribution that is **uniform** over the set of all permutations of the integers $(1, \ldots, n)$.

Result 3. Let Z be a **random variable** with a probability distribution that is symmetric about the point θ. Define the indicator function $\Psi(\cdot)$ by

$$\Psi(t) = 1, \quad \text{if } t > 0,$$
$$= 0, \quad \text{if } t \leq 0.$$

Then the random variables $|Z - \theta|$ and $\Psi(Z - \theta)$ are independent.

Statistics based solely on Result 1 are referred to as counting statistics, those based solely on Result 2 are commonly known as ranking statistics, and those based on an appropriate combination of all three results are called **signed-rank statistics**. Over the years of development in the field, distribution-free procedures have certainly become more sophisticated, both in the problems they address and in their complexity. However, the underlying premise behind almost all such hypothesis tests continues to rest with these three basic results or with modifications thereof.

Much of the early work in distribution-free hypothesis tests followed the general approach of mimicking a standard normal theory procedure for a statistical problem by replacing the sample values with some combination of rank or counting statistics. The first nonparametric test statistics looked quite similar in form to their classical normal theory counterparts. However, more recent advances in nonparametric statistics have been less tied to previously developed normal theory structure and, in fact, there have been a number of settings where nonparametric procedures were the first to be developed, and classical procedures followed a few years later.

It is the intent of this article to provide some brief overview of nonparametric statistics. However, the field has grown over the years to such a size that one must rely on standard textbooks in the area for a truly complete picture. The very first such textbooks in nonparametric statistics were the pioneering works of Siegel [49] and Fraser [17], both arriving on the scene in the infancy of the field. Walsh [55–57] published a three-volume handbook covering those nonparametric procedures available at the time. Other texts and reference books have added to the literature

of nonparametric statistics over the years, including the applications-oriented books by Bradley [3], Conover [5], Daniel [10], Gibbons [21], Hollander & Wolfe [27], and Marascuilo & McSweeney [39]. The text by Lehmann [36] occupies an intermediate place in the literature. It has a general application orientation, but a considerable amount of the basic underlying theory of some of the procedures is also presented in a substantial appendix. Textbooks dealing primarily with the theory of rank tests and associated point estimators and confidence intervals have been published by Gibbons [20], Hájek [22], Hájek & Šidák [23], Hettmansperger [25], Noether [44], Pratt & Gibbons [46], and Randles & Wolfe [47]. The monograph by Kendall [32] covers the specialized topic of rank correlation methods. These resources vary on the extensiveness of their bibliographies, but it is safe to say that the vast majority of published literature in the field of nonparametric statistics is cited in at least one of these volumes.

One of the necessities in the application of distribution-free test procedures and confidence intervals is the availability of the exact null distributions of the associated test statistics (*see* **Null Hypothesis**). Extensive tables of many of these null distributions are available in some of the applications-oriented texts mentioned previously. In addition, recent software developments have made it a good deal easier both to compute the appropriate test statistics and to obtain the associated ***P* values** for many of these test procedures (*see* **Software, Biostatistical**). Of particular note in this regard are the Minitab and **StatXact** software packages, for both their rather complete coverage of the basic nonparametric procedures and their ability to circumvent the need for exact null distribution tables by providing the associated exact or approximate P values for many of the test procedures (*see* **Exact Inference for Categorical Data**). StatXact also has the option of actually generating the required exact null distributions for some of the better known test statistics, including the appropriate modifications necessary in the case of tied observations.

We first turn our attention to brief descriptions of the most commonly used nonparametric procedures in standard statistical settings involving one, two, or more samples, including one- and two-way **analysis of variance** and **correlation**. In each case, the emphasis will be on the description of the problem and a particular standard approach to its solution, rather than on attempting to cover the myriad of different nonparametric procedures that are commonly available for the problem.

Finally, we will discuss briefly a few nonstandard topics where the development of nonparametric methods has been particularly motivated by the need to analyze medical and health sciences data. Included in these topics will be **censored data** and **survival analysis**, as well as **proportional hazards models**, **counting processes**, and **bootstrap methods**.

One-sample Location Problem

Continuity Assumption Only

Let $Z_1, \ldots, Z_n$ be a random sample arising from an underlying probability distribution that is continuous with cdf $F(\cdot)$ and median θ. Here the primary interest is in inference about θ.

Test Procedure. For this setting, we are interested in testing the null hypothesis that $\theta = \theta_0$, where θ_0 is some preset value appropriate for the problem. If no additional assumptions are reasonable about the form of the underlying F, the most commonly used inference procedures are those associated with the sign statistic

$$B = [\text{number of sample } Z\text{s that exceed } \theta_0]$$

(*see* **Sign Tests**). The properties of B follow from the basic counting Result 1 with the set $A = (\theta_0, \infty)$. In particular, B has a binomial distribution with number of trials n and success probability $p = \Pr(Z_1 > \theta_0)$. When the null hypothesis is true, we have $p = 1/2$ (since θ_0 is then the **median** of the underlying distribution) and the null distribution of B does not depend on the form of F. The associated level α sign procedure for testing H_0, vs. the alternative $H_1 : \theta > \theta_0$, is to reject H_0 if the observed value of B exceeds b_α, the upper αth percentile for the null distribution of B, namely, the binomial distribution with parameters n and $p = 1/2$ (*see* **Level of a Test**). The appropriate tests for the other directional alternatives $\theta < \theta_0$ and $\theta \neq \theta_0$ rely on the fact that the binomial distribution with n trials and $p = 1/2$ is symmetric about its mean $n/2$.

Point Estimation and Confidence Intervals/ Bounds. Natural nonparametric **confidence intervals** and confidence bounds for θ are associated with these sign test procedures through the common process of inverting the appropriate hypothesis tests. These intervals and bounds are based on the ordered sample observations $Z_{(1)} \le Z_{(2)} \le \cdots \le Z_{(n)}$. The $100(1-\alpha)\%$ confidence interval for θ associated in this manner with the level α two-sided sign test is given by $(Z_{(n+1-b_{\alpha/2})}, Z_{(b_{\alpha/2})})$, where $b_{\alpha/2}$ is again the upper $(\alpha/2)$th percentile for the binomial distribution with parameters n and $p = 1/2$. The corresponding $100(1-\alpha)\%$ lower and upper confidence bounds for θ (obtained by inverting the appropriate one-sided sign tests) are given by $Z_{(n+1-b_\alpha)}$ and $Z_{(b_\alpha)}$, respectively. The Hodges–Lehmann [26] point estimator of θ associated with the sign test is $\tilde{\theta}$ = median $\{Z_1, \ldots, Z_n\}$.

Continuity and Symmetry Assumption

Let $Z_1, \ldots, Z_n$ be a random sample from an underlying probability distribution that is continuous and symmetric about its median θ. Once again the primary interest is in inference about θ.

Test Procedure. We remain interested in testing the null hypothesis that $\theta = \theta_0$. However, the additional symmetry assumption now enables us to provide generally more powerful test procedures. For this setting, the most commonly used inference procedures are those associated with the **Wilcoxon signed-rank test** statistic [58],

$$T^+ = \sum_{i=1}^{n} R_i \Psi_i,$$

where $\Psi_i = 1, 0$ as $Z_i >, < \theta_0$, and R_i is the rank of $|Z_i - \theta_0|$ among $|Z_1 - \theta_0|, \ldots, |Z_n - \theta_0|$. Thus, the Wilcoxon signed-rank statistic corresponds to the sum of the $|Z - \theta_0|$ ranks for those Zs that exceed the hypothesized median value θ_0. [Since we have a continuous underlying distribution, the probability is zero that there are ties among the absolute values of the $(Z_i - \theta_0)$s. Likewise, the probability is zero that any of the Z_is actually equals θ_0. However, these events may occur in actual data sets. In such an event, it is standard practice to discard the Z_is that equal θ_0 and reduce n accordingly. Ties among the absolute values of the $(Z_i - \theta_0)$s are generally broken by assigning average ranks to each of the absolute differences within a tied group.]

Properties of T^+ under $H_0: \theta = \theta_0$ derive directly from Result 3, which yields the independence of the ranks of the $|Z_i - \theta_0|$s and the Ψ_is, and Result 2, which implies that the ranks of the $|Z_i - \theta_0|$s are uniformly distributed over the set of permutations of the integers $(1, \ldots, n)$ under H_0. The associated null distribution of T^+ does not depend on the form of the underlying $F(\cdot)$ and has been extensively tabled (see, for example, [27] and [59]). The associated level α signed-rank procedure for testing H_0 vs. the alternative $H_1: \theta > \theta_0$ is to reject H_0 if the observed value of T^+ exceeds t_α, the upper αth percentile for the null distribution of T^+. The appropriate tests for the other directional alternatives $\theta < \theta_0$ and $\theta \ne \theta_0$ rely on the fact that the null distribution of T^+ is symmetric about its mean $n(n+1)/4$.

Point Estimation and Confidence Intervals/ Bounds. Once again, natural confidence intervals and confidence bounds for θ are associated with these signed-rank procedures through inversion of the appropriate hypothesis tests. These intervals and bounds are based on the ordered values of the $M = n(n+1)/2$ Walsh averages of the form $W_{ij} = (Z_i + Z_j)/2$, for $1 \le i \le j \le n$. Letting $W_{(1)} \le \cdots \le W_{(M)}$ denote these ordered Walsh averages, the $100(1-\alpha)\%$ confidence interval for θ associated with the level α two-sided signed-rank test is given by $(W_{(M+1-t_{\alpha/2})}, W_{(t_{\alpha/2})})$, where once again $t_{\alpha/2}$ is the upper $(\alpha/2)$th percentile for the null distribution of T^+. The corresponding $100(1-\alpha)\%$ lower and upper confidence bounds for θ (obtained by inverting the appropriate one-sided signed-rank tests) are given by $W_{(M+1-t_\alpha)}$ and $W_{(t_\alpha)}$, respectively. The Hodges–Lehmann [26] point estimator of θ associated with the signed-rank test is $\hat{\theta}$ = median $\{W_{ij}, 1 \le i \le j \le n\}$.

We note that both the sign and signed-rank inference procedures can be applied to paired replicates data (X_i, Y_i), where X_i represents a pretreatment measurement on a subject and Y_i represents a posttreatment measurement on the same subject, and we collect such paired data from $i = 1, \ldots, n$ independent subjects. The appropriate sign or signed-rank procedures are then applied to the post-minus-pre differences $Z_i = Y_i - X_i, i = 1, \ldots, n$.

Two-sample Location Problem

Let $X_1, \ldots, X_m$ and $Y_1, \ldots, Y_n$ be independent random samples from the continuous probability distributions with cdfs $F(\cdot)$ and $G(\cdot)$, respectively. We consider here the case where $G(y) = F(y - \Delta)$, with $-\infty < \Delta < \infty$; that is, the X and Y distributions differ only by a possible location shift Δ, and we are interested in inference about Δ.

Test Procedure. For this setting, the appropriate null hypothesis is that $\Delta = \Delta_0$, where Δ_0 is some preset value (often zero) of interest for the shift. The most commonly used nonparametric inference procedures for this setting are those associated with the rank sum version of the **Wilcoxon–Mann–Whitney** [38, 58],

$$W = \sum_{j=1}^{n} R_j,$$

where R_j is the rank of Y_j among the combined sample of $N = (m + n)$ observations $X_1, \ldots, X_m$, $Y_1, \ldots, Y_n$. (Once again, ties among the Xs and/or Ys are broken by assigning average ranks to each of the observations within a tied group.)

Properties of W under H_0: $\Delta = 0$ (corresponding to no differences between the X and Y probability distributions) follow directly from the basic ranking Result 2, which implies that the joint ranks of $X_1, \ldots, X_m, Y_1, \ldots, Y_n$ are uniformly distributed over the set of permutations of the integers $(1, \ldots, N)$ under H_0. The associated null distribution of W does not depend on the form of the common (under H_0) underlying distribution $F(\cdot)$ and has been extensively tabled (see, for example, [27] and [59]). The associated level α rank sum procedure for testing H_0 vs. the alternative H_1: $\Delta > 0$ is to reject H_0 if the observed value of W exceeds w_α, the upper αth percentile for the null distribution of W. The appropriate tests for the other directional alternatives $\Delta < 0$ and $\Delta \neq 0$ rely on the fact that the null distribution of W is symmetric about its mean $n(m + n + 1)/2$.

Point Estimation and Confidence Intervals/ Bounds. As in the one-sample setting, natural confidence intervals and bounds for Δ are associated with these rank sum procedures through inversion of the appropriate hypothesis tests. These intervals and bounds are based on the ordered values of the mn differences $U_{ij} = Y_j - X_i$, $i = 1, \ldots, m$, $j = 1, \ldots, n$. Letting $U_{(1)} \leq \cdots \leq U_{(mn)}$ denote these ordered differences, the $100(1 - \alpha)\%$ confidence interval for Δ associated with the level α two-sided rank sum test is given by $U_{(\{[n(2m+n+1)+2]/2\}-w_{\alpha/2})}$, $U_{(w_{\alpha/2}-[n(n+1)/2])}$, where once again $w_{\alpha/2}$ is the upper $(\alpha/2)$th percentile for the null distribution of W. The corresponding $100(1 - \alpha)\%$ lower and upper confidence bounds for Δ (obtained by inverting the appropriate one-sided rank sum tests) are given by $U_{(\{[n(2m+n+1)+2]/2\}-w_\alpha)}$ and $U_{(w_\alpha-[n(n+1)/2])}$, respectively. The Hodges–Lehmann [26] point estimator of Δ associated with the rank sum test is $\hat{\Delta} =$ median $\{U_{ij}, i = 1, \ldots, m, j = 1, \ldots, n\}$.

Other Two-sample Problems

The possibility of differences in location between the X and Y distributions is certainly the most common problem of interest in the two-sample setting. However, there are circumstances where differences in scale are of primary concern, as well as situations where it is important to detect differences of *any* kind between the X and Y distributions. For discussion on nonparametric two-sample procedures designed for scale differences, see **Wilcoxon-type scale tests**. The development of nonparametric procedures designed to be effective against *any* differences between the X and Y distributions was initiated by the pioneering work of Kolmogorov [34] and Smirnov [50]. These papers have inspired a substantial body of research on such omnibus two-sample procedures (*see* **Kolmogorov–Smirnov Test**).

One-way Analysis of Variance: $k \geqslant 3$ Populations

This is a direct extension of the two-sample location problem. The data now represent k mutually independent random samples of observations from continuous probability distributions with cdfs $F_1(x) = F(x - \tau_1)$, $F_2(x) = F(x - \tau_2), \ldots, F_k(x) = F(x - \tau_k)$, where $F(\cdot)$ is the cdf for a continuous population with median θ and $\tau_1, \ldots, \tau_k$ represent the additive effects corresponding to belonging to population $1, \ldots, k$, respectively. Here, our interest is in possible differences in the population effects $\tau_1, \ldots, \tau_k$.

Test Procedures. For the one-way analysis of variance setting, we are interested in testing the null hypothesis H_0: $[\tau_1 = \cdots = \tau_k]$, corresponding to no differences in the medians of the k populations. For this setting, the most commonly used test procedures correspond to appropriate extensions of the Mann–Whitney–Wilcoxon joint ranking scheme as specifically directed toward the particular alternative of interest. For testing the null H_0 vs. the standard class of general alternatives H_1: (not all τ_is equal), the Kruskal–Wallis [35] test is the most popular procedure. For one-sided ordered alternatives of the form H_2: $(\tau_1 \leq \tau_2 \leq \cdots \leq \tau_k$, with at least one strict inequality), the appropriate extension is that proposed independently by Jonckheere [28] and Terpstra [54]. Finally, for umbrella alternatives H_3: $(\tau_1 \leq \tau_2 \leq \cdots \leq \tau_{q-1} \leq \tau_q \geq \tau_{q+1} \geq \cdots \geq \tau_k$, with at least one strict inequality), with either the peak of the umbrella, q, known a priori or estimated from the data, the standard test procedures are those proposed by Mack & Wolfe [37].

Multiple Comparisons and Contrast Estimation. After rejection of H_0: $(\tau_1 = \cdots = \tau_k)$ with an appropriate test procedure, one is most often interested in deciding *which* of the populations are different and then in estimating the magnitudes of these differences. This leads to the use of **multiple comparison** procedures, based either on pairwise or joint rankings of the observations. With pairwise rankings, where two-sample ranks are used to compare separately the sample data for each of the $\binom{k}{2}$ pairs of populations, the most commonly used multiple comparison procedures are those considered by Dwass [12], Steel [53], and Critchlow & Fligner [7] for two-sided all-treatment differences, and by Hayter & Stone [24] for one-sided all-treatment differences. The corresponding two-sided all-treatment multiple comparison procedure based on joint rankings, where the sample data from all k populations are ranked jointly, has been studied by Nemenyi [43] and Damico & Wolfe [8], while the joint rankings multiple comparison procedure for one-sided treatments vs. control decisions can be found in [43] and [9]. Point estimation of any **contrasts** in the τs (that is, any linear combination $\beta = \sum_{i=1}^{k} a_i \tau_i$, with $\sum_{i=1}^{k} a_i = 0$) is discussed in Spjøtvoll [52]. Simultaneous two-sided confidence intervals for *all* simple contrasts of the form $\tau_j - \tau_i$ have been developed by Critchlow & Fligner [7], while the corresponding simultaneous one-sided confidence bounds (*see* **Simultaneous Inference**) were studied by Hayter & Stone [24].

Two-way Analysis of Variance

We consider here the standard two-way layout setting, where the data consist of one observation on each combination of k treatments and n blocks (*see* **Randomized Complete Block Designs**). The observation in the ith block and jth treatment combination, denoted by X_{ij}, arises from a continuous probability distribution with cdf $F(x - \beta_i - \tau_j)$, where $F(\cdot)$ is the cdf for a continuous distribution with median θ, for $i = 1, \ldots, n$; $j = 1, \ldots, k$. Moreover, the nk Xs are assumed to be mutually independent random variables. (This is known as the additive two-way layout model.) Here, our interest is in possible differences among the treatment effects $\tau_1, \ldots, \tau_k$.

Test Procedures. For the two-way layout with one observation per cell, we are interested in testing the null hypothesis H_0: $(\tau_1 = \cdots = \tau_k)$, corresponding to no differences in the k treatment effects. For this setting, the most commonly used procedures correspond to appropriate extensions of the sign test procedure for paired replicates data as specifically directed toward a particular alternative of interest. For testing the null H_0 vs. the standard class of general alternatives H_1: (not all τ_is equal), the Friedman [18] test procedure is based on within-blocks ranks of the observations across treatment levels. For ordered alternatives of the form H_2: $(\tau_1 \leq \tau_2 \leq \cdots \leq \tau_k$, with at least one strict inequality), the appropriate test based on within-blocks ranks is that given by Page [45].

Multiple Comparisons and Contrast Estimation. After rejection of H_0: $(\tau_1 = \cdots = \tau_k)$ with an appropriate test procedure, one can use either the multiple comparison procedure studied by Nemenyi [43] and McDonald & Thompson [40] to reach the $k(k-1)/2$ all-treatments two-sided decisions of the form $\tau_i = \tau_j$ vs. $\tau_i \neq \tau_j$, or the corresponding treatments vs. control multiple comparison procedure due to Nemenyi [43], Wilcoxon & Wilcox [60], and Miller [41] to reach the $k-1$ treatments vs. control one-sided decisions of the form $\tau_j > \tau_{\text{control}}$. A method for point

estimation of a contrast in the τs can be found in Doksum [11].

Independence

Let $(X_1, Y_1), \ldots, (X_n, Y_n)$ be a random sample from a continuous bivariate probability distribution (*see* **Bivariate Distributions**). The most common distribution-free tests for the independence of the X and Y variables are those considered by Kendall [31] and Spearman [51] (*see* **Rank Correlation**). The null distribution properties of both of these test procedures are based on the basic Result 2 and the fact that the ranks of the Xs and the separate ranks of the Ys are themselves independent under the independence of X and Y. Approximate $100(1-\alpha)\%$ confidence intervals and bounds for the Kendall correlation coefficient $\gamma = \{2\Pr[(Y_2 - Y_1)(X_2 - X_1) > 0] - 1\}$ have been provided by Noether [44], Fligner & Rust [16], and Samara & Randles [48].

Censored Data

One of the areas where nonparametric methods have played a major role in the analysis of medical and health sciences data in particular has been that of survival analysis of censored lifetime data. We discuss the basic concepts involved in dealing with censored data in the one-sample setting and then provide brief descriptions of the most important nonparametric methods available for other selected settings.

There are times in the collection of data that we are prevented from actually observing the values of all of the observations. Such censoring leading to only partial information about the random variables of interest can be a direct result of the statistical design governing our data collection or it can be purely a consequence of additional random mechanisms affecting our data collection process.

Considerable attention in the literature has been devoted to three particular types of censoring, which we now describe. The first of these, known as type I censoring, corresponds to a fixed (preset) censoring time, t_c, at which the study is to come to an end. In this setting, instead of observing the random variables $Z_1, \ldots, Z_n$ of interest, we are only able to observe the truncated variables $W_i = \min(Z_i, t_c), i = 1, \ldots, n$. Type I censoring corresponds to medical and health sciences studies conducted for a fixed period of time after initiation and no entry to the study once begun.

A second type of censoring, known as type II censoring, corresponds to collecting survival (lifetime) data until a fixed number, say $r < n$, of the subjects have failed. Once this has occurred, the study is terminated. In this setting, we only observe the r smallest lifetimes (i.e. the first r **order statistics**) among $Z_1, \ldots, Z_n$. All we know about the remaining $n - r$ unobserved lifetimes is that they are at least as long as the final observed failure.

A third type of censoring, called random censoring, is probably the most common and the most complicated type of censoring associated with medical and health sciences data. In this setting, not only are the lifetimes random but the censoring times are also random. In clinical trials, for example, such random censoring could correspond to a study where not all subjects enter the study at the same time, but the study ends at one time, or to subjects leaving a study because they moved from the area or because of serious side-effects leading to discontinuation of the treatment.

Probably the earliest nonparametric approach to dealing directly with censored lifetime data was provided by **Kaplan & Meier** [30] in their development of the product limit estimator for the survival function $S(t) = 1 - G(t), -\infty < t < \infty$ (*see* **Survival Distributions and Their Characteristics**). The first two-sample rank procedure designed specifically to test hypotheses with censored data was provided by Gehan [19]. He proposed a direct extension of the Mann–Whitney form of the Mann–Whitney–Wilcoxon test statistic that provided a natural way to handle censored values occurring in either the X and/or Y sample data. A generalization of the Gehan two-sample test to the k-sample ($k \geq 3$) setting has been provided by Breslow [4]. For additional discussion of such rank-based procedures for censored data, the reader is referred to [42].

Other Important Nonparametric Approaches

Brief mention must also be made here of three other major initiatives in the development of nonparametric approaches to the analysis of medical and health

sciences data. Paramount among such developments is that of the proportional hazards model initially proposed by Cox [6] (*see* **Cox Regression Model**). Seldom has any single paper had such an impact on further research in the field. Kalbfleisch & Prentice [29] provide a nice discussion of the analysis of survival data by the use of the Cox proportional hazards model and extensions thereof. A second important thrust of more recent vintage has been the application of **counting process methods in survival analysis**. For a good discourse on this important methodology, the reader is referred to [1]. Finally, we need to mention the advent of the **bootstrap** as an important tool in the analysis of medical data. The survey articles [14] and [15] serve very well as introductions to this important topic, and its application to the analysis of censored data is discussed in [13].

DOUGLAS A. WOLFE

Nonparametric Regression Analysis of Longitudinal Data

Introduction

Longitudinal data involve repeated measurements that are recorded over a period of time on the same subject. The number of measurements for each subject may be different and is denoted by n_i for the ith subject when there are a total of n subjects in the study. We use $N = \sum_{i=1}^{n} n_i$ to denote the total number of observed measurements on all subjects. The time points at which those measurements were taken are also often different and are denoted by $t_{i1}, \ldots, t_{in_i}$. We use $Y_{ij} = Y(t_{ij})$ to denote a measurement for the ith subject at the jth time point, and $\mathbf{Y_i} = (Y_{i1}, \ldots, Y_{in_i})$ to denote the observed vector for the ith subject. This leads to a correlation structure between the repeated measurements within the same subject. Longitudinal data arise commonly in health sciences and engineering research, but different terms have been applied to describe them. They are usually referred to as "longitudinal data" in biomedical applications, where a small number of repeated measurements, n_i, over time per subject is common, and as "functional data" in engineering and biological applications, where n_i is often large. Statistical approaches to analyze such data have also been intrinsically different for longitudinal and functional data. Longitudinal data are treated as vectors, $\mathbf{Y_i}$, with subject-specific dimension n_i for the ith subject, while functional data are regarded as realizations of random processes with smooth paths, $Y(t)$, that are observed at discrete time points. Parametric GEE-based marginal models and parametric random effects models are the predominant approaches for longitudinal data, and non- or semiparametric approaches are the standard practice to analyze functional data. Recent challenges in the biomedical and biological fields prompted the development of more complex and flexible approaches to model longitudinal data. Nonparametric regression, well known to be more data adaptive and less restrictive than parametric approaches, thus emerged as a promising alternative to handle longitudinal data. For readers searching for such nonparametric approaches in the literature, a keyword to include is "functional data" in addition to "longitudinal data". The two books [20] and [21] on functional data analysis provide an excellent introduction to this topic.

In this article, we focus on situations in which the responses for the experimental subjects are longitudinal data. The covariates can be a baseline vector (X), a time-varying covariate vector $(X(t_{ij}))$, which is longitudinal data itself, or a combination of both. Key issues in nonparametric regression for such data include inference for the overall mean and nonparametric fixed effects, and modeling of the within-subject covariance structure through nonparametric random effects. We will use the fecundity data set described in the next section to illustrate these issues.

We begin with nonparametric mean function estimation, treating the overall mean as a function on a time interval, $[0, T]$, over which data were recorded for the subjects. This overall mean function is assumed to be smoothed and is often referred by researchers as the mean curve.

Estimating the Overall Mean as a Function of Time

We assume that the overall mean function (or mean curve), $\mu(t) = E(Y(t))$, is an unknown but smooth function on $[0, T]$. Hence, $E\ (Y_{ij}) = \mu(t_{ij})$. If we ignore for the moment the within-subject correlations, then the mean function can be regarded as a nonparametric regression function with the regressor being the time variable. A scatter-plot smoother can then be applied to all N observed data points (t_{ij}, Y_{ij}) to estimate the mean function $\mu(\cdot)$. Specifically, the estimate at a particular time t is

$$\hat{\mu}(t) = \sum_{i=1}^{n} \sum_{j=1}^{n_i} w_{ij} Y_{ij}. \tag{1}$$

This is simply a weighted average of all the N measurements, where the weights w_{ij} depend on the design points t_{ij} and the particular smoother. The choice of the smoother can be subjective and common choices include the kernel method [8], local polynomials [6], [14] and [32] and splines [22], [23] and [24].

Standard software such as S-plus can be employed easily to obtain a mean function estimate. The only difference with respect to the standard nonparametric regression setting is that repeated measurements

are available for each subject. For this reason, the estimated mean function in (1) can be expected to be consistent if n tends to infinity, provided the time points t_{ij} are spread out over the design interval $[0, T]$.

However, standard nonparametric smoothing methods may need to be adjusted for longitudinal data. An example for such an adjustment is the choice of smoothing (or tuning) parameter that is required by all smoothing methods. For the popular cross-validation method, it was shown in [22] that a leave-one-subject-out scheme should be employed for longitudinal data rather than the standard leave-one-observation-out scheme. All smoothing procedures require the proper choice of a tuning parameter. This problem is less understood and studied in longitudinal settings, and further research is needed.

Example of Reproductive Fecundity Data: We illustrate here the mean function estimate through a data set collected on 1000 female Mediterranean fruit flies (medflies) that was analyzed in [6]. Daily egg production, in terms of the number of eggs laid, were recorded individually until death for each of the 1000 female medflies. This results in a sample of 1000 longitudinally recorded fecundity curve data, with $Y_{ij} =$ number of eggs laid on day j by fly i. The goal is to explore the reproductive behavior of medflies through the pattern and modes of variation of these fecundity curves, $Y(t)$. Such information is important because reproduction is considered by evolutionary biologists as the single most important life history trait besides lifetime itself. See [6] and the references therein for details and information on biological features of the experiment.

Figure 1 provides the mean function estimates at various bandwidths based on a local linear scatter-plot smoother. Details of the procedure, including the leave-one-subject-out cross-validated bandwidth choice, are available in [6]. Because of the large number of subjects (there are 1000 flies) in the study and the dense recording per subject (repeated measurements were available daily), cross-validation selected a very small bandwidth at 2.5 days. The mean curve based on the larger bandwidth 15 is smoother but has larger bias than the mean curve based on the smaller bandwidth 2.5, as is expected for any nonparametric smoothing procedure.

The smoothing weights for the scatter-plot smoothing procedure in Figure 1 were determined by the choice of the local linear smoother and

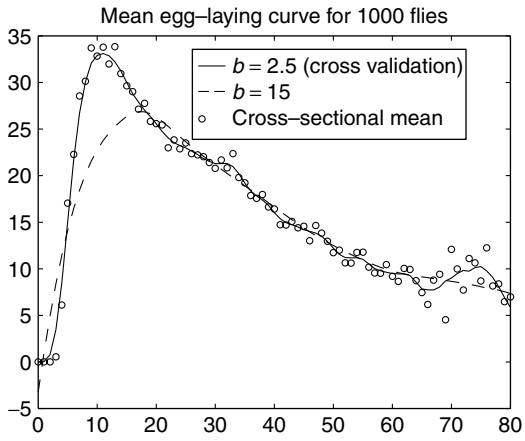

Figure 1 Mean egg-laying curves of 1000 female Mediterranean fruit flies. (a) Daily cross-sectional means of flies alive at the beginning of the day (○); (b) smoothed mean curve with fixed bandwidth $b = 15$ (- - - - - -); (c) smoothed mean curve with cross-validated bandwidth choice $b = 2.5$ (———)

the corresponding bandwidths following the standard practice in nonparametric regression. The within-subject correlation structure was not incorporated. An intriguing question for longitudinal data is how to effectively adjust the weights w_{ij} in (1) in the smoothing step to reflect the within-subject correlation structure of $\mathbf{Y_i}$. This was cleverly demonstrated for the case of smoothing splines in [29], and for local polynomial smoothers in [27] and [28]. It was shown that the asymptotic variance of the mean function estimators can be minimized if the weights are selected properly. However, these optimal weights require the use of the true within-subject correlation structure and do not necessarily minimize the asymptotic bias. The bias issue is more elusive and has not been resolved.

Nonparametric Fixed-effects Covariates

The procedures and discussion in the previous section apply directly to covariates other than time. To estimate the regression function $E(\mathbf{Y_i}|\mathbf{X_i})$, corresponding to fixed effects of covariates $\mathbf{X_i}$, simply replace in the scatter-plot smoother the t_{ij} by X_{ij} for time-varying covariates, and by $\mathbf{X_i}$ for vector covariates. Another framework mimicking the marginal approach of (Generalized Estimating Equations) can be found

in [14], [27], [28] and [29], where $E(Y_{ij}|X_{ij}) = \mu_{ij} = h(g(X_{ij}))$, with h a known and differentiable link function, and g an unknown smooth function. Here, the covariance structure of the response $\mathbf{Y}_i$ is also assumed to be a function of the means μ_{ij}, as suggested in the generalized linear model setting. The asymptotic variance of the minimum variance estimate, $\hat{g}(\cdot)$, was derived in [29] for smoothing splines and in [28] for local polynomial estimators. Additional results on semiparametric marginal models are also available in these two articles and [15] and [18].

Nonparametric Random effects

The overall mean function in Section 2 represents the population average, but individual trajectories may vary owing to subject effects, which also contribute to correlated repeated measurements within the same subject. Subject-specific random effects can be added for example by assuming as follows:

$$Y_i(t) = \mu(t) + v_i(t) + e_i(t), \quad i = 1, \ldots, n, \quad (2)$$

where μ is the unknown overall mean function, v_i are unknown subject-specific random effects reflecting the individual variation from the overall mean function, and e_i are measurement errors independent of v_i. The random effects are often regarded as realizations of a mean zero random process with smooth paths. It is thus expected that both the smoothed mean and random effects functions in (2) can be approximated using some basis functions. A B-spline basis, such as cubic splines, is a common choice and was proposed independently in [23] and [24], resulting in the following mixed-effects model:

$$Y_i(t) = \sum_{k=1}^{K} \beta_k B_k(t) + \sum_{k=1}^{K} b_k B_k(t) + e_i(t). \quad (3)$$

Here, β_k are coefficients, b_k are random variables with mean zero, $B_k(\cdot)$ is a basis of spline functions on $[0, T]$, and $e(t)$ is the measurement error. Consequently, the first summand yields the population mean function and corresponds to a fixed effect, while the second summand represents the random effects attributed to subject variations and describes the within-subject correlation structure. It is possible to use separate bases for random and fixed effects in equation (3). If we further assume normality for b_k and e_i, then model (3) becomes a linear mixed-effects model and thus can be fitted using either S-PLUS LME or SAS PROC MIXED. This computational advantage is an attractive feature of the B-spline approach. However, it requires the choice of the spline basis and the number of basis functions K, which in turn involves fairly complex choices of the number and location of knots. Cross-validation procedures or information-based criteria such AIC and BIC are among the suggestions in [23] for the choice of knots, but the issue is elusive and remains unsettled.

The B-spline basis approach may have difficulties for a data set that requires a large number of basis functions. This is because the degrees of freedom involved in (3) may be too small or even negative for sparse data. One solution is to use instead a local basis such as local polynomials in model (3) as only a low-degree polynomial is needed locally to fit the data, and often a linear polynomial suffices. This is explored in [32]. The trade-off is computation time as smoothing is done locally at each point while the B-spline approach is a global smoothing procedure.

Another remedy for the B-spline procedure is proposed in [10] and is based on the reduced rank procedure that involves the use of principal components. This approach aims at reducing the actual number of parameters needed in the nonparametric mixed-effects model (3) so that one can increase the degrees of freedom. However, it often involves a compromise in terms of computational feasibility and model flexibility. An alternative is the principal component analysis approach, a commonly used method for functional data that can be adapted to longitudinal data.

Principal Component Analysis Approach

Simply put, this approach just replaces the prespecified basis B_k in (3) by the eigenfunctions of the covariance operator of the response. This is the essence of principal component analysis and results in a data-adaptive basis that can effectively reduce the number of basis functions needed to model the random effects. They are effective dimension reduction tools for longitudinal data. The concept is similar to the problem to find the best K-dimensional linear model for stochastic processes, and has been extended in [4] and [22] to the case of functional or longitudinal data and termed functional principal components analysis.

Here, the response functions $Y_i(t)$ are considered realizations of smooth L^2 process with mean $\mu(t)$ and covariance function $\text{cov}(Y(s), Y(t)) = \gamma(s,t)$. The covariance function γ allows a spectral decomposition into orthonormal eigenfunctions $\rho_k(\cdot)$.

$$\gamma(s,t) = \sum_{k=1}^{\infty} \lambda_k \rho_k(s)\rho_k(t), \tag{4}$$

with ordered nonnegative eigenvalues $\lambda_1 \geq \lambda_2 \geq \ldots \geq 0$.

Let $\langle \cdot, \cdot \rangle$ denote the inner product in L^2 space. The Karhunen-Loève representation for a randomly selected curve is

$$Y(t) = \mu(t) + \sum_{k=1}^{\infty} A_k \rho_k(t), \tag{5}$$

where the random variables a_k correspond to the principal component scores, and are given by

$$A_k = \langle \rho_k, Y - \mu \rangle. \tag{6}$$

The principal components A_k in (6) are uncorrelated random variables with

$$E(A_k) = 0, \quad \text{var}(A_k) = \lambda_k, \quad \sum_{k=1}^{\infty} \lambda_k < \infty,$$

that is, the kth eigenvalue in (4) corresponds to the variance of the kth principal component as in the multivariate case. The principal components A_k and basis functions ρ_k in (5) can be interpreted as defining the variation of the stochastic process about its mean function, and $A_1\rho_1$ explains the maximum amount of variation in Y among all functions that involve a single real-valued random variable. Similarly, the function $A_2\rho_2$ explains the maximum additional amount of process variation that is unexplained by $A_1\rho_1$, and so forth, for $k = 3, 4, \ldots$.

Methods to estimate the eigenfunctions and principal components are described in [22] on the basis of smoothing splines. The leave-one-subject-out cross-validation method to select the number of eigen-basis is also first proposed there. Theoretical properties of the functional principal components estimates can be found in [19] under the hypothetical assumption that the entire process $Y(t)$ is observable. Similar theoretical results for another functional principal components approach based on kernel smoothers are provided in [2].

Compared to the nonparametric mixed-effects model in (3), functional principal component analysis is more data adaptive and therefore typically requires fewer basis functions. It also has the advantage to allow direct interpretations in terms of modes of variation of the underlying process and is favored by biologists to explore the covariance structure of the data. Although functional principal component analysis is not yet available on standard statistical packages, it is not difficult to write code in either MATLAB or S-PLUS to perform this analysis.

Example of Fecundity data: To incorporate subject-specific random effects of the reproduction process of medflies, we perform principal component analysis on the fecundity data. As in [6], we restricted the analysis to the first 50 days of lifetime owing to high variability of the fecundity curves beyond day 50. This circumvents the problem of the eigen-analysis being dominated by erratic tail behavior of the data and provides a more sensible analysis. See [6] for more details. The rest of the principal component analysis presented below is based on the first 50 days of daily egg counts for the 167 flies that lived beyond day 50. The egg-laying curves $Y_i(t)$, $i = 1, \ldots, 167$, are considered as realizations of a stochastic process on the interval $T = [0, 50]$.

We applied the eigen-analysis based on local linear smoothing as described in [6]. The optimal number of principal components based on AIC is nine, but there is little gain after four components as these four components explain 95.88% of the total variation of the fecundity data. The eigenfunctions corresponding to the largest four eigenvalues of the covariance function, $\gamma(s,t)$, are shown in Figure 2. This example demonstrates how principal component analysis effectively reduces the dimension of the data from an infinite-dimensional curve to a few components. In fact, selecting two components may suffice as they explain already 82% of the total variation based on Figure 2. To see whether one can reasonably predict the shape of the fecundity curve using just two principal components, we proceed to fit the fecundity curves of four randomly selected flies using the Karhunen-Loève representation (5) with two components.

Figure 3 exhibits the observed and predicted egg-laying profiles of individual flies, as well as the overall mean curve. The overall mean curve would be the predicted curve when no random effects are included. As can be seen form Figure 3, the functional PCA

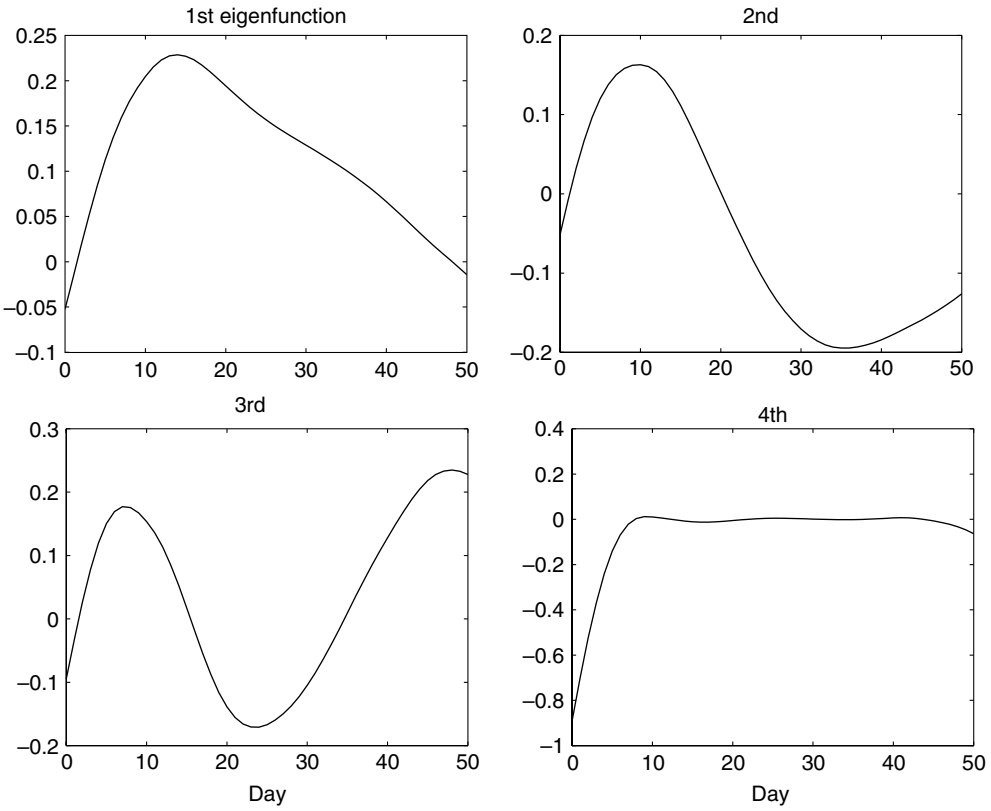

Figure 2 First four eigenfunctions for egg-laying data. The fraction of variation explained by each of these components are 0.6183, 0.2090, 0.0779 and 0.0536 respectively

approach seems to fit the curves reasonably well and has much less bias than the overall mean curve. We have thus demonstrated the effectiveness of the nonparametric principal components analysis approach for longitudinal data.

Although the fecundity data illustrated here were sampled at the same time points (daily in this case), the procedure can as well be applied to longitudinal data sampled at irregular time points.

Nonparametric Mixed-effects Models with Covariates

The procedures in the previous section allow to handle the time effects for a sample of individuals from the same population. When there are other covariates $\mathbf{X}$ that affect the longitudinal response data, one needs to incorporate these covariate effects in addition to the time effects. This has been explored for vector covariates in [6] by taking the conditional expectation with respect to $\mathbf{X}$ on both sides of (5). As a result, we have the following model:

$$E(Y_i(t)|\mathbf{X_i}) = \mu(t) + \sum_{k=1}^{\infty} E(A_{ik}|\mathbf{X_i})\rho_k(t) \qquad (7)$$

Procedures to estimate all the components including the mean function, the eigenfunctions and the conditional principal components $E(A_{ik}|\mathbf{X_i})$ can be found in [6], which also includes a semiparametric index model to tackle situations when the vector $\mathbf{X}$ is high dimensional. It is interesting to note here that the fixed effect of a covariate in (7) is derived from the unconditional principal components A_{ik} and eigenfunctions $\rho_k(t)$. This is because although A_{ik} has overall mean zero, the conditional mean $E(A_{ik}|\mathbf{X_i})$ in (7) is not zero and thus contributes to the fixed effects. Additional random effects can then be added to the model through $b_{ik} = A_{ik} - E(A_{ik}|\mathbf{X_i})$ to reach

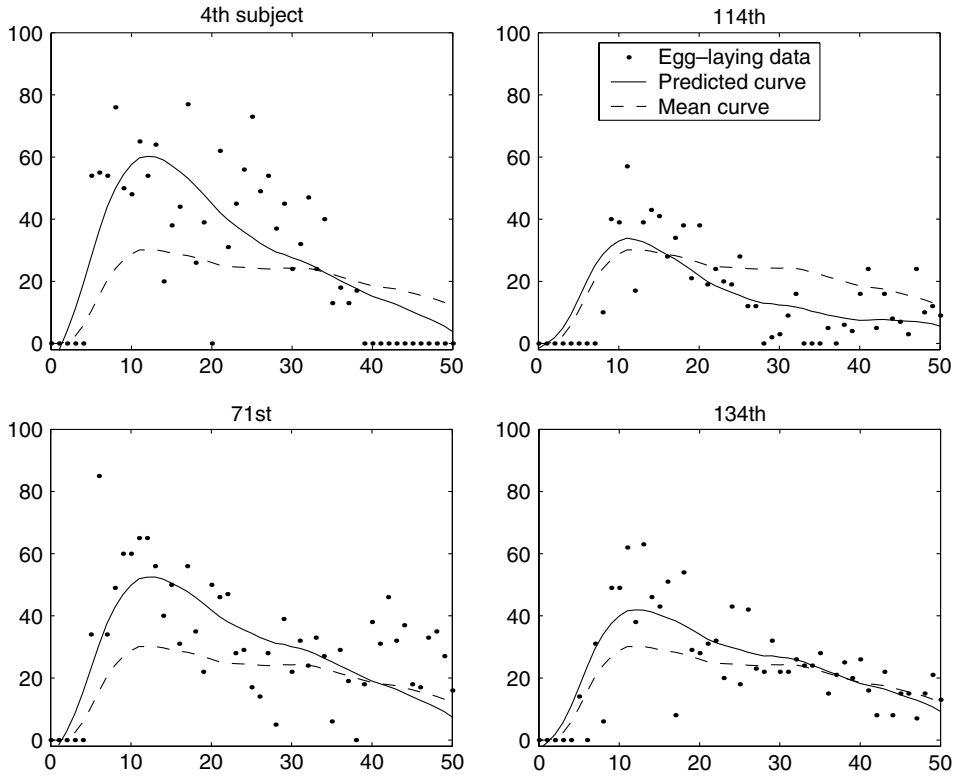

Figure 3 Observed data, predicted egg-laying curves and mean egg-laying curves for four randomly selected subjects

the following nonparametric mixed-effects model:

$$Y_i(t) = \mu(t) + \sum_{k=1}^{\infty} E(A_{ik}|\mathbf{X_i})\rho_k(t) + \sum_{k=1}^{\infty} b_{ik}\rho_k(t). \tag{8}$$

Other types of mixed-effects functional PCA regression models include [3] and [25], and more parsimonious semiparametric mixed-effects models include [26] and [33].

Other Non- and Semiparametric Regression Approaches

So far, we have discussed briefly a few nonparametric approaches for longitudinal/functional data. There are many other non- and semiparametric alternatives. One of them is the Generalized Additive Model (GAM) of the form:

$$E(Y_i(t)) = \beta_0 + \sum_{k=1}^{P} g_k(X_{itk}) + e_i(t), \tag{9}$$

where $(Y_i(t), X_{it1}, \ldots, X_{itP})$ is observed at time t for the ith subject with P-dimensional covariates denoted by X_{itj} at time t_j. The functions g_k in (8) are unknown smooth functions. Backfitting algorithms were proposed in [1] and [30], and inference procedures studied in [16].

When the data exhibit a common shape or structure, a smooth curve g can be used to model this common shape with individual responses adjusted by some parametric transformation of the common curve. This is referred to as self-modelling regression (SEMOR) in [13] and studied in [12] and [17] among others. A more general semiparametric model that includes SEMOR is recently proposed in [11].

Another approach that has emerged recently to model longitudinal data is the varying-coefficients model of the form:

$$Y_i(t) = \mu(t) + \sum_{k=1}^{K} \beta(t)X_i(t) + e_i(t). \tag{10}$$

This was first applied to longitudinal data in [9], and subsequently studied in [5], [7] among others. See the review of this model in [31] for details.

J.-L. WANG

Nonparametric Regression

Nonparametric methods of regression seek to describe the relationship between an explanatory variable, x and a **response variable**, Y, whilst making only the most general type of assumptions about the functional form of this relationship. The idea is that when a scatterplot (*see* **Graphical Displays**) does not indicate any simple pattern of dependency of Y on x, the data are allowed to "speak for themselves" in determining which function fits them best. With data such as these, nonparametric regression provides a useful tool for exploratory analysis. The resulting fitted curve may suggest a simple parametric model, and provides a method of prediction when this is not the case.

If n data pairs $(x_1, Y_1), \ldots, (x_n, Y_n)$ have been observed then the relationship may be modeled by

$$Y_i = m(x_i) + \varepsilon_i, \quad i = 1, \ldots, n, \tag{1}$$

where ε_i is an error term with zero mean and the function $m(x)$ is the conditional expectation, $\mathrm{E}(Y|x)$. In linear regression, for example, this function is defined by $m(x) = \alpha + \beta x$, where α and β are unknown parameters. Nonparametric regression methods, on the other hand, make only the assumption that $m(x)$ is a smooth function whose form is unknown. The problem is then to find an automatic method for constructing an estimate of $m(x)$ from the data. There are a number of nonparametric techniques for doing this, the most popular being kernel regression [7] and spline smoothing [2]. Hardle [3] describes both these and other nonparametric regression methods.

In the context of kernel regression the simplest method is due to Nadaraya [5] and Watson [8]. Their method works by estimating $\mathrm{E}(Y|x)$, i.e. $m(x)$, by a weighted average of the responses. The weights are chosen so that Y_i provides a large contribution to the average if x_i is close to x, and a small contribution if x_i is distant. Specifically, the Nadaraya–Watson estimator is defined by

$$\hat{m}(x) = \frac{\sum_{i=1}^{n} K(x - x_i) Y_i}{\sum_{i=1}^{n} K(x - x_i)}.$$

In this equation K is a kernel function, typically positive, symmetric about zero and integrating to one. The parabolic shaped kernel given by

$$K(u) = \begin{cases} \frac{3}{4} h^{-1} \left[1 - \left(\frac{u}{h} \right)^2 \right], & -h < u < h, \\ 0, & \text{otherwise}, \end{cases}$$

is a typical choice. This kernel is defined in terms of a scaling parameter, h, called the *bandwidth* (or *window width* by some authors). In practice, the value of h should be chosen so that the range of the kernel function is appropriate for the scale of the data. The manner in which this should be done has been the subject of much research. See Chapter 5 of Simonoff's monograph [6], for example. With the use of this kernel, $K(x - x_i)$ will take smaller values as the relative distance $|x - x_i|/h$ increases.

Kernel estimators fit into the class of local **polynomial regression** models. In this approach $\mathrm{E}(Y|x)$ is estimated by fitting a weighted polynomial regression, of degree r, say, to data whose x_i value is local to x. The kernel function defines the weights. The Nadaraya–Watson estimator corresponds to the case $r = 0$.

Spline smoothing is a somewhat different approach to nonparametric regression; its motivating philosophy is as follows. In fitting a curve to a scatterplot there are two (conflicting) interests. In the first place the regression function should be close to the data points. Thus, if $\tilde{m}(x)$ is a function estimating $m(x)$, then we wish the residual sum of squares, $\sum_{i=1}^{n} [Y_i - \tilde{m}(x_i)]^2$, to be small. However, there is usually good reason to believe that the function $m(x)$ is relatively smooth, so our estimator $\tilde{m}(x)$ should reflect this. The smoothness of $\tilde{m}(x)$ (assumed twice differentiable) can be measured by $\int \tilde{m}''(x)^2 \, \mathrm{d}x$, with larger values indicating greater roughness. Hence, the expression

$$\sum_{i=1}^{n} [Y_i - \tilde{m}(x_i)]^2 + \lambda \int \tilde{m}''(x)^2 \, \mathrm{d}x$$

is a penalty criterion, taking large values if $\tilde{m}(x)$ fits the data poorly or is unacceptably rough. It can be shown that the particular estimator, $\hat{m}(x)$, which minimizes this criterion is a cubic spline – that is, a piecewise cubic polynomial. The balance between goodness of fit to the data and smoothness of function is controlled by the parameter λ, with larger values

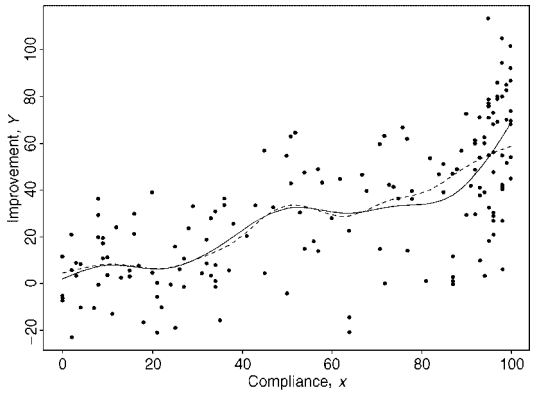

Figure 1 Nonparametric regressions for cholostyramine data [1]. Men were supposed to take six packets of cholostyramine (a cholesterol-lowering drug) per day. Compliance, x, is the percentage of the intended dose actually taken, whilst improvement, Y, is the decrease in total plasma cholesterol over the period of the treatment. The broken line is fitted using kernel regression, the unbroken one using spline smoothing

of λ leading to smoother $\hat{m}(x)$. The choice of an optimal λ, resulting in an estimator $\hat{m}(x)$ which picks up true trend but ignores haphazard variation in the data, is of considerable importance in the practical implementation of spline smoothing.

Both kernel and spline methods are illustrated in Figure 1 using data on the drug cholostyramine, given in [1]. The fitted curves bring out structure in the data, such as the rapid rise in the response for compliance of 90% or more, which would have been lost had a linear regression been fitted.

Nonparametric regression techniques can be generalized to cope with multiple explanatory variables, although the resulting methods tend to be computer-intensive. If there are p explanatory variables, with x_{ij} denoting the value of the jth one for the ith observation, then a natural extension of (1) is

$$Y_i = \sum_{j=1}^{p} m_j(x_{ij}) + \varepsilon_i, \quad i = 1, \ldots, n.$$

This type of model is referred to as a **generalized additive model**, and is discussed in detail in [4].

MARTIN L. HAZELTON

Nonrandomized Trials

A comparative **clinical trial** is a planned experiment in human subjects involving two or more treatments, where the primary purpose is to evaluate the relative effectiveness of the treatments. Often, the comparison is between two treatments, a proposed new treatment for the disease and standard therapy. Usually, the standard therapy has been utilized in other clinical trials, often those at the same institution(s) conducting the comparative trial, so patient characteristics related to **prognosis** may be known. In many clinical trials, patients entering are randomized to the available treatments (*see* **Randomized Treatment Assignment**), but there may be circumstances for conducting a nonrandomized trial in which the **control** group might be from: a historical control series of patients; concurrent controls, either at the same or other institutions; control patients from a computerized database (*see* **Administrative Databases**); or controls from articles reported in the literature. Byar et al. [4] have summarized the major arguments for conducting randomized clinical trials (RCTs), and Pocock [13] gives reasons why nonrandomized studies are likely to yield misleading results.

Articles giving arguments in favor of conducting nonrandomized trials are given by Gehan and Freireich [7–9]. The general arguments for conducting a nonrandomized trial involving a historical control treatment are that all knowledge is historical and that modifications are made as evidence accumulates. In a nonrandomized historical control trial (HCT), results of the proposed new treatment administered to consecutive patients are compared with those from a historical control group. This approach is consistent with the acquisition of knowledge by application of the principles of the scientific method. Results for patients on the new treatment can be compared with predictions of outcome for the standard treatment based on the premise that the past is the best guide to knowledge about the future. Even advocates of RCTs must accept some historical data; namely, the results of their own studies, to make predictions about future results for treatment. Confirmation of results of experimental therapies in multiple studies makes their acceptance more likely.

HCTs require much smaller numbers of patients and shorter time periods for their conduct than RCTs designed to meet equivalent objectives. Also, it is likely that a larger number of patients will be available for an HCT, since some patients will not accept randomization to treatment, whereas they would accept assignment to a new treatment that has promise of being better than a standard therapy. If an investigator is studying a proposed new (A) vs. standard (B) therapy in a nonrandomized trial and sufficient prior data are available so that the response rate (say p) for the standard therapy may be assumed known, then the number of patients required to compare A with B is only one-quarter of that required for an RCT with an equivalent statistical significance level (*see* **Level of a Test**) and **power** [9]. When the response rate is not assumed known, but is estimated from a historical control series of moderate size, Makuch & Simon [11] give tables for the number of patients needed. For example, if there are 100 patients in the historical control series and the response rate of the standard therapy is 40% and it is desired to detect a 20% improvement in response rate for the proposed new therapy at a 5% significance level (one-sided test) with a statistical power of 80%, then 52 patients are needed on the new therapy rather than 76 patients in an RCT. When the historical control series is moderate in size (about 50 patients or more), the number of patients required on the new treatment is generally less than that for the new treatment group alone in an RCT (*see* **Sample Size Determination for Clinical Trials**).

A clinical investigator conducting a nonrandomized trial with a historical control group has no ethical dilemma when advising his patients about entry into the study (*see* **Ethics of Randomized Trials**). If it is accepted that all clinical investigators should seek results that are better than those observed in the past, then it follows that no study should be started unless there is some evidence suggesting that the new therapy is at least as good or possibly better than the standard therapy. In such a circumstance, a clinical investigator doing a nonrandomized study would be entering all patients on the new treatment that was predicted to be better. In contrast, the ethical basis of the RCT depends upon the absence of convincing evidence about the relative merits of the two treatments.

Further, ethical concerns arise in an RCT, but not in an HCT, when interim results suggest that the new treatment is better than the standard therapy at some level of statistical significance, say $P = 0.25$. Such results could arise in a clinical trial designed to accrue a fixed number of patients or in

a sequential trial (*see* **Data and Safety Monitoring**) when a boundary point for deciding in favor of one of the treatments had not quite been reached. In such a circumstance, could a clinical investigator honestly seek the informed consent (*see* **Ethics of Randomized Trials**) of a potential patient by stating that the evidence favoring each of the treatments was equivalent? Of course, the same ethical concerns could also arise in an HCT, if interim results suggested that the standard therapy was better.

For randomized comparative trials sponsored by the **National Institutes of Health**, **data and safety monitoring boards** (DSMBs) have been set up to evaluate data accrued during the trials at regular intervals and decide about their continuation, without informing the clinical investigators participating. In such circumstances, the participating clinical investigators could ask for the informed consent of patients to enter the trial without the burden of knowing the interim results.

The outstanding criticism of nonrandomized studies involving historical control groups is that, consciously or unconsciously, patients may be selected to receive the new treatment that have a more favorable prognosis than patients receiving the standard therapy (*see* **Bias from Historical Controls**). Thus, the clinical trial of the new treatment may yield a positive result because the prognosis of the group of patients and not the treatment was more favorable. When a large body of data is available on the standard treatment, techniques for determining prognostic factors are well known [3], and knowledge of these factors may be used to stratify (*see* **Stratification**) patients or to adjust the comparison of the new vs. standard treatment by the use of **regression** models.

If a **multivariate multiple regression** model involving prognostic factors (e.g. a **logistic** or **proportional hazards** model) is available relating the outcome of treatment to prognostic factors and the model explains a substantial amount of the total variation in outcome (*see* **Explained Variation Measures in Survival Analysis**), the model may be used to test for treatment effects after adjustment for the prognostic features of the patients. An example of a proportional hazards model comparing disease-free survival and survival between treatment groups in a breast cancer HCT study is given by Buzdar et al. [5]. Simon [14] describes some statistical regression models, and their usefulness in **prediction** and **inference**, and gives methods for examining adequacy of fit (*see* **Goodness of Fit**) and some uses of regression models in clinical oncology. A crucial assumption needed to utilize the regression modeling approach is that the relationship of patient characteristics to outcome is essentially the same in the historical control and current study period.

Planners of RCTs rely primarily on randomization and secondarily on stratification and regression models as techniques for ensuring the validity of comparisons between treatments, whereas those preferring nonrandomized studies with historical control groups can use only the latter two procedures. Arguing that a historical control group might not be comparable with a new treatment group involves asserting either that there was an unknown prognostic feature of major importance (in addition to those known) or that factors related to the difference in time periods were responsible for the observed treatment difference. If such unfavorable events did occur in a single study, then the investigator who did not randomize would have to discover in a subsequent confirmation study that the new treatment was not as beneficial as expected, whereas the investigator who randomized would discover this within the trial.

Nonrandomized studies, possibly involving concurrent treatment groups, might be used to resolve controversial questions, such as those when preliminary data suggest that one treatment is substantially better than the other or when radically different types of therapy are being compared. In the latter circumstance, proponents of the differing forms of therapy (e.g. radiotherapy vs. radical surgery) might enter consecutive patients on a single therapy and use stratification and/or regression models involving prognostic factors to test for differences in effectiveness between treatments. Gehan [8] gives some examples in clinical oncology of studies in osteosarcoma, brain metastases, and localized stomach cancer in which RCTs were planned, but had substantial difficulties in their conduct because the studies involved controversial questions. Patients were unwilling to give informed consent to be randomized to the differing forms of therapy.

Baker & Lindeman [1] have proposed a nonrandomized paired availability design for evaluating epidural analgesia during labor. In their application, the design consists of independent pairs of experimental (epidural analgesia available) and control (epidural analgesia not available) groups, each group being patients treated at a hospital before

(control group) or after (experimental group) epidural analgesia became available. The fundamental characteristics of the design are: the intervention is availability of treatment; the **target population** from which subjects arise is well defined with little migration in or out; and the study involves many pairs of control and experimental groups. Baker & Lindeman developed a test of the **null hypothesis** that the receipt of intervention will increase response (measured by the percentage of patients having Caesarean sections) by some specified nonzero amount, and applied their results to a study of epidural analgesia.

Since clinical research in recent years has produced many efficacious new treatments, it is reasonable to ask which of the important advances in an area of clinical medicine in the last 25 years can be attributed to HCTs and which to RCTs. At least in cancer research there is strong evidence that new treatment regimens for acute leukemia, choriocarcinoma, lymphoma, lung cancer, osteosarcoma, breast cancer, testicular cancer, and sarcoma have come from nonrandomized studies. It should also be stated that RCTs have debunked false claims made for some new treatments [6]. Grage & Zelen [10] pointed out that historical controls tend to exaggerate the value of a new treatment, using as an example the treatment of metastatic colorectal carcinoma to the liver.

Although Pocock [13] argues strongly in favor of the RCT, he gives the requirements for a nonrandomized study involving a valid historical control group [12]. These are: the control group has received a precisely defined treatment in a recent previous study; the criteria for **eligibility**, work-up, and evaluation of treatment must be the same; important prognostic features should be known and be the same for both treatment groups; and there should be no unexplained indications leading one to expect different results. A further proviso might be that if there are some modest differences between treatment groups with respect to these features, then it should be established that these were not sufficient to explain any observed differences in outcome between treatment groups.

The use of computerized data banks with information on previous patients in a given institution has been advocated as a substitute for the RCT by some enthusiasts. For example, Starmer et al. [15] give an example of the utilization of a data bank in the management of chronic illness. However, Byar [2] gives strong arguments why databases should not be a substitute for RCTs. Literature controls might be considered for a nonrandomized study in which the control group is made up of patients previously reported in the literature. Of course, it is possible that there are substantial differences in patient selection and the experimental environment, such that a meaningful comparison of the new with the standard therapy would not be possible. Gehan & Freireich [9] give some examples in which it seemed reasonable to compare a new with the standard therapy involving control patients from the literature.

In clinical oncology, **phase I trials**, designed to find a maximum tolerated dose of therapy, and **phase II trials**, designed to determine whether or not the therapy is worth pursuing further, are generally nonrandomized, but such trials do not include a standard therapy comparison group and are conducted prior to the comparative (phase III) trial. **Outcomes research** studies are also nonrandomized, and a critical component of such research is inferring the relationship between the therapeutic process and outcomes – the major difficulty being the evaluation of processes when these are not randomized.

Without question, the "gold standard" in clinical research is the RCT. However, a nonrandomized trial with a historical control group might be considered in some circumstances. For planners of such studies, the difficulty to be overcome is to demonstrate that the groups of patients receiving the new vs. the standard therapy had comparable probabilities of favorable outcomes.

Nonresponse

It would be preferred in virtually any **sample survey** to obtain an answer to every questionnaire item from every sample member who is eligible to participate. Unfortunately, almost all surveys fail to achieve that level of performance. Nonresponse may occur at the level of the sample unit (*unit nonresponse*) or in an individual questionnaire item *(item nonresponse)*. It is a potential source of error in survey estimates because it may cause some segments of a **target population** to be underrepresented. Also, nonresponse may reduce statistical **power** by resulting in a measured sample that is smaller than the desired sample size. Concern about nonresponse has increased over the past two decades as survey researchers have observed a general decline in response rates [6, 7, 14, 19–21]. This article reviews the causes of survey nonresponse, the nature of nonresponse error and its potential impact on survey estimates, and techniques for measuring and reporting nonresponse.

Causes of Nonresponse

Total Nonresponse

Some researchers categorize nonresponse as **nonsampling error**, considering it as a function only of the data collection process. However, as will be described below, at the unit level, nonresponse may be a function of the sampling process as well. Therefore, overall it is most appropriate to consider survey error attributable to nonresponse as *nonobservation error* [14]. This broader concept appropriately casts survey nonresponse as the failure of the survey process to obtain full participation from all eligible members of a sample.

The *total nonresponse* for any particular measured variable is the sum of the two levels of nonresponse: unit nonresponse and item nonresponse (both expressed as percentages). For example, if a survey fails to obtain participation from 20% of the eligible sample, and if among the 80% who participate no response is obtained from 10% for the variable of interest, total nonresponse for that variable is $0.20 + 0.10 \times 0.80 = 28\%$. Therefore, although in most surveys unit nonresponse accounts for the largest proportion of total nonresponse, it is important for researchers to account for both levels of nonresponse, in combination as well as individually.

The above example applies to the typical **cross-sectional** sample survey. Total nonresponse is both more complicated and usually more serious in the case of sample attrition in a longitudinal **panel study**, a design in which repeated measures are to be obtained from the same respondents over two or more waves (observation points). Total nonresponse for any particular variable in a panel study is cumulative over the nonresponse at each wave. Therefore, it is important to account for overall nonresponse for the duration of a panel study as well as wave-specific nonresponse.

Unit Nonresponse

Unit nonresponse occurs when members of a sample who are eligible to participate in a survey either do not participate at all or participate only partially, such that sufficient data are not obtained to include them in the analysis. Depending on the survey design, a unit may be an individual, a household, an institution or organization (e.g. a school), or other group (*see* **Unit of Analysis**). Unit nonresponse is a function of two components. The first is failure to contact sample members (noncontacts), which appears to account for most cases of unit nonresponse [20]. Examples of this type of problem include cases where, for the entire survey period, persons are not at home (e.g. due to business or vacation travel) or constantly use a telephone answering machine or voice-mail system. The second component of unit nonresponse is failure to obtain participation. This includes two types of cases. One is where a sample member refuses to complete an interview/questionnaire. The other is where a sample member who otherwise would complete an interview/questionnaire is unable to do so, for example because of an illness or injury, or being too busy with other activities.

Although hard data are lacking, researchers have attributed recent increases in unit nonresponse to secular trends in the US, especially in urbanized areas [14, 21], whereby the population has become more mobile, resulting in people being available at their usual place of residence for shorter periods. In particular, the Council of American Survey Research Organizations (CASRO) [7] noted that is has become more difficult to contact women because of their increased participation in the labor force.

Kessler et al. [16] observed that there is an increased tendency for entire households to be away from home when interviewers call because of growing proportions of single-member households and dual-earning couples, increased commuting time, and an increase in evening activities outside the home. Moreover, people appear to be more protective of their more limited personal time at home, making them less receptive to requests to participate in a survey [6].

Two particular aspects of survey methodology may effect unit nonresponse. The first is the mode of initiating contact and collecting data. In general, unit nonresponse is lowest for face-to-face interviews, slightly larger for telephone interviews, and largest for mail (postal) surveys [1, 10]. The second is the burden participation places on respondents. For example, nonresponse tends to be larger for longer interviews/questionnaires, less salient survey topics, and sensitive or threatening survey topics. Additionally, nonresponse tends to vary among population subgroups. In particular, nonresponse tends to be greater among young adults, the elderly, the poor, persons with little education, and persons with certain disabilities such as impaired hearing [1, 14]. Other factors such as characteristics of the survey sponsor and the time of year also may effect unit nonresponse [11, 15]. Finally, the sampling process may contribute to unit nonresponse in instances when problems with the **sampling frame** prevent the researcher from contacting a sample member, such as if the frame contains erroneous or out-of-date address and/or telephone information.

A special case of unit nonresponse is when a respondent begins to participate in a survey but fails to complete an interview/questionnaire. These *partial completes* occur more often in face-to-face and telephone interview surveys than in mail surveys, when the respondent "breaks off" from an interview before it is completed (for example, because of a lack of time or a refusal to answer any more questions). Further complicating the matter is that some so-called *complete* questionnaires may include unanswered questions (item nonresponse). Thus, although partial completes usually are categorized as a component of unit nonresponse, they are strongly related to item nonresponse. The larger the item nonresponse for a case, the more likely it is to be considered a partial complete. Because there is no standard definition of a partial complete, the researcher's decision about whether to include a case in the analysis or to count it as a unit nonresponse usually is guided by two factors: the proportion of the questions answered by the respondent; and whether responses are obtained for questionnaire items measuring key variables for the analysis.

Item Nonresponse

Item nonresponse occurs when an eligible sample member participates in a survey but does not provide a usable response to one or more of the survey questionnaire items (questions). For a survey where the questionnaire contains some items that do not apply to all respondents, item nonresponse refers only to questions that apply to a particular respondent. Thus, the data record for some respondents regarded as "completes", because their overall participation in a survey was acceptable, may include **missing values** for some variables.

Item nonresponse is a function of two components. The first is failure to obtain an answer to a question, which may occur for several reasons. The most obvious one is when a question is presented but the respondent refuses to answer or is unable to provide the requested information. However, item "nonresponse" also includes cases where a question is not presented because a respondent or interviewer does not follow instructions correctly (e.g. does not understand that a question applies to the respondent, or records only one response to a multiple response question). Also, an interviewer may fail to present a question because the interviewer feels uncomfortable with the subject matter, or the interviewer may fail to encourage a respondent properly to answer a difficult question. Finally, item "nonresponse" also includes cases where a respondent "answers" a question but the response is not recorded (by the respondent or interviewer).

The second component of item nonresponse is failure to obtain a usable response to a question. In a mail survey or other type of self-administered questionnaire study a respondent's handwriting may be illegible, or a respondent may record two response choices where only one response is requested and/or logical (e.g. a respondent may record both "yes" and "no" for a dichotomous question). For an interview survey an interviewer may fail to probe properly to obtain a clear and complete response. This is particularly a problem for open-ended questions or "other – specify" type responses (*see* **Interviewing**

Techniques). Similar problems of lack of clarity and completeness are even more likely to occur in a mail survey or other type of self-administered questionnaire study.

A special issue for item nonresponse is when a respondent answers "don't know" to a question, which may or may not be a case of missing data. In some cases, a respondent may use this response as a convenient and polite way to refuse to answer. In others, it may indicate that a respondent is unable to answer because of inability to retrieve the necessary information (e.g. from memory or records), the respondent has no opinion about the subject of a question, or because none of the response choices is appropriate. In still other cases, "don't know" may indicate that the respondent has no knowledge about the subject. For example, "I don't know" may be a valid response to a question such as "Whom would you call if a member of your household needs emergency medical treatment?". Before data collection begins, the researcher should anticipate the possibility that a respondent may answer "don't know" to virtually any question and decide whether to treat it as a nonresponse or as a valid response to be included in the analysis. This decision, even for identical questions, may vary from one survey to another depending on the purposes of the study and how the data will be interpreted. In general, the issue is whether it is reasonable to expect respondents to have adequate knowledge (e.g. about their age) or hold an opinion (e.g. about their health status) so as to be able to answer a question, as opposed to a situation where "don't know" may be a relevant substantive response (e.g. indicating a lack of knowledge about a health service).

Nonresponse Error and its Potential Impact

Nonresponse error is a function of two components: the magnitude of nonresponse (i.e. nonresponse rate); and the extent to which nonrespondents systematically differ from respondents. Concern about survey nonresponse has been driven mainly by the increase in unit nonresponse rates, probably because unit nonresponse results in fewer cases in the analysis, reducing statistical power and the precision of survey estimates. All things being equal, a higher rather than lower survey response rate is preferred because a higher rate indicates that unit nonresponse is lower. Moreover, when unit nonresponse is low, total nonresponse probably is low (for most variables) because item nonresponse is fairly low in most well-conducted surveys [8]. In general, the lower the total nonresponse rate the less concern about whether the participation of nonrespondents would have changed the survey estimates, simply because there are relatively few nonrespondents.

However, a high response rate does not mean that nonresponse error necessarily is trivial. For example, nonrespondents may differ substantially from respondents in terms of relatively rare characteristics [16] or if most nonrespondents are concentrated within one or two sample strata or population subgroups [23]. Also, nonresponse error may be substantial even when nonresponse is low if the factors causing nonresponse are associated strongly with important variables in the study. Ironically, as Kessler et al. [16] have observed, sometimes the techniques used to increase response rates and reduce nonresponse (e.g. special types of contact strategies or monetary incentives) can *increase* nonresponse error if they are more effective among some population subgroups than others, and if an underrepresented subgroup differs strongly from the others in terms of key study variables.

Nonresponse often is correlated with important demographic or other background characteristics (e.g. education in mail surveys, or health status in interview surveys) [6, 8]. But even if nonrespondents are similar to respondents on those characteristics, they may differ in terms of other important variables, such as attitudes and behaviors [23]. For example, persons who engage in risky behaviors may be less willing than others to participate in a survey about the epidemiology of the human immunodeficiency virus [22]. Therefore, the key nonresponse issue is *nonobservation* **bias**, whereby the absence of nonrespondents from the analysis causes one or more survey estimates to be consistently lower or higher than their population parameter (true value). This may substantially change the univariate and/or **multivariate distributions** of the survey data and result in erroneous interpretations of a study's findings.

The methods for taking account of sampling error in survey estimates (e.g. **confidence intervals**) assume that nonresponse error (as well as other nonsampling error) is zero. As nonresponse error increases, the model on which the computation and

interpretation of **inferential** statistics are founded becomes less appropriate. Therefore, the investment in carefully designing and selecting a large, random sample of a target population to minimize sampling error may be subverted by a substantial nonresponse bias. In most cases when the potential for nonresponse bias is relatively large, a researcher should consider using data collection strategies that have been shown to obtain high response rates. Also, the researcher may consider employing various strategies for obtaining information about the nonrespondents that can be used to take nonresponse error into account in the analysis. These decisions about survey design must balance available resources with a study's objectives. For example, an exploratory study may be able to tolerate larger amounts of both nonsampling and sampling errors than a study that is intended to provide a rigorous test of an important hypothesis. In most cases a researcher will invest more resources in the latter type of study.

Measuring and Reporting Nonresponse

Unfortunately, no model exists for taking nonresponse error into account in a way similar to that for assessing statistical inferences based on **probability theory**. Moreover, in most cases it is very difficult or impossible to estimate nonresponse error because reliable knowledge, independent of the survey, about the population regarding the variables measured in the survey usually is not available. Tests for nonresponse bias usually are limited to comparisons of nonrespondents with respondents, or respondents with the target population, in terms of aggregate characteristics such as socioeconomic status and other demographic variables based on data from existing sources (sometimes with questionable reliability) such as the US Census, institutional records (e.g. from schools or clinics), information that may be available from the sampling frame (e.g. residential location), or interviewer observation (e.g. type of dwelling unit) [9, 14]. Such comparisons may be useful if the criterion variables are strongly associated with the main variables of interest in the survey. Although it rarely is possible to make comparisons directly regarding the main variables of interest, researchers sometimes try to approximate this by comparing early respondents with late respondents [18] or by conducting brief follow-up interviews with subsamples of nonrespondents [8, 14, 16].

In addition to using techniques that tend to reduce nonresponse, researchers also sometimes apply various *post hoc* adjustments to improve the representativeness of survey estimates. These include techniques such as **poststratification** and a variety of strategies to impute values for missing questionnaire items (*see* **Missing Data**; **Multiple Imputation Methods**).

Survey researchers usually report a *response rate* (or a similar rate that may go by another name, such as cooperation rate or completion rate) rather than a *nonresponse rate*. It seems reasonable to regard a survey nonresponse rate as the complement of its response rate, obtained by subtracting the percentage response rate from 100% [14]. Unfortunately, despite attempts to encourage survey researchers to adopt a standard definition of response rate, there is no universally accepted definition for either a survey response rate or nonresponse rate [5, 7, 14, 17, 20, 24]. Thus, there is considerable confusion in comparing the quality of survey data across studies (meta-analysis), time periods, and survey methods.

The prevailing concept appears to be that a survey response rate should reflect the degree to which a survey succeeds in obtaining the cooperation of all potential respondents in the sample. Accordingly, the response rate may be calculated as the proportion of sample members known or estimated to be eligible for participation in the survey, from whom a complete/usable set of data is obtained. While there appears to be general agreement about the numerator for the response rate calculation (i.e. complete/usable cases), there is substantial variation in specifying the denominator, especially regarding the definition and estimation of eligible sample members [19, 20]. Moreover, the factors that effect eligibility vary with the sampling design and data collection procedures. In particular, this issue becomes quite complex in surveys using methods such as **random-digit dialing** telephone interviews, in which it is difficult and sometimes impossible to determine the eligibility of a substantial proportion of the initial sample.

The best guidance for computing response rates is available from the American Association for Public Opinion Research (AAPOR) both in the form of a report [2] and a Response Rate Calculator spreadsheet that may be downloaded free at the AAPOR web site [3]. However, until standard definitions of response and nonresponse rates are adopted, it is recommended that survey reports state how the response rate (or

similar term) is calculated, including the definition of eligible sample members [8, 17, 24].

Response rates rarely are reported for individual items. Item nonresponse usually is indicated by reporting the number of cases and/or **degrees of freedom** when presenting results in the text and/or tables of a survey report. However, when appropriate, it is recommended that an item nonresponse rate should be calculated as the proportion of respondents from whom a usable response was not obtained to a questionnaire item, from among the number of respondents who were eligible to answer that item.

Finally, because nonresponse error is not necessarily a direct function of the response rate, and because the definition and calculation of response rate are not consistent, it is not possible unequivocally to specify acceptable levels of survey response/nonresponse. However, some gross guidelines are that a survey with a response rate lower than 50% is very likely to contain a substantial nonresponse error [4, 10, 12]. A response rate greater than 75% generally may be regarded as good to excellent [10, 13]. However, it is strongly recommended that virtually any response rate should be compared with the response rate for other surveys addressing similar topics, dealing with similar populations, and using similar methods. Also, the study's goals should be considered: the more at stake in terms of the study's findings, the less the tolerance for nonresponse error.

Nonsampling Errors

It has become conventional to partition the total survey error into components representing sampling and nonsampling errors. Sampling error arises from the sampling process itself, i.e. from the fact that we are making **inferences** from observations on a randomly chosen subset of units, rather than observing the whole population. Nonsampling errors include all the errors not attributable to this incomplete enumeration. Every step in the survey process is a potential source of nonsampling error, from imperfections in the initial specification and listing of the **target population**, through failure to obtain complete information from all units drawn in the sample (*see* **Nonresponse**) or to obtain correct information from the units that we do contact, to errors in recording and managing the data after the survey has been completed (*see* **Data Management and Coordination**).

Sampling error is relatively easy to deal with, at least in principle. We can reduce its effect by increasing the sample size or by clever choice of design and estimator (*see* **Estimation**). Moreover, we can estimate its size internally from the sample measurements themselves. In contrast, nonsampling errors often increase as we increase the sample size or the complexity of the sampling procedure and, although special surveys can be designed to get information on some components, it is difficult to measure the size of most components without external information of some sort. Unfortunately, the nonsampling component of the total error is likely to be at least as large as the sampling component in a well-designed survey. Since the impact of this component of total survey error is not captured by conventional formulas for the **standard error**, published estimates of survey error almost always underestimate the true state of affairs.

In the following sections we look at some specific sources of nonsampling error, with special reference to health surveys (*see* **Surveys, Health and Morbidity**), under three general headings: coverage errors (frame errors and nonresponse); **measurement errors** (question and format effects, respondent errors, interviewer effects); and processing errors. The choice of survey mode can have a substantial impact on all these components. In health research, this usually involves a choice among personal interviews, telephone interviews or mailed questionnaires. Some useful advice on the relationship between the survey mode and data quality for a variety of health outcomes is given by Van der Zouwen et al. [32], Siemiatydi [30], and Sibbald et al. [28]. Once the mode has been chosen, most methods aimed at reducing the nonsampling errors involve more resources being spent on preparation, pre-testing and piloting, training and supervision, and processing. These methods tend to be expensive and, with a limited budget, mean that the sample size will need to be reduced.

Coverage Errors

Coverage errors arise when the population from which the sample is really drawn differs from the target population. Two major sources of such errors are deficiencies in the **sampling frame** or listing from which the sample of units is drawn, and a failure to elicit responses from every unit that is drawn in the sample.

Frame Errors

A key requirement in the early stages of planning for any survey is the development of a frame, i.e. a list of units from which the sample will be drawn. In a telephone survey the frame will consist of a list of phone numbers, in a mail survey it will be a list of addresses, while in a personal interview survey it might be a list of households, area sampling units, hospitals or physicians' practices. Except in the very simplest situations, the population defined by the frame is likely to differ from the target population whose characteristics we really want to measure. For example, in a telephone survey any member of the target population who is not accessible by telephone will be excluded [7]. Similarly, in any survey based on a register or list of patients held by a health facility, such as a practice, a certain proportion will have either moved address or left the facility entirely [25].

Frame error can take the form of overcoverage. This can occur when the frame contains units that do not belong to the target population, or when there are multiple or duplicate listings such that single population units are identified with more than one frame element. However, the most common type of frame error takes the form of undercoverage (or incomplete coverage), with some units in the target population omitted from the frame. The effect of

undercoverage depends both on the proportion of missing units and on the magnitude of the difference between the values of the missing units and those listed in the frame. For example, consider a simple **mean** or proportion, θ. If we use subscripts T, F, and NC to denote values for the target population, the frame, and the units not covered by the frame respectively, then we have

$$\theta_T = \theta_F + \pi_{NC}(\theta_{NC} - \theta_F),$$

where π_{NC} denotes the proportion of the target population units that are not covered by the frame. We see that the **bias** (i.e the difference between the target and frame population values) is the product of the proportion of undercoverage and the difference between the means of the units in the frame and the omitted units. Most health surveys are concerned with more complex quantities than means and proportions (**relative risks**, **regression** parameters, etc.). Here the effect cannot be expressed quite so simply, but the basic idea still applies; there is little bias from undercoverage if the proportion of units not covered by the frame is small or if parameter values for the omitted units are very similar to those of the frame units.

Unfortunately there is no way to detect the presence of undercoverage either from the frame or from the sample itself, and no simple way to overcome the problem completely. Some ways to help alleviate this and other frame problems are discussed by Lessler & Kalsbeek [19, pp. 80–102] and Groves [13, pp. 81–128].

Nonresponse

Even if we have a reasonably complete frame from which to draw our sample, we may not be able to elicit responses from every unit. People may not return mailed questionnaires, or they may be out when the interviewer calls. Some people may be unwilling or unable to respond even if they are contacted. Some units may not provide any information at all (*unit* nonresponse) while others may provide responses for some items but not others (*item* nonresponse). Nonresponse can be regarded as another aspect of undercoverage, and the effect is very similar to that for incomplete frames; the degree of bias depends both on the response rate and on the extent to which nonresponders differ from responders. The response bias will be small if the proportion of nonrespondents is small (i.e. a high response rate) or if there is little difference between responders and nonresponders. Differences between responders and nonresponders can be substantial in many health surveys. For example, readiness to respond may be influenced by recently experienced health events, which may engender greater interest in participating in a health survey [3], or by health status, with those having the symptoms under investigation more likely to respond [20, 31]. One difference between nonresponse and frame undercoverage is that we do at least know the proportion of nonrespondents so that the possibility of a problem is clearly signalled, even if we have no idea of its size. Perhaps for this reason, there has been more attention paid to nonresponse than to any other source of nonsampling error.

As with most nonsampling errors, prevention is usually the best form of cure. It is hard to do much to control differences between responders and nonresponders, but it may be possible to increase the response rate. The choice of survey mode can have a big impact on response rates. In general, response rates for postal surveys tend to be lower, but older people who feel threatened by face-to-face interviews with a stranger may respond well to a mail survey [15]. The design of questions (*see* **Questionnaire Design**) and the quality of interviewers (*see* **Interviewing Techniques**) can also affect the response rate [4]. Extra training and extensive piloting can improve things here. Once the survey is in progress, we can make vigorous attempts to contact initial nonrespondents. For example, we might get interviewers to call back several times if a person is not at home, or send several reminder letters with a mailed questionnaire (*see* **Call-backs and Mail-backs in Sample Surveys**). Providing incentives such as paying people to take part may also improve response rates in some circumstances (although this can accentuate differences between responders and nonresponders if, for example, low-income people are more likely to be attracted by the offer [27]). Most of these measures are costly and implementation will usually have to be at the expense of sample size. This tradeoff will be worthwhile if the extra responses are sufficiently different to alter the survey estimate.

Getting an indication of the size of the difference between responders and nonresponders is difficult. Direct subsampling of nonrespondents, although expensive, may be worthwhile in some circumstances.

If we have auxiliary information on all units listed in the frame, then we can calculate differences between the means of the auxiliary variables for respondents and nonrespondents. If these variables are **correlated** with the study variables, this will give some indication of the potential problems. For example, Andersen et al. [1] compared respondent reports of care received with medical record data and derived adjustments. Frequently, however, such auxiliary information is not available. Another approach is possible if we are prepared to assume that willingness to respond lies on a continuum of cooperation. Then we may get some idea of the likely magnitude of problems by looking at differences between estimates for early and late responders, or those who respond only after additional prompting [15]. A number of studies have shown that nonresponders are more like late responders than early responders [9, 29].

One way of getting direct information on nonrespondents which is particularly useful in health surveys is through the use of proxy (or surrogate) respondents. Questionnaires constructed using concrete items which require less interpretation by the proxy and a shorter range of possible responses are more likely to yield responses congruent with subject response. In health surveys, studies have shown that proxies are able to report accurately on areas of health and functioning, although they tend to rate patients as slightly more impaired than patients rate themselves [11, 22]. Agreement between subject and proxy tends to be lower for conditions that are not observable, relatively private and not likely to be discussed, such as mental conditions and general aches and pains [22]. The best agreement is achieved in subject–proxy pairs where the respondents live together; correlation is reduced as contact between subjects is reduced.

Finally, a whole range of statistical procedures have been proposed to mitigate the effects of unit nonresponse. These include **post-stratification** and weighting adjustments based on estimates of the probability of response. These estimates might be based on auxiliary information, for example, or on extra information collected from respondents. A common procedure uses data on how often each respondent has been available for interview in the past week. A good review of these procedures is given in Lessler & Kalsbeek [19, pp. 161–233]. The most common procedure of all, particularly for item nonresponse, is to impute the missing values from respondent data. Many different imputation procedures have been proposed and a good overview can be found in Kalton & Kasprzyk [16]. There can be problems making inferences, and particularly with estimating precision, if too many values are imputed. Rao [26] and the ensuing discussion give some idea of the problems (*see* **Missing Data**; **Missing Data Estimation, "Hot Deck" and "Cold Deck"**; **Multiple Imputation Methods**).

Measurement Errors

Measurement errors arise from complex interactions among the survey mode, the instrument (i.e. the questionnaire in most health surveys), the particular question, the respondent, and, in personal interview and telephone surveys, the interviewer. For convenience, we group common problems under three general headings, but most problems involve all of these components to some extent.

Question and Format Effects

It is obvious that asking the right questions is critical if we are to obtain good information about the quantities in which we are interested. Common sense tells us that questions should be clear and unambiguous and expressed in language that the respondent can understand. Unfortunately, the situation is much more complex than this. The survey mode (personal interview, telephone interview, mailed questionnaire) can have a big impact. For example, telephone respondents tend to indicate a more favorable health status than mail respondents [23]. Differences can be large; in a study reported in Moore [24], 44% of people interviewed personally answered "Yes" when asked if they favored contraceptives being made freely available to unmarried women, in contrast to 75% of those questioned by telephone or mail. Even for a given choice of mode, very subtle changes in the wording, context, format, and layout of a questionnaire can have a measurable effect on the survey response. The order in which questions are asked affects the way that people respond in all modes, but even seemingly inconsequential factors such as the placement of instructions and the color of print has been shown to affect the responses. **Questionnaire design** is a specialist subject with a huge literature of its own. A

good introduction can be found in Kalton & Schuman [17] which is essential, if chastening, reading for anyone planning a survey for the first time.

Respondent Errors

The respondent is the ultimate source of information. Even if the question is understood clearly, he or she must have access to the information that is sought and must be able (and willing) to access this information accurately. Accuracy of recall is related to respondent motivation, the degree of detail required, the significance of the event and the time elapsed since it occurred, and also to the nature of the topic. For example, illness in healthy subjects may be underreported because it is not of current concern to the respondent (*see* **Recall Bias**).

Many surveys ask about events that occur in a specific time-period, such as the number of visits to a doctor over the past year. This requires respondents to place events in time, and a common distortion is "telescoping", where an event is remembered as having happened more recently than was actually the case. Fortunately, this has the opposite effect to loss of recall and the two errors may partially offset each other. Surveys asking for sensitive or personal information (e.g. about diet, sexual activity or alcohol consumption) may engender a "social desirability bias" resulting from the wish of a respondent to convey a positive image in keeping with social norms and to avoid criticism. This can distort the measurement of the variable of interest significantly [14, 33].

Methods to reduce respondent measurement errors require some understanding of their causes. The literature on this topic is wide-ranging, and includes work in cognitive psychology on memory and judgment as well as work in social psychology, survey methodology, and other disciplines. A good introduction is given by Groves [13, Chapter 9]. The Survey Research Center at Michigan has conducted a long-term study aimed at improving the quality of reporting of health events. Some of the results are summarized by Cannell et al. [5]. Successful techniques tried by Cannell and his colleagues at Michigan include the use of instructions to respondents asking them to think carefully about their responses and emphasizing that accurate and complete answers are important, the use of feedback, and securing a formal agreement of respondent commitment. Some of their findings are surprising. For example, they found that longer questions sometimes gave an increase in the number of health events reported, suggesting that the common advice to "keep the questions short" might be better phrased as "keep the questions simple" (see [17]).

Interviewer Effects

In personal interview and telephone surveys, the interviewer introduces a further source of measurement error. Some interviewers may simply not adhere to the survey protocol. Most problems stem from the interaction between the interviewer and respondent. The effect is likely to vary according to the type of question, with attitude questions, questions requiring probing, fixed-alternative and forced-choice items, together with poorly worded and ambiguous questions, being particularly susceptible to interviewer variability. When questions are unclear and consistently require additional interviewer input, there is a greater likelihood that results may be influenced by the interviewer; different interviewers may interpret questions differently, or may rephrase questions in a directive manner [10]. "Acquiescence bias" arising from the disposition to answer "yes" (or, less commonly, "no") regardless of the question asked, may be more severe in interviews with respondents who are of low socioeconomic status, or belong to minority cultures, when the interviewer is perceived to be of higher status.

The impact of interviewer variability depends on several things. For simple means and proportions, the **variance** of the sample estimate in **simple random sampling** is inflated by a factor $1 + (n - 1)\rho_{\text{int}}$, where n is a weighted average of the interviewers' case-loads and ρ_{int} is the intra-interviewer correlation as defined by Kish [18]. This correlation is a scale-free measure of the size of the variability among interviewers. The effect is similar with more complex survey designs. The impact depends both on the interviewer variability, as measured by ρ_{int}, and on the size of the case-load. Even very small values of ρ_{int} can have a big impact on the precision of the estimate if the average case-load is large. Most medical and health surveys are interested in more complex issues such as making comparisons between subgroups, comparing **relative risks**, estimating **regression** coefficients, and so on. There is a general belief that the impact of interviewer variability is much less severe for more complex parameters.

The special case of comparisons between subgroups is examined by Davis & Scott [8]. They show that the impact depends on the distribution of the case-loads between the subgroups and on the interaction between the interviewers and the members of the subgroups. The effect will usually be smaller than for a single mean but can be almost as large if the case-loads are very unbalanced and the interviewer effect differs between subgroups.

Most suggestions for reducing interviewer effects involve putting effort into the initial selection of interviewers, and into their training and supervision. A quality control protocol for checking interviewing consistency using audio tapes of randomly selected interviews has been shown to reduce interviewer variability [10]. The number of interviewers involved in a survey is an important factor since small differences between interviewers may give rise to appreciable reductions in the precision of sample estimates if each interviewer has a large case-load. With a constant ρ_{int}, the impact of interviewer variance can be reduced by increasing the number of interviewers and so reducing the number of individuals responding to each interviewer. However, this will usually result in a more heterogeneous pool of interviewers, particularly in heath surveys, where the interviewer often needs special expertise, and in less intensive training and supervision, all of which will tend to increase ρ_{int}. Data quality can sometimes be improved by careful deployment of the interviewers. We have seen above that making sure that interviewers see respondents from all subgroups can improve the precision of subgroup comparisons. Matching interviewers to respondents, such as using an interviewer of the same gender for examining sexual behavior [6], can also sometimes be effective. For example, older white male interviewers gained more reports of substance abuse in a study by Johnson & Parsons [15].

Processing Errors

Once the respondents have answered the questions, the responses have to be coded, edited and entered in a machine-readable form. Supplemental editing will usually be needed to clean the data. Finally, the raw data will be manipulated into a form suitable for analysis. Missing values may be imputed at this stage. The processing stage is the least glamorous but often the most important step in the whole survey process. Errors can creep in at every step; we may find coding errors, transcription errors, and errors introduced by the editing. However, we have an opportunity to remedy some of the nonsampling errors introduced earlier in the survey operation. All large survey organizations have their own specialized editing procedures for detecting inconsistencies and unlikely responses. In some cases we may have to check back with the original respondent to get clarification of responses that do not pass the editing checks.

Coding and transcription errors can be minimized by cutting down the human component of the process as far as possible with the use of computer-assisted data entry techniques. **Computer assisted telephone interviewing** (CATI) is one of these techniques. Providing interviewers with laptop computers so that data entry and editing can be carried out at the time of the original interview as with CATI is another. Most of the effective methods to control human errors involve careful selection, training, and supervision of personnel, just as with other sources of nonsampling errors. A good survey of modern methods for process control in surveys is given by Lyberg et al. [23].

Further Reading

Good general surveys of the broad field of nonsampling errors can be found in the books by Groves [13] and Lessler & Kalsbeek [19] and in the collections edited by Biemer et al. [2] and Lyberg et al. [21].

Normal Clinical Values, Design of a Study

Ideally, a study to determine normal ranges for a cross-section of a specified population should start by selecting a random (i.e. probability) sample of healthy individuals from that population (*see* **Probability Sampling**). Since participation in such a study requires informed consent, which many randomly selected individuals may decline, an attempt should be made to test whether those agreeing to participate are representative of the entire population. Unfortunately, these conditions have only rarely been met in normal range studies. There have been exceptions, however, and we will mention these later.

The key stumbling block is the word "healthy". If one were interested in a cross-section of the entire population (as defined, for example, by location, age, or gender), a reasonably straightforward plan would be to select individuals according to a probability sample from existing **census** records and then invite them to participate in a study to measure the variation in some physiological function or blood test. For example, the National Health and Nutrition Examination Surveys (NHANES) conducted by the **National Center for Health Statistics** were based on samples of the civilian noninstitutionalized US population following a highly stratified (*see* **Stratification**), **multistage sampling** design. More familiar perhaps to epidemiologists is the **Framingham Heart Study**. Begun in 1948, this was a prospective study of risk factors in myocardial heart disease. A list of town residents was stratified by family size and precinct of residence. A sample of two families was selected at random from every three successive families in each stratum. All persons aged 30–59 in each selected family were included in the study.

The problem becomes more complicated when one wants to restrict the selected sample of reference subjects to healthy persons. At some point in the selection process a screen must be applied to detect those who do not qualify as healthy. This requires the development of a medical history questionnaire (*see* **Questionnaire Design**) (which many people might refuse to fill out) and evaluation of each individual return. Nevertheless, probability sampling may be applied to obtain the initial sample of individuals. A good example is a study undertaken in 1974 by Munan et al. [9] of the University of Sherbrooke in Quebec province, Canada, to establish population-based normal values for a variety of blood constituents. A total of 900 households in the Eastern Townships of Quebec (just north of the Vermont–New Hampshire border) were chosen randomly from 75 census enumeration districts. Within these families, approximately 2400 persons agreed to participate and were interviewed through a standard questionnaire. This questionnaire covered certain exclusion criteria listed in the next section. On the basis of the responses to these criteria, slightly over 50% of these individuals were selected as reference subjects.

During the 1970s, many studies were undertaken to develop normal ranges from large samples of individuals. The guiding principle in most cases was to obtain data from individuals presumed a priori to be healthy, so that every measurement could be used in the calculations. Often, blood donors were assumed to fit this description, although we recognize now that paying blood donors can attract many who are not really healthy. In addition, their ages are younger, in general, than the population as a whole. Other sources of subjects included attendees at a well-person screening clinic, or an outpatient clinic for some disability that was not expected to influence the variables measured. For example, an orthopedic clinic might meet this specification for many blood constituents. In some studies, data were obtained from instruments set up in a booth at an amusement park or a fair that gathered large numbers of presumed healthy persons. Under these circumstances, only the most superficial criteria for judging health could be applied.

If the variable for which normal values are desired is an indicator of a specific disease, the general health status of an individual in the population is not of concern; rather, the question is whether or not a prospective reference subject is suffering from that particular disease. It is then more feasible to obtain a statistically **random sample**, provided one has available some highly sensitive diagnostic tests, apart from the variable of interest, to detect the presence of the disease. The study of biochemical tumor markers often fits this description. An example is prostatic specific antigen (PSA), now well known as an indicator of prostate cancer. In a recent study by Oesterling et al. [11], a sample of almost 4000

white males aged 40–79 years, without a history of prostate cancer, was selected at random from a population of over 100 000 in Olmsted County, Minnesota. Only slightly over 55% agreed to participate in a prostatic evaluation, so the potential **bias** of self-selection loomed (*see* **Selection Bias**). Comparison of the medical records of those who agreed to participate, and those who declined, did not show "significant differences". Of this slightly over 2000-man group, about 25% were selected at random for the evaluation, which included not only the PSA measurement but also two additional diagnostic tests for prostate cancer. From this sample, the authors determined normal ranges for PSA as a function of age.

It remains that the vast majority of published normal ranges for blood constituents are not derived from random samples but from "samples of convenience"; for example, hospital or laboratory employees, blood donors, medical students, or other groups assumed to be "healthy" (or, at least, functioning normally in their daily occupations) and convenient to the laboratory desiring to obtain these ranges. In some sample groups, the restriction to a certain age group will be obvious. The situation is worse for many physiological functions where an "average normal" value is repeated in many medical textbooks. A prime example is cardiac output, for which the figure of 5–6 l/min is often cited as representing the average 73 kg male.

Exclusion Criteria

In 1975, Alström et al. [1] of the Scandinavian Committee on Reference Values (SCRV) published an extensive, rather rigid, set of exclusion criteria, including upper limits for blood pressure, hematocrit, serum cholesterol and triglycerides, urine albumin, and glucose. In addition, the use of therapeutic drugs or drugs of abuse was barred, as well as a long list of diagnosed diseases. Immediately on publication, these criteria were applied to a randomly drawn sample of potential reference subjects in Kristianstad, Sweden. Results [2] showed that use of these criteria excluded all but 11% of the men and 24% of the women from further testing. Clearly, some loosening of the criteria was needed. The criteria employed by Munan et al. were simpler and worked better. Even here, however, about 50% of the randomly selected persons who agreed to participate were finally excluded from the study, and the differences, if any, between selected and original population were not explored. The exclusion criteria of Munan et al. were as follows:

1. No chronic disease reported at the time of interview.
2. No disease leading to confinement to bed during the 15 days preceding the interview.
3. No medication intake in the 48 hours preceding the interview, except for vitamins.
4. No alcohol intake in the 48 hours preceding the interview.
5. Did not smoke more than 50 cigarettes during the 48 hours preceding the interview.

During the 1980s, the Expert Panel on the Theory of Reference Values (EPTRV) of the International Federation of Clinical Chemistry (IFCC) published a series of recommended practices with respect to the determination of normal values and ranges. One of these recommendations [6] dealt with the selection of reference subjects. The EPTRV did not formally adopt the rigid criteria of the SCRV, although they suggested the 1975 list of criteria as a guide. The EPTRV specifically recommended the exclusion of individuals suffering from systemic disease and such pathophysiological disorders as renal failure, congestive heart disease, chronic respiratory disease, liver disease, malabsorption syndrome and nutritional anemia. Moreover, individuals on either therapeutic drugs or drugs of abuse were barred, as well as persons using oral contraceptives, alcohol, and tobacco. Possible further criteria for exclusion include pregnancy and recent surgery.

It appears that the problem of developing a set of exclusion criteria that will bar those in a state of ill health from contributing to a normal range study, while not excluding the great majority of potential reference subjects who agree to participate, has not yet been resolved satisfactorily. It would seem, however, that every randomly sampled individual who agrees to participate should be allowed to do so; that is, should complete a medical questionnaire and should be measured for the variables of interest. Then, blind to these data, a reasonable set of predetermined exclusion criteria should be applied to the information in the questionnaires. This would allow comparison of the distributions of measured values in the group of subjects acceptable under the criteria and in those excluded. From such comparisons, information may be obtained not only for determining normal

ranges but also for judging the effects of the exclusion criteria on the distribution of each variable.

Partitioning Criteria

The planning for a normal range study should include consideration of separate ranges for different subgroups of the population. A smaller number of reference subjects within a given subgroup will provide an **unbiased** and more precise range for future application to patients of that subgroup than would a larger number of subjects from many subgroups with clinically important differences in the variable measured. However, as discussed elsewhere, the fact that mean values of different subgroups are significantly different by the usual statistical tests is an insufficient reason for calculating separate normal ranges. The differences must have a known physiological basis or, at least, be large enough to be recognized as clinically important even if the medical world is not sure why they exist. Depending on the sample size in each subgroup, this will demand mean differences whose probability levels under the **null hypothesis** are far smaller than 5% or 1%.

Most commonly, demographic groups (gender, age, race) are the partitioning criteria that come to mind first. Since these separate subgroups are not equally represented in the population sampled (except, in most cases, for gender), different sampling rates must be applied to each subgroup to assure an adequate number of reference subjects for calculating a normal range of acceptable precision (see next section). For example, the criterion of age usually does not imply equally spaced age intervals across the life span. Rather, it refers to approximate age intervals that are known to be associated with important physiological changes. Thus, separate normal ranges may be desired for selected variables in women before and after menopause. This, then, becomes the partitioning criterion, not a specified age boundary. However, information on menstruation will not become available until the medical questionnaires are received from those women willing to participate in the study. It may be, therefore, that an additional random sample of older women will be needed to bolster the sample size in the postmenopausal group.

Other partitioning criteria that might be clinically significant for certain variables include blood group, ethnic background, geographic location, stage of pregnancy, and tobacco use. If one or another of these is thought to be important, the relevant questions must be included in the questionnaire. A recent document published by the National Committee for Clinical Laboratory Standards (NCCLS) [10] contains a sample questionnaire as a planning guide.

Partitioning, if warranted clinically, may improve the homogeneity of within-group data. But whether the measurements are eventually to be subdivided into separate groups or not, certain rules followed during the execution of the study will help greatly to achieve a homogeneous distribution of the results. Among these are conditions on the premeasurement behavior of the reference subjects. For example, they should not engage in strenuous exercise during 24 hours preceding the drawing of a blood specimen. Specimens should be obtained in a fasting state and should be drawn during the morning hours to eliminate variations due to **circadian** rhythms. It is obviously important that the same measurement process (e.g. analytical method) be used throughout the study, and that stable environmental conditions be maintained in the laboratory during this time.

Sample Size

Curiously, the EPTRV of the IFCC did not address the question of how many reference subjects should be sampled to provide the data for calculating a normal range (*see* **Sample Size Determination**). Until recently, this issue has emerged only sporadically in the clinical literature.

Sample size calculations assume that the data represent a random sample from the given population. As indicated above, we believe that a statistically random sample of healthy individuals can, and should, be drawn from the population, although this practice has not been followed in the great majority of studies from which published normal ranges have been derived. Beyond the implicit assumption of random sampling, recommended sample sizes depend on the statistical method used to estimate the normal range. Various parametric and **nonparametric methods** have been described elsewhere.

For a given sample size, the most precise estimating procedure becomes available when the reference values are **normally distributed** or can be transformed to a scale on which they are normal (*see* **Transformations**). In this case, the percentile

limits (*see* **Quantiles**) of the range are estimated from the sample **mean** $\overline{x}$ and **standard deviation** s. Assuming large samples (say, $n \geq 100$), the **variance** of each limit on the normal scale is given approximately by $(3/n)\sigma^2$. For comparison, if these limits had been estimated by the corresponding sample quantiles, their large-sample variances would be approximated by the formula $\text{var}Q_p = p(1-p)/nf_p^2$, where f_p is the normal ordinate at the pth percentile. For $p = 0.025$ or 0.975, $\text{var}Q_p = (7.13/n)\sigma^2$. In other words, on the normal scale, the variance of the quantile estimator of a 95% normal limit would be expected to be 2.4 times larger than that of the normal estimator. The weighted quantile estimate (Harrell–Davis formula), described elsewhere (*see* **Normal Values of Biological Characteristics**), is more precise than the simple quantile, but the reduction in variance is not great, averaging about 20%.

Let us assume that when a normalizing transform can be found, the normal estimators will be used to derive normal limits. Then, a general criterion is needed for obtaining a recommended sample size from which to estimate normal limits for a variable that is normally distributed on either the original or transformed scale. Until recently, this problem was not addressed. Instead, in the few papers considering the question of sample size for normal ranges, it was assumed that the great majority of distributions of clinically important variables were either not normal and could not be normalized satisfactorily through the usual transforming functions, or that the process of trying to find a successful transform and testing for normality was generally too difficult and expensive for most clinical investigators to undertake.

For example, Reed et al. [12] include a table of exact nonparametric 90% **confidence intervals** for upper and lower normal limits for sample sizes from 120 to 369. They recommend a minimum sample size of 120, since this is the smallest number for which an exact nonparametric 90% confidence interval can be calculated (i.e. for any smaller sample size, the lower 90% confidence bound for the lower normal limit is less than the smallest observation, while the upper 90% confidence bound for the upper normal limit is greater than the largest observation). More recently, Miller et al. [8] arrived at a rule for the minimum number of reference subjects based on **bootstrap**-like resampling from a highly skewed empirical distribution: creatine kinase in women. They found that the standard deviation of the quantile $Q_{0.975}$ declined approximately as the square root of sample size up to size 400, but thereafter the decline was less than expected. These authors concluded that samples of less than 200 subjects were clearly inadequate to define 95% normal limits for highly skewed distributions using the sample quantile estimator, but that 400 would probably be sufficient.

It was Linnet [7], however, who proposed a general criterion for sample size that can be applied conveniently to normally distributed variables. This criterion and examples of its application are given in Harris & Boyd [5]. Briefly, Linnet suggested that the width of the 90% or 95% confidence interval for the true normal limit (e.g. the 97.5th percentile of the sampled population) be set equal to a fixed proportion of the normal range; say, 0.1, 0.2, or 0.3. To illustrate the application of this criterion, suppose that we are concerned with a variable whose measurements form a skewed distribution that can be normalized by a square root transformation; that is, the Box–Cox (3) transform parameter $\lambda = 1/2$. Then the width of the 95% normal range, after backtransforming the normal estimators to the original scale, is given by

$$W_{\text{nr}} = (\overline{y} + 2.0s_y)^2 - (\overline{y} - 2.0s_y)^2 = 8\overline{y}s_y, \quad (1)$$

where $\overline{y}$ is the mean and s_y the standard deviation of the square roots.

Similarly, the width of the 90% confidence interval for the true 97.5th percentile will be the difference between the square of the upper limit of the confidence interval computed from the normal estimator minus the square of the lower limit. We noted earlier that the **large-sample** variance of the normal estimator is $(3/n)\sigma^2$. Substituting s_y for σ, the width of the confidence interval on the original scale may be written $W_{\text{ci}} = 11.40\overline{y}s_y(1 + 2.0C_y)/n^{1/2}$, where C_y is the coefficient of variation of the distribution of square roots. Then, the ratio, say R, of W_{ci} to W_{nr} becomes $R = (1/n^{1/2})(1.25 + 2.85C_y)$. Setting $R = 0.2$, say, we obtain an expression for the minimal required sample size n as a function of C_y. This is graphed in Figure 1 ($\lambda = 1/2$).

For $C_y = 0.2$, the sample size must exceed 100 to satisfy the condition on R. This number rises to 400 when $C_y = 1.0$. Also included in Figure 1 are similar graphs for $R = 0.2$ when the power transformation parameter λ is 1/3 or 1/4. Harris & Boyd [5, p. 72] present a graph for the **lognormal distribution**, but

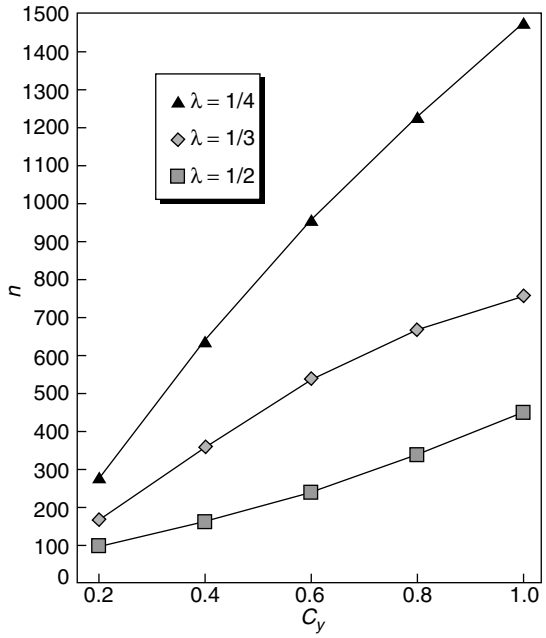

Figure 1 Sample size needed to estimate 2.5% or 97.5% normal limit with confidence interval 20% as wide as 95% normal range, using square root, cube root, or fourth root transformation to normalize the distribution; $C_y = CV$ on transformed scale

here n is a function of the coefficient of variation (*see* **Standard Deviation**) of the measured values on the original scale. They recommend that a pilot sample of 150–200 reference subjects be measured to determine a suitable power transform, if necessary, to achieve normality, and the appropriate coefficient of variation. Then, the foregoing results may be used to estimate the final number of subjects needed to attain the desired value of R. In circumstances where such numbers cannot be obtained, the investigators must settle for wider confidence limits relative to the overall normal range or for a smaller confidence level.

Even if investigators finally decide that no transform path will produce an acceptable normal distribution of their data, it is useful to estimate the Box–Cox power parameter because in most cases a power transform will greatly reduce **skewness** and **kurtosis**. Then, a baseline sample size can be estimated following Linnet's ratio. If a nonparametric estimation procedure is selected, general formulas for Linnet's criterion are not possible because confidence intervals and normal ranges are expressed only in terms of the rankings of the order statistics. In this case, we return to the definition of the normal range as a **tolerance interval** to contain at least a proportion p of the population with confidence $(1 - \alpha)$. To avoid an overly wide interval, Table A.30 in Hahn & Meeker [4] gives the nonparametric sample sizes needed to satisfy these conditions while guaranteeing a specified low probability of including a given proportion greater than p. For example, setting $p = 0.95, 1 - \alpha = 0.90$ and specifying that the probability of including a proportion greater than 0.98 should be no more than 0.1, the minimal sample size is 258.

Given the data from a study of this size, one may calculate Linnet's ratio on an ad hoc basis using the table of Reed et al. [12] to obtain 90% confidence intervals for the upper and lower normal limits. Then one may judge whether additional observations are needed to achieve a satisfactory R value. For sample sizes greater than 369, large-sample approximate confidence limits are given by the **order statistics** $x_{(r)}$ and $x_{(s)}$, where r is the largest integer less than or equal to $np + 1/2 - z_{\alpha/2}[np(1-p)]^{1/2}$, s is the smallest integer greater than or equal to $np + 1/2 + z\alpha/2[np(1-p)]^{1/2}$, and $z_{\alpha/2}$ is the **standard normal deviate** cutting off the upper 100 $(\alpha/2)$% of the normal curve.

EUGENE K. HARRIS

Normal Clinical Values, Reference Intervals for

The idea of trying to detect or diagnose a disorder in an individual by comparing a relevant measurement from that individual with a range of values expected in a healthy or "normal" population is both ancient and intuitive. However, it was made systematic and scientific only in the 1950s when Wootton et al. [33] proposed the use of specific probability distributions to describe variation in biochemical measurements in blood samples from 100 active, working volunteers. Since then an enormous number of papers on "reference values", "normal ranges", "reference ranges" or "reference intervals" (all may be regarded as synonymous) have appeared in the medical, laboratory-based, and statistical literatures. A key controversy in the 1960s was whether hospital patients, a convenient resource for hospital biochemistry laboratories, were a suitable population on which to base reference ranges for application to the general public. This was proposed by Pryce [19], but was effectively dismissed by the work of Elveback [8] who showed major differences in the distributions of important serum variables between healthy working individuals and patients at the Mayo Clinic.

Leaving aside the vexed question of how to choose appropriate reference populations, the notion that an "abnormal" value (i.e. outside defined reference limits) is reliably indicative of disease is open to several criticisms. Since reference ranges are intended to include a fixed proportion of the population (see the section "Definitions" below), inevitably a proportion of "normal" individuals will lie outside the limits and will be falsely classified as "abnormal". Moreover, concentrations of biochemical analytes form a continuous scale, so useful diagnostic information may be lost by dichotomizing at fixed values. Since, nowadays, clinicians tend to order the batteries of tests that are routinely available from multichannel analyzers, there is an obvious problem of multiplicity (*see* **Multiple Comparisons**) when interpreting the results. More fundamentally, for effective discrimination between normal and diseased states the distributions of test values in diseased populations are required. Such distributions are rarely available, doubtless due to the high cost and difficulty of obtaining enough appropriate data.

Despite these and other criticisms, reference ranges remain a continuing feature of everyday clinical practice. In most cases they are used more as informal indicators that "something is wrong" in a particular physiological system when forming a clinical picture of a patient, rather than as formal decision rules in screening (*see* **Decision Analysis in Diagnosis and Treatment Choice**; **Screening, Overview**).

Harris & Boyd [10] is a comprehensive recent text on statistical aspects of reference values in laboratory medicine. It includes useful contextual information and several example data sets.

Definitions

A univariate $p\%$ reference interval is a pair of numbers (the *reference limits*) that enclose the central $p\%$ of a sample of observations (the set of *reference values*) obtained from a specified group of individuals (the *reference subjects*). Thus $(100 - p)/2\%$ of the values lie below the lower limit and the same proportion above the upper limit. The reference subjects are (supposedly) representative of some larger population, more or less well defined. A typical value of $p\%$ in clinical settings is 95%.

When extended to k-dimensional multivariate distributions, the reference interval becomes a reference region and is bounded by a suitable $(k - 1)$-dimensional surface. If the distribution of the reference values is **multivariate normal**, the surface is an ellipsoid.

Note that, by default, reference intervals are **"cross-sectional"**; that is, derived from samples with one observation per subject, though they may depend on factors such as age. Construction of intervals for changes, as in studies of human growth (*see* **Growth and Development**), or in individual patient monitoring, requires longitudinal data and generally more complex methods of statistical analysis (*see* **Longitudinal Data Analysis, Overview**; **Multilevel Models**), and is not considered here.

Design and Sample Size

The choice of reference subjects should be appropriate to the clinical use to which the resulting intervals will be put. In some cases, this may involve

measurements on special groups. For example, children with cerebral palsy are known to grow less rapidly than unaffected individuals, so age-specific reference intervals for, say, height should be constructed from a suitable population of children with the condition, not those from the general population. The selection of individuals is considered by the International Federation of Clinical Chemistry (IFCC) [12] in the clinical chemistry context and by Altman & Chitty [3] for studies of fetal growth.

Choice of sample size, n, is not necessarily straightforward, since no comparison of an outcome variable between groups (as in a **clinical trial**) is to be made. Since adequate information about the tails of the reference distribution is required, methods tend to focus on the precision of estimated reference limits. Stated simply, the width of a **confidence interval** for a centile (*see* **Quantiles**) depends on $\sqrt{n}$, so n may be determined by specifying this width, either in absolute (measurement) units or relative to the width of the reference interval. For example, a possible criterion (illustrated by Harris & Boyd [10, pp. 68–69]) is to take n large enough to ensure that the width of a 90% confidence interval for a reference limit is no more than 20% of the width of a 95% reference interval. One may use **nonparametric methods** or the properties of the **normal distribution** to calculate n. In the latter case, one must allow for estimation of a shape parameter if **transformation** towards normality is needed (see below). It is less clear how to use the approach in the age-specific case, since the width of the confidence interval will vary with age. In addition, the question of a suitable choice of ages arises (*see* **Sample Size Determination**).

Estimation

Univariate Case: Homogeneous Samples

One may determine reference intervals from a set of reference values either by nonparametric methods of quantile estimation or by fitting parametric densities and calculating intervals from the resulting parameters. Nonparametric estimation is distribution-free and therefore **"robust"**, but is usually inefficient in comparison with parametric modeling when a suitable distribution has been found. For example, if the underlying distribution is normal, the **variance** of the simplest nonparametric estimator of the 97.5th centile is 2.44 times that of the normal-based estimator, representing a relative efficiency of only 41%. The situation is less unfavorable with skewed distributions.

One may use the simple quantile estimator obtained by ordering the values and choosing the appropriate **order statistics** (with interpolation if needed). Harrell & Davis [9] proposed a method that gives efficiency gains of about 20% at the cost of additional computation. It is equivalent to applying **bootstrap** resampling to the simple estimator. Alternatively, kernel **density estimators** [27, 28] may be used.

As regards parametric estimation, the most popular method involves the normal distribution or a functional transformation towards normality. Transformation is often needed because the distribution of reference values is positively **skewed**. If we denote the measurement variable by Y, the most commonly used functions are the identity (Y is normal), log Y (Y is **lognormal**), $(Y^{\lambda} - 1)/\lambda$ (Box–Cox transformation) [5], $[\exp(\gamma Y) - 1]/\gamma$ (scaled exponential transformation, closely related to Box–Cox) [17], and $\log(Y + C)$ (origin-shifted logarithmic transformation, e.g. [23]). If we choose the value of the shape parameter (λ, γ, or C) correctly, the transformed measurements will have zero skewness. However, there is still no guarantee that they will be normal. Residual **kurtosis** (nonnormal tails) or other peculiarities may remain. Kurtosis may be removed by further transformation, such as the modulus function [15]. The IFCC [13] recommend use of the exponential transformation, followed by the John–Draper modulus transformation [15], if needed, to remove kurtosis. **Maximum likelihood** is the preferred method of estimating the parameters of these distributions. In most cases, the densities for Y corresponding to the power, origin-shifted logarithmic and exponential transformations may be shown by Taylor expansion to be very similar. They lead to reference intervals that are for practical purposes indistinguishable. (See the example below for an illustration of this assertion.)

Univariate Case: Subgroups and Covariates

The distributions of clinical variables such as blood pressure or serum biochemicals are usually age- or sex-specific. To retain their proper meaning, reference intervals should be constructed to take such **covariates** into account. Categoric variables present

little difficulty provided sample sizes are adequate, because the methods described above may be applied to subgroups. Modeling continuous variables such as age is more challenging and has stimulated statisticians to propose a variety of approaches to estimation. Wright & Royston [34] summarize the main techniques and compare them using several real data sets. Nonparametric techniques have included a window-based quantile estimator followed by polynomial smoothing, both over age and over normal equivalent deviates of selected quantiles [11, 18], and bivariate kernel density estimation [21]. Most current parametric approaches stem in essence from the methods of Cole [6] and Cole & Green [7]. Cole [6] applied the Box–Cox power transformation to remove skewness of Y in each of several contiguous age groups. In a second stage, he smoothed each of the parameter estimates across age by fitting polynomials (*see* **Polynomial Regression**). He called the resulting functions the L, M, and S curves; they represent the age-specific **power**, **median**, and coefficient of variation (*see* **Standard Deviation**) for Y. In a later refinement, which may be described as a **semiparametric** method, Cole & Green [7] used natural cubic **splines** to model the LMS curves by **penalized maximum likelihood**. This method is extremely flexible. Fully parametric methods are proposed by Royston [22], Altman [2], and Royston & Wright [25]. The last is based on the Manly [17] exponential transformation and uses fractional polynomials [24] to represent the age-specific parameter curves. No age grouping is needed.

Example

In a study [14] to compute age-specific reference intervals, the serum concentration of immunoglobulin-G (IgG) was measured in 298 children aged between six months and six years. A scatter plot of IgG concentrations against age is shown in Figure 1.

The continuous lines in Figure 1 are estimated 2.5th and 97.5th age-specific centile curves for IgG. In fact, the curves show the fitted values from three separate parametric models, based on the Box–Cox, shifted logarithmic, and scaled exponential transformations, respectively. (Further details of the modeling, which is based on fractional polynomials and maximum likelihood estimation, are given by Royston & Wright [25].) The results from the three models are essentially identical, and this is typical of such comparisons. The dashed lines show the fit from Cole & Green's natural cubic spline algorithm [7], using respectively 1, 5, and 3 equivalent **degrees of freedom** for the L, M, and S parameter curves. Although there are differences between the parametric and semiparametric curves, they are minor.

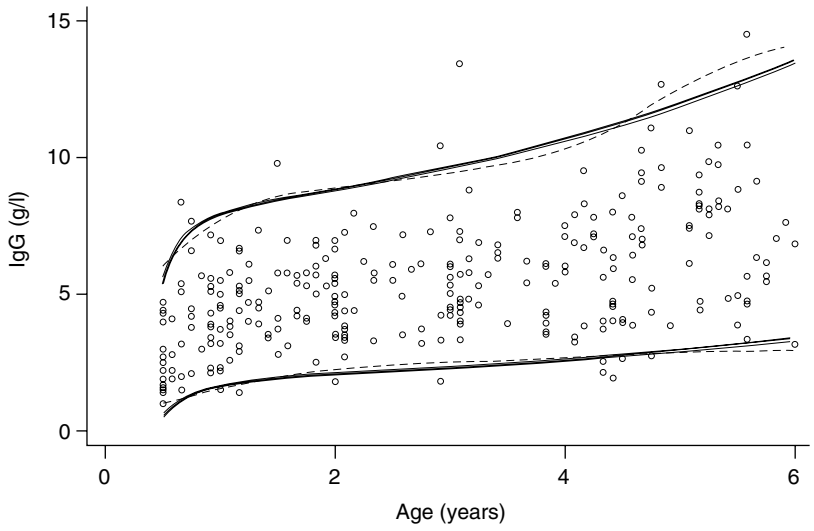

Figure 1 Serum IgG concentrations with estimated 95% age-specific reference intervals according to four models. Continuous lines: three parametric models based on data transformation; broken lines, semiparametric model based on natural cubic splines. See text for further details

Parametric or Nonparametric?

Ultimately, parametric methods are more rewarding because, *provided the model is approximately correct*, they usually offer greater precision and (in the age-specific case) smoother centile curves than do nonparametric methods. A second advantage is in dissemination; parametric models have concise equations that are easily published and, for example, incorporated into computer **software**. A disadvantage is that more initial effort may be required to find a suitable model, if one even exists. Since the validity of parametric models depends strongly on the correctness of their assumptions, such models must be subjected to rigorous **goodness-of-fit** checks (see below).

Multivariate Case

Methods of constructing reference regions for several (usually related) laboratory variables are described in detail by Albert & Harris [1]. Their approach is parametric and is based on the multivariate normal distribution, with preliminary univariate transformation of nonnormal components. Nonparametric **multivariate** density estimation does not seem to have been proposed in the context of clinical reference regions, nor has the age-specific case been discussed. In both cases, construction of reference regions is not straightforward. It is likely that since clinicians will wish to inspect the individual test results anyway, multivariate reference regions are little used in practice, despite the problem of multiplicity mentioned above.

Goodness of Fit and Outliers

Essentially, two methods of assessing goodness of fit of a $p\%$ reference interval have been proposed: direct (e.g. [11]) and model-based (e.g. [6]). The first involves counting the number of points that lie between the reference limits. Apart from **binomial** sampling variation, this number should be approximately $np/100$. The method is applicable in all cases except when the simple quantile estimator has been used to estimate the interval. Unless the sample size is enormous, however, it lacks **power**. The second method relies on the assumption that the data, possibly after transformation, have a known distribution, usually normal. Data transformed to standard normal (i.e. with mean 0 and variance 1) are known as SD scores or Z scores (*see* **Normal Scores**). The normality assumption may be checked by well-known graphical methods such as a histogram or a normal quantile–quantile (Q–Q) plot and by hypothesis tests such as the Shapiro–Francia [26] or Anderson–Darling [31] statistics.

Two major difficulties arise with the model-based method. First, if a shape parameter has been estimated, the distribution of a normality test statistic is affected, invariably in the direction of conservatism (not rejecting the **null hypothesis** often enough). Linnet [16] offered a corrected Anderson–Darling test when the data have been power transformed. Secondly, it is unclear how best to assess the fit of models for age-specific reference intervals. Departures from the model may be age dependent, and overall plots and tests of Z scores may be insensitive to them. Further research is needed in this area.

The detection of **outliers** is mainly relevant to the parametric approaches, as nonparametric methods tend to be robust. There is a huge statistical literature on outliers (a well-known text is [4]) and little may need adding in the present context. A particular problem that arises with power transformation of Y (namely, whether the transformation depends on just a few values) is considered by Tango [32].

Computation

When the reference values are homogeneous and apparently normally distributed, their sample mean and SD are all that are required to calculate any desired reference interval. For example, a $p\%$ interval is given by mean $\pm \mathrm{SD} \cdot \Phi^{-1}[(1 - p/100)/2]$. Essentially the same formula is used when Y has been transformed; the limits are calculated on the transformed scale and finally back-transformed. For the normal age-specific case, Altman [2] proposed a simple approximate solution using absolute **residuals** that does not require iteration. Some difficulty arises in finding maximum likelihood estimates of the parameters when Y has been transformed. **Estimation** is iterative as no closed-form solution is available, and, in general, it is necessary to use special purpose software (either stand-alone programs or routines written for use with particular statistical packages).

Software Sources

Solberg [29] has implemented the exponential/modulus transformation method recommended by the IFCC [13] for homogeneous samples in a stand-alone program (RefVal). It is available from Dr H. E. Solberg, Department of Clinical Chemistry, Rikshospitalet, N-0027 Oslo, Norway. Under the auspices of the **World Health Organization**, an MS-DOS-based package GROSTAT [20] has been developed that implements the nonparametric methods of Healy and colleagues [11, 18]. It is available from Dr H. Pan, Institute of Education, Bedford Way, London WC1H 0AL, UK. A FORTRAN program that implements the semiparametric method of Cole & Green [7] is available from Dr T. J. Cole, MRC Dunn Nutrition Unit, Downham's Way, Cambridge, UK. Software that implements the parametric methods of Royston & Wright [25] for use with the package Stata [30] may be obtained from Dr P. Royston, Department of Medical Statistics and Evaluation, Imperial College School of Medicine, Ducane Road, London W12 0NN, UK.

Normal Distribution

This article describes the univariate normal distribution, with brief references also to the **bivariate normal distribution** and the **multivariate normal distribution**. For each of these, there are brief historical remarks, and discussions of distributional properties, **sampling distributions**, and related applications.

The Univariate Normal Distribution

Historical Remarks

The univariate normal distribution is probably *the* most important distribution in classical statistical theory and methods. This distribution has a "bell-shaped" continuous probability density function. In the history of statistics, it was first discovered by the German mathematician **Carl F. Gauss** in the early nineteenth century while studying certain problems in physics and astronomy. As a result, this distribution is also known as the *Gaussian distribution*.

Distributional Properties

A continuous univariate **random variable** X is said to follow a normal distribution with parameters μ and σ^2 if its probability density function $f(x)$ is of the form

$$f(x) = \left[\frac{1}{(2\pi)^{1/2}\sigma}\right] \exp\left[\frac{-(x-\mu)^2}{2\sigma^2}\right],$$
$$-\infty < x, \mu < \infty, \text{ and } \sigma > 0;$$

in symbols, $X \sim \mathrm{N}(\mu, \sigma^2)$. It can be shown by elementary calculus that the mean and the variance of this distribution are, respectively, μ and σ^2.

A random variable Z is said to follow a *standard* normal distribution if $Z \sim \mathrm{N}(0, 1)$ (*see* **Standard Normal Deviate**). The distribution function of Z, $\Phi(z)$, is then given by

$$\Phi(z) = \int_{-\infty}^{z} \left[\frac{1}{(2\pi)^{1/2}}\right] \exp\left(\frac{-u^2}{2}\right) \, \mathrm{d}u.$$

Since the function $\exp(-u^2/2)$ is symmetric about 0, $\Phi(z)$ satisfies $\Phi(z) = 1 - \Phi(-z)$ for all z. The $(1-\alpha)$th **quantile** [or $100(1-\alpha)$th percentile] of a standard normal distribution, often denoted as z_α in most textbooks, is the quantity that satisfies $\Phi(z_\alpha) = 1 - \alpha, \alpha \in (0, 1)$. Since the function $\Phi(z)$ cannot be expressed in a closed form, tables for the numerical values of $\Phi(z)$ and z_α are needed. Such tables can be found in most statistics books.

The following theorem, which can be proved by calculus, shows how a normal distribution with mean μ and variance σ^2 is related to the standard normal distribution.

Theorem 1. If $X \sim \mathrm{N}(\mu, \sigma^2)$, then the random variable $Z = (X - \mu)/\sigma$ is distributed according to the standard normal distribution.

As a simple application of Theorem 1, it follows that:

Fact 2. If $X \sim \mathrm{N}(\mu, \sigma^2)$, then:

1. $\Pr[a < X \le b] = \Phi((b-\mu)/\sigma) - \Phi((a-\mu)/\sigma)$ for all $a < b$;
2. The $(1-\alpha)$th quantile of the distribution of X is $\mu + z_\alpha \sigma$.

Thus, tables for the standard normal distribution can be used for any univariate normal distribution.

More detailed distribution properties of the univariate normal distribution can be found in Patel & Read [4] and other related sources.

Sampling Distributions

The **chi-square distribution, Student's *t* distribution**, and the ***F* distribution**, generally considered to be the cornerstones of classical statistical analysis, are closely related to the normal distribution. Specifically, let $X_1, X_2, \ldots, X_N$ be a random sample of size N from an $\mathrm{N}(\mu, \sigma^2)$ distribution; let

$$\overline{X} = \frac{1}{N}\sum_{i=1}^{N} X_i \quad \text{and} \quad \mathbf{S}^2 = \frac{1}{N-1}\sum_{i=1}^{N}(X_i - \overline{X})^2$$

denote the sample mean and the sample variance, respectively. Then:

1. $\overline{X}$ has an $\mathrm{N}(\mu, \sigma^2/N)$ distribution and $(N-1)S^2/\sigma^2$ has a chi-square distribution with $N-1$ **degrees of freedom**. Furthermore, $\overline{X}$ and S^2 are independent.
2. $t = N^{1/2}(\overline{X} - \mu)/S$ has a Student's t distribution with $N-1$ degrees of freedom, where $S = \sqrt{S^2}$ is the sample standard deviation.

3. t^2 has an F distribution with degrees of freedom $(1, N-1)$.

Another important sampling distribution result related to the normal distribution is a fundamental theorem in probability theory, called the **central limit theorem**:

Theorem 3. Let $X_1, X_2, \ldots, X_N$ be a random sample of size N from any population with mean μ and finite variance σ^2. Then, for every fixed z,

$$\lim_{N\to\infty} \Pr[\{N^{1/2}(\overline{X}-\mu)/\sigma\} \le z] = \Phi(z).$$

This theorem provides an approximation for the distribution of $\overline{X}$ when N is large. In most applications,

$$\Pr[a < \overline{X} \le b] \doteq \Phi(N^{1/2}(b-\mu)/\sigma) - \Phi(N^{1/2}(a-\mu)/\sigma)$$

when $N \ge 30$.

Related Applications

In various applications of statistical **inference** problems – including, **estimation** of the parameters and **hypothesis testing** – the above sampling distribution results are applied. These include the following:

1. For inference on μ when σ^2 is known, the results for the distribution of $\overline{X}$ and Theorem 3 may be applied.
2. For inference on μ when σ^2 is unknown under the assumption of normality, Student's t distribution may be used.
3. When making statistical inference on σ^2 under the assumption of normality, the chi-square distribution may be used.
4. The normal distribution may be applied for inference on the difference of two normal means when their variances are known. Similarly, the Student's t distribution may be applied for the same purpose when the variances are unknown but equal; in the hypotheses-testing problem, this is known as the two-sample t test (*see* **Student's *t* Statistics**).
5. The F distribution may be applied for testing the equality of $k \ge 2$ normal means when the variances are assumed to be equal but unknown. This method is known as the one-way **analysis of variance** (ANOVA) method. When $k = 2$, it reduces to the two-sample t test as a special case.
6. Other results related to Theorem 3 are useful in **large-sample** inference problems. For example, it is known that under regularity conditions the **maximum likelihood** estimator has an asymptotically normal distribution, and that the asymptotic null distribution of $-2\ln\lambda$ is chi-square, where λ is the likelihood ratio function in a **likelihood ratio test**.

The Bivariate Normal Distribution

Historical Remarks

Studies of the bivariate normal distribution seem to begin in the middle of the nineteenth century, and moved forward dramatically when **Galton** published his work [3] on the applications of correlation analysis in genetics. As **Karl Pearson** noted in his 1920 *Biometrika* paper [6], "In 1885 Galton had completed the theory of bivariate normal correlation" but, because he "was very modest and throughout his life underrated his own mathematical powers, he did not at once write down the equation" of the bivariate normal density function. Consequently, it was Pearson himself who gave a definitive mathematical formulation of the bivariate normal distribution in his 1896 paper [5] on **regression** and heredity.

Distributional Properties

A two-dimensional random vector (X_1, X_2) is said to have a bivariate normal distribution if their joint density function $f(x_1, x_2)$ is of the form

$$f(x_1, x_2) = [2\pi\sigma_1\sigma_2(1-\rho^2)^{1/2}]^{-1} \exp\left[-\tfrac{1}{2}Q_2(x_1, x_2; \boldsymbol{\mu}, \boldsymbol{\Sigma})\right], \quad -\infty < x_1, x_2 < \infty;$$

where

$$Q_2(x_1, x_2; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = (x_1-\mu_1, x_2-\mu_2)\boldsymbol{\Sigma}^{-1} \times \begin{pmatrix} x_1-\mu_1 \\ x_2-\mu_2 \end{pmatrix}$$

defines an ellipse centered at $(\mu_1, \mu_2) \equiv \boldsymbol{\mu}$ (which is the mean vector), the 2×2 matrix

$$\boldsymbol{\Sigma} = \begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix}$$

is the **covariance matrix**, and $\rho \in (-1, 1)$ is the **correlation** coefficient.

The marginal and conditional distributions of a bivariate normal random vector are univariate normal. For details, see the article on **bivariate normal distribution** and Tong [7, Section 2.1].

Sampling Distributions and Related Applications

The sampling distribution results involve the distributions of the sample mean vector $\overline{\mathbf{X}}$, the sample covariance matrix $\mathbf{S}$, the independence property of $\overline{\mathbf{X}}$ and $\mathbf{S}$, and the distribution of the sample correlation coefficient. Those results may be applied for estimation and hypotheses testing purposes. For details, see the article on **bivariate normal distribution**, Anderson [1, Section 2.3], and Tong [7, Sections 2.1 and 2.2].

The Multivariate Normal Distribution

Historical Remarks

The development of the multivariate normal distribution theory, which originated mainly from the studies of regression analysis and multiple and partial correlation analysis (*see* **Multiple Linear Regression**), was treated comprehensively for the first time by **Edgeworth** in his 1892 paper [2]. The development of the sampling distribution theory under the assumption of normality (such as Fisher's work on the distributions of sample correlation coefficients and **Hotelling's T^2 distribution**) then followed.

Distributional Properties

An n-dimensional random vector $\mathbf{X} = (X_1, \ldots, X_n)$ is said to follow a multivariate normal distribution with mean vector $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)$ and covariance matrix $\boldsymbol{\Sigma}_{n\times n} = (\sigma_{ij})$, in symbols $\mathbf{X} \sim \mathrm{N}_n(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, if its joint probability density function is of the form

$$f(\mathbf{x}) = [(2\pi)^{n/2}|\boldsymbol{\Sigma}|^{1/2}]^{-1} \exp\left[-\tfrac{1}{2}Q_n(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma})\right], \quad \mathbf{x} \in \mathbb{R}^n,$$

where

$$Q_n(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = (\mathbf{x} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu})'.$$

The marginal and conditional distributions of a multivariate normal random vector are also normal. For details, see the article on **Multivariate Normal Distribution**, Anderson [1, Sections 2.3, 2.4 and 2.5], and Tong [7, Section 3.3].

Sampling Distributions and Related Applications

The sampling distribution results also involve $\overline{\mathbf{X}}$, $\mathbf{S}$, and their independence property; in particular, the results are related to Hotelling's T^2 distribution and the **Wishart distribution** (generalizations of the Student's t distribution and chi-square distribution, respectively). There also exist distributional results on the sample regression equations and various types of sample correlation coefficients. Such results have been found useful for the purposes of prediction and correlation analysis. For details on sampling distributions, see the article on **Multivariate Normal Distribution**, Anderson [1, Chapters 4, 5, and 7], Tong [7, Sections 3.4 and 3.5], and other related sources. For related applications in inference, a classical reference is Anderson [1].

Normal Scores

Normal scores are the **expectations** of the **order statistics** of a sample from the standard **normal distribution**. They are widely used in plots (*see* **Normality, Tests of**) and tests to assess the **goodness of fit** of the normal distribution to data, and also in other procedures (*see* **Normality, Tests of**).

The key idea in assessing fit is that a sample from a continuous distribution will tend to have a shape characteristic of that distribution. This shape is given by the *order statistics* of the sample – that is, its ordered values – comparison of which with their expected values will be informative about distributional fit. Their most common use is in normal scores plots, as outlined below, but the same basic idea can be extended to quantitative tests of fit.

Another use of normal scores is in **transformations** to normality, when it is desired to apply a technique suitable for normal data to data that are visibly nonnormal.

Normal Scores Plots

A widely used procedure for assessing normality and screening data for **outliers** is a normal scores plot, in which the sample order statistics are plotted against normal scores. This is a *Q–Q plot* of the data and the normal scores, and is sometimes also called a *rankit plot*. It is also used to assess the fit of **linear regression** *models*, where a common assumption is that the **residuals** have approximate normal distributions.

The upper two rows of Figure 1 show normal scores plots for six simulated normal samples. In each case, the intercept and slope provide rough estimates of the mean and standard deviation of the sample. For example, the top left panel shows data from the N(0, 1) distribution, while the data in the top right panel have mean and standard deviation approximately −4 and 3. The three panels in the bottom row of the figure show (from left) data from a distribution skewed to the right, to the left, and a long-tailed distribution. In each case there is a systematic departure from the straight-line pattern seen in the top six panels, indicating various types of nonnormality. Outliers would show up as observations lying well away from the upper or lower tails of the data, as in the central panel in the middle row and the left and right panels in the bottom row – although in fact none of those observations are outliers.

Tests of Fit

As shown in Figure 1, purely graphical assessment of normality can be inconclusive, especially when sample sizes are small. Consequently, tests using normal scores have been proposed for use when it is critical to know whether data are normal. For example, *Shapiro–Wilk tests* are based on the correlation between the data and normal scores, with low values of the **correlation coefficient** indicating nonnormality. These and other tests of normality should be used in conjunction with a normal scores plot. For references and a fuller account, see D'Agostino [1].

Transformation

When data clearly do not have a normal distribution, but it is desired to use a procedure based on the assumption of normality, one possibility is to replace each original data value with its corresponding normal score and to perform the procedure on the transformed data.

As an example, suppose that it is intended to perform a test to compare the locations of two sets of data the shapes of which are similar, but that it is clear (perhaps from normal scores plots) that the two samples are not normal. More precisely, we have two random samples $X_1, \ldots, X_m$ and $Y_1, \ldots, Y_n$, where the distributions of X and $Y - \theta$ are the same for some θ, and we wish to test the null hypothesis that $\theta = 0$. A test statistic based on normal scores is $T = \sum_{r=1}^{N} e(r, N) I_r$, where $N = n + m$, the normal score $e(r, N)$ is defined below, and

$$I_r = \begin{cases} 1, & \text{if the } r\text{th largest of the combined} \\ & \quad \text{sample } X_1, \ldots, X_n, \\ & \quad Y_1, \ldots, Y_m \text{ is an } X, \\ 0, & \text{otherwise.} \end{cases}$$

This is like a rank test (*see* **Nonparametric Methods**) but with the ranks replaced by normal scores.

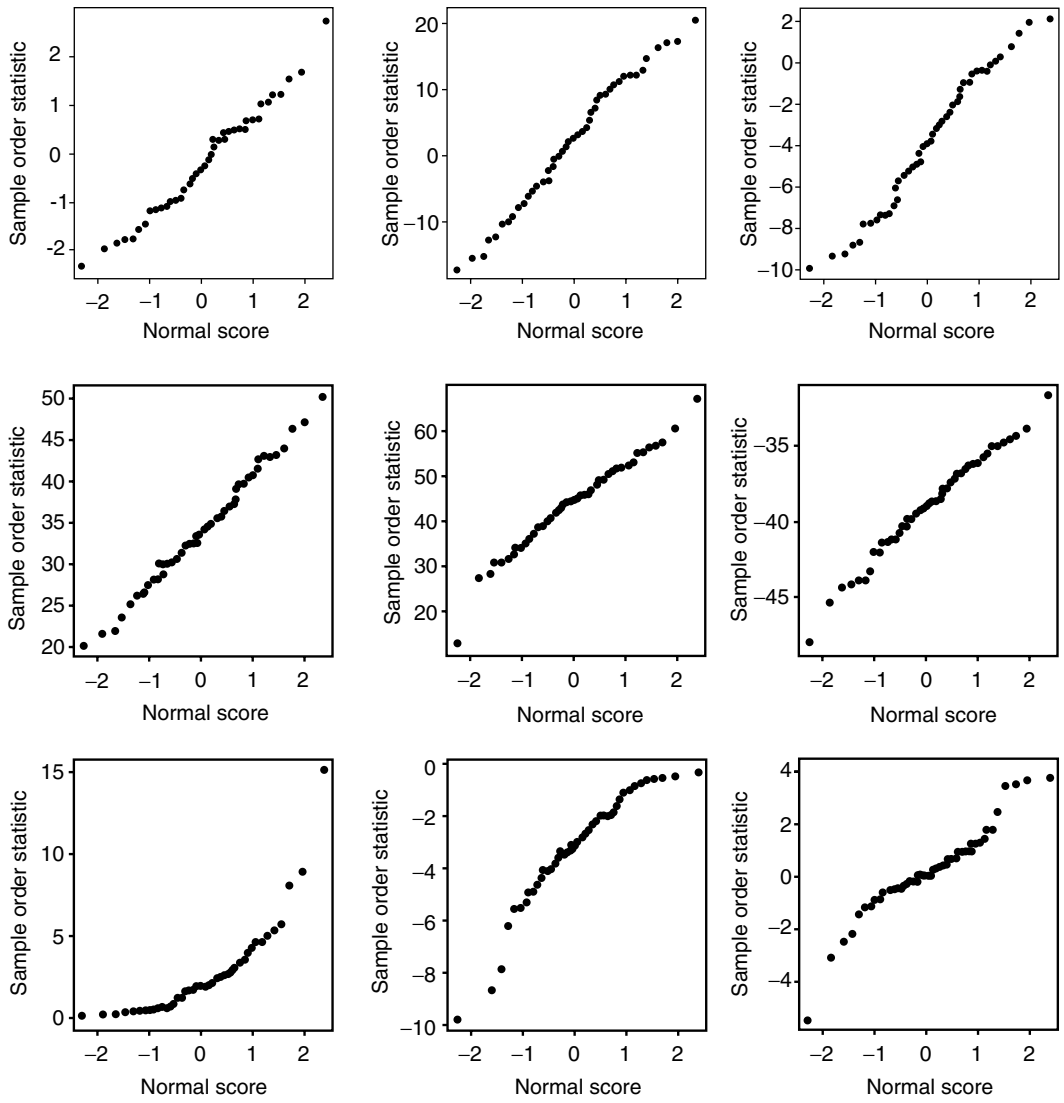

Figure 1 Normal scores plots for simulated samples of size 49. The top two rows show data from normal distributions. The bottom row shows data from a distribution skewed to the right (left), a distribution skewed to the left (center), and a long-tailed distribution (right)

Its advantage over rank tests is its high power when the distribution of X is close to normal. In practice, it may be more convenient to replace the exact normal scores by their approximation give in (1) below. For more details and related tests, including references to tabulated significance points for T, see Gibbons [2].

Computation

Suppose that $Z_1, \ldots, Z_n$ is a sample from the standard normal distribution, and let $Z_{(1)} \leq \cdots \leq Z_{(n)}$ denote the corresponding order statistics. Let $\Phi(z)$ and $\phi(z)$, respectively, denote the cumulative distribution function (cdf) and probability density

function pdf of the standard normal distribution. Then the exact value of the rth normal score is

$$\mathrm{E}(Z_{(r)}) = e(r,n) = \frac{n!}{(r-1)!(n-r)!} \times \int_{-\infty}^{\infty} z\Phi(z)^{r-1}[1-\Phi(z)]^{n-r}\phi(z)\,\mathrm{d}z.$$

This is awkward to work with, and an approximation that is adequate for most purposes is

$$e(r,n) = \Phi^{-1}\left(\frac{r-\frac{3}{8}}{n+\frac{1}{4}}\right), \qquad (1)$$

where $\Phi^{-1}(\cdot)$ is the inverse of the normal cdf. The approximation given in (1) is readily calculated in standard statistical **software** packages.

Royston [5] gives FORTRAN algorithms for $e(r,n)$ (available in machine-readable form from URL `http://lib.stat.cmu.edu/apstat/177`), while Harter [3] has tabulated their values for $n = 2(1)100(25)250(40)400$; see also Pearson & Hartley [4].

Normal Values of Biological Characteristics

This article focuses on clinical biochemistry (e.g. blood glucose or serum cholesterol) and hematology measurements (e.g. hemoglobin or hematocrit) because this is the area where most progress has been made in the collection and statistical treatment of normal values. There are, of course, many nonchemical variables used to assess physiological status. A familiar example is brachial arterial pressure which is routinely measured before a clinical examination. Other examples will be noted in passing. The statistical methods described below should be applicable to all clinical (or, more generally, biological) variables that are measured on a continuous quantitative scale.

The "normal range" is commonly understood to be that interval which contains the measured values of a specified clinical variable in 95% of a population of healthy individuals. Since this range is estimated from a sample of individuals, we should rather define the estimate as a **tolerance interval** that has probability $100(1-\alpha)\%$ of including *at least* 95% of the population. In routine clinical practice the normal range is used as a **prediction** interval for the value in a healthy patient. However, when used for this purpose over and over again, as is always the case, it no longer satisfies the limited conditions of a statistical prediction interval (i.e. to predict the next observation or the **mean** or all of a fixed number of future observations). Therefore, we fall back on the definition of the normal range as a statistical tolerance interval. The interval is usually not estimated directly but only as the range of values between the estimated 2.5th and 97.5th percentiles of the population distribution. In many clinical situations, only one percentile (usually the upper) is important for diagnosis (*see* **Quantiles**).

The word "normal" is somewhat ambiguous, usually meaning "typical" but sometimes representing the "ideal". It also refers to a particular statistical distribution. Moreover, an analogous range (perhaps overlapping) could be defined for persons suffering from a particular disease. For these reasons, the term "reference range" has supplanted the normal range, at least in the clinical laboratory. However, since the discussion here will be confined to reference ranges in healthy individuals, and since the term "normal range" is still commonly used outside the clinical laboratory, we will continue this usage here.

A study to determine normal values requires, first of all, a set of criteria for judging whether a potential reference subject is really healthy. This and other aspects of the design of a study to establish normal clinical values are considered elsewhere (*see* **Normal Clinical Values, Design of a Study**). We assume here that a collection of measured values on a given variable has been obtained from a group of healthy subjects (one value per person). We describe first various statistical procedures (including tests of **outliers**) for deriving a normal range from this collection. Next, we examine the question of whether two or more collections of normal values obtained, say, from different sexes or races or geographic locations are sufficiently distinct to warrant separate normal ranges. We then review some recently published methods for estimating time-dependent normal ranges. We close with a brief discussion of multivariate normal indexes or regions.

Methods of Estimation

Parametric

Both parametric and **nonparametric** methods are routinely used to estimate the percentile limits of the normal range. Since most clinical variables are not **normally distributed**, the parametric method applies some mathematical **transformation** to the original values in the hope that they will conform to a normal distribution on the transformed scale. The log transform has often been used when the observed distribution shows positive skewness (*see* **Lognormal Distribution**). Occasionally, the square root or $\log(x + C)$ transforms are tried, estimating C by trial and error using the coefficients of **skewness** and **kurtosis** as guides. Unfortunately, the more general Box–Cox **power transform** [3] has only rarely been applied to normal values.

The Expert Panel on the Theory of Reference Values (EPTRV) of the International Federation of Clinical Chemistry (IFCC) has recommended [8] either the Box–Cox function or Manly's exponential transform [12] to remove skewness, followed by a second transform (e.g. the modulus function of

John & Draper [10]), if necessary, to remove any residual kurtosis. The Anderson–Darling **goodness-of-fit** test is recommended to test final agreement with a normal distribution. If the transform(s) have been successful, the normal range would be estimated as $\overline{x} \pm 1.96s$ (or $2.0s$) where $\overline{x}$ and s are the mean and **standard deviation** of the measurements on the transformed scale. The estimated 2.5th and 97.5th percentiles would be backtransformed to the original measurement scale for practical use.

Strictly speaking, the multiple of s should be taken from a table of normal tolerance factors for the given sample size, n, and level of confidence, $1 - \alpha$. For example, for $n = 100$ and $\alpha = 0.05$, the proper multiplier for at least 95% coverage would be 2.23. The factor 2.0 offers only about 50% confidence. However, assuming this value for simplicity, the large-sample **standard error** of the estimated upper or lower 95% normal limit on the normalized scale is given by $s(3/n)^{1/2}$, and **confidence limits** for the 2.5th and 97.5th percentiles of the population may be calculated as usual.

Nonparametric

When the parametric method achieves a normal distribution, it produces more precise estimates of the true normal limits than would a nonparametric method applied to the same data on the normalized scale (*see* **Standard Normal Deviate**). Clearly, however, some sophistication in statistics and computing is needed to pursue this approach. Moreover, there is no guarantee that a transform will be found to normalize the distribution. Therefore, since the collection of normal values has been carried out by clinicians or clinical chemists, often without statistical advice, the normal limits are more likely to be estimated by the simplest nonparametric method, namely ranking the data by order of magnitude and determining the 2.5th and 97.5th sample quantiles, interpolating between adjacent data points if necessary. Computing exact nonparametric confidence limits for the population percentiles is more complicated. Let $x_{(r)}$ and $x_{(s)}$ be the rth and sth **order statistics,** the sample values whose ranks are r and s, respectively. Then, $x_{(r)}$ and $x_{(s)}$ will be the bounds of a $100(1 - \alpha)\%$ confidence interval for the true percentile ζ_p if

$$\sum_{i=r}^{s-1} \binom{n}{i} p^i (1-p)^{n-i} \geq 1 - \alpha. \qquad (1)$$

The summation may be written as the difference between two **binomial distributions** (the first summing from r to n and the second from s to n) and may be calculated from the incomplete **beta distribution**. Reed et al. [14] have listed the ranks of the ordered observations that provide 90% confidence intervals for $\zeta_{0.025}$ and $\zeta_{0.975}$ from samples in the size range 120–369.

The drawback of the simple nonparametric method is that it places great weight on two or three sample quantiles in the tails of the observed distribution. A more recent nonparametric method for estimating the percentiles that define the normal range is the weighted quantile procedure proposed by Harrell & Davis [5]. These authors estimate ζ_p by a weighted average of all the observed order statistics, expressed as

$$\hat{\zeta}_p = \sum_{i=0}^{n} W_{n,i} x_{(i)}, \qquad (2)$$

where the weight function is given by the difference between two incomplete beta functions, and the sum of the weights equals unity. The Harrell–Davis estimate has been shown to be equivalent to a **bootstrapped** estimate, i.e. the average of a large number of resamples of the reference values. Bootstrapping is probably more familiar than incomplete beta functions to nonstatisticians; more importantly, it provides a standard error of the estimate for use in calculating confidence limits. With modern computing equipment, the Harrell–Davis formula may be speedily applied to many percentiles of the population. Results could then be smoothed by eye to provide a nonparametric guideline that would allow the clinician to estimate the exact percentile corresponding to any measured value in a new patient. Discussion and examples of the Harrell–Davis estimate are given in Harris & Boyd [6, Chapter 2].

The Harrell–Davis estimate produces a more precise result than the sample quantile, but the variance does not appear to decline by more than 20%. Therefore, it remains considerably less efficient than the parametric estimator, provided the normalizing transform(s) succeed. However, Linnet [11] has demonstrated that sampling variation in the estimated transformation parameter may widen the confidence interval around a normally estimated limit by 25%, increasing the variance of the normal estimator by 1.25^2, or a factor of 1.56. This implies that, in practice, the efficiency of the simple quantile on the

normal scale is not 41% (1/2.4) but 64% (1.56/2.4), while that of the weighted quantile estimate is actually about 77%. This conclusion has been supported by empirical results with distributions of blood chemistries [17]. Given the ease with which bootstrapping programs may be implemented today, the Harrell–Davis estimate should be more widely used, especially where the statistical expertise and the programs necessary to apply the parametric method may not be available.

Treatment of Outliers

Observations whose values differ substantially from the bulk of the observed distribution should be investigated further to discover, if possible, why they occurred. One or two outliers in a large sample of reference values (say, more than 100) may indicate sick persons whose conditions affected the variable being measured. If this is confirmed by further investigation, then these observations should be deleted before calculating normal ranges. A cluster of outlying observations is more likely to indicate a temporary dysfunction in the analytical system producing the measured values, or possibly the inadvertent use of a different analytical system than that used to obtain the rest of the values. In such cases, one might expect the outlying observations to have been obtained within a relatively short time period, although this would not necessarily be the case if the analytical problem were highly transient and unpredictable. Again, the circumstances surrounding these observations should be investigated, and if clear discrepancies with expected conditions are found, these observations, too, should be deleted from the reference sample.

If no specific reason(s) can be found to explain extreme results, and especially if they occur in the long tail of a skewed distribution, they should be retained. As Barnett & Lewis [2] and others have pointed out, such apparently aberrant values may be the result of chance selection from a skewed distribution representing all the observations. In this case, a normalizing transform may be tried, at least to separate the bulk of the distribution from the outliers. If this succeeds, then one may either apply an outlier test based on the assumption that the population distribution is normal (e.g. one of the Dixon ratio tests discussed by Barnett & Lewis), or estimate the mean and standard deviation of the (assumed normal) population by a **robust** method. Healy [7] has described a symmetric **trimming** procedure for this purpose. If normalizing transforms do not seem to work, then extreme observations should still be retained (given no reason for doubting them), and a nonparametric method applied to estimate the normal limits. If the total number of observations is small (50–100), the bootstrapped estimates are preferred over simple quantiles to minimize the effects of outliers and provide estimates of the standard errors of the estimated limits.

Separate Normal Ranges for Population Subgroups

During the 1960s and 1970s, many studies of blood constituents showed statistically significant differences in mean values of men and women and often significant trends with age. Most of these studies were based on large samples of presumed healthy individuals (e.g. blood donors or attenders at a well-person screening center). An example of a highly significant trend with age was shown in serum albumin by Wilding et al. [19]. Results are listed in Table 1.

The weighted **least-squares** slope is −0.054/decade, with standard error 0.000445, a highly significant decline with age. However, results like these rarely affect routine clinical practice. Laboratory reports to clinicians list normal ranges by sex for very few blood constituents and by age for none. This is partly due to the expense of obtaining separate normal ranges for the same variable, but more importantly, either no physiological basis has been found to explain the subgroup differences or the statistical difference is considered of no clinical significance. Small differences of no clinical

Table 1 Mean and standard deviation (g/100 ml) of serum albumin in men, by age [19]. Reproduced from [6] by permission of Marcel Dekker Inc.

Age decade (i)	Number (n_i)	Mean ($\overline{x}_i$)	Standard deviation (s_i)
20–29	96	4.41	0.20
30–39	721	4.35	0.21
40–49	1268	4.29	0.21
50–59	1112	4.24	0.22
60–69	415	4.19	0.22
70–79	105	4.13	0.30
Combined	3717	4.27	0.225

importance between subgroup means will inevitably become statistically significant if the sample size is large enough. In addition, it may be shown [6] that separate normal ranges are very little narrower than the combined range unless the difference between the means of subgroups is far greater than that required to achieve statistical significance. A clear example of this is seen in Table 1 by comparing the weighted average standard deviation in each decade with the standard deviation over all decades combined.

Many nonchemical variables show much stronger effects of aging. Examples are forced expiratory volume (FEV) and pulmonary diffusing capacity, both measures of lung function that decline sharply with increasing age after 20–29 years. In addition, the FEV is generally higher in men than in women.

Where separate normal ranges for men and women are recognized in practice, the physical or physiological basis for the difference is well known and accepted. With respect to blood tests, separate ranges for men and women are routinely reported for serum calcium, creatine and uric acid as well as hemoglobin and hematocrit. Cholesterol in various forms and triglycerides are known to increase significantly in healthy women after menopause; however, the normal range in cholesterol has been replaced by two decision points: 200 and 240 mg/dl. Wong et al. [20] have found substantial racial and gender differences in creatine kinase, while Sinton et al. [18] have presented evidence favoring separate reference ranges for alkaline phosphatase in pre and post-menopausal women.

Is there a statistical criterion that might help to answer the question of whether statistically significant subgroup differences should be recognized clinically, assuming that a physiological basis for such differences is known? Sinton et al.suggested that separate normal ranges not be considered unless the difference between subgroup means is at least 25% as large as the 95% normal range for the combined group. This is a rather stringent guideline. For example [6, p.79], with 400 subjects in each of two subgroups, the usual z-statistic for comparing the two means would have to exceed 16.3 before separate ranges would be recommended under this criterion. Separate ranges for calcium or high-density lipoproteins would not meet this criterion, nor would racial and gender differences in creatine kinase, although the data of Wong et al.make it clear that these separate categories for creatine kinase are justified.

Harris & Boyd [6] argue that real differences between two population subgroups imply that normal limits based on the combined group would cut off proportions much less than or much greater than the nominal 2.5% for either one subgroup or the other. From **simulation** studies of two normal subgroup distributions with 120 subjects in each, they find that a z-statistic of 5–8 would imply that in the subgroup with the smaller mean, less than 0.5% of the distribution would exceed the upper 95% normal limit based on the combined group, while only 0.5% of the distribution with the larger mean would be less than the lower normal limit of the combined group. These results assume the larger standard deviation to be within 30% of the smaller. (In most cases, subgroup standard deviations are little different despite statistically significant differences in mean values.) These authors recommend $z = 5$ as a minimal criterion for recognizing two separate subgroup normal ranges when 120 subjects have been sampled in each group. Under this criterion, the ratio of the difference between subgroups means to the width of the combined 95% normal range is 15.3%, considerably less than the ratio of 25% proposed by Sinton et al. [18] However, the critical value of z depends on the sample size according to the formula $z^* = 5(n/120)^{1/2}$. Thus, for $n = 400$, say, z^* would rise to 10.2.

When three or more subgroups are involved, it is not immediately clear how to apply this criterion. One possibility is to carry out **analysis of variance** followed by simultaneous comparison of paired means. Any pair of means whose difference is statistically significant should then be reassessed using the higher z^* values (*see* **Multiple Comparisons**).

Time-dependent Normal Values

In the preceding section we developed the idea that justifying separate normal ranges for demographic or age subgroups requires a more stringent statistical criterion than simply the result of a standard significance test of subgroup differences. However, clinicians and clinical chemists have long recognized that certain clinically important variables will change with the aging of a healthy individual. For example, as noted above, serum cholesterol in healthy women rises after menopause. Changes in selected biochemistries during infancy and childhood have also been reported, as have changes during pregnancy. Recently, Oesterling

et al. [13] have found that prostate-specific antigen in healthy men shows a clear increase with age beyond 50 years. All of these studies have been **cross-sectional** (single-sample) from healthy subjects at different ages or duration of pregnancy.

Age-specific percentile values for height and weight in normal children have long been familiar to parents and physicians (*see* **Anthropometry**; **Growth and Development**). Within the past decade, however, British statisticians have published a variety of new statistical methods for analyzing cross-sectional age- or other **covariate**-dependent measurements. The aim of these methods has been to produce mathematically smooth curves across the entire age span, in contrast to the earlier habit of arbitrarily defining age groups and joining with a straight line the estimated percentiles in adjacent age groups. Some of these techniques are too complicated to include here but have been described in Harris & Boyd [6].

Simpler methods proposed by Isaacs et al. [9], Royston [16], and Altman [1] should meet the objectives of smooth percentile curves without predefined age groups. Both Isaacs et al.and Royston seek a single transform function to convert the conditional distribution of the measurements at any age to normal form, assuming that they are not normally distributed on the original scale. Isaacs et al., working with immunoglobulin data, chose the logarithmic transform for IgA and IgM and the square root for IgG. Royston tried both log and $\log(x + C)$ functions on increasing values of serum cholesterol with age in women and on declining fetal triglycerides with gestational age.

The success of the transform function was assessed in the following way. Before and after applying the transform, a **polynomial** of appropriate degree was fitted to the scatter diagram of values vs. age (or other covariate). Then, the **residuals** from this curve were tested for normality. Royston [15] suggests the Shapiro–Wilk test for large samples. The polynomial estimates the mean value of the variable at any given age within the span of the data. Therefore, a normal distribution of the residuals implies that all conditional distributions by age are normal.

On the other hand, failure to achieve normality may arise from a nonconstant standard deviation of the residuals on the transformed scale across the age range. This question is critical to the establishment of other percentile curves (e.g. the 90th or 95th). Both Isaacs et al. [9] and Royston [15] suggested subdividing the residuals into a number of age brackets, testing the homogeneity of standard deviations across age, and, if needed, fitting a straight line or quadratic to represent the change of standard deviation with age. The drawback with this procedure is that it requires arbitrary division of the data into age groups. Altman [1] resolved this problem by noting, first, that if the standard deviation is a function of age, then age-standardized residuals (residuals divided by their standard deviations) should be used to test normality. But how are these to be determined without age-grouping? Assuming normality to begin with, Altman showed that if the absolute values of the unstandardized residuals were plotted against age, and a linear or quadratic curve, as suggested by the plot, were fitted, then multiplying the coefficients by $(\pi/2)^{1/2}$ produces an equation for the standard deviation of the original (signed) residuals as a function of age. Using this equation to derive age-standardized residuals, their conformity to a normal distribution may be tested. An example of the use of this technique is given in Harris & Boyd [6, p. 170].

From the estimated mean at any age, the age-dependent equation for the standard deviation, and evidence that the age-standardized residuals are normally distributed, upper or lower percentile curves can easily be calculated on the transformed scale and backtransformed for clinical use. The final test of validity is to calculate the proportion of observations falling outside each estimated percentile. These proportions should agree closely with expected values.

Multivariate Normal Indexes or Regions

Many diagnostic tests are grouped around specific organ systems, such as the liver (whose status is judged by measuring different enzymes) or the lung (various tests of breathing capacity) or the kidneys (serum creatinine, uric acid, urea nitrogen). One might expect that measurements on a cluster of organ-based variables would be **correlated**. Then, a single multivariate index capturing these correlations along with the normal means and variances would seem to be an attractive diagnostic tool. In fact, although multivariate normal indexes and regions have been discussed in the clinical literature for over 20 years, they are seldom, if ever, used in regular clinical practice.

A multivariate statistical index would usually be limited to a linear function of the measured variables,

in contrast to the common use of **nonlinear** models applied to measurements of physiological functions in clinical medicine. For example, in determining the condition of the cardiovascular system, several measured variables are often combined into a nonlinear physico-mathematical model. A simple example is the Fick principle for calculating cardiac output. This is defined as systemic flow (l/min) obtained by dividing the body's oxygen consumption (ml/min) by the difference between arterial and mixed venous (i.e. pulmonary arterial) oxygen contents. Textbooks in clinical medicine will frequently quote a single "average" normal value for each of these measured variables.

In one of the rare studies of the potential use of **multivariate normal** regions or indices, Durbridge [4] presented to clinicians over a 4-month period a "distance" index reflecting six hepatobiliary tests. Results for the individual tests were also presented in the laboratory report along with the obligatory normal ranges. Durbridge reported that about one-third of the physicians found that the index failed to shed further light on organ status, beyond that given by the individual tests. However, the majority of clinicians either thought the index was useful to them or said they needed more experience to reach a conclusion. Given the innate conservatism of medical practice, this result should not discourage further studies of the use of multivariate normal regions. Of course, values of individual variables and associated normal ranges will continue to be included in reports to the clinician. Moreover, anomalies between the multivariate index and the univariate normal ranges must be investigated and explained to the clinician. These include cases where the multivariate index is "significantly" high but none of the variables included in the index falls outside its normal range, or where one or more of the univariate results lie outside their normal ranges while the multivariate index is within bounds. Without clear interpretation of such results, the physician will find the conflicting information confusing and will probably reject any further use of the multivariate index.

The conventional multivariate index for k variables in the ith patient may be written as $D_k^2(\mathbf{x}_i) = (\mathbf{x}_i - \overline{\mathbf{x}})\mathbf{S}^{-1}(\mathbf{x}_i - \overline{\mathbf{x}})$, where x_i represents the patient's vector of results, $\overline{\mathbf{x}}$ is the mean vector over the (presumed nondiseased) reference group, and $\mathbf{S}$ is the sample variance-**covariance matrix** from this group. Then $D_k^2(\mathbf{x}_i)$ represents the "distance" between this patient's profile of test results and the mean profile for the reference group (*see* **Mahalanobis Distance**). The general form $D_k^2(\mathbf{x})$, with data coming solely from the reference group, may be used to define the boundary of a multivariate normal region, assuming that the reference profiles form a sample from a k-variate normal distribution. However, the multivariate index is more suitable for clinical practice because it is a single number for the ith patient just like an individual test result. In addition, the multivariate index computed for each member of the reference group can be used nonparametrically. That is, the 95th percentile (say) of its true distribution may be estimated by the nonparametric methods described earlier (e.g. the Harrell–Davis procedure). This estimate can then serve as a guideline for making a decision about a particular patient's index.

EUGENE K. HARRIS

Normality, Tests of

The **normal distribution** has played a major role in statistical analysis ever since the work on the theory of errors by **Gauss** and **Laplace** in the early decades of the 1800s. It is used as a model for populations and random processes. It is the major distribution in asymptotic situations (*see* **Large-sample Theory**) because of the **central limit theorem**. Many statistical procedures are based on the assumption of normality. In response to this widespread use, numerous techniques for judging or testing for normality (or for departures from normality) have been developed.

Moment Tests: $\sqrt{b_1}$, and b_2

The field of tests for normality was initiated by **Karl Pearson** [18], who realized that deviations from normality could be described by the standardized third and fourth **moments** of a distribution, defined as

$$\sqrt{\beta}_1 = \frac{\mu_3}{\sigma^3} \quad \text{and} \quad \beta_2 = \frac{\mu_4}{\sigma^4}. \tag{1}$$

Here μ_i is the ith central moment for $i = 3, 4$ and σ^2 is the variance,

$$\mu_i = \mathrm{E}(X - \mu)^i, \quad \sigma^2 = \mathrm{E}(X - \mu)^2, \quad \text{and}$$
$$\mu = \mathrm{E}(X). \tag{2}$$

If a distribution is symmetric about its mean, then $\sqrt{\beta}_1 = 0$. Values different from zero indicate **skewness** and so nonnormality. β_2 characterizes **kurtosis** (or peakedness and tail thickness) of a distribution. For the normal distribution, $\beta_2 = 3$; other values indicate nonnormality (see Figure 1 for illustrations of varying $\sqrt{\beta}_1$ and β_2).

Tests of normality following from this are based on the sample third and fourth standardized moments, respectively, given as

$$\sqrt{b}_1 = \frac{m_3}{m_2^{3/2}} \quad \text{and} \quad b_2 = \frac{m_4}{m_2^2}, \tag{3}$$

where

$$m_k = \sum \frac{(X - \overline{X})^k}{n} \quad \text{and} \quad \overline{X} = \sum \frac{X}{n}. \tag{4}$$

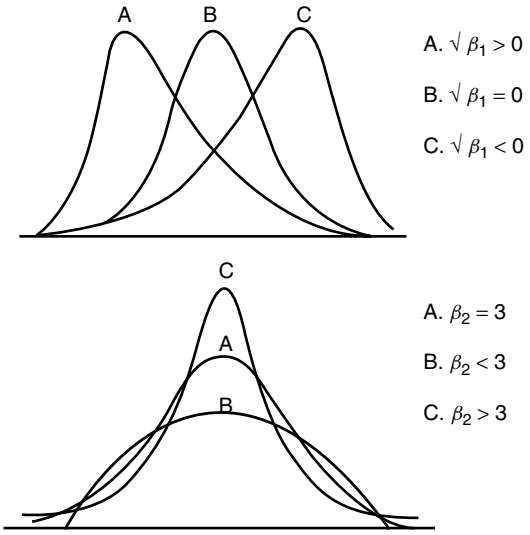

Figure 1 Distributions with varying $\sqrt{\beta}_1$ and β_2

Here, n is the sample size. Extensive tables of critical points and approximations for the sampling distributions of $\sqrt{b}_1$ and b_2 are readily available [2; 9, Chapter 9; 10; 11; 16; 17].

These moment statistics can be applied separately to tests of nonnormality due specifically to skewness or kurtosis. They can also be applied jointly for an omnibus test of nonnormality by employing various suggestions given by D'Agostino & Pearson [8]. One particular statistic for an omnibus test is given by

$$K^2 = X^2(\sqrt{b}_1) + X^2(b_2), \tag{5}$$

where $X(\sqrt{b}_1)$ and $X(b_2)$ are the **standard normal deviates** equivalent (in probability) to observing $\sqrt{b}_1$ and b_2 [8; 9, Chapter 9]. D'Agostino et al. [12] supply a simple computer macro program. Bowman & Shenton [4; 9, Chapter 7] present graphs that make possible the performance of the test for samples of size $n < 1000$. This test is available for basically all practical applications.

Normal Probability Plots

The moment tests are formal procedures for statistical inference (*see* **Hypothesis Testing**). A **graphical display** called normal probability plotting or probit plotting was developed as an informal technique for judging deviations from normality. The objective is

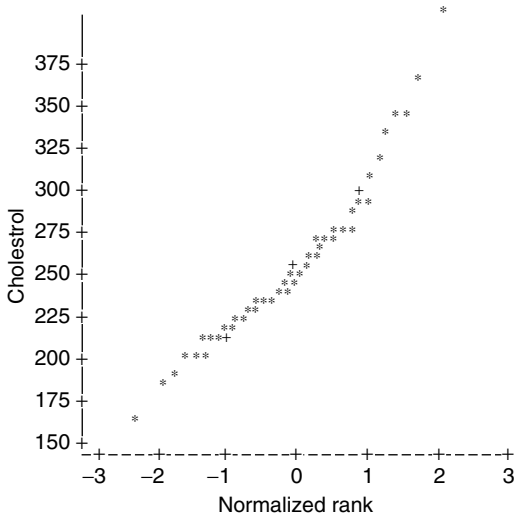

Figure 2 Normal probability plot of cholesterol data

to graph the data in such a way that, if the underlying population is normally distributed, then the graph will be a straight line. The deviation from linearity indicates the degree and type of nonnormality. Figure 2 shows such a plot for cholesterol data from the Framingham Heart Study. The ordered observations $X_{(1)} \leq \ldots \leq X_{(n)}$ are plotted on the vertical axis. The horizontal axis contains the inverse of the cumulative of the standard normal distribution

$$Z_{(i)} = \Phi^{-1}_{(q_i)}, \quad i = 1, \ldots, n. \tag{6}$$

There has been much discussion on the appropriate value of q_i (*see* **Normal Scores**). One standard choice is $q_i = (i - 0.5)/n$ for $i = 1, \ldots, n$. More details are given in D'Agostino & Stephens [9, Chapter 2] and by Brown & Hettmansperger [5].

Figure 3 contains a number of idealized normal probability plots with possible explanations for the deviation from a straight line. D'Agostino et al. [12] have emphasized the usefulness of the joint use of the moment tests with the normal probability plots in data analysis.

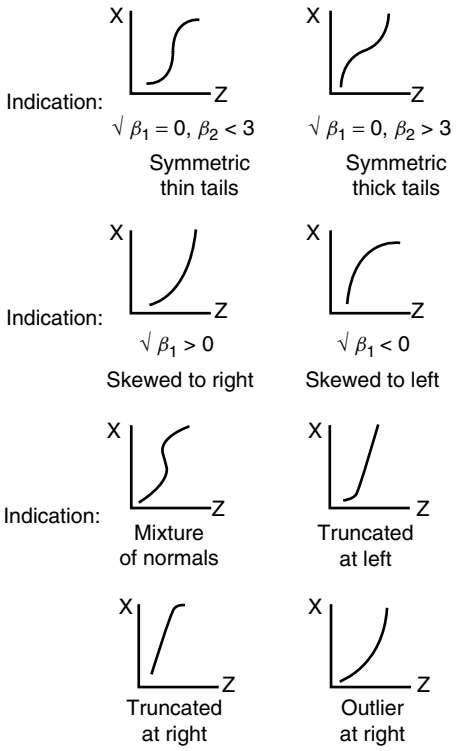

Figure 3 Normal probability plots with diagnosis nonnormality

Chi-square Test

The **chi-square test** developed by Karl Pearson in 1900 [19] can also be used for testing for normality. For this test the data are categorized into k categories. Each category has O_i observed values for $i = 1, \ldots, k$ with $n = \sum O_i$. Under the null hypothesis of normality, expected values e_i are computed. The chi-square statistic is then computed as

$$X^2 = \sum \frac{(O_i - e_i)^2}{e_i}. \tag{7}$$

For large samples this statistic has an approximate **chi-square distribution**. The appropriate **degrees of freedom** depend upon how the expected values are obtained and the choice and number of categories k. A full discussion of this test is given by David Moore in D'Agostino & Stephens [9, Chapter 3]. A nice feature of this test is that it can be employed for **censored** samples. The moment tests need complete samples.

Empirical Distribution Function (EDF) Tests

Another general procedure applicable for testing normality is the class of tests called the edf test. For these

tests the theoretical cumulative distribution function of the normal distribution, $F(x : \mu, \sigma)$, is contrasted with the empirical distribution function (edf) of the data, defined as

$$F_n(x) = \frac{\#(X \leq x)}{n}. \tag{8}$$

A famous test in this class is the Kolmogorov test [14] (*see* **Kolmogorov–Smirnov Test**), defined by the test statistic

$$D = \sup_x |F_n(x) - F(x, \mu, \sigma)|. \tag{9}$$

Large values of D indicate nonnormality. If μ and σ are known, then the original Kolmogorov test can be used. When they are not known they can be replaced by sample estimates. Stephens [23], employing **simulations**, developed adjusted critical values for D of (9) for this situation.

There are a large number of edf tests which involve various weighting of the deviations $F_n(x) - F(x, \mu, \sigma)$, with or without μ and σ known. Stephens [23] simulated critical values for four of these: the Cramér–von Mises W^2 test [6], the Kuiper V test [15], the Watson U^2 [24], and the Anderson–Darling A test [1], when μ and σ not known. Many of these tests are given in detail in D'Agostino & Stephens [9, Chapter 4]. Stephens has also extended these tests to censored samples [9, Chapter 4].

Transformation Tests

A variation of the edf tests involves first transforming the observations into independent observations free of unknown parameters and then applying an edf test. Quesenberry [9, Chapter 6] presents a general theory of these. These **transformation** procedures unfortunately require **randomization** of the data – a feature many find unattractive.

Regression and Correlation Techniques

Probably the most interesting innovative test of normality after the moment tests is the Shapiro & Wilk W test [22] and the extension of it by Shapiro & Francia [21]. The original W statistic can be viewed in a number of different ways. It is the ratio of the best linear estimator of σ to the sample standard deviation. It can also be viewed as the R^2 (square of the **correlation** coefficient) obtained from the normal probability plots. In this latter framework it arises in a **regression** and correlation context. Computationally, W is

$$W = \frac{\left(\sum w_{(i)} X_{(i)}\right)^2}{(n-1)S^2}, \tag{10}$$

where $w_{(i)}$ are the optimal weights for the **least squares** estimate of σ, and S^2 is the sample variance. Originally, the test required extensive computer work to obtain the $w_{(i)}$. D'Agostino [7] developed a simple approximation to W, called the D test. However, Shapiro & Francia produced more direct approximations of the $w_{(i)}$ which produced a true extension of W for large sample sizes [21]. Stephens [9, Chapter 5], and Royston [20] also generated transformations of W that provide good approximations to the null distribution.

Other Tests

There are a number of other tests for normality based on the sample **range**, spacings of observations, the properties of the **characteristic function, *U*-statistics**, etc. Some of these are outlined in D'Agostino & Stephens [9, Chapter 9].

Power Studies, Recommendations

Given the large number of tests for normality, the choice of which to use in practice is not easy. Fortunately, a large number of **power** studies have been performed. Many of these are summarized in D'Agostino & Stephens [9, Chapter 9]. Other, more modest ones, are recent [3, 13]. While it is not possible to give definitive answers, some general recommendations can be made:

1. Popular textbook tests such as the chi-square and Kolmogorov test have poor power in comparison to other tests and should not be used to test for normality.
2. $\sqrt{b_1}$ and b_2 have excellent power over a range of alternative distributions which deviate from normality with respect to skewness and kurtosis, respectively. These appear to be especially powerful as one-sided tests (*see* **Alternative Hypothesis**).

3. K^2 of (5) and other such tests are sensitive over a wide range of alternatives. They are *omnibus* tests.
4. The most powerful of the edf tests is the Anderson–Darling test as modified by Stephens. Its power is comparable to that of K^2.
5. The Shapiro–Wilk W test and its extensions are very sensitive omnibus tests. For many skewed distributions they are the most powerful.
6 While the D'Agostino D test is an omnibus test, it has the best power for the distributions with $\beta_2 > 3$.

Lastly, the usefulness of an investigation to judge the normality or nonnormality of data usually comes not from deciding to accept or reject normality, but rather from understanding the nature of the nonnormality and then performing appropriate statistical analyses given this knowledge. To achieve this knowledge one needs to look deeply at the data. The use of formal tests in addition to informal analyses, such as come from normal probability plots, is needed to achieve this understanding.

Nuisance Parameter

Consider a probabilistic model involving a set of parameters θ divided into two subsets θ_1 and θ_2 for which **inference** is required only about θ_1. The set θ_2 are then called *nuisance parameters*. Because the likelihood $f(x|\theta)$ involves θ_2, estimation for θ_1 must also involve the nuisance parameters.

Handling nuisance parameters is conceptually straightforward in a **Bayesian** context. The marginal posterior distribution for θ_1 may be found by integrating out the nuisance parameter as

$$f(\theta_1|x) = \int f(\theta_1, \theta_2|x)\, \mathrm{d}\theta_2.$$

If θ_2 is high-dimensional, this computation may be numerically intensive, but is always theoretically possible by **simulation**.

In non-Bayesian inference, a standard way to handle nuisance parameters is to find a set of statistics T_2 that are **sufficient** for the nuisance parameters θ_2 given θ_1 and to make inferences for θ_1 based on the **conditional** sampling distribution of $T_1|T_2, \theta_1$, where $\{T_1, T_2\}$ are the complete set of sufficient statistics for x. Because T_2 is sufficient for θ_2, the distribution of $T_1|T_2$ cannot involve θ_2 and therefore provides information only about θ_1 [1, pp. 27–28]. It can be shown [3, p. 145] that this is the only way to make the inference independent of the nuisance parameters.

This conditional approach simplifies the problem because it assumes that the probabilistic properties of the sampling procedure are completely independent of the nuisance parameters, but this simplification can result in a loss of **information** and suboptimal inference. Consider the full **likelihood** written as $f(x|\theta) = f(T_1, T_2|\theta_1, \theta_2)$. Because T_2 is sufficient for θ_2, we may write

$$f(x|\theta) = f(T_1|T_2, \theta_1) f(T_2|\theta_1, \theta_2).$$

Use of $f(T_1|T_2, \theta_1)$ to make inferences about θ_1 is then optimal only if the second term $f(T_2|\theta_1, \theta_2) = f(T_2|\theta_2)$; that is, only if T_2 is **ancillary** for θ_1 given θ_2.

An example involves the comparison of two **binomial** probabilities, p_1 and p_2, drawn from samples with size n_1 and n_2. Let x_1 be the number of successes in the first group and let x_2 be the number of successes in the second group. Then, reparameterizing in terms of the log **odds ratio**

$$\delta = \log\left[\frac{p_2/(1-p_2)}{p_1/(1-p_1)}\right]$$

and the logit of the success probability in the first group (*see* **Logistic Regression**),

$$\alpha = \log\left[\frac{p_1}{(1-p_1)}\right],$$

the likelihood may be written

$$L = \frac{\exp(\alpha x_1)}{(1+\exp\alpha)^{n_1}} \times \frac{\exp\left[(\alpha+\delta)x_2\right]}{\left[1+\exp(\alpha+\delta)\right]^{n_2}}.$$

It can be shown that sufficient statistics for α and δ are $x_\cdot = x_1 + x_2$ and x_2. For fixed δ, inference about α may be made from the total number of successes, $x_\cdot$ which are then sufficient. Thus, the distribution of x_2 given $x_\cdot$ is independent of α and, accordingly, can be used to make inferences about δ. When $\delta = 0$, this distribution is the **hypergeometric** and leads to the well-known **exact test** of significance due to Fisher [1, pp. 43–48] (*see* **Fisher's Exact Test**). This "exact" inference is not optimal, however, because $x_\cdot$ is not ancillary for δ given α.

Another common technique for handling nuisance parameters for which sufficient statistics exist is to make inferences for θ_1 from a sampling distribution conditional on θ_2 with the sufficient statistics substituted for θ_2. For example, the mean $\overline{x}$ of a sample of size n from a $\mathrm{N}(\mu, \sigma^2)$ distribution follows a $\mathrm{N}(\mu, \sigma^2/n)$ distribution. Often, if we do not know σ^2, we may replace it by its sample estimate s^2 in making inferences about μ. This procedure is exact if $\sigma^2 = s^2$ and will be good enough for large samples. Of course, in this problem, the exact solution for the unknown nuisance parameter is based on the pivotal quantity $t = n(\overline{x} - \mu)/s$ that follows a **Student's *t* distribution**, but in many problems such pivotal quantities may not exist. In general, assuming nuisance parameters to be known will place too much precision on the estimates of the other parameters because of the failure to consider the added variation from the unknown parameters. It can be shown that the asymptotic variance of an **efficient estimator**, when some parameters are unknown, is always at least as large as its value when they are all known [2, pp. 437–438].

Null Hypothesis

A *null hypothesis* (usually symbolically represented as H_0:) is a statement about a population or set of populations which is tested through completion of an experiment. If only one population is being studied, then the null hypothesis is generally stated in the form that a parameter, θ (a measure of the population), is equal to a hypothetical value, θ_0; thus, $H_0{:}\theta = \theta_0$. To illustrate, if the parameter of interest is the mean, μ, then a statement of a null hypothesis might be $H_0{:}\mu = \mu_0$, where μ_0 is specified by the experimenter. For example, it might be hypothesized that the mean length of hospital stay for patients undergoing coronary artery bypass surgery (CABG) is 7 days (or $H_0{:}\mu = 7$ days). If $k \geq 2$ populations are being investigated, then the null hypothesis is generally presented as a statement specifying how the value of a parameter, θ_i for the ith population, is related to that parameter from each of the other $k - 1$ populations. Most often this hypothetical statement takes the form that these values, θ_j, $j = 1, 2, \ldots, k$, are all equal, i.e. $H_0{:}\theta_1 = \theta_2 = \cdots = \theta_k$. To illustrate, if the parameter of interest is the mean, μ, then the statement of a null hypothesis might be $H_0{:}\mu_1 = \mu_2 = \cdots = \mu_k$. For example, if μ_1 is the mean length of hospitalization for a population of males post-CABG, and μ_2 is the comparable parameter for a population of females, then $H_0{:}\mu_1 = \mu_2$. The usual presentation of a null hypothesis that values of the parameter across the k populations are equal suggests the derivation of the term *null* (a nullity or no difference) in the testing terminology. The word *null* is not always used, and one may call this underlying hypothetical statement merely the *hypothesis*, or equivalently the *statistical hypothesis* or *tested hypothesis*.

A null hypothesis most often takes the form that a parameter, θ, for a single population is equal to a specified value, θ_0, or that values of a parameter for a set of populations are all equal. However, a null hypothesis can be directional, that is, specifying a bound on a parameter, say, $H_0{:}\theta < \theta_0$, or a relationship among values of a parameter for several populations, for example, $H_0{:}\theta_1 < \theta_2$ for $k = 2$ populations.

A researcher should note the distinction between the null hypothesis (which is a statement about the *statistical* character of a parameter for one or several populations) and the *clinical* or *subject matter* hypothesis. The latter hypothesis frequently expresses a parameter relationship desired for the area of study and thus is not stated in the null (no effect) form. Often this clinical hypothesis indicates the magnitude of an anticipated effect of importance in the subject area. A finding from an experiment which results in the rejection of the null hypothesis is said to be *statistically significant*. This conclusion must be interpreted in light of what constitutes an *important or relevant* finding in the subject area (clinically) (*see* **Clinical Significance Versus Statistical Significance**; **Hypothesis Testing**).

Number Needed to Treat (NNT)

Introduction

The number needed to treat (NNT) was originally proposed as a way of presenting the results of randomized **clinical trials** with **binary** outcome [16, 32, 33, 47, 48, 50]. Defined as the inverse of the **absolute risk** reduction (ARR), the number needed to treat is the average number of patients needed to be treated to prevent an adverse outcome in one additional patient compared to a control or standard treatment group. For example, in the Diabetes Control and Complications Trial (DCCT) the five-year **risk** of neuropathy in type 1 diabetic patients was 16.9% in the standard treatment group compared to 6.7% in the intensive insulin treatment group [18]. The absolute effect of the treatment can be described by $\text{ARR} = 16.9\% - 6.7\% = 10.2\%$. This translates to $\text{NNT} = 1/0.102 = 9.8 \approx 10$, that is, on average 10 patients are needed to be treated with intensive diabetes therapy to prevent one additional case of neuropathy compared to the standard therapy. For an adequate interpretation of NNTs, the characteristics of patients being treated, the outcome being measured, and the type and duration of interventions being compared have to be known.

NNT as well as ARR represent absolute measures of the treatment effect. Relative effect measures such as the **odds ratio** (OR), the **relative risk** (RR), or the relative risk reduction (RRR) frequently result in impressive numbers, even though the absolute effect of the treatment might be low. For example, if the two risks are $\pi_0 = 0.6$ and $\pi_1 = 0.1$, then $\text{RRR} = 83\%$, $\text{ARR} = 0.5$ and $\text{NNT} = 2$; if the two risks are $\pi_0 = 0.006$ and $\pi_1 = 0.001$, then $\text{RRR} = 83\%$ remains the same, but $\text{ARR} = 0.005$ and $\text{NNT} = 200$. Owing to the low baseline risk, the absolute effect of the treatment is also low, which is described by ARR and NNT. The information given by ARR and NNT is mathematically identical. However, the statement "200 patients are needed to be treated in order to avoid one event" is potentially more informative and comprehensible than "the treatment reduces the risk of an event by 0.005". Several studies demonstrated that assessment of health-care intervention effects by consumers is affected by the way in which study results are presented. The inclination of physicians to prescribe drugs and to treat patients is stronger when study results are presented by means of relative effect measures than when the same study is described by using absolute effect measures [12, 23, 40]. Health authority members are more willing to support health programs when results are expressed as RRRs compared with absolute effect measures [22]. Likewise, more patients assent to receive a therapy when potential benefits are reported in terms of RRR rather than ARR or NNT [29].

NNT has become the standard for presenting results of randomized clinical trials in the journal *Evidence-Based Medicine* [47] and the *ACP Journal Club* [1] and use of NNT to express study results is suggested in the **CONSORT** explanation and elaboration document [6]. However, the widespread application and extension of NNT in different settings is not without difficulties and care is required to use and interpret NNT appropriately. Recent developments regarding NNT are given by the development of methods to express benefit as well as harm, the calculation, presentation, and interpretation of confidence intervals, the application in screening studies, public health research, **epidemiology** (case–control and cohort studies), crossover studies, studies measuring continuous and time-to-event data, risk-benefit analyses, and systematic reviews. In the following, the characteristics and application areas of NNT are summarized.

General Characteristics

Relation to Other Effect Measures

A large number of effect measures exist to express the magnitude of difference between two groups concerning the risk of an adverse event. Let π_0 be the risk in the control group and π_1 be the risk in the treatment group. In the case of a beneficial treatment ($\pi_0 > \pi_1$) the most frequently used effect measures derived from a simple **2 x 2 table** are

$$\begin{aligned}
&\text{Absolute risk reduction:} && ARR = \pi_0 - \pi_1 \\
&\text{Relative risk:} && RR = \frac{\pi_1}{\pi_0} \\
&\text{Relative risk reduction:} && RRR = \frac{\pi_0 - \pi_1}{\pi_0} \\
& && \quad = 1 - RR
\end{aligned}$$

Odds ratio: $$OR = \frac{\pi_1 \times (1-\pi_0)}{\pi_0 \times (1-\pi_1)}$$

Number needed to treat: $$NNT = \frac{1}{\pi_0 - \pi_1} = \frac{1}{ARR}$$

The relation between NNT and ARR is obvious. It is helpful in practice to also express NNT as a function of RR, RRR, OR, and the control event rate π_0. The respective formulae are given by

$$NNT = \frac{1}{(1-RR) \times \pi_0} = \frac{1}{RRR \times \pi_0} \quad (1)$$

$$NNT = \frac{1-(1-OR) \times \pi_0}{(1-OR) \times \pi_0 \times (1-\pi_0)} = \frac{1}{(1-OR) \times \pi_0} + \frac{OR}{(1-OR) \times (1-\pi_0)} \quad (2)$$

Similar formulas are published for the case of harmful treatments [7, 9], for considering desirable instead of adverse outcomes [39], and for the inverse definitions of RR and OR [28].

Quantifying Benefit and Harm

NNT represents the inverse of the difference of two risks. On principle, the difference of two risks can be positive, zero, or negative. The concept of NNT was originally developed for the situation of a beneficial treatment, so that the risk of an adverse event in the treatment group is lower than in the control group [33]. Thus, calculating the risk difference as control minus treatment leads to a positive ARR value. Considering only beneficial treatments, the term "number needed to treat" was proposed to describe the inverse of ARR. In the case of a harmful treatment, this calculation leads to a negative risk difference and a negative NNT. To avoid negative numbers, the risk difference is calculated as treatment minus control if the risk of the treatment group is higher than that of the control group leading to a positive value called absolute risk increase (ARI). To describe the inverse of ARI, the unfavorable term "number needed to harm" (NNH) was used [39]. Recognizing that NNT and NNH are not good abbreviations, Altman suggested the terminology "number of patients needed to be treated for one additional patient to benefit" (NNTB) or "be harmed" (NNTH) [2]. This terminology should be used when it is necessary to indicate the direction of the effect. In the case of desirable outcomes, such as healing or improvement of **quality of life**, the order of the two probabilities in the calculation of NNT is reversed. Here, NNTB represents the average number of patients needed to be treated to gain one additional beneficial outcome compared to a control or standard treatment group [55].

Confidence Intervals

As with other estimated effect measures, it is important to document the uncertainty of the estimation by means of an appropriate **confidence interval**. In principle, confidence intervals for NNTs can be obtained by inverting and exchanging the confidence limits of the corresponding risk difference [17]. Nevertheless, calculating, presenting, and interpreting confidence intervals for NNTs is not straightforward. Owing to the reciprocal **transformation**, the NNT has undesirable statistical properties [34]. To obtain meaningful confidence intervals for NNT two issues have to be considered. Firstly, the unusual scale of NNT has to be taken into account, and secondly, an appropriate method to calculate confidence intervals for the risk difference is required.

The key to understand the confidence interval for NNT is that the domain of NNT is the union of 1 to ∞ (in the NNTB region) and $-\infty$ to -1 (in the NNTH region). The best value of NNT indicating the largest possible beneficial treatment effect is 1, the NNT value indicating no treatment effect (ARR = 0) is $\pm\infty$, and the worst NNT value indicating the largest possible harmful effect is -1. Values between -1 and 1 are impossible for NNT. Owing to estimation uncertainty, the estimated NNT may be negative even when the true NNT is positive and vice versa. Even when the sign of the estimated and true NNT are identical, the estimation uncertainty can be so large that neither a harmful nor a beneficial effect can be excluded. In this case, the confidence interval covers both the NNTB and the NNTH region. Thus, the result NNT = 10 with confidence limits 4 and -20 means that the two regions 4 to ∞ and -20 to $-\infty$ form the confidence interval. To make this clear, a confidence interval for an NNT estimate that is not statistically significant should be presented as NNTB = 10 (NNTB 4 to ∞ to NNTH 20) [2]. This presentation indicates that a beneficial treatment effect of NNTB = 10 is estimated, but the uncertainty

of this estimation is so large that a more beneficial effect up to NNTB = 4 and a less beneficial effect up to NNTB = ∞ (no effect at all) as well as a harmful effect up to NNTH = 20 is compatible with the observed data.

For large sample sizes and risks not close to 0 or 1, the usual Wald method can be used to calculate confidence intervals for risk differences (*see* **Estimation, Interval**). However, Wald confidence intervals have poor coverage probabilities and a propensity to aberrations in many practical situations. Thus, Newcombe proposed to calculate confidence intervals for risk differences based upon Wilson scores [42]. This method was also recommended for NNT [8].

Let n_0 and n_1 be the number of patients in the control and the treatment group, respectively, and let e_0 and e_1 be the number of patients having an event in the control and the treatment group, respectively. The risks of an event in the two groups can then be estimated by the proportions $p_0 = e_0/n_0$ and $p_1 = e_1/n_1$. The effect measures can be estimated by ARR $= p_0 - p_1$ and NNT $= 1/(p_0 - p_1)$. Using this notation, the $100 \times (1 - \alpha)\%$ confidence interval for ARR based upon Wilson scores is given by:

$$LL(ARR) = p_0 - p_1 - \delta \text{ and}$$
$$UL(ARR) = p_0 - p_1 + \varepsilon, \qquad (3)$$

where

$$\delta = \sqrt{(p_0 - l_0)^2 + (u_1 - p_1)^2},$$
$$\varepsilon = \sqrt{(u_0 - p_0)^2 + (p_1 - l_1)^2},$$
$$\mathrm{l}_i = \varphi_i - \sqrt{\varphi_i^2 - \psi_i}, \mathrm{u}_i = \varphi_i + \sqrt{\varphi_i^2 - \psi_i}, \mathrm{i} = 0, 1,$$
$$\varphi_i = \frac{2e_i + z_{1-\alpha/2}^2}{2(n_i + z_{1-\alpha/2}^2)}, \psi_i = \frac{e_i^2}{n_i^2 + n_i z_{1-\alpha/2}^2}, \mathrm{i} = 0, 1,$$

and $z_{1-\alpha/2}$ is the $(1 - \alpha/2)$-quantile of the **standard normal** distribution.

The corresponding confidence limits for NNT can then be calculated by LL(NNT)=1/UL(ARR) and UL(NNT)=1/LL(ARR) in consideration of the NNT scale ranging from 1 through ∞ to -1 (see above). An SAS program can be used for calculations [8].

Confidence intervals for NNT based upon Wilson scores seem to be adequate for most practical applications. For very small sample sizes or applications, which require that the true confidence level under no circumstances remains under the nominal level, exact [14] or quasi-exact methods [15] should be used (*see* **Exact Inference for Categorical Data**).

Extensions and Applications

The principle of NNT has been extended and suggested for use in a wide variety of circumstances. The most important ones are summarized below.

Screening

Rembold extended the NNT concept to compare strategies for disease **screening** [44]. The analogous statistic termed "number needed to screen" (NNS) describes the number of people that need to be screened to prevent one death or adverse event. In clinical trials that directly investigate the benefit of a screening strategy, the point and interval estimation of NNS is identical to that of NNT. However, the intervention under study is a screening strategy applied to a population, rather than a treatment applied to patients. If no study exists that evaluates directly the benefit of a screening strategy, NNS estimation can be performed by combining the knowledge of clinical trials investigating the benefit of treating **risk factors** and the **prevalence** of persons with inadequately treated risk factors in the community. Under the assumption that screened individuals with positive results will show full compliance with subsequent treatment, NNS can be calculated by dividing the corresponding NNT by the prevalence of unaware or untreated disease.

Expressing the absolute effect of screening strategies as NNS values has the same advantages as the presentation of treatment effects by means of NNTs. However, the NNS approach has some limitations. Firstly, the division of NNTs by an estimated prevalence of untreated disease is subject to propagation of errors. A method to calculate confidence intervals for NNS taking the uncertainty of both the NNT and the prevalence estimation into account is required. Secondly, NNS values calculated from clinical trials investigating the benefit of a screening strategy directly (*see* **Screening Trials**) may not be comparable to NNS values calculated from NNTs divided by the prevalence of unaware or untreated disease. The former may be more affected by participation and selection effects than the latter. Hence, Richardson suggested to multiply the directly estimated NNS

by the participation rate adjusted for **selection** to obtain an NNS value free of participation and selection effects [45]. However, this method is even more exposed to propagation of errors. Moreover, the benefit of a screening strategy should be described including participation and selection effects. Analogous to the **intention to treat** analysis of clinical trials, the gold standard is the unadjusted NNS estimated from trials directly investigating the benefit of screening strategies.

Public Health Research

The NNT statistic relates to those patients actually treated and gives no information how many people of all patients with the disease or of the total population will benefit from the treatment. Heller & Dobson proposed two new statistics offering a public health perspective [27]. The idea is similar to that of NNS calculated by NNT divided by the prevalence of unaware or untreated disease. The "disease impact number" (DIN) takes into account the number of people in the population with the disease, not just those eligible for treatment according to the entry criteria of the considered clinical trial. DIN is calculated by dividing NNT by the proportion of patients with the disease who are eligible for treatment. The "population impact number" (PIN) takes into account the total size of the population from which the patients with the disease are drawn. PIN is calculated by dividing DIN by the prevalence of disease in the population. DINs and PINs suffer from limitations similar to those of indirectly estimated NNS values. Owing to the division of NNTs by estimated proportions they are subject to greater **random error** than NNT. However, they may play a role as communication tool for treatment effects from a population perspective [52].

Case–control Studies

Bjerre & LeLorier proposed to use the NNTH statistic to express the magnitude of harmful exposures effects in **case–control studies** [11]. As information about the absolute risk is not directly available from case–control studies, they calculated NNTH by using the odds ratio provided by the case–control study and the unexposed event rate obtained from external sources. Although not mentioned by the authors, an additional advantage of this approach is that adjusted NNTs can be calculated by using adjusted ORs to estimate the corresponding NNT values (see next section). Confidence intervals for NNTH are calculated by transforming the confidence limits of OR. Unfortunately, to calculate NNTH as function of OR, formula (1) was used, which actually represents the relation between NNT and RR. Thus, NNTH is systematically underestimated, that is, the exposure effect is overestimated. The magnitude of this error is negligible if OR and RR are approximately equal. Thus, in case-control studies, in which usually rare diseases are investigated, the error is unimportant. However, in situations where OR and RR are quite different, either formula (1) with RR or formula (2) with OR must be applied to obtain correct results. Let $NNTH_{1,\mathrm{OR}}$ be the *NNTH* value calculated by formula (1) with OR and let $NNTH_{\mathrm{true}}$ be the true *NNTH*. It can be shown that $(NNTH_{\mathrm{true}} - NNTH_{1,\mathrm{OR}})/NNTH_{\mathrm{true}} = \pi_1$, that is, the relative error of $NNTH_{1,\mathrm{OR}}$ equals the exposed event rate [7]. Even, if the correct formula is used, a limitation of this approach is that the confidence interval for NNTH takes into account the uncertainty of the OR estimation but not that of the unexposed event rate. A possible solution is given by the methods developed by King & Zeng for point and interval estimation of risk differences in case–control studies based upon **Bayesian methods** or a range of possible values for the unexposed event rate [30].

Cohort Studies

The NNT concept has been applied to compare exposed and unexposed persons in **cohort studies** [9]. For this application, the term "number needed to be exposed" (NNE) was suggested. When it is necessary to distinguish between harmful and beneficial **exposures**, the abbreviations NNEH and NNEB should be used. In the case of a harmful exposure, NNEH represents the average number of persons needed to be exposed for one additional case of disease or death compared to the unexposed persons. NNEs are calculated as a function of the odds ratio and the unexposed event rate by means of formula (2). This approach allows the calculation of adjusted NNEs by using adjusted odds ratios, estimated, for example, by multiple **logistic regression**. Within the framework of logistic regression, the adjusted odds ratio is constant over the distribution of the considered **confounders**. However, the event rates and their differences are dependent on the confounder

values. Thus, NNE also varies with the values of the confounding variables, which has to be taken into account when adjusted NNEs are estimated. Two methods were proposed to calculate adjusted NNEs. In the first approach, the mean risk of the unexposed persons is used and NNE is calculated for the corresponding confounder profile. In the second approach, NNE is calculated for some fixed confounder profiles, which gives an impression about different absolute effects of the exposure in cohorts with varying confounder values. A similar principle is applied to calculate pooled NNTs in meta-analysis (see below).

Confidence intervals for adjusted NNEs can be calculated indirectly via confidence intervals for the corresponding risk difference. Within the framework of logistic regression analysis applied to prospective cohort data, risk differences between the exposed and unexposed persons can be expressed as functions of the logistic regression coefficients. Thus, approximate **standard errors** and confidence intervals for risk differences can be calculated by means of the multivariate **delta method** [9]. In contrast with the calculation of NNTs in case–control studies, this method takes the estimation uncertainties of both the odds ratio and the unexposed event rate into account. The adequacy of the approximate confidence intervals was investigated via **simulations** demonstrating sufficient quality for most epidemiological applications [10].

Continuous Data

NNT represents a summary statistic for the comparison of two groups concerning a binary outcome. Nevertheless, in some applications, investigators want to express their study results in terms of NNT although the outcome variable is measured in a continuous scale (*see* **Random Variable**). One obvious method to calculate NNTs for continuous outcomes is to dichotomize the response in both groups and to apply the usual methods. Alternatively, one can dichotomize the difference of the responses between the two groups. Walter examined the probability that the difference of the responses between the two groups is larger than the minimally important difference (*see* **Sample Size Determination for Clinical Trials**) [55]. Without loss of generality, we assume that higher response values correspond to adverse outcomes (such as hypertension). Let X_0 and X_1 be the control and treatment responses of a given subject and c be the minimally important difference. The probability described above is given by $\theta = P(X_0 - X_1 > c)$. The continuous data version of NNT is then calculated by $NNT = 1/\theta$. Under the assumption of **bivariate normality** of (X_0,X_1), θ is given by

$$\theta = \Phi\left(\frac{\mu_0 - \mu_1 - c}{\sqrt{\sigma_0^2 + \sigma_1^2 - 2\rho\sigma_0\sigma_1}}\right), \qquad (4)$$

where Φ denotes the distribution function of the standard normal distribution, μ_0 and μ_1 and σ_0 and σ_1 are the means and standard deviations of X_0 and X_1, respectively, and ρ is correlation of X_0 and X_1 [55]. Estimation of θ and NNT is performed by substituting the usual estimates of μ_0, μ_1, σ_0, σ_1 and ρ into (4). Formulas for the standard error of the estimated probability θ can be derived by means of the delta method both for paired and unpaired data [55].

It should be noted that formula (4) is first of all only useful in studies, which provide an estimate of ρ (such as **crossover** studies, see below). In all designs considered so far (randomized clinical trials with parallel group design, cohort studies, and case–control studies with two independent groups) the within-subject correlation is not estimable. In this case, Walter proposed to use a variety of different assumed values of ρ and investigate the **sensitivity** of θ to the unknown correlation value [55]. Alternatively, in studies observing independent groups, the first mentioned approach of dichotomizing the response in both groups could be used.

In practice, continuous outcomes are frequently subject to random **measurement error**. Even in the case of **nondifferential** measurement error, dichotomization of continuous variables leads to a **bias** in the estimated proportions and estimated NNTs. Walter & Irwig investigated the effect of measurement error in continuous outcomes on NNT estimation [56], and methods to reduce the bias by adjusting for measurement error are in development [38]. In general, even in the case of no measurement error, one should be aware of the potential loss of information due to **categorizing of continuous variables**. Hence, calculation of NNTs from continuous data can only serve as supplement to the analysis of data in the original continuous scale by using means and differences of means.

Crossover Studies

Originally, the NNT statistic was developed for use in studies investigating two independent groups. Walter systematically examined NNT estimators and their variances for both crossover and parallel group designs [55]. Owing to the undesirable statistical properties of NNT, it is preferable to calculate the standard errors of the corresponding risk differences instead of the NNTs themselves. The NNT estimators are identical in both designs, whereas standard errors are different. Approximate confidence intervals for risk differences can be calculated in both designs by using the Wald method [55]. As described before, confidence intervals for NNTs can be obtained by inverting and exchanging confidence limits of the corresponding risk difference [17]. For the parallel group design, it was shown that the Wald method is unreliable in many practical situations. The same holds for crossover studies, in which it is preferable to calculate confidence intervals for the difference between paired proportions based upon the Wilson score method [41].

As crossover studies provide an estimate of the within-subject correlation, the continuous data version of NNT based upon the minimally important difference (see above) can be estimated directly. Under the assumption of normality of the continuous response, NNT can be estimated by using equation (4). Without making distributional assumptions, NNT is given by the inverse proportion of subjects for which the difference between the responses is larger than the minimally important difference [55].

Survival Data

The concept of NNT was originally developed for binary outcomes measured at a specific fixed time point. Nevertheless, NNTs are also calculated and presented for studies where the outcome is the time to an event (*see* **Survival Analysis, Overview**). Unfortunately, unclear and questionable methods have been used for point and interval estimation of NNT in studies in which follow-up times are not equal for all patients. Owing to the application of questionable *ad hoc* methods, different and confusing results have been published for the same data [8].

First, it should be noticed that in studies with varying follow-up times, NNT would also vary according to the length of follow-up. In such studies, no single NNT value exists. NNT can be calculated at any time point after the start of the treatment. Frequently used methods to analyze survival times are given by **Kaplan–Meier** survival curves providing estimates of the survival probabilities $S_0(t)$ and $S_1(t)$ of the control and treatment group, respectively, and the **Cox regression model**, providing an estimate of the **hazard ratio** (HR), possibly adjusted for other **prognostic** variables. Altman & Andersen proposed to estimate NNT by means of

$$NNT(t) = \frac{1}{S_1(t) - S_0(t)} \tag{5}$$

if the survival probabilities $S_0(t)$ and $S_1(t)$ are given, or by

$$NNT(t) = \frac{1}{(S_0(t))^{\mathrm{HR}} - S_0(t)} \tag{6}$$

if the assumption of **proportional hazards** is fulfilled and $S_0(t)$ and the HR for the comparison of the control and treatment group are given [3]. If one fixed time point is specified, one NNT value is obtained. Otherwise, (5) and (6) will lead to a NNT curve as a function of time.

To get an NNT statistic independent of time, Lubsen et al. proposed to calculate NNTs by the reciprocal of the difference of two **hazards** [36]. However, this approach requires the assumption of constant hazards. Moreover, the difference of hazards is not the same as the difference of risks. Thus, this approach leads to a statistic with a different meaning than that of the usual NNT. It should be noted that in the presence of confounders survival probabilities are dependent on the confounder values even if we can assume a constant HR. Thus, NNT not only depends on time but also on confounders. Altman & Andersen proposed to calculate NNT curves for different subsets of patients with varying **prognosis** [3]. However, more work is required to develop methods for estimation of adjusted NNTs from survival times.

Combining and Pooling

Risk-benefit Analysis

The decision about the use of a treatment should not be based upon its effect on the target event alone. Adverse side effects attributable to treatment as well as costs of therapy and costs avoided by preventing target events should also be considered (*see* **Decision Analysis in Diagnosis and Treatment Choice**). The

"threshold NNT" (NNT_T) was defined as the NNT value at which the therapeutic benefit equals the therapeutic risks [25, 26, 51]. If the estimated NNT is below the threshold NNT, then treatment should be administered. If the estimated NNT is above the threshold NNT, the patients should not be treated because the risks and costs of treatment are larger than the expected benefit. The threshold NNT is given by

$$NNT_T = \frac{TEC + TEV}{DC + AER \times (AEC + AEV)}, \quad (7)$$

where TEC represents the costs of treating one target event, TEV the value of one target event avoided (given in the same economic units as costs), DC the direct costs of therapy, AEC the costs of treating one adverse side effect, AEV the value of the side effect and AER the event rate of the side effect [51]. Similar formulas for considering multiple side effects and omitting costs can be found elsewhere [51].

While the concept of the threshold NNT seems to be appealing, the practical application is challenging. For an adequate decision making, the estimation uncertainties should be taken into account. The specification of the data (costs and values) required for the calculation of the threshold NNT is not easy and the quantification of these data uncertainties is much more difficult. Especially, the values one is willing to pay for one target or one side effect avoided are highly subjective. Thus, it is quite important to disclose all data and assumptions used for calculating a threshold NNT.

Combined NNT Measures for Different Outcomes

Several approaches have been published to combine the NNTB of the target event and the NNTH of a side effect into one measure incorporating benefit as well as harm. Let π_0, π_1 be risks of the target event and ν_0, ν_1 the risks of the side effect in the control and the treatment group, respectively. We consider the case of an adverse target event, an adverse side effect and a treatment that is beneficial concerning the target event ($\pi_0 > \pi_1$) but harmful concerning the side effect ($\nu_1 > \nu_0$). For other situations, appropriate modifications of the following measures are required. Riegelman & Schroth proposed the combined measure

$$NNT_{\text{comb}} = \frac{1}{(\pi_0 - \pi_1) - (\nu_1 - \nu_0)}, \quad (8)$$

that is, the reciprocal of the difference between ARR of the target event and ARI of the side effect [46]. The authors proceeded by adjusting this measure for the qualities and timings of the considered outcomes [46]. This procedure was criticized because a decision analysis has to be carried out before the quality-adjusted NNT can be calculated [19]. Thus, the intuitive meaning, which is one advantage of the NNT statistic, is lost. It is only possible to interpret a quality-adjusted NNT if the underlying decision analysis is understood. The statistical properties of the quality-adjusted NNT statistic have not been investigated and no methods to calculate confidence intervals have been developed.

A second approach of an NNT measure incorporating benefit and harm was proposed by Schulzer & Mancini [49]. They tried to calculate the number of patients needed to treat to produce one "unqualified success" (US), that is, the situation in which one adverse target event is avoided while simultaneously no treatment-induced side effect occurred. The NNT for one unqualified success is given by

$$NNT_{\text{US}} = \frac{1}{(\pi_0 - \pi_1) \times [1 - (\nu_1 - \nu_0)]}. \quad (9)$$

Formula (9) is based upon the assumption that the target event and the adverse side effect are independent in both the untreated and the treated population. This assumption will rarely be true in practical applications. Although a procedure was proposed to handle situations in which an association between the prevention of a target event and the induction of a side effect is expected [37], this approach suffers from the lack of an appropriate method to estimate the association from the data. Moreover, no adequate method to calculate confidence intervals for NNT_{US} has been developed.

Willan et al. proposed the benefit–risk ratio

$$R = \frac{NNTH\,(\text{side effect})}{NNTB\,(\text{target effect})} = \frac{\pi_0 - \pi_1}{\nu_1 - \nu_0}$$
$$= (\pi_0 - \pi_1) \times NNTH\,(\text{side effect}), \quad (10)$$

which can be interpreted as increase in the expected number of prevented target events achieved for each additional adverse side effect induced by treatment [57]. For large sample sizes, Willan et al. developed a statistical procedure to construct confidence intervals for the benefit–risk ratio based upon **Fieller's theorem** [57].

The development of a combined NNT statistic incorporating benefit and harm of multiple events is not straightforward. Before one of the proposed combined NNT measures considering multiple events can be routinely applied in practice, more work is required concerning the practical utility of these measure as well as their statistical properties, especially in small samples.

Meta-analysis

Since NNT has been advocated as a useful effect measure for systematic reviews [39], a number of authors have pointed out that particular caution is needed in deriving pooled NNTs in **meta-analyses** [5, 13, 20, 21, 53]. A single pooled NNT value over all studies in a meta-analysis may be misleading, especially if there is a variation in the baseline risk, different lengths of follow-up, differences in the outcomes considered, or different clinical settings. The naive approach of simply adding the raw totals of all considered trials as if the data came from one trial should be avoided. The calculation of a pooled NNT should be based upon a pooled effect measure, which should be independent of the baseline risk. Using empirical data, Furukawa et al. showed that the relative effect measures OR and RR calculated by means of an appropriate **fixed** or **random effects** regression model often appear to be reasonably constant across different baseline risks [24]. Meaningful NNTs can be obtained by inserting the pooled RR or OR from meta-analyses in formula (1) or (2). If there is variation in the baseline risk, different NNTs relevant to specific patient subgroups should be calculated [20, 24, 53]. If there is evidence that even the relative effect measures vary substantially between subgroups in a meta-analysis, no meaningful pooled NNT can be calculated.

Conclusion

The use of NNT as effect measure for the comparison of risks between two groups has been advocated in medical journals for several years [16, 33, 39, 43, 47, 50] but was recently criticized [53, 58] or even rejected [28]. There seems to be a gap in the assessment of the practical usefulness of NNTs between some statisticians and clinicians [4, 28, 35]. Some mathematical arguments against the use of NNTs, such as undesirable distributional properties, are surely justified. However, strict mathematical arguments lose their importance when NNT is considered as a way of presenting results, not as a tool for statistical computations [4, 35]. A clear distinction should be made between data analysis and subsequent risk communication [54]. In the light of the effects on consumers of the scale in which benefits and risks are reported, it is frequently advisable to choose a statistical model and a corresponding appropriate summary measure for the task of data analysis, but alternative effect measures to report the most important results. For the translation of research findings to consumers, the number needed to treat may represent a useful tool, because it gives an intuitive impression of the absolute effect of a therapy or an intervention. NNTs contain the same information as risk differences, but in the unit of patient numbers instead of probabilities, which is easier to understand.

The attempt to extend and apply the simple NNT concept developed for randomized clinical trials with two independent groups and a binary outcome for a variety of other settings led to the development of more sophisticated approaches and procedures for NNT calculation. Some useful approaches have been developed, but situations remain for which further work is needed to calculate meaningful NNTs, for example, survival time studies or the combination of NNTs for multiple outcomes. These extension and adjustment procedures can alleviate problems with NNTs. However, the extended and adjusted NNTs can no more be considered as "one simple single yardstick" [31]. Particular caution is required to apply and interpret NNTs adequately in practice, especially in meta-analyses and in the presence of confounders. Nevertheless, if handled appropriately, NNTs represent a useful communication tool to express the absolute effects of interventions and exposures.

Numerical Analysis

Numerical analysis is concerned with the accurate and efficient evaluation of mathematical expressions, especially on computers with **floating point arithmetic**. While scientists have always been concerned to some extent with numerical computation, the modern discipline of numerical analysis is almost entirely a product of the period since 1950, during which there has been an explosion in the availability of electronic computers. There are three main issues:

1. to organize computations so that there is minimum accumulation of error in floating point arithmetic
2. to organize computations efficiently, so that they consume the least possible resources
3. to obtain accurate numerical approximations to quantities which may not have explicit mathematical expressions.

In other words, do it accurately, do it quickly, and do it cheaply.

It might be thought that numerical evaluation consists largely of translating textbook formulas into a **computer programming language** – a mere coding exercise – but this is very far from the case. Direct translations of expressions from mathematical theory are seldom optimal, and very often are found to fail in circumstances when a less obvious numerical process would have succeeded.

The focus on numerical results means that one is not limited to direct expressions, but can evaluate functions which are defined only indirectly, for example through integrals, differential equations, series, or as solutions to equations. An important example is the **maximum likelihood** estimator for a nonlinear statistical model (*see* **Nonlinear Regression**). Indeed, an indirect method is often preferred for numerical evaluation even when a direct expression exists.

While efficiency and accuracy are both aims, it is accuracy which takes precedence, since a slightly slower accurate program is invariably preferred to a faster one with unreliable accuracy. Errors arise from three sources: (i) errors in the input data; (ii) computation errors due to finite precision arithmetic; and (iii) approximation error. The first of these is not under the control of the calculation; in fact it might be considered to be the special concern of the statistician. Computation error appears because of the difference between exact arithmetic and the finite-length arithmetic available on digital computers and hand calculators. Approximation error occurs when the computed expression is not exactly equal to the theoretical quantity even in exact arithmetic. An integral is replaced with a sum, for example, or an infinite series is evaluated only to a finite number of terms.

Efficiency is usually measured by counting basic floating point operations (flops), such as additions, subtractions, multiplications, and divisions. Another consideration is to minimize the use of computer memory and other space requirements, especially for large jobs. More recent concerns which arise from modern **computer architecture** include parallel computing (designing algorithms so that they can be evaluated in parallel streams on fast computers with multiple processors) and local referencing (minimizing unnecessary paging of virtual memory).

It is also desirable to keep programs simple and understandable, thus making the programs easy to maintain and to modify. Users must often choose between using compact programs which can be tinkered with for their own use, and using sophisticated high-performance software from public libraries, which cannot be modified and must be taken somewhat on trust.

Most biostatisticians can benefit from familiarity with numerical analysis. An understanding of the numerical methods being used and an idea of when they will perform well or poorly is necessary even for users of standard statistical package programs (*see* **Software, Biostatistical**). You must still understand the program's purpose and limitations to know whether it applies to your particular situation or not. More importantly, many problems cannot be solved by simple application of a standard program. If you develop your own software, a knowledge of numerical analysis can help avoid numerical pitfalls that can occur easily in a number of problems.

A justifiably popular text on scientific computing is Press et al. [9], which contains a lot of advice on routines to use. Other good general texts on numerical analysis are by Atkinson [3] and Stoer & Bulirsch [12]. An introduction with some statistical orientation is by Thisted [13]. An elegant and elementary introduction to the fundamental ideas of numerical analysis is given by Stewart [11].

The remainder of this article discusses the basic ideas of accuracy and describes briefly key topics in

numerical analysis which are treated at more depth in separate articles. Pointers to available software are given at the end of the article.

Conditioning

The concept of conditioning refers to the intrinsic difficulty of a numerical problem. A problem is ill-conditioned if it is sensitive to perturbations in the data, and well-conditioned if it is not. Conditioning is often quantified by a *condition number* which refers to the amplification of relative errors. Suppose that x is the exact argument to a function f but unfortunately only an approximation $\tilde{x}$ is available. The *condition number* κ of f at x is defined, with respect to a given norm $(||\cdot||)$, by the relation

$$\frac{||f(\tilde{x}) - f(x)||}{||f(x)||} \approx \kappa \frac{||\tilde{x} - x||}{||x||}$$

for $\tilde{x}$ near x. If κ is large, then errors in x are magnified in the evaluation of $f(x)$, while the opposite is true if κ is small. If $\kappa = 10^k$, then k is roughly the number of significant figures of accuracy we can expect to lose in the computation.

For univariate, differentiable functions, the condition number is essentially $\kappa = |xf'(x)/f(x)|$. For example, $f(x) = (x-1)^6$ is an ill-conditioned function near $x = 1$, while $f(x) = x^{1/2}$ is well-conditioned for any $x > 0$.

For general multivariate functions, the specific definition of condition number depends on the problem. For example, the computation of regression coefficients from a **multiple regression** is ill-conditioned when the design matrix **X** displays **collinearity**. Conditioning also depends on the quantity of interest. A **least squares** regression may be ill-conditioned from the point of view of the regression coefficients but well-conditioned from the point of view of the fitted values.

Stability

A stable **algorithm** is one which evaluates a function to the accuracy allowed by the function's condition number. A stable algorithm therefore will evaluate a well-conditioned function accurately, and will do as well as can be expected on an ill-conditioned problem. For example, consider the problem of computing the sample **variance** of the three numbers:

$$62, 63, 64$$

using four-digit decimal arithmetic. A commonly taught formula for the variance is

$$s^2 = \frac{1}{n-1}\left(\sum_{i=1}^{n} x_i^2 - n\overline{x}^2\right),$$

where n is the sample size and the x_i are the observations. Since the data are given to two significant figures, it might be thought that carrying four significant figures through the calculation will leave a more than adequate safety margin. In this case $\sum x_i^2 = 3844 + 3969 + 4096$, which is 1191×10^1 in 4-digit arithmetic. Similarly, $n\overline{x}^2 = 3(63^2)$ is 1191×10^1 to 4 digits. Therefore, s^2 is computed to be 0, a 100% error compared with the true value of 1. Alternative algorithms are available: for example, $s^2 = \sum(x_i - \overline{x})^2/(n-1)$, which evaluates to $[(-1)^2 + 0^2 + 1^2]/2 = 1$ – the correct answer in this case. The first formula is unstable, while the second formula is stable. There are many other algorithms for computing the sample variance, some of which are of great interest to manufacturers of hand calculators; see Chan et al. [4] for a discussion.

The error in the first formula above arises in the rounding errors of $\sum x_i^2$ and $n\overline{x}^2$, and the error is revealed when the difference is taken of the two large and nearly equal quantities. This is often called *subtractive cancellation*, although rounding error occurred not in the subtraction but in the previous summation. It is a general principle that one cannot add a large value to a floating point number and later subtract it without losing accuracy. One concern, therefore, of numerical analysis is to limit the growth in size of intermediate quantities in calculations. For example, a summation is generally stable if the summands are all of one sign. In this case, the partial sums cannot be greater in absolute value than the final sum.

There is often a close relationship between stability in numerical analysis and in statistics. Frequently, parameters which are statistically interpretable because they measure some invariant characteristic of a problem appear also in a stable algorithm, because of the need to compute quantities which do not grow without bound. Even the small example above gives

an example of this, as the $x_i - \overline{x}$ are the well-known residuals, while in the textbook formula $\sum x_i^2$ and $n\overline{x}^2$ are merely intermediate quantities, not statistically useful quantities in their own right.

Let $\tilde{f}(x)$ be the approximation to $f(x)$ which arises from an algorithm. The algorithm is called *backwardly stable* if $\tilde{f}(x)$ can be shown to be equal to the exact evaluation of f at $\tilde{x}$, where $\tilde{x}$ is close to x. In this way, a (backwardly) stable algorithm will compute a well-conditioned function accurately, and will compute an ill-conditioned function as accurately as is allowed by its conditioning.

Although proving error bounds is an important part of modern numerical analysis, the specific bounds obtained are usually pessimistic and are seldom used in practice. In general, rounding-error analyses are less valued for their final bounds than for the insight they provide about a numerical algorithm. A thorough treatment of rounding-error analyses can be found in Higham [6].

Floating Point Arithmetic

There are an infinite number of real numbers, but only a finite number can be represented on a computer. Therein lies the fundamental difference between exact and computer arithmetic, alluded to above. Numbers are represented on computers in floating point form, i.e. $f \times \beta^e$ in terms of a base β, fraction f, and exponent e. For example,

$$2.597 \times 10^{-3}$$

is a base-10 floating point number with four figures of accuracy. Most computers use base 2, and the resulting arithmetic is called binary arithmetic.

Finite computer arithmetic produces three types of errors. When an arithmetic operation produces a number with an exponent that is too large, the result is said to have *overflowed*. Similarly, an arithmetic operation that produces an exponent that is too small is said to have *underflowed*. Even within the limits of the exponent, most numbers cannot be represented exactly on floating point arithmetic of a fixed word length. The resulting inaccuracy is called *rounding error*. It is a central concern of numerical analysis that rounding errors do not accumulate during a long computation (*see* **Floating Point Arithmetic**).

Linear Equations and Matrix Computations

The theory and practice of solving a linear system

$$\mathbf{Ax} = \mathbf{b}$$

for $\mathbf{x}$, and, more generally, the whole subject of computations involving matrices, is now very well developed (*see* **Matrix Computations**). Here, we outline two applications of interest to biostatisticians.

In least squares regression of a response vector $\mathbf{y}$ on a design matrix $\mathbf{X}$, numerical analysts have influenced statisticians to move away from the normal equations for the regression coefficients in favor of methods based on the decomposition

$$\mathbf{X} = \mathbf{QR},$$

where $\mathbf{Q}$ is an orthogonal matrix and $\mathbf{R}$ is upper triangular. This is because the $\mathbf{QR}$ approach is backwardly stable, while the normal equations are not.

Conditioning for the least squares problem is determined by that of $\mathbf{X}$, which can be analyzed through the singular value decomposition

$$\mathbf{X} = \mathbf{UDV}^{\mathrm{T}},$$

where $\mathbf{U}$ and $\mathbf{V}$ are orthogonal and $\mathbf{D}$ is diagonal containing the singular values. The condition number of $\mathbf{X}$ is usually defined to be the ratio of the largest to the smallest singular value. If the columns of $\mathbf{X}$ are standardized; say, by dividing by the sample standard deviation of the column, then the singular values entirely capture the idea of ill-conditioning and collinearity for the least squares problem. The singular value decomposition therefore gives statisticians the means to quantify collinearity, and there are those who propose its routine use in regression computations for that reason [9, Section 15.4].

Numerical linear algebra is dealt with in more detail in the article on **Matrix Computations**.

Optimization and Nonlinear Equations

Optimization means to find that value of $\mathbf{x}$ which maximizes or minimizes a given function $f(\mathbf{x})$. This is a central concern in statistics, because statistical **estimation** principles such as least squares, maximum likelihood, posterior mode (*see* **Bayesian Methods**) and M-estimation (*see* **Robustness**) are defined in

terms of optimizing an appropriate objective function. Numerical optimization strategies come into play when the statistical model is nonlinear and analytic estimators of the parameters are not available.

A closely related problem is that of solving nonlinear equations. Many algorithms for optimizing $f(\mathbf{x})$ are, in fact, derived from algorithms for solving $\partial f/\partial \mathbf{x} = 0$, where $\partial f/\partial \mathbf{x}$ is the derivative vector of f with respect to $\mathbf{x}$.

Details are given in the article on **Optimization and Nonlinear Equations**.

Interpolation and Approximation

The purpose here is accurately to approximate complex functions with ones which are easy to evaluate. For example, rational function approximations to the standard normal distribution function and its inverse allow it to be computed rapidly within statistical programs. Typical methods include series expansions, rational functions, and polynomials (see, for example, Press et al. [9, Chapter 5] and **Polynomial Approximation**). A great many approximation formulas are given in Abramowitz & Stegun [1].

Numerical Integration

After matrix computations, numerical integration is one of the largest areas of numerical analysis. A large number of sophisticated and reliable methods are available for numerical integration in one dimension. Unfortunately, for statisticians wanting to evaluate mixture models or Bayesian marginal posteriors, the picture is less clear in high dimensions. Statisticians have made a substantial contribution to high-dimensional integration through the development of efficient **Monte Carlo** methods. A survey of integration methods is given in the article on **Numerical Integration**.

Available Software

The final goal of numerical analysis is to make numerical methods generally available through high-quality portable software. Numerical analysts were also early users of the **internet**, and a wide range of software is available online. Netlib is the most extensive collection of numerical programs. Its URL is `http://www.netlib.org`.

Worthy of special mention are the LINPACK library [5] for linear algebra and the EISPACK library [10] for **eigenvalue** computations, both from the Argonne National Laboratory. These are published, documented and freely available, and have gained wide acceptance by statisticians and other scientists. The two libraries have now been combined and updated as LAPACK [2]. Other libraries of note include the QUADPACK library [8] for numerical integration, and the SLATEC library – an enormous library of FORTRAN programs.

The Guide to Available Mathematical Software (GAMS) at `http://gams.nist.gov` provides a virtual database of documented and supported programs, searchable by program and problem type. The journal *ACM Transactions of Mathematical Software* is a source of refereed software, also searchable by GAMS.

Commercial subroutine libraries include the NAG Library (Numerical Algorithms Group) and the IMSL Mathematics and Statistics Libraries. LINPACK, EISPACK, and other routines have also been incorporated into the interactive matrix programming language, MATLAB [7].

Another popular commercial source is Numerical Recipes [9], accessible through `www.nr.com`. Numerical Recipes supplies smaller, understandable programs, which may be modified by users for specific applications. Netlib, GAMS, NAG, and IMSL provide more sophisticated routines designed for high performance on large problems. Considerable effort has been expended to make the high-performance routines efficient, memory-compact, and capable of trapping most errors.

Programs developed by statisticians, dealing specifically with statistical problems, can be found at Statlib, the statistical database maintained at Carnegie-Mellon University. The URL is `http://lib.stat.cmu.edu`.

Numerical Integration

Numerical integration is the study of how the numerical value of an integral can be found. Also called *quadrature*, which refers to finding a square whose area is the same as the area under a curve, it is one of the classical topics of **numerical analysis**. Of central interest is the process of approximating a definite integral from values of the integrand when exact mathematical integration is not available. The corresponding problem for multiple dimensional integration is known as multiple integration or *cubature*.

Numerical integration has always been useful in biostatistics to evaluate distribution functions and other quantities. Emphasis in recent years on **Bayesian** and **empirical Bayesian** methods and on mixture models has greatly increased the importance of numerical integration for computing **likelihoods** and posterior distributions and associated **moments** and derivatives. Many recent statistical methods are dependent especially on multiple integration, possibly in very high dimensions.

Although there exist many high-quality automatic integration programs, no program can be expected to integrate all functions, even in one dimension. It is therefore useful for the user to know something about the limitations of the commonly used methods.

This article describes classical quadrature methods and, more briefly, some of the more advanced methods for which software is widely available. The description of the elementary methods in this article borrows from introductory notes by Stewart [31]. An excellent general reference on numerical integration is [5]. More recent material can be found in [7] and [29]. Recent surveys of numerical integration with emphasis on statistical methods and applications are [9] and [8].

Trapezoidal Rule

The simplest quadrature rule in wide use is the *trapezoidal rule*. Like many other methods, it has both a geometric and an analytic derivation. The idea of the geometric derivation is to approximate the area under the curve $y = f(x)$ from $x = a$ to $x = b$ by the area of the trapezoid bounded by the points $(a, 0)$, $(b, 0)$, $[a, f(a)]$, and $[b, f(b)]$. This gives

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{b-a}{2}[f(a) + f(b)].$$

The analytic derivation is to interpolate $f(x)$ at a and b by a linear polynomial.

The trapezoidal rule cannot be expected to give accurate results over a larger interval. However, by summing the results of many applications of the trapezoidal rule over smaller intervals, we can obtain an accurate approximation to the integral over any interval. We begin by dividing $[a, b]$ into n equal intervals by the points $a = x_0 < x_1 < \cdots < x_{n-1} < x_n = b$. Specifically, if $h = (b-a)/n$ is the common length of the intervals, then $x_i = a + ih, i = 0, 1, \ldots, n$. Applying the trapezoidal rule to each interval $[x_{i-1}, x_i]$ gives the *composite trapezoidal rule*

$$\int_a^b f(x)\,\mathrm{d}x \approx h\left\{\frac{f(x_0)}{2} + f(x_1) + \cdots + f(x_{n-1}) + \frac{f(x_n)}{2}\right\}.$$

An error formula for the composite trapezoidal rule can be obtained from polynomial approximation theory. If f is twice continuously differentiable on (a, b), then the error of integration decreases as h^2, so that doubling the number of points reduces the error by a factor of four.

Simpson's Rule

More sophisticated quadrature rules can produce higher-order error terms. Even more popular than the trapezoidal rule is *Simpson's rule*:

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{b-a}{6}\left[f(a) + 4f\left(\frac{a+b}{2}\right) + f(b)\right].$$

Simpson's rule can be derived by interpolating $f(x)$ by a quadratic polynomial at a, $(a+b)/2$, and b.

As with the trapezoidal rule, Simpson's rule is usually applied to many short intervals. Letting the x_i be as above for n even, and writing $f_i = f(x_i)$ the *composite Simpson rule* is

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{h}{3}(f_0 + 4f_1 + 2f_2 + 4f_3 + \cdots + 2f_{n-2} + 4f_{n-1} + f_n).$$

If $\mathrm{CS}_h(f)$ denotes the result of applying the composite Simpson rule to f over the interval $[a, b]$, and if f has a continuous fourth derivative on (a, b), then

$$\int_a^b f(x)\,\mathrm{d}x - \mathrm{CS}_h(f) = -\frac{(b-a)f^{(4)}(\xi)}{180}h^4$$

for some $\xi \in [a, b]$. Although Simpson's rule was derived to integrate quadratic polynomials exactly on each interval, the presence of the fourth derivative in the error term signals that it in fact integrates cubics exactly as well. This property follows from the fact that Simpson's rule is a special case of Gaussian quadrature, treated below.

Newton–Cotes Formulas

The trapezoidal rule integrates any linear polynomial exactly. In general, we might look for an $(n+1)$-point rule which integrates exactly any polynomial of degree n. Such a quadrature rule is the *Newton–Cotes formula*.

Let $x_0, x_1, \ldots, x_n$ be distinct points in the interval $[a, b]$. We wish to determine constants $A_0, A_1, \ldots, A_n$ such that

$$\int_a^b f(x)\,\mathrm{d}x = A_0 f(x_0) + \cdots + A_n f(x_n)$$

for any polynomial f of degree $\leq n$. Strictly speaking, as Newton–Cotes usually refers to formulas with equally spaced abscissas, this is a slight generalization.

Although there is an elegant analytic expression for the A_i in terms of *Lagrange polynomials* [31], they are difficult to evaluate stably. For rules of low degree, one can substitute in $f(x) = 1$, $f(x) = x$, $f(x) = x^2$, etc. to obtain a system of linear equations which can be solved for the A_i.

Clenshaw–Curtis Integration

Newton–Cotes formulas with equally spaced abscissas are of practical use only for small point numbers, say $n \leq 8$. For n as low as nine, the coefficients A_i vary in sign. As n increases, the coefficients become large in absolute value, leading to unstable evaluation of the integral. This problem can be avoided by choosing the abscissas in a more sophisticated way. One choice for which the coefficients are not only positive but have stable analytic expressions is the Chebyshev points on $[a, b]$,

$$x_i = \frac{b+a}{2} + \frac{b-a}{2}\cos\left(\frac{i\pi}{n}\right), \quad i = 0, 1, \ldots, n.$$

Define the modified Fourier coefficients,

$$a_j = \frac{2}{n}{\sum_{i=0}^{n}}'' f(x_i)\cos\left(\frac{ij\pi}{n}\right),$$

where $''$ indicates that the first and last terms in the sum are to be halved. If n is even, then the *Clenshaw–Curtis formula* can be written

$$\int_a^b f(x)\,\mathrm{d}x \approx \frac{b-a}{2}\left[a_0 - \frac{2a_2}{(1)(3)} - \frac{2a_4}{(3)(5)} - \cdots - \frac{2a_{n-2}}{(n-3)(n-1)} - \frac{a_n}{(n-1)(n+1)}\right].$$

Like other formulas of the Newton–Cotes type, Clenshaw–Curtis will integrate exactly polynomials of order n or less. In practice, it does rather better than other rules of the same order, because of the bounded variation properties of Chebyshev polynomials. The error of Clenshaw–Curtis integration can be estimated from the rate of decrease of the coefficients a_j. O'Hara & Smith [22] suggest the use of bounds such as $\max(2|a_{n-4}|, 2|a_{n-2}|, |a_n|)$ for the approximation error.

Treatment of Singularities

Provided that the integrand f is sufficiently smooth, the Newton–Cotes formulas converge as $n \to \infty$. It sometimes happens, however, that one has to integrate a function with a singularity. Suppose, for example, that, for x near zero,

$$f(x) \approx \frac{c}{x^d}$$

for some constant c and $0 < d < 1$. Then $\int_0^1 f(x)\,\mathrm{d}x$ exists, but the Newton–Cotes formulas will not obtain good results because f is not at all polynomial on $[0, 1]$. A better approach is to incorporate the singularity into the quadrature rule itself.

First define

$$g(x) = x^d f(x),$$

and look for a rule that evaluates the integral

$$\int_0^1 g(x)x^{-d}\,\mathrm{d}x,$$

where g is a well-behaved function on [0, 1]. The function x^{-d} is called a *weight function*. Given any modest number of points $x_0, \ldots, x_n$ in the interval (0,1], the method of undetermined coefficients can easily determine an integration rule of the form

$$\int_0^1 g(x)x^{-d}\,\mathrm{d}x = A_0 f(x_0) + \cdots + A_n f(x_n)$$

by substituting in $g(x) = 1, g(x) = x, g(x) = x^2$, etc.

The appearance of derivatives in the error terms for Newton–Cotes rules (and for the Gaussian rules below) shows that the method is troubled not only by singularities in the integrand, but by singularities in its derivatives as well. A weight function may therefore need to remove singularities in the derivatives as well as in the function itself.

Gaussian Quadrature

A polynomial of degree n is determined by its $n + 1$ coefficients. We have seen that the $n + 1$ coefficients $A_0, \ldots, A_n$ in the $(n + 1)$-point Newton–Cotes formula can be chosen to make the rule exact for polynomials of degree n or less. The idea behind Gaussian quadrature is that the abscissas $x_0, \ldots, x_n$ represent another $n + 1$ degrees of freedom, which may be used to extend the exactness of the rule to polynomials of degree $2n + 1$.

Gauss quadrature formulas have the form

$$\int_a^b f(x)w(x)\,\mathrm{d}x \approx A_0 f(x_0) + \cdots + A_n f(x_n),$$

where $w(x)$ is a weight function which is greater than zero on the interval $[a, b]$. The correct choice for $x_0, \ldots, x_n$ turns out to be the zeros of an orthogonal polynomial $P_{\{n+1\}}$ of order $n + 1$. An important point is that the coefficients A_i are positive. Moreover, $A_0 + A_1 + \cdots + A_n = \int_a^b w(x)\,\mathrm{d}x$, so no coefficient can be larger than $\int_a^b w(x)\,\mathrm{d}x$. Consequently, we cannot have a situation in which large coefficients create large intermediate results that suffer cancellation when they are added.

Gaussian quadrature has error formulas similar to those for Newton–Cotes formulas. Specifically, if f is $2n + 2$ times continuously differentiable on (a, b), and $G_n f$ is the quadrature approximation, then

$$\int_a^b f(x)w(x)\,\mathrm{d}x - G_n f = \frac{f^{(2n+2)}(\xi)}{(2n+2)!}\int_a^b p_{n+1}^2(x)w(x)\,\mathrm{d}x,$$

where $\xi \in [a, b]$. If f does not satisfy the smoothness property, then the accuracy of Gaussian quadrature is generally reduced by at least an order of magnitude. However, it is a consequence of the positivity of the coefficients A_i that Gaussian quadrature converges for any continuous function as $n \to \infty$.

Particular Gauss formulas arise from particular choices of the interval $[a, b]$ and the weight function $w(x)$. The workhorse is *Gauss–Legendre* quadrature in which $[a, b] = [-1, 1]$ and $w(x) = 1$, so that the formula approximates the integral

$$\int_{-1}^1 f(x)\,\mathrm{d}x.$$

The corresponding orthogonal polynomials are called Legendre polynomials.

If we take $[a, b] = [0, \infty)$ and $w(x) = \mathrm{e}^{-x}$, we get a formula to approximate

$$\int_0^\infty f(x)\mathrm{e}^{-x}\,\mathrm{d}x.$$

This is called *Gauss–Laguerre* quadrature.

If we take $[a, b] = [-\infty, \infty]$ and $w(x) = \mathrm{e}^{-x^2}$, we get a formula to approximate

$$\int_{-\infty}^\infty f(x)\mathrm{e}^{-x^2}\,\mathrm{d}x$$

This is *Gauss–Hermite* quadrature.

Computing the abscissas and coefficients for these and other Gauss rules in a stable and efficient manner is a challenging nonlinear problem. Two successful **algorithms** are those of Golub & Welsch [12] and Sack & Donovan [28]. A FORTRAN program implementing the Golub–Welsch method can be obtaining by searching the NETLIB* database for GAUSSQ. The expense of computing the abscissas and coefficients is sufficiently great that they are usually stored and reused rather than generated afresh for each problem.

Simpson's rule is actually a variant of the Gauss–Legendre three-point rule in which x_0 and x_n are constrained to be the end points. Rules with such constraints are called *Gauss–Radau* or *Gauss–Lobatto* quadrature [5].

Progressive Formula

Despite their optimal properties, the Gaussian formulas are not universally used in practice. The main reason for this is the difficulty of determining in advance the required number of points to achieve a given level of accuracy. In some cases, mathematical analysis of the function to be integrated makes it possible to use the analytic error bounds of the quadrature rules. It is more common, however, to estimate the error empirically by applying the same quadrature rule twice with different point numbers. Often the point number is doubled until the successive values of the integral agree to the required number of figures.

A succession of integration formulas with increasing point numbers is said to be *nested* or *progressive* if each formula reuses the abscissas of the earlier formulas. The composite Simpson and Clenshaw–Curtis rules with n doubling at each step are important examples of progressive formulas. Gaussian formulas are generally not progressive, as the abscissas at any point number are different from those for any other point number. The relative advantage of the Gauss formulas is therefore lost in the expense of computing addition abscissas and function evaluations.

One possibility is to construct progressive formulas starting or finishing with a Gaussian formula. Kronrod [18] gave a method for adding points to a Gauss–Legendre formula in an optimal way. The Kronrod rule adds $n+1$ points to a n-point Gauss–Legendre formula, resulting in a rule which integrates exactly polynomials of order $3n+1$ (n even) or $3n+2$ (n odd). The desirable properties of Gaussian quadrature are preserved in that the abscissas remain in the integration interval and the coefficients A_i remain positive. When the n-point Gauss rule is combined with its Kronrod optimal extension, a very economical pair of formulas result for the simultaneous calculation of an approximation for an integral and the respective error estimate. The problem of extending arbitrary quadrature formulas in a progressive fashion was studied by Patterson [17, 23, 24], who also gave a stable computation for the Kronrod rules. Together, the Kronrod and Patterson methods provide a nested sequence of quadrature rules based on an initial Gauss rule, and are the basis of some of the most widely used integration programs.

Adaptive Methods

A quadrature rule is *adaptive* if it compensates for a difficult subrange of an integrand by automatically increasing the number of quadrature points in the awkward region. Adaptive strategies divide the integration interval into subintervals and, typically, employ a progressive formula in each subinterval with some fixed upper limit on the number of points allowed. If the required accuracy is not achieved by the progressive formula, then the subinterval is bisected and a similar procedure carried out on each half. This subdivision process is carried out recursively until convergence is achieved in each of the terminating subintervals. Most general purpose integration programs are adaptive, since such a strategy can be successful over a very wide range of integrands.

Multiple Integration: Product Rules

Multiple integration is concerned with the numerical approximation of integrals of two or more variables. It is not a simple extension of one-dimensional integration. The diversity of possible integration regions and singularities for d-dimensional functions is daunting. As a general rule, it is not possible to obtain the same accuracy with higher-dimensional integrals as with one-dimensional integrals for reasonable computing times.

The problem addressed by multiple integration is to evaluate integrals of the form

$$\int f = \int_{a_d}^{b_d} \int_{a_{d-1}(x_d)}^{b_{d-1}(x_d)} \cdots \int_{a_1(x_1,\ldots,x_d)}^{b_1(x_1,\ldots,x_d)} f(x_1, x_2, \ldots, x_d) \times \mathrm{d}x_1\, \mathrm{d}x_2 \ldots \mathrm{d}x_d.$$

The most obvious approach is to treat the multiple integral as a nested sequence of one-dimensional integrals, and to use one-dimensional quadrature with respect to each argument in turn. The resulting multiple integration formula is a *product rule*.

Suppose that the integration region is a hyperrectangle, so that the integration interval $[a_j, b_j]$

for x_j in the above integral is independent of $x_{j+1}, \ldots, x_d$. If Gauss quadrature is used to integrate f with respect to x_j, with abscissas $x_{j0}, x_{j1}, \ldots, x_{jn}$ and coefficients $A_{j0}, A_{j1}, \ldots, A_{jn}$, then the product rule is

$$\int f \approx \sum_{i_0, i_1, \ldots, i_d = 0}^{n} A_{0i_0} A_{1i_1} \ldots A_{di_d} \times f(x_{0i_0}, x_{1i_1}, \ldots, x_{di_d}).$$

This rule integrates exactly any sum of monomials $x_1^{\alpha} x_2^{\beta} \ldots x_n^{\gamma}$, where each $\alpha, \beta, \ldots, \gamma$ is an integer between zero and $2n + 1$, a result which derives directly from the corresponding result for the one-dimensional Gauss rule.

The number of evaluations of f in the product rule is $(n + 1)^d$, which grows exponentially with d. Rapid growth in the number of function evaluations usually limits the practical use of product rules to around five or six dimensions. One special case common in statistical applications is that in which $x_1, \ldots, x_d$ are exchangeable. This arises when $x_1, \ldots, x_d$ is an independent sample from some distribution and f is a function of the probability density. In that case only one evaluation of f is needed for all points which are permutations of one another. The total number of evaluations required is then $\binom{n+d}{d}$, which is considerably smaller than $(n + 1)^d$, so that calculations for sample sizes up about 10 are manageable.

Despite the above limitations, Gauss product rules have been the basis of at least one general approach to implementing Bayesian analysis methods, discussed in [20] and [30].

Rules of Polynomial Degree

As with quadrature, most cubature rules are designed to integrate a certain class of polynomials exactly. A rule is said to be of polynomial degree r if it integrates exactly any sum of monomials $x_1^{k_1} \ldots x_d^{k_d}$ with $k_1 + \cdots + k_d \leq r$. Although Gauss product rules integrate certain monomials of higher order, they do not integrate x_j^{2n+2} exactly and are therefore of polynomial degree $2n + 1$.

By allowing rules that are not product rules, it is usually possible to find rules which are more efficient than the Gauss product rules in the sense of having polynomial degree $\geq 2n + 1$ yet requiring fewer than $(n + 1)^d$ points. Methods for constructing rules of prescribed polynomial degree are surveyed in [3]. For a compilation of such rules see [32] and [4].

Polynomial rules of degrees five and seven on the hyper-rectangle serve as basic integrating rules for the popular multiple integration program ADAPT [11], which is described further below.

Globally Adaptive Algorithms

One-dimensional adaptive programs usually consider each subinterval in turn, subdividing each until a specified accuracy is obtained. This straightforward strategy is called *locally adaptive* because the behavior of the algorithm in each local subinterval depends only on the error estimates in that interval. However, for multiple integrals it is often unknown at the beginning of the calculation whether the given accuracy can be obtained in a reasonable amount of time. A popular adaptive strategy, originally proposed by van Dooren & de Ridder [33], always subdivides the integration subregion with the largest error. Such a strategy is known as *globally adaptive* because it makes subdivision decisions using information about all the current subregions. Although globally adaptive algorithms require more memory space to maintain the current subregion list and take more time to select subregions for subdivision, at each stage in the calculation the global estimate for $\int f$ is in some sense the best one available using the computation that has been done so far.

The globally adaptive program ADAPT [11] and its successor DCUHRE [1, 2] build on the work of van Dooren & de Ridder [33]. ADAPT uses the difference between nested pairs of polynomial rules, of degrees seven and five, respectively, to estimate the error in each subregion. Some of the degree seven integrand values are also used to compute fourth differences in directions parallel to each of the coordinate axes. When a subregion is selected for subdivision, it is divided in half in the direction of largest absolute fourth difference. This clever strategy for halving in only one direction, using fourth differences to measure integrand irregularity, is probably one of the main reasons for the practical effectiveness of the algorithm. The later program DCUHRE gives the user a choice of integration rules, uses a more sophisticated error estimate, and is organized to facilitate parallel integration of a vector of related integrands.

Lattice Methods

Lattice rules were originally called "number theoretic" or "quasi-random" methods [32]. The integration region is translated to the unit cube, and the integral approximated by a multiple sum of the form

$$Qf = \frac{1}{n_1 n_2 \ldots n_t} \times \sum_{j_t=0}^{n_t-1} \cdots \sum_{j_1=0}^{n_1-1} f\left(\frac{j_1}{n_1}\mathbf{z}_1 + \cdots + \frac{j_t}{n_t}\mathbf{z}_t\right),$$

where $\mathbf{z}_1, \ldots, \mathbf{z}_t$ are carefully selected integer vectors. This is the simple unweighted mean of the integrand evaluated over a regular lattice of abscissas in the unit cube. For the method to work well, the integrand must be transformed to be periodic in the cube so that its Fourier coefficients go to zero rapidly.

A lattice method originated by Korobov [16] and extended by Patterson & Cranley [25] is implemented in the NAG library* routines D01GCF and D01GDF. Lattice methods are not yet in widespread use, but there is some evidence [10, 29] that they can outperform other available methods when the number of dimensions is between about 10 and 20.

Monte Carlo Methods

The idea of estimating an integral by random sampling is a natural one in a statistical context. In the classical **Monte Carlo method** [13, 19], points $\mathbf{x}_1, \ldots, \mathbf{x}_n$ are chosen randomly in the integration region and the integral is estimated by

$$\overline{f} = \frac{V}{n}\sum_{i=1}^{n} f(\mathbf{x}_i),$$

where V is the volume of the integration region. Convergence is guaranteed almost surely by the central limit theorem under very weak conditions on f. Moreover, the rate of convergence is independent of the dimensionality. The error $\overline{f} - \int f$ is approximately normal with mean zero and standard deviation

$$\frac{\sigma(f)}{\sqrt{n}}V,$$

where

$$\sigma^2(f) = \frac{1}{V}\int f^2 - \left(\frac{1}{V}\int f\right)^2$$

is the variance of f. Finally, and most importantly, a free estimate of the error is available as $\sigma^2(f)$ may be estimated by the sample variance of $f(\mathbf{x}_1), \ldots, f(\mathbf{x}_n)$.

The slow $n^{-1/2}$ rate of convergence means that Monte Carlo methods are usually limited to low accuracy; say, three significant figures. However, this accuracy can be achieved with comparable work for any number of dimensions and for a very wide range of integration regions. In many statistical applications higher accuracy is not required; computational error need only be small relative to the inherent statistical uncertainty that enters the process of drawing inferences from data.

Practical use of the Monte Carlo method depends on techniques for reducing the $\sigma^2(f)$ variance term in the error. Central amongst these is *importance sampling*, in which $\mathbf{x}_1, \ldots, \mathbf{x}_n$ are sampled from a distribution which is as much like f in shape as possible. This has the effect of sampling most densely in those parts of the integration region where the integrand is greatest. Specifically, write the integral as

$$\int f(\mathbf{x})g(\mathbf{x})\,\mathrm{d}x,$$

where g is a density function on the integration region, and f is as close to a constant function as possible. Points $\mathbf{x}_1, \ldots, \mathbf{x}_n$ are sampled from g, and the integral is approximated as before by $\overline{f}$. The standard deviation of $\overline{f}$ is now

$$\frac{\sigma_g(f)}{\sqrt{n}},$$

where

$$\sigma_g^2(f) = \int f^2 g - \left(\int fg\right)^2$$

is the variance of f with respect to the density g.

Other variance reduction techniques include **stratified sampling** and **antithetic** acceleration. Antithetic acceleration involves generating pairs of identically distributed but negatively correlated points $\mathbf{x}_i^1$ and $\mathbf{x}_i^2$. This tends to produce negatively correlated terms in the sum; the more negative the correlation, the lower the variance of the sum. See [5], [13], [15], or [8] for references to variance reduction methods. The use of Monte Carlo integration to solve Bayesian problems is treated more fully in the article, **Markov chain Monte Carlo**.

The NAG library subroutine D01GBF uses an adaptive Monte Carlo algorithm to integrate over a hyper-rectangle. The number of subregions is doubled at each iteration, and in each the integral and variance are estimated by Monte Carlo sampling. Algorithms also exist which are adaptive in terms of the importance sampling density. Such algorithms refine the importance sampling density adaptively so as to minimize σ^2 during the Monte Carlo process [5, 21].

Conclusions

If a large number of well-behaved one-dimensional integrands are to be integrated, and the user is willing to do some analytic analysis to obtain efficiency, then it is hard to go past the classical Gauss quadrature methods. More usually, though, users will choose to use an automatic integration program of some kind, using computer time to save their own time and to gain reliability.

Reliable and well-documented software for numerical integration can be found by searching the NIST GAMS online catalogue at `http://gams.nist.gov` under class "h2". See [14] for brief reviews of much of this software. It is also worth searching the STATLIB database for statistical functions based on these routines. Simple integration programs, suitable for modification by users, can be found in [27]. Most major statistical and mathematical programming languages include numerical integration programs, often based on the programs found in GAMS.

In one and two dimensions there is a wealth of reliable and effective programs. The leading one-dimensional package currently is QUADPACK by Piessen et al. [26]. This is available from the NETLIB database and is cross-classified by GAMS. It has also been incorporated into the NAG, IMSL, and SLATEC subroutine libraries. QUADPACK provides a suite of programs designed for different types of difficulties, such as singularities and oscillatory integrands, and includes a decision tree to guide the user in choosing the appropriate routine. The program QAGS is a particularly robust general purpose integration program, as is the non-QUADPACK program CADRE [6] which is included in the IMSL library. In statistical applications, however, the integrands are often smooth with a single dominant peak, so the more efficient programs QNG and QAG, which use higher-order Gauss, Gauss–Kronrod and Patterson rules, may suffice.

So far there is no reliable suite of programs for multiple integration. Up to 10 or perhaps 15 dimensions, globally adaptive routines such as ADAPT and DCUHRE can be recommended. When the number of dimensions exceeds about 20, Monte Carlo methods are the only ones possible. Mark 20 of the NAG library includes 10 multiple integration programs, including one which implements a Monte Carlo method.

Nursing

Most people will have some idea of what nursing is, perhaps believing it is the general care of sick people, as opposed to medical attention to their disease. In fact, the definition of nursing has been and continues to be a topic of much debate in the nursing profession. **Florence Nightingale** [6], in her work *Notes on Nursing – What It Is And What It Is Not*, said, in essence, that what nursing has to do is "...put the patient in the best condition for nature to act upon him". A more recent and widely accepted definition of nursing is that of Virginia Henderson [4]: "The unique function of the nurse is to assist the individual, sick or well, in performance of those activities contributing to health or its recovery (or to a peaceful death) that he would perform unaided if he had the necessary strength, will or knowledge. And to help him gain independence as rapidly as possible."

History of the Nursing Profession

Nursing was not suddenly invented during the Crimean War. In the middle ages several religious orders provided and staffed hospitals caring for the sick and needy. The world's first school of nursing was established by Theodore Fliedner at Kaiserswerth in 1833, and Florence Nightingale undertook a course there in 1851.

In 1854, Florence Nightingale led, at the government's expense, a party of nurses to Scutari to work in the British Army hospital treating the sick and wounded of the Crimean War. From the inception of this mission, Florence Nightingale was to be an administrator. Woodham-Smith [7] suggests it was not as an angel of mercy that she was asked to go to Scutari; the consideration of overwhelming importance was the opportunity to advance the cause of nursing. Florence Nightingale returned to England in 1856 as a national hero. The position of nursing as a profession was now established.

In 1860, Florence Nightingale established, at St. Thomas's Hospital London, a school of nursing that became a model for schools of nursing everywhere. Since that time the nursing profession and nurse training have continued to change and develop as health care advances. Nurses work as advanced specialists in all clinical areas and have an increasingly important role in the community, in general practice, and in health education.

Nursing Research

Florence Nightingale is often regarded not only as the founder of the nursing profession but also as the first nurse researcher. Her research influenced health care in general, and nursing specifically. Nightingale's *Notes on Nursing* [6] describe her initial research activities, which focus on the importance of a healthy environment in promoting the patient's physical and mental well-being. She changed the attitudes of the military and society towards the care of the sick.

Following Nightingale's work there was very little further nursing research carried out until the 1950s, when a research trend started, particularly in the US. Through the 1950s and 1960s, a number of nursing journals started to appear; for example, *Nursing Research* was first published in 1952. Through the 1960s, clinical research started to expand as specialty groups such as pediatric, obstetric, and community nursing developed standards of care. By the 1970s, nursing research was a growing activity in the UK, and the *Journal of Advanced Nursing* began publication in 1976. The teaching of research methods was introduced to the nursing curriculum in the 1970s, providing nurses with a basic understanding of research methods.

Nursing research has always struggled for funding. A major political victory for nursing research was the creation of the National Center for Nursing Research, in the US, in 1985.

The Briggs report [1] suggested the need for nursing practice to be based on research. Subsequent reports and nursing authorities, such as the Royal College of Nursing, have continued to stress this issue; however, there is still little evidence of wide-scale adoption of this idea.

Types of Study Used in Nursing Research

Cross-sectional surveys have been commonly used in nursing research: however, randomized controlled trials (*see* **Clinical Trials, Overview**) have not been used much in nursing research studies. The dominant approaches to nursing research through the 1980s have been the so-called qualitative approaches, phenomenology, ethnography, and grounded theory,

approaches borrowed from sociology, anthropology, and psychology (*see* **Social Sciences**). They are thought by many nurse researchers to be a better way of gaining an understanding of the rather subjective and personal phenomena with which nursing care is concerned. Such approaches have no place for statistics.

The preference of these qualitative techniques shown by nursing in the past two decades during a time when medicine has been dominated by the randomized controlled trial has enhanced the divide between nursing and medicine. Each side often chooses to disregard the knowledge of the other in the belief that the philosophical approach of the other side is irrelevant.

Statistical Development

Florence Nightingale is often referred to as "The Passionate Statistician". She strongly believed in the importance of figures, and that the collection of reliable data was essential to any worthwhile determination of policy. While in Scutari, Nightingale organized the record-keeping practices, resulting in a systematic method for data collection. From her data it was clear that preventable or, as she called them, "Zymotic", diseases were responsible for many more deaths than were wounds. She used these data to support her case for sanitary reforms, after which mortality declined rapidly, from 42.7% in February 1855 to 2.2% by June 1855.

Nightingale believed in the value of publicizing statistical findings through diagrams. In 1857, she reported to Sidney Herbert "I have written to Dr Farr for the diagram which is to affect thro' the Eyes what we may fail to convey to the brains of the public through their word-proof ears" (quoted in Diamond & Stone [2] from Florence Nightingale's letter to Sidney Herbert of August 7, 1857). Nightingale drew on the help and statistical advice of **William Farr**. The statistical tables in her reports owed much to Farr and the diagrams were prepared under Farr's guidance, although the inspiration for them lay with Florence Nightingale. She herself claimed to have invented her "coxcombs", which were polar area charts, a type of pie chart. An example, shown in Figure 1, is a reproduction of a diagram in Nightingale [5]. It clearly shows the dramatic reduction in mortality following the commencement of sanitary improvements.

Nightingale was elected a Fellow of the **Royal Statistical Society** in 1858, being proposed by William Farr and seconded by **William Guy**, she was among the first (if not the first) female fellows of the society. In 1859, she began a campaign for uniform hospital and surgical statistics to enable one to ascertain the relative mortality in different hospitals. She worked on this idea with Farr and he got the "model forms" that Florence Nightingale had drawn up discussed at an International Statistical Congress in 1860. The "model forms" duly went into hospitals, and uniform statistics for hospitals were published in the ***Journal of the Royal Statistical Society*** from 1862 to 1866, by which time the forms were considered to be out of date and based on a classification of disease that was too rudimentary.

In addition to working with Farr, Florence Nightingale held the work of **Quetelet** in high regard. The influence of Quetelet is discussed by Diamond & Stone [2]. Florence Nightingale wanted to endow a chair of Applied Statistics at Oxford University (it would have been the first chair of statistics), but a dispute with **Francis Galton** over the purpose of the endowment led Nightingale to revoke the legacy [2].

Use of Statistical Methods

It is perhaps surprising, given Nightingale's strong and passionate belief in the need for statistics, that there has been no further development of statistics in nursing research; indeed, the 1980s and 1990s have seen relatively little use of any statistics in nursing research. There have been occasional series of articles about statistical methods in journals such as *Nursing Research* in the Methodology Corner. There have also been a few articles, similar to those appearing in the medical literature, discussing **clinical significance versus statistical significance** and giving examples of misuse of statistical methods in the nursing literature.

The majority of published nursing research has used little more than elementary univariate methods. However, the relatively extensive use of **Cronbach's alpha** for measuring reliability and of **factor analysis** illustrate that nursing tends to use approaches from psychology rather than medicine.

Nursing journals do not currently make extensive use of statistics. When statistics are used,

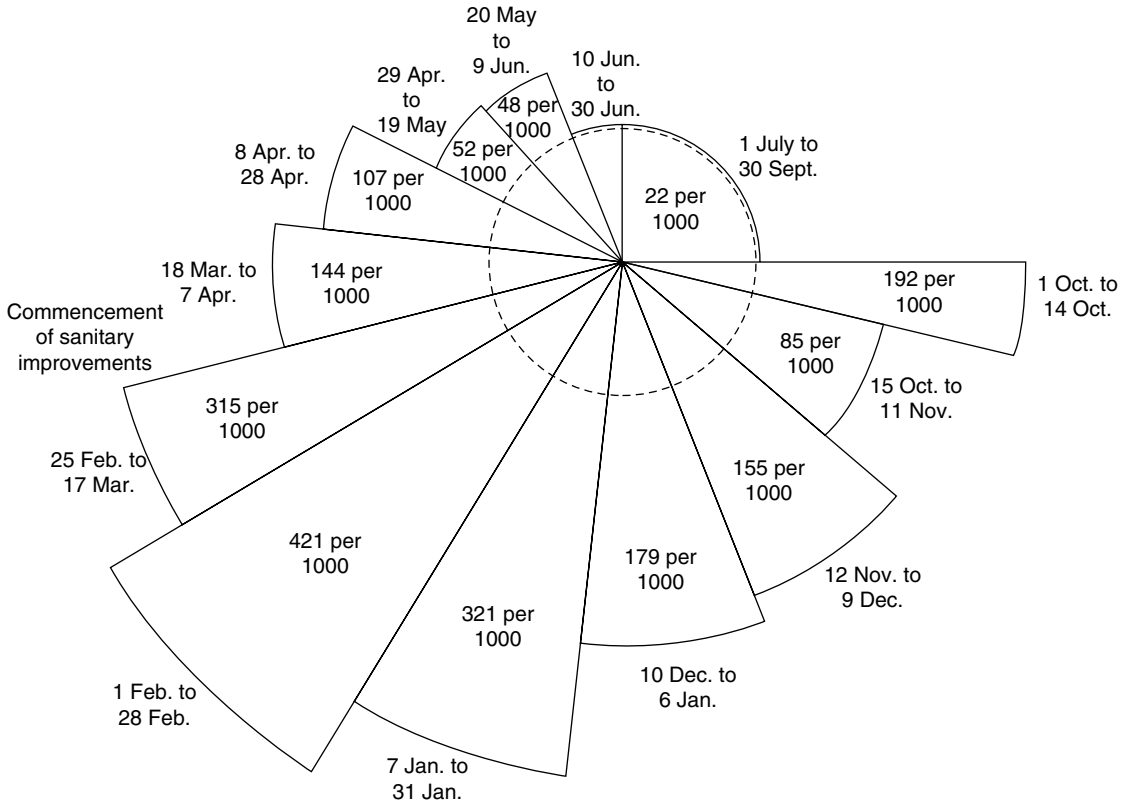

Figure 1 A diagram representing mortality in the hospitals at Scutari and Kulali, from October 1, 1854, to September 30, 1855. The area within the dashed circumference represents the average annual mortality in the military hospitals in and near London, 20.9 per 1000

they are often used and presented poorly. **Confidence intervals** are rarely reported in nursing journals.

The Future

Funk et al. [3] found that a great or moderate barrier to the use of research for 68% of the nurses in their sample was that the statistical analyses were not understandable. The amount of statistical education that nurses receive is negligible, and this is an issue that will need to be addressed if the research-based practice initiative is to become a reality (*see* **Teaching Statistics to Medical Students**).

The emphasis on systematic reviews and **meta-analysis** has started to have an impact on nurses. Good quality systematic reviews of the literature on nursing problems would be welcomed, but will not be easy. The current criteria used to assess study quality will need expansion and development if they are to work well for nursing literature, in which randomized controlled trials are rare. Bayesian approaches to meta-analysis (*see* **Bayesian Methods**) look a promising approach, but they will need to be developed to summarize qualitative as well as quantitative aspects of research.

NICOLA J. CRICHTON

Nutritional Epidemiology

Epidemiology is the study of the etiology of illness and related phenomena in human populations [38]. Nutritional epidemiology, a branch of epidemiology, seeks to unfold the causal relationship between aspects of the diet and occurrence of human illness (*see* **Causation**). Historically, nutritional epidemiology was concerned mainly with nutritional deficiency diseases where a gross deficiency in a particular food or nutrient caused an untoward condition to occur. An early example, which took place in 1753, was the observation that consumption of lemons and oranges prevented the occurrence of scurvy among sailors on British ships, and this has led to the discovery of vitamin C deficiency as a cause of scurvy.

In recent years, the focus of nutritional epidemiology has been shifted from nutritional deficiency syndromes to the dietary determinants of chronic diseases such as heart disease and cancer. The underlying premise in contemporary nutritional epidemiology is that a person's long-term habitual diet has an impact on the occurrence of chronic disease. However, because the etiology of chronic diseases is a great deal more complex than that of deficiency syndromes, this shift in focus has indeed presented immense challenges. Whereas the occurrence of a deficiency syndrome typically has a single cause (deficiency in a food or nutrient item), the risk of a chronic disease not only can be attributed to numerous causal factors, including genetic, environmental, personal lifestyle (e.g. smoking, drinking, physical exercise) as well as dietary, but also the factors exert varying effects with complex **interactions** on disease occurrence. Moreover, a person's diet is made up of a myriad of dietary components, all of which tend to be correlated with each other, and some of which may increase the risk of disease while others may have a protective effect. Whereas a deficiency syndrome has a short **latent period** of exposure to a single cause (the time interval between onset of deficiency and onset of disease), many chronic diseases have latent periods of exposure that are protracted and ill-defined. Because humans are exposed to most dietary factors for their entire lives, there is no clear standard for comparison. Unlike a deficiency syndrome, where the exposure variable can be categorized as "not deficient" or "deficient", the degree of risk for a chronic disease attributed to most dietary factors varies on a continuum. Also, choosing the most relevant time (person's age) at which to begin measuring diet relative to disease onset (the reference period) is difficult and subjective because the reference period is seldom known and may vary not only from one disease to another but also among persons. Additionally, diet can at any time affect the disease process, and its effects may vary over time. The greatest challenge of all which confronts nutritional epidemiology of chronic diseases is how to measure accurately and precisely a person's long-term diet. Clearly these factors make it difficult to attribute the occurrence of a chronic disease to any single food or nutrient item, and consequently any observed relationship between a food or nutrient item and chronic disease must be interpreted with care and replicated in multiple studies. Notwithstanding, nutritional epidemiology has made important contributions to our knowledge regarding the influence of diet on the etiology of human diseases. The intent of this article is to present a brief overview of nutritional epidemiology. A comprehensive and lucid treatise of the subject is given by Willett [44]. Other general references on nutritional epidemiology include [20] and [25].

Types of Nutritional Epidemiologic Study

Different methods and procedures can be used to carry out a nutritional epidemiologic study on the dietary etiology of human disease occurrence, and comprehensive accounts on epidemiologic study designs are available in the literature [25, 38]. Most of the nutritional epidemiology studies conducted to date are **observational** in nature, in that the allocation of persons to dietary exposure group is not under the control of the investigator. Instead, disease frequency is observed and compared between groups of subjects with different dietary exposures. In this section, we select a sampling of research findings from the different types of nutritional epidemiologic studies.

Group-based correlational studies, which correlate the aggregate disease rate with the average dietary intake for different groups of people, provided the earliest clues that a person's diet may affect the risk of chronic disease. A *geographic correlational study* compares the disease rate and average food intake of groups of people living in diverse geographic areas

(*see* **Ecologic Study**). As an example, Armstrong & Doll in 1975 [3] correlated the cancer **incidence** and mortality rates with the per capita consumption of foods and nutrients from various countries. The **correlations** ranged from 0.7 to 0.8 for meat and animal fat consumption with colon cancer incidence and mortality in men and women; for fat intake with breast cancer incidence and mortality in women; and for fat intake with mortality from cancer of the corpus uteri. These remarkably high correlations stimulated further research on intake of animal products and cancer risk.

Other group-based correlational studies that make use of experiments ongoing in nature are studies of migrants, time trend, and special populations. **Migrant studies** compare disease rates defined by migration status. The disease rates of the first and second generation migrants are compared with rates of people in the country of origin as well as people in the host country. Haenszel & Kurihara in 1968 [15] compared the mortality from cancer and other diseases of the first generation Japanese migrants (Issei), US born second generation Japanese (Nisei), the Japanese in Japan, and US whites. Table 1 summarizes the results for selected causes of death for men. The standardized mortality ratio (SMR) is the ratio of the rate of each index group to the rate of the standard population (Japanese in Japan) statistically adjusted to the age distribution of the standard population. The rate of the standard population is reexpressed as 100 [38] (*see* **Standardization Methods**).

It can be seen that stomach cancer and CVA mortality rates show steady progressions from those in the parent country, where rates are high, to those in the host country, where rates are low. Similarly for colon cancer and heart disease, the mortality experience of the Issei and Nisei increased dramatically towards that of the US whites. The mortality rates for all four sites are higher in the Issei than in the Nisei, and part of this difference can be attributed to the considerable age difference between the two groups with the Issei being older than the Nisei. (The SMR corrects for age differences between the index groups and the standard population, but not between index groups.)

Table 1 SMR comparing male mortality rates with those of Japanese men in Japan, adapted from Haenszel et al. [15]

Cause of death	Japan	Issei	Nisei	US whites
Stomach cancer	100	74	38	17
Colon cancer	100	374	288	489
Intracranial lesions of vascular origin (CVA)	100	32	24	37
Arteriosclerotic heart disease	100	226	165	481

Migrant studies have provided strong evidence for the existence of environmental causes for chronic disease by finding that disease rates of the migrant populations diverged from those of the people in their country of origin and approached the rates of the people in their host country. Since the migrant populations and the people in their country of origin share the same genetic background, the change in disease rates must be attributed to environmental and lifestyle factors.

Studies of time trends can also be helpful in determining the role of the environment in disease etiology. For instance, mortality from stomach cancer in the US declined by more than 30% between 1950 and 1960, and this decline is coincident with a dramatic increase in the per capita consumption of fresh fruits and vegetables (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**). *Studies of special populations* whose diet is restricted also provide a unique opportunity to evaluate the role of the environment and lifestyle factors on disease etiology. For example, disease rates may be compared between Mormons, who abstain from caffeine intake, and a similar group of non-Mormon individuals, to assess the role of caffeine on disease development.

Although useful for generating diet–disease hypotheses, group-based correlational studies have fundamental weaknesses. The most crucial drawback of group-based data is **confounding**. Exposure data are collected at the group rather than at the individual subject level, making confounding a virtual certainty because the high correlations between exposure variables at the individual subject level cannot be disentangled. For example, in many populations where meat intake is high, vegetable intake tends to be low, and consequently any apparent association between average meat consumption and disease rate would be confounded by vegetable intake. When comparing populations of different races (and genetic backgrounds), as in a geographic correlation study, confounding by different genetic predispositions to diseases also renders the findings equivocal.

Table 2 Relative risks for hip fracture by quintiles of calcium intake (mg/day), adapted from Lau et al. [23] and Cooper et al. [11]

	Hong Kong			Britain		
	Calcium intake	Relative risk		Calcium intake	Relative risk	
Quintile	Range	Women	Men	Range	Women	Men
Q1 (low)	<75	1.9	2.1	<433	1.2	6.2
Q2	75–82	1.9	1.4	433–566	1.4	5.8
Q3	83–128	1.1	1.7	567–683	1.1	3.3
Q4	129–243	1.2	1.5	684–837	1.2	6.2
Q5 (high)	≥244	1.0	1.0	≥838	1.0	1.0

Table 3 Odds ratios for prostate cancer by quantiles of dietary fat intake, for cases diagnosed after age 69 and their matched controls, adapted from Kolonel et al. [21]

Quantile[a]	Total	Caucasians	Japanese	Filipinos	Hawaiians	Chinese
Q1	1.0	1.0	1.0	1.0	1.0	1.0
Q2	1.1	2.0	0.6	4.0	1.2	1.1
Q3	1.5	2.3	0.8	5.8	1.3	1.6
Q4	1.7	2.6	1.2	2.8		

[a]Quartiles for total, Caucasians, Japanese, and Filipinos, and tertiles for Hawaiians and Chinese.

The quality of the **cause of death** data on the death certificates can also vary considerably among countries (*see* **Death Certification**), and this may render the disease rates not comparable.

The types of study described below record dietary exposure and disease status from individual subjects, thus avoiding many of the drawbacks inherent in group-based data. The most widely used study design in nutritional epidemiology is the **case–control study**. With this study design, people with the disease (cases) and comparable individuals without the disease in question (**controls**) are asked about their dietary and nondietary exposures. Nutritional factors associated with disease occurrence are determined by comparing the past diet of the cases with that of the controls.

Two case–control studies were undertaken, one in Hong Kong [23] and one in the UK [11], to assess the effect of dietary calcium on hip fracture in men and women. Dietary calcium intake was estimated based on the frequency of consumption of nine food items in the Hong Kong study and six food items in the British study. A total of 400 radiologically confirmed fracture cases, 400 hospital controls, and 400 community controls were recruited in Hong Kong, and 300 cases were compared with 600 community controls in the UK. A clear protective effect of calcium intake on hip fracture was found in all groups excepting the British women (Table 2).

Case–control studies have largely been consistent in demonstrating the adverse effect of dietary fat for prostate cancer. One of these studies, conducted in Hawaii, included 452 histologically confirmed prostate cancer cases diagnosed between 1977 and 1983, and 899 age-matched (*see* **Matching**) population controls [21]. The participants were administered a diet history questionnaire with over 100 food items. Table 3 shows a monotonic effect of saturated fat on the risk of prostate cancer in older cases (those diagnosed after age 69), and the finding is consistent in most of the ethnic groups.

The case–control study offers many strengths in the investigation of the dietary etiology of chronic diseases. It is relatively inexpensive and efficient, typically requiring several hundred study participants and 2–4 years to complete the study; individual diet is measured and related to the risk of disease; and confounding can be minimized through appropriate selection of controls, by using appropriate statistical analysis techniques, or both. The case–control study is often the only feasible choice of study design for rare diseases. The primary disadvantage in all case–control studies is that the measurement

of exposure data relies on recall. This is particularly a problem in nutritional studies where cases must remember their past diets before the onset of disease. The diet may also have changed as a result of the disease process, and the current diet has been found to influence the recall of past diet. The results from a case–control study will be invalid if the cases remember their past diets differently than the controls do (**recall bias** of exposure), and if the controls are not comparable with the cases (**selection bias**). Healthy control bias can be especially problematic in studies of nutritional epidemiology if only health-conscious volunteers serve as controls.

Cohort studies avoid the inherent problems which afflict the case–control study, namely recall bias and selection bias. In this study design, diet is measured on a large number of disease-free individuals who are then monitored for disease occurrence. To date, cohort studies in nutritional epidemiology have been few in number, primarily because of their considerable high cost in terms of resources and length of follow-up. More than a decade of follow-up on thousands or even hundreds of thousands of individuals may be required in a cohort study of diet and chronic disease. Because a person's diet is likely to change with age, it is important to record dietary intake on several occasions from each study subject throughout the follow-up period. Repeated measurements will provide more accurate information about the average long-term exposure (*see* **Longitudinal Data Analysis, Overview**). As noted earlier, nutritional epidemiology of chronic disease is based on the premise that long-term dietary exposure affects disease risk.

In one large cohort study, 43 757 male health professionals in the US were recruited to investigate the etiology of the intake of dietary fiber on the occurrence of myocardial infarction. The cohort members completed a mailed dietary questionnaire with over 100 food items; they were then followed for 6 years for the occurrence of heart disease. Intake of dietary fiber, particularly from cereal, was found to be statistically associated with a decreased risk for myocardial infarction [32]. Table 4 shows the **relative risks** adjusted for relevant **covariates**.

Another cohort study example is the Iowa Women's Health Study, used to investigate the postulation that aspects of the diet influence the occurrence of endometrial cancer [47]. A cohort of over 23 000 women was recruited and a questionnaire with 127 food items was administered to each participant. After 7 years of follow-up, dietary intake was correlated with the incidence of endometrial cancer. Although the findings are on the whole equivocal, caloric intake from animal sources and intake of processed meat appear to be associated with a slight increase in the risk of endometrial cancer, especially during the early years of follow-up (Table 5).

In an *intervention study* or *controlled trial* (*see* **Clinical Trials, Overview**), study participants are randomly allocated to the different dietary regimens (*see* **Randomization**). If the subjects have

Table 4 Relative risks for myocardial infarction by quintile of energy-adjusted dietary fiber, adapted from Rimm et al. [32]

Type of fiber	Q1 (low)	Q2	Q3	Q4	Q5
Total	1.00	1.01	0.96	0.92	0.64
Fruit	1.00	0.93	0.83	0.84	0.82
Vegetable	1.00	1.06	0.98	1.00	0.84
Cereal	1.00	0.98	0.90	0.88	0.73

Table 5 Relative risks for endometrial cancer by tertile of intake for selected dietary factors, adapted from Zheng et al. [47]

	≤4 years after cohort entry			≥5 years after cohort entry		
	T1 (low)	T2	T3	T1 (low)	T2	T3
Caloric intake from animal foods	1.0	1.3	1.2	1.0	0.9	0.9
Total meat	1.0	1.0	1.3	1.0	1.0	0.9
Red meat	1.0	0.9	1.2	1.0	0.9	0.9
Seafood	1.0	1.4	1.0	1.0	1.4	2.0
Processed meat	1.0	1.4	1.6	1.0	1.0	1.3
Dairy products	1.0	1.2	1.2	1.0	0.8	1.0
Eggs	1.0	1.2	1.4	1.0	1.4	1.3

the disease, the dietary component is tested as a therapeutic agent, and if the subjects are disease-free, the dietary component is tested as a chemopreventive agent. The controlled trial has one crucial advantage over the cohort study described above, and that is randomization. Because random allocation of subjects to different exposure groups tends to reduce confounding, the controlled trial is able to establish with greater confidence whether a dietary component is a causal factor. However, practical limitations concerning **compliance**, dosage, latency (*see* **Latent Period**), and cost seriously diminish the usefulness of intervention studies in nutritional epidemiology. Most free-living individuals will not strictly follow a dietary regimen, and the persons in the control group may adopt a diet similar to the test diet, particularly if it is perceived to be beneficial (a phenomenon known as control drift). These compliance issues will obscure the differences between the treatment groups, making it more difficult to ascertain a true effect of the diet on disease risk. An example of "control drift" was found in the Multiple Risk Factor Intervention Trial (MRFIT) which randomly allocated 12 866 men at high risk for coronary heart disease to either a special intervention program or usual care [27]. The intervention program was a three-pronged intervention aimed at smoking cessation, blood pressure, and serum cholesterol reduction through lifestyle and dietary modification. Although serum cholesterol dropped from 254 to 236 mg/dl over 72 months in the intervention group, a similar reduction occurred in the nonintervention group: from 254 to 240 mg/dl.

A randomized, double blind, placebo controlled trial of 29 133 male smokers, the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study, was undertaken to determine whether supplementation of alpha-tocopherol and beta-carotene would prevent lung cancer [7]. The study failed to confirm results from observational studies that had found a protective effect for these dietary components. Lack of precise dosage and latency information have been postulated as factors in the results.

Community intervention trials are experimental studies carried out at the population level; they are generally concerned with the effectiveness of an education or incentive program on behavior. For example, a number of participating communities may be randomly allocated either to receive information about the benefits of low-fat diets (test) or to receive no such information (control). **Cross-sectional** surveys, based typically on a sample of subjects from each community, are conducted before and after the information campaign to determine if there is a greater change in diet in the test communities than in the control communities. "Contamination" between groups, where the control communities also receive the test information, can be a problem in community trials.

Variation in Dietary Intake

As noted previously, the underlying premise of nutritional epidemiology is that a person's true "average" diet affects the occurrence of chronic diseases. It would be an easy task to ascertain a person's true diet provided that a person eats the same foods and the same quantity of each food day in and day out (no day-to-day variation), and that a person's diet and its nutrient content can be measured perfectly (no measurement error). In reality, a person's diet varies not only from day to day, but food preference and quantity consumed may be altered as one ages and as circumstances change. In contrast to simple exposures such as smoking, a person's diet is a composite exposure consisting of many food and beverage items consumed in varying amounts, and each food and beverage item contains numerous macro and micronutrients. It is unlikely that an instrument ever will ever be developed which will ascertain dietary intake exactly. Indeed, accurate assessment of a person's long-term average diet is a major concern of nutritional epidemiologic research today, and methods and procedures for estimating the long-term diet are still evolving. In this section we delineate the concepts and definitions of variation in dietary intakes. Measurement error will be discussed in the next section.

The day-to-day variation in a person's food and nutrient intake is assumed to be random, that is, a person's daily diet fluctuates randomly about his or her "average" diet. This assumption implies that the average dietary intake over a number of randomly selected days will approach a person's true habitual intake, and that any deviation of intake on a given day from the true average diet is a reflection of imprecision (sampling error) rather than **bias**.

Some dietary components have been found to be more variable than others. Macronutrients, such as

fat which is present in most foods, tend to show less day-to-day variation than substances that are present in only a few foods or whose amount is very high in a particular food. For instance, eating a mango can drastically increase the intake of beta-carotene for that day. The day-to-day dietary intake variation for a given person is referred to as *within-person variance*. And the variation in dietary intake among different persons is called *between-person variance*. To estimate within-person variance, more than one measurement per person is required.

It might be useful to depict the within-person and between-person components of dietary variation by a statistical model. The **random effects analysis of variance** model, also called the **variance components** model, is given as:

$$Y_{ij} = \mu + \alpha_i X_i + \varepsilon_{ij},$$

where Y_{ij} is the nutrient or food of interest for the ith person and the jth day of measurement, μ is the mean intake across persons and days, X_i is a **dummy variable** that identifies person i, α_i represents the random effect due to person i, and ε_{ij} represents the random day-to-day variability, or the within-person variability.

The variance components model assumes that these conditions hold: the variance of ε_{ij}, designated by σ_ε^2, is constant across days and persons, and the covariance between ε_{ij} and $\varepsilon_{i'j}$ is zero when $i \neq i'$. The variance of α_i, designated by σ_α^2, is constant across persons, and the covariance between α_i and $\alpha_{i'}$ is zero when $i \neq i'$. Models of dietary components often violate the first variance homogeneity assumption because persons with higher intake tend to have a larger within-person variance (i.e. the variance of ε_{ij} is proportional to Y_{ij}). The assumption is usually upheld after a suitable **transformation** (usually log) is applied to the nutrient data Y_{ij}.

The total variance (σ_y^2) is the sum of the between-person variance (σ_α^2) and the within-person variance (σ_ε^2). (With m replicated observations per person, total variability is $\sigma_\alpha^2 + \sigma_\varepsilon^2/m$.) The ratio of these quantities ($\sigma_\varepsilon^2/\sigma_\alpha^2$) gives an indication of the relative importance of the within-person to the between-person variance components. A ratio close to zero indicates that most of the dietary intake variability occurs between persons, in which case the intake level for an individual would be fairly constant from day-to-day. A ratio around one indicates an equal split between the two components, and ratios greater than one indicate that the within-person variance exceeds between-person variance. Another useful statistic based on the variance components is the "intraclass correlation coefficient" (*see* **Correlation**), which will be described later under **validation studies**.

Numerous investigators have estimated the within-person and between-person variance components for the daily intake of common nutrients based on repeated food records [5, 16, 24, 28, 39]. Table 6 presents a summary of the results in the form of ratios. Although between-person variation is substantial, within-person variability is the larger variance

Table 6 Ratio of within-person to between-person variance components, adapted from [5, 16, 24, 28], and [39]

Nutrient	Number of studies	Median ratio	Range of ratios
Energy (kcal)	12	1.4	0.8-2.2
Protein	10	1.4	1.2–3.9
Carbohydrate	9	1.2	0.8–2.0
Fat	9	1.3	0.9–2.8
Percent of calories from fat	8	2.4	1.3–4.8
Saturated fat	8	1.5	1.0–2.8
Cholesterol	11	4.4	1.8–6.8
Vitamin C	9	2.3	1.6–4.0
Vitamin A	7	4.6	1.6–>100
Iron	8	2.4	1.5–3.6
Calcium	10	1.6	1.0–2.6
Zinc	6	2.4	1.7–11.7
Dietary fiber	3	1.7	1.1–2.2

component, accounting for 55% (carbohydrate) to 82% (vitamin A) of the total variation.

Measurement Error

Error in measuring the exposure variable is a common concern in all etiologic research. Measurement error may be minimal in simple exposures such as smoking history, but it may be quite consequential in complex exposures such as long-term dietary cholesterol intake. **Measurement error** occurs when the true exposure value in the ith person, X_i, is not directly observable, but instead a surrogate value, Z_i, is measured. Measurement error, defined as $(Z_i - X_i)$, may be *random* (unbiased) or *systematic* (biased). The error is random if the expected (long-range average) value of Z_i is X_i, and is systematic if the expected value of Z_i is not X_i. Random measurement error will occur if a person is just as likely to overreport as underreport, by the same amount, the consumption of a food item. **Systematic error** will occur if a person is more likely to underreport than overreport, or vice versa, the consumption of an item.

Systematic measurement error of the exposure variable may or may not bias the exposure–disease association. If measurement error is constant for all persons (e.g. all persons underreport the use of cooking oil by the same amount), the exposure–disease association will not be biased, and the **power** will not be diminished. However, systematic measurement error is seldom, if ever, the same for all individuals.

Although systematic measurement error may not be constant for all persons, the overall average error in persons with disease (cases) may be the same as that in persons without disease (controls). This is called **nondifferential measurement error**. Nondifferential error will not bias the exposure–disease association, but it will reduce the statistical power. **Differential measurement error** occurs when the overall average error in the cases is not the same as that in the controls (e.g. the cases on average underestimated the use of cooking oil more so than the controls). Systematic errors which are differential between cases and controls will lead to invalid estimates of the exposure–disease association, and the extent and direction of the bias are difficult to predict.

The consequence of **random measurement error** in the exposure variable will depend on the specific situation. If the exposure variable is a single continuous or dichotomous variable, random measurement error will attenuate the exposure–disease association, that is, **bias towards the null** the **correlation** coefficient, **regression** coefficient or relative risk. Random measurement error also tends to inflate the **standard deviation** for the association, thereby reducing power of statistical tests. If the exposure variable is **polytomous** (with more than two exposure levels), the **odds ratio** or relative risk for the most extreme exposure level will be biased toward the null value, while those for the intermediate levels can be biased away from the null [6, 13, 26]. When confounding variables are measured with random error, the effect of the exposure variable on disease risk may be biased away from the null, even if the exposure variable were measured without error [22]. Also random measurement error in the exposure variable can lead to incomplete adjustment of confounding, resulting in residual confounding in the adjusted exposure–disease **association** estimates [2, 14].

It is a useful practice to estimate the extent of measurement error in the exposure variables so that more reliable exposure–disease associations can be ascertained by taking into account these errors. Correction of measurement error may help to clarify whether an observed null exposure–disease association is real or attenuated. A *reproducibility study* with repeated measurements of the exposure variables can be deployed to estimate random exposure measurement error (*see* **Reliability Study**). To evaluate systematic measurement error, a **validation study** of the dietary instrument against a **"gold standard"**, or at least a more superior instrument, is required.

The simplest approach to reduce random measurement error in the exposure variable is to use the average value obtained from repeated measurements of the exposure, as an average based on replicated values has less random error than a single measured value. For example, study subjects are asked to keep food records on several occasions. This approach may be feasible in a small etiologic study but is likely to be prohibitive in a large study.

An alternative strategy to minimize the effect of exposure measurement error on the exposure–disease association is to estimate the association correcting statistically, for the measurement error in the exposure variable. The general approach is to quantitate the statistical relationship between the measured value, Z_i, and the true value, X_i, of the exposure

variable obtained from a **"calibration"** study and to use this relationship in the correction of measurement error (*see* **Measurement Error in Epidemiologic Studies**). The "calibration" study is either a reproducibility or validation substudy based on a sample of subjects taken from the main etiologic study. Statistical methods pertaining to the correction of exposure measurement error abound in the literature, and they are still evolving. Because of the broad nature of these methods, which encompass different statistical models and assumptions and different types of measurement error, the account given below is intended only to provide a brief and incomplete sketch of the topic, with a sampling of references for the reader to turn to for more information.

The basic concept underlying the measurement error correction methods can be depicted by a simplified model. The expected value of X, given the observed Z, is substituted for every study participant in the main etiologic study, based on the calibration substudy information. $E(X|Z)$ is then substituted for Z in the disease etiology model in the main study to obtain an estimate of the true exposure–disease association. A critical assumption of this model is that the relationship between X and Z in the main study is the same as that in the calibration substudy sample. Wacholder et al. [41] warn that the value from the "gold standard" in the calibration study is almost always measured with error, albeit with less error than the measurements used in the main study. They show that correction to such an "alloyed gold standard" only partially eliminates the bias when the measurement errors between the two methods are moderately to strongly positively correlated. But when the measurement errors are either inversely correlated, uncorrelated, or weakly positively correlated, the corrected exposure–disease association estimate will tend to be overcorrected (anticonservative). It is clear that care needs to be exercised in the application of these statistical correction techniques.

The two examples shown below illustrate the effect of exposure measurement errors on the exposure–disease association and the role of the statistical correction method. Both the examples assume that results from a calibration substudy are available, that the relationship between X and Z in the calibration substudy can be extrapolated to the main study, and that the exposure measurement error is nondifferential, that is, it does not depend on disease status.

Example 1

This example illustrates a statistical technique for correcting systematic and random measurement errors in a dichotomous exposure variable [12]. Results from a validation study are required. Table 7 shows the frequencies for the association between a "true" exposure (X) and disease status.

The relationship between the true exposure (X) and the observed exposure (Z) from the calibration substudy is given in Table 8. Even with a moderately high **sensitivity** of 0.60 and **specificity** of 0.70, the exposure–disease associations are severely attenuated. As shown in Table 9, the true odds ratio of 5.0 becomes 1.6 and the true relative risk of 2.3 becomes 1.2.

The odds ratio or relative risk estimates can be corrected for measurement error when sensitivity (ξ) and specificity (ψ) estimates are available from a validation substudy, using the identities in Table 10:

In our example,

$$a_{\text{true}} = \frac{400(0.70) - 190}{0.6 + 0.7 - 1} = 300,$$

$$b_{\text{true}} = \frac{400(0.6) - 210}{0.6 + 0.7 - 1} = 100,$$

Table 7 Association between true exposure (X) and disease status

	True exposure		
Disease status	Yes	No	Total
Yes	300	100	400
No	150	250	400
Total	450	350	800

Case–control study: odds ratio $= (300 \times 250)/(150 \times 100) = 5.00$
Cohort study: relative risk $= (300/450)/(100/350) = 2.33$

Table 8 Relationship between true exposure (X) and observed exposure (Z)

	True exposure		
Observed exposure	Yes	No	Total
Yes	60	30	90
No	40	70	110
Total	100	100	200

Sensitivity $= \xi = 60/(60 + 40) = 0.60$.
Specificity $= \psi = 70/(30 + 70) = 0.70$.

Table 9 Association between observed exposure (Z) and disease status

	Observed exposure		
Disease status	Yes	No	Total
Yes	210	190	400
No	165	235	400
Total	375	425	800

Case–control study: odds ratio $= (210 \times 235)/(165 \times 190) = 1.57$
Cohort study: relative risk $= (210/375)/(190/425) = 1.25$

Table 10 Correction identities

	Exposure		
Disease	Yes	No	
Yes	a	b	n_{D}
No	c	d	n_{ND}

$$a_{\mathrm{true}} = \frac{n_{\mathrm{D}}\,\psi - b_{\mathrm{obs}}}{\xi + \psi - 1}, \qquad b_{\mathrm{true}} = \frac{n_{\mathrm{D}}\,\xi - a_{\mathrm{obs}}}{\xi + \psi - 1}$$
$$c_{\mathrm{true}} = \frac{n_{\mathrm{ND}}\,\psi - d_{\mathrm{obs}}}{\xi + \psi - 1}, \qquad d_{\mathrm{true}} = \frac{n_{\mathrm{ND}}\,\xi - c_{\mathrm{obs}}}{\xi + \psi - 1}$$

$$c_{\mathrm{true}} = \frac{400(0.70) - 235}{0.6 + 0.7 - 1} = 150,$$

$$d_{\mathrm{true}} = \frac{400(0.6) - 165}{0.6 + 0.7 - 1} = 250.$$

This technique can be generalized to correct for differential measurement error if sensitivity and specificity estimates are available separately for cases and controls. Note the **standard error** for the corrected association will be larger than that for the uncorrected value to account for the sampling error in the estimation of sensitivity and specificity. A corrected standard error is not available in the literature. Rarely are epidemiologic studies focused on one dichotomous exposure variable without other covariates.

Example 2

This example illustrates that random measurement error in two dietary exposures will tend to bias their correlation towards zero. If information is available from a reproducibility study for the two measurements W and U, and no systematic error is present, then the following variance components model hold,

$$W_{ij} = \mu_W + \alpha_i X_i + \varepsilon_{ij},$$
$$U_{ij} = \mu_U + v_i X_i + \zeta_{ij},$$

so that the overall variances are $\mathrm{var}W = s_{\mathrm{b}}^2 + s_{\mathrm{w}}^2/n$ and $\mathrm{var}U = v_{\mathrm{b}}^2 + v_{\mathrm{w}}^2/m$. All errors are assumed to be uncorrelated. The estimate of the "true" correlation can be computed as

$$r_{\mathrm{true}} = r_{\mathrm{obs}} \left[\left(1 + \frac{s_{\mathrm{w}}^2}{(s_{\mathrm{b}}^2 n)}\right)\left(1 + \frac{v_{\mathrm{w}}^2}{(v_{\mathrm{b}}^2 m)}\right)\right]^{1/2}$$

where r_{obs} is the observed correlation between W_{obs} and U_{obs}, s_{w}^2 is the within-person variability of W from a reproducibility study, s_{b}^2 is the between-person variability of W from a reproducibility study, n is the number of replicated values of W from a reproducibility study, v_{w}^2 is the within-person variability of U from a reproducibility study, v_{b}^2 is the between-person variability of U from a reproducibility study, and m is the number of replicated values of U from a reproducibility study.

The proof is given below:

$$\begin{aligned}
r_{\mathrm{obs}} &= \frac{\mathrm{cov}(W_{\mathrm{obs}}, U_{\mathrm{obs}})}{[\mathrm{var}(W)\mathrm{var}(U)]^{1/2}} \\
&= \frac{\mathrm{cov}(\mu_W + a_i X_i + \varepsilon_{ij}, \mu_U + v_i X_i + \zeta_i j)}{[(s_{\mathrm{b}}^2 + s_{\mathrm{w}}^2/n)(v_{\mathrm{b}}^2 + v_{\mathrm{w}}^2/m)]^{1/2}} \\
&= \frac{\mathrm{cov}(\mu_W, \mu_U)}{[s_{\mathrm{b}}^2 v_{\mathrm{b}}^2 (1 + s_{\mathrm{w}}^2/(n s_{\mathrm{b}}^2))(1 + v_{\mathrm{w}}^2/(m v_{\mathrm{b}}^2))]^{1/2}} \\
&= \frac{\mathrm{cov}(\mu_W, \mu_U)}{(s_{\mathrm{b}}^2 v_{\mathrm{b}}^2)^{1/2}} \\
&\quad \times \frac{1}{[(1 + s_{\mathrm{w}}^2/(n s_{\mathrm{b}}^2))(1 + v_w^2/(m v_{\mathrm{b}}^2))]^{1/2}} \\
&= r_{\mathrm{true}} \frac{1}{[(1 + s_{\mathrm{w}}^2/(n s_{\mathrm{b}}^2))(1 + v_{\mathrm{w}}^2/(m v_{\mathrm{b}}^2))]^{1/2}}.
\end{aligned}$$

When only one variable U is measured with error, the formula relating the true and observed correlations becomes

$$r_{\mathrm{true}} = r_{\mathrm{obs}} \left(1 + \frac{v_{\mathrm{w}}^2}{(v_{\mathrm{b}}^2 m)}\right)^{1/2}.$$

Similarly, if only random error is present in the exposure variable, the slope in a **linear regression**

can be corrected as

$$b_{\text{true}} = b_{\text{obs}} \left(1 + \frac{v_{\text{w}}^2}{(m v_{\text{b}}^2)}\right)^{1/2}.$$

As an example suppose a reproducibility study includes 14 food records from which fat and vitamin E intake were computed. Assume the within to between person variance ratios of 1.5 for fat and 4.0 for vitamin E. In a large epidemiologic study, the correlation between these two nutrients was found to be 0.55. An estimate of the correlation corrected for measurement error is

$$0.55 \times \left[\left(1 + \frac{1.5}{14}\right)\left(1 + \frac{4.0}{14}\right)\right]^{1/2} = 0.66.$$

Again, the standard deviation for the corrected correlation coefficient or regression coefficient must account for the variability in the estimation of s_{b}^2, s_{w}^2, v_{b}^2, and v_{w}^2. Rosner et al. [34] derived a standard deviation for the corrected correlation based on the **delta method**. Readers are referred to Beaton et al. [5] for a more general formula where the measurement errors cannot be assumed uncorrelated, and to Kupper [22] for the effect on partial correlations when a confounder is measured with error.

Statistical principles and procedures for the correction of exposure measurement errors in relative risk and odds ratio estimates under more complex models and assumptions are expounded in the following references: [1, 2, 4, 31, 33, 35–37], and [43]. These methods address multiple continuous or categorical exposure variables, confounding variables, both systematic and random measurement errors, and other situations often encountered in nutritional epidemiologic research.

Dietary Assessment Methods

As noted earlier, the day-to-day variation and the measurement errors inherent in ascertaining a person's long-term diet constitute the major challenge in modern day nutritional epidemiology. Continuing research efforts are still being devoted to developing better methods for measuring a person's "average" diet. All the instruments used for assessing dietary intake rely on information supplied directly by the study participants, usually in the form of a questionnaire. Selection of a dietary assessment instrument for a given nutritional epidemiologic study is motivated by the intended use of the dietary data, and considerations include whether the short-term or long-term "average" diet is relevant, what dietary components are most germane, and whether absolute intake or relative intake (i.e. the ranking of individuals by intake) is desired (*see* **Nutritional Exposure Measures**).

The most commonly used tools for dietary assessment are food records, 24-hour recalls, and food frequency questionnaires. Food records and 24-hour recalls, methods that assess recent diet, are generally not feasible for use in large-scale epidemiology studies. Both methods provide information on the total diet (daily calories) and can give information concerning patterns of food consumption.

Food records are arguably the most accurate method for assessing dietary intake. Participants are required to record in a diary all foods at the time they are eaten, as well as ingredients to all recipes. Weighing foods before eating and any leftovers afterward is a common method for evaluating the amount of food consumed. The record-keeping typically covers 3–7 days. Clearly, this technique puts a heavy demand on the participants and is suitable only for literate and motivated volunteers. Another disadvantage with food records is that the very act of recording of foods consumed can change dietary behavior, either by avoiding foods that are considered undesirable or by simplifying the diet to facilitate the transcription. However, food diaries are often the assessment method of choice when high accuracy in the measurement of diet is needed, as for example in validation studies (described later).

In the *24-hour recall* method, a trained interviewer elicits information about the foods consumed and their amounts, during the past day. This technique is rapid, typically taking 10–20 minutes to complete, and is not very burdensome to the study participants. The quality of the 24-hour recall is directly related to the skill of the interviewer, who uses structured probes to facilitate an individual's memory, but who must be careful not to influence the responses. Interviews should be unannounced to avoid having the persons change their diets for ease of recall. Telephone administration of 24-hour recalls is feasible, although the estimation of amounts is more difficult (*see* **Interviewing Techniques**).

The crucial drawback of food records and 24-hour recalls is that the large within-person variability in most dietary components causes such short-term

dietary information to be highly imprecise, deviating substantially from a person's usual or average diet. We illustrate this with the variance components model. Person k has true mean intake of $\mu + \alpha_k$, but with a single record or recall the measured value would be $\mu + \alpha_k + \varepsilon_{kj}$ with variance σ_ε^2. Averaging data across multiple records improves the estimation of the person's true average diet; with m replicated days of collection, person k's measured value would be $\mu + \alpha_k + \sum_j(\varepsilon_{kj})/m$ with variance σ_ε^2/m. It can be seen that the within-person variation becomes negligible as m increases. The number of replicated days required to characterize a person's "true" long-term average diet with high precision has been estimated from numerous dietary variability studies. Briefly, the estimates range from 4 days to 15 days for energy intake, 6 to 14 for fat intake, 6 to 23 days for vitamin C intake, and 47 to 105 days for vitamin A intake. Adjustment for calories (described later) tends to decrease the number of days slightly. Because many different methods were used to estimate the required number of replicated measurements, interested readers are directed to the following selected references: [5, 16, 24, 28], and [39].

The dietary assessment method best suited for use in large-scale nutritional epidemiologic studies is the *food frequency questionnaire* (FFQ), also referred to as the *diet history method*. With the FFQ technique, the frequency (and sometimes amount) of consumption of a list of commonly eaten foods is obtained. The list may consist of only a few highly selected food items, or as many as 100–200 food items, depending on the etiologic hypothesis being tested. The questions may be open ended, where the respondent gives the frequency of consumption for each food item as times per day, week, month or year, or they may be close ended where several frequency categories are listed. Seasonal food items are incorporated by asking for their intake during the season they are available. Many of these questionnaires have "write-in" options where more detail is obtained about specific foods or where participants can add food items important to their diets that are not covered by the list. If the amount consumed is also estimated, typically by incorporating usual portion size or serving size of each food item, the questionnaire is then referred to as "quantitative". The serving sizes of foods with natural units such as eggs are relatively easy to assess. For other foods, aids such as household measures, food models, or photographs are often used to facilitate estimation.

The FFQ method is flexible in that it can be used for short-term or long-term dietary recall, and for estimating a partial or comprehensive diet; it can be administered by an interviewer or self-administered. When the long-term average diet is desired, as is the case with most nutritional epidemiologic research, it is important to inquire about a person's diet covering the relevant time frame or reference period. In a case–control study, the case is asked about his or her "usual" diet before the onset of symptoms, and the control is typically asked about last year's diet, provided there has not been a recent change in the diet. In a cohort study, it is important to administer the FFQ more than once to increase the precision of the estimate of a person's average diet.

A comprehensive diet (or total caloric intake) is sometimes required as overnutrition or undernutrition may have a direct effect on disease risk. Also, measurement of dietary components relative to the total diet may be of interest (see caloric adjustment below).

A drawback of the FFQ is that its list format makes it "population sensitive". A questionnaire that is well suited to one population (e.g. Caucasians) may not include the necessary items to cover adequately the diet in another group (e.g. Japanese). It is crucial to ensure that a FFQ covers all the commonly consumed food items in the population. The FFQ interview can be lengthy, typically requiring between 1 and 2 hours to complete, and this may adversely affect the response rate. Because the FFQ inquires only about consumption of selected foods, it measures relative rather than absolute dietary intake. Administration of different FFQs to the same person is likely to produce different absolute values on intakes, such as grams of fat consumed per day. However, the dietary intakes of a group of persons as assessed by the two FFQs should show comparable rankings. Measurement of relative intake is generally adequate for etiologic research because comparison between cases and controls is of central interest.

Dietary Components

Diet consists of many substances, such as nutrients, additives, contaminants, and other unknown compounds. Information collected on a limited set of relevant foods may be adequate when the dietary

component of interest is concentrated in those foods. In most studies on nutritional etiology of disease, however, a wide variety of dietary components are of interest, such as intake of total calories; macronutrients, including fat, protein, and carbohydrate; micronutrients, including vitamin A, vitamin E, and iron; and intake of particular foods or groups of food, such as red meat or fruits.

In many of the early studies, information on a brief list of foods was collected, and analysis was focused on food intake. More recently, questionnaires on comprehensive diet were introduced, and the emphasis was on nutrient rather than food intake. There is now some realization that both nutrients and foods are important. A nutrient may react in the same way biologically regardless of its food source, in which case the nutrient intake is relevant. Also, nutrient analyses allow comparison across studies from populations with different food intakes. An example where food intake may be the relevant exposure is the recent interest in the influence of soy product consumption on the risk of certain cancers. Analyses often incorporate both nutrients and food sources. For instance, fat from meat sources and fat from dairy products can be studied as separate exposures. Because food choices are correlated, it is desirable to study food patterns and disease risk. Analysis of food patterns with techniques such as **factor analysis** has been attempted but is very preliminary.

Use of dietary supplements can substantially alter a person's dietary profile, and information on supplement use should be collected. However, the nutrient data should be analyzed separately from food alone and from foods and supplements, as it is not known if a nutrient from a food and from a supplement behave the same way biologically.

Computation of Nutrients

Computation of nutrients requires information on the nutrient composition of the food. Information generally comes from published nutrient composition tables, but may be supplemented by food analysis. National nutrient composition data are available from many countries; the US Department of Agriculture (USDA) publishes information about the nutritional content of foods in the US. Investigators need to use food composition data from food sources similar to those under study whenever possible. Nutrient content can vary dramatically by locale. For example, the carotene content of plants is affected by soil type, and the iodine content of fish is affected by seawater content. The nutrient composition data in national tables usually represents an average value from analyses of that food from different sources and locales. The tables generally have information on hundreds of nutrients, given as units, such as grams and milligrams, per 100 grams of food. The nutrient composition data have varying degrees of accuracy. Macronutrients such as protein and fat content tend to vary less between food samples than micronutrients. Some nutrients, like selenium, are so variable between samples that usefulness of the nutrient composition data is questionable.

The **algorithm** for nutrient computation is to compute, for each food in the recall or FFQ, the daily grams of consumption. If portion size is asked, each serving size needs to be assigned a weight in grams. Otherwise, weight in grams should be assigned to a standard serving size. Daily grams are computed for each food as frequency of intake per day times the gram weight of that food. These quantities are compared against a food composition table, and daily nutrients from each food are computed as daily grams of consumption times the nutrient content of that food per 100 grams, multiplied by 100. These quantities are summed across foods for each person to obtain nutrients per day. Note that each food on the dietary assessment instrument must be associated with a food in the composition table. This assignment is very labor intensive for food records and 24-hour recalls and requires a person knowledgeable about nutrition, such as a dietitian. A questionnaire specific food composition table is required for FFQs where several foods are grouped into a single question. For example, an item for beef may include steak and roasts. The corresponding item in the food composition table will be a weighted average of nutrient composition data for each beef item. Complex questionnaires generally require initial preparation before comparison with food composition data, such as adjustment for oils added during cooking and fats eaten on meats.

Reproducibility and Validity

With food frequency questionnaires (FFQ), volunteers are asked to estimate their own usual diets. In the parlance of the variance components model,

a participant is being asked to recall the true average intake $\mu + \alpha_k$, thereby "eliminating" the within-person day-to-day variability. It is of course essential to gauge how well the FFQ measures true average diet. Desirable qualities for a FFQ are reproducibility and validity.

A *reproducible*, or reliable, instrument will give consistent answers on repeated administrations. To study reliability, a FFQ is given to the same person at two or more points in time and their responses are compared. The time period between administrations cannot be too short so that participants remember what they reported earlier. It also cannot be too long as an intervening dietary change can affect responses. Therefore, a period of several months is typical. Correlations between multiple administrations of questionnaires have ranged from 0.5 to 0.7; these correlations compared favorably with the reproducibility for many biological measures, such as blood pressure, over similar time intervals.

A *valid* instrument measures what it is intended to measure. A valid instrument is reproducible, although the reverse is not necessarily true. To verify validity of an instrument, measurements are compared against accurate measurements from a "gold standard". Because no perfect gold standard exists for diet, FFQs are typically compared against superior dietary measurements, mostly commonly against repeated food records, Burke's dietary history, or repeated 24-hour recalls. Biological markers are also used. Generally, a **random sample** of subjects from the population of interest is asked to give information on their diets via multiple records or recalls. These records or recalls need to span different days of the week and different seasons for the average across measurements to match closely the person's true average diet. Timing of the administration of the FFQ is problematic. Administration prior to the recalls and records prevents the more detailed record keeping from altering the questionnaire responses, that is, a learning effect. However, the reference periods will be different, in that the questionnaire will ask about the year prior to the period of detailed dietary information. Administration several months after the last record or recall has the benefit that the reference periods will be similar. As the participants cannot be told at the beginning that a subsequent questionnaire will be requested, drop out can be a problem; the records or recalls of persons unwilling to do the subsequent questionnaire will be unusable. Also, fatigue may detrimentally affect the quality of responses to the FFQ. It is crucial that the same food composition table be used to compute the nutrient intakes from both dietary methods so that the difference between them cannot be attributed to differences in the nutrient computation methods.

Ideally, correlation between the test method (FFQ) and the gold standard should only reflect the extent to which the FFQ measures diet accurately. However, the food record, the 24-hour recall, and the FFQ methods all require the participants to record their diets, which may induce spurious correlations: a person who is a poor recorder of diet will tend to report low intake values on all instruments, regardless of true intake. In this regard, use of biomarkers as the gold standard in validation studies seems appealing, as the measurement procedure is completely unrelated to recording of the diet. However, there are serious limitations to their use, as few biomarkers exist and those that do, such as doubly-labeled water and 24-hour urine nitrogen, only measure current nutritional status, not "usual" status. In addition, biomarkers are not only inordinately expensive, but they can only validate one nutrient at a time, and are dependent on a person's metabolism as well as dietary intake.

Analysis of Validation Studies

Measurements of validity need to be adjusted or stratified (*see* **Stratification**) for variables that will be controlled for in the final epidemiologic analysis. For instance, validation should be performed separately for different gender, age, ethnic, and education groups if the questionnaire is intended for use in these groups. Inclusion of groups with diverse diets in the validation study will increase between-person variation which will inflate the correlation. The between-person variance will be reduced through stratification or adjustment in the epidemiologic analysis, and therefore the adjustment should be performed in the validation study also. For instance, without adjustment for sex, a FFQ that poorly assesses calories could yield a high correlation with a "gold standard", simply because it is able to distinguish the substantial difference in caloric intake between men and women.

Several statistical methods can be used to compare the performance of a dietary questionnaire with that of a "gold standard". The choice of statistical method will depend on the intended use of the

validation study. Means and standard deviations can be presented for both methods, and a **paired *t* test** used to compare the means. For most etiologic studies, it may be sufficient for a questionnaire simply to rank people correctly, in which case a systematic overestimation or underestimation in nutrient values will not bias the exposure–disease association. A single number comparing the two dietary methodologies for each nutrient is desirable as a moderate number of nutrients are generally compared in a validation study. The most frequently used agreement measure is Pearson's correlation coefficient r on log transformed nutrient data, which measures the linear relation between the two measurements. A disadvantage to this statistic is that it depends not only on the agreement between the methods, but also on between-person variability in the population. Use of r, however, allows for easy comparison with past studies. The intraclass correlation coefficient, defined as $r_I = (\sigma_\alpha^2 - \sigma_\varepsilon^2)/(\sigma_\alpha^2 + \sigma_\varepsilon^2)$ from the variance components model, measures **agreement**, rather than correlation, because it accounts for the between-person variability. The r_I can be thought of as the proportion of the total variation accounted for by between-person variability. Often in a validation study, an investigator would like to know if the questionnaire performs equally well for different groups. The correlation coefficients can be statistically compared between subgroups by converting the correlations to Fisher z statistics (*see* **Correlation**), which approximately have a **normal distribution**, and comparing the z' values by a **chi-square statistic** [40].

The **kappa** statistic is a measure of agreement for **nominal** variables that adjusts for chance agreement. To use kappa in validation studies of dietary questionnaires, the nutrients from each of the two measurements must be categorized. A disadvantage to this statistic is that the agreement depends on the categorization, and it must be decided whether to use different cutpoints for the food records and the questionnaire, in which case the kappa measures correlation, or whether to use the same cutpoints, in which case agreement is measured. A weighted kappa is a generalization where cells other than those representing complete agreement are counted as partial agreements; with specific weights, the weighted kappa is related to the intraclass correlation coefficient. Regression coefficients cannot be used to measure the strength of the relationship, since the slope is not scale-free but depends on the standard deviations of the measurements.

Numerous studies have been conducted to validate the FFQ against repeated food records or 24-hour recalls, or Burke's diet history [25]. A summary of the results is presented in Table 11. It can be seen that the correlation varies substantially between studies, attributed to differences in the period between assessments, the number of repeated food records or recalls, and the populations studied. Most correlations appear to be in the range of 0.35 to 0.60. In one of the most detailed validation studies, women completed a FFQ at the beginning of the study, collected four 1-week food records at 3-month intervals, and then completed another FFQ [44]. In this study, the correlations ranged from 0.28 for iron to 0.61 for carbohydrate. Adjustment for caloric intake tended to improve the correlations. Questionnaires can be validated for food intake as well, although the correlations tend to be low because of the high within-person variability for foods.

Table 11 Pearson's correlation coefficients between FFQs and a superior dietary assessment method, adapted from [25]

Nutrient	Number of investigations	Median	Range	Interquartile range
Energy (kcal)	12	0.48	0.29–0.74	0.35–0.58
Protein	10	0.42	0.18–0.80	0.41–0.58
Carbohydrate	7	0.48	0.27–0.60	0.42–0.58
Fat	12	0.52	0.08–0.94	0.36–0.59
Cholesterol	6	0.50	0.42–0.67	0.46–0.60
Vitamin C	9	0.46	0.33–0.64	0.38–0.58
Vitamin A	6	0.40	0.21–0.63	0.33–0.51
Vitamin E	4	0.49	0.39–0.64	0.44–0.56
Calcium	3	0.63	0.61–0.66	–

Statistical Methods

As noted previously, nutritional epidemiology investigates the influence of the diet (exposure variable) on disease occurrence or death (outcome variable). Because nutritional epidemiology is a branch of chronic disease epidemiology, all of the statistical principles and methods for chronic disease epidemiology [8, 9, 38] are applicable to nutritional epidemiology. Thus, the exposure–disease association in nutritional epidemiology is quantified by the odds ratio, **risk** ratio, or **hazard ratio**, depending on the study design, and the statistical models used to estimate this association include the **logistic regression**, **Cox regression**, and **Poisson regression** models. What is unique about nutritional epidemiology is that the primary exposure variable (a person's long-term diet) is imprecisely measured, due to considerable within-person variation and measurement errors. As highlighted in the previous sections, many of the statistical methods were developed to address this problem. In this section, several other statistical topics that are especially germane to nutritional epidemiology will be highlighted.

Grouping of the Exposure Variable

In the statistical analysis of data from nutritional epidemiology, the exposure variable (food or nutrient intake) is often initially categorized into approximately evenly sized groups, such as tertiles, quartiles or quintiles (*see* **Quantiles**), and then entered into the appropriate statistical model as indicator or dummy variables. The cutpoints are generally based on the distribution of the controls, although the joint distribution of cases and controls can also be used and provides the best dispersion of counts by exposure category. This grouping of continuous exposure variables serves several purposes: the distribution of a nutrient tends to be skewed to the right and categorization dampens the effect of the extreme values; the effect of measurement error is reduced in that the dietary questionnaire needs only to categorize people into broad categories of intake; and the relationship between exposure and risk of disease occurrence can be assessed for **dose–response** trend. If the exposure is to be used as a continuous variable, then it is important to check that the relationship is indeed monotonic prior to analysis. Statistical evaluation of trend can be performed in a number of ways, such as using a continuous predictor or assigning scores to categories [38].

Multiple Comparisons

Some dietary questionnaires have more than 100 food items, which are then converted to between 20 and 30 nutrients. Statistical analysis of exposure–disease associations for all of these exposure variables will give rise to many statistical tests of "significance". Moreover, statistical analysis if often repeated in subgroups defined by such factors as gender, race, age, or subcategory of disease (e.g. stage of disease). It is not uncommon to perform an overwhelmingly large number of statistical tests from a single study, giving a high likelihood of finding many "statistically significant" test results purely by chance (*see* **Multiple Comparisons**). It is crucial that the investigator is aware of this problem. It is equally important to make clear in the research report which hypotheses constitute a priori or a posteriori tests. A stricter criterion for reporting "statistical significance" should be deployed for a posteriori tests.

Multicollinearity

Certain types of eating patterns are generally seen together in individual diets, such as high fat and low fiber diets. These eating patterns sometimes create very high correlations, or multicollinearity, between dietary exposures, leading to problems in model estimation. If two exposure variables, such as fat and dietary fiber, are highly inversely correlated, then the regression coefficient (and hence the effect measure) for fat will vary depending on whether dietary fiber is in the model. Therefore, with multicollinearity, the regression coefficient does not reflect any underlying effect of the variable on disease, but rather a marginal effect that depends on what other variables are included in the model. Additionally, standard errors of regression coefficients are inflated when the independent variables in the model are highly correlated with each other, and the correlated variables may not individually be statistically significant even if there is a strong relationship between the set of predictor variables and the outcome variable. In nutritional epidemiologic studies, correlations between foods and nutrients need to be investiaged prior to building a model with multiple nutritional predictors.

Remedial measures for multicollinearity, such as ridge regression, are available. However, effects of nutrients with near perfect correlation cannot be estimated separately.

Energy Adjustment Methods

Almost all of a person's total energy (caloric) intake is contributed by three macronutrients: intake of fat, protein, and carbohydrate. (Alcohol intake may also contribute substantially to some peoples' energy intake.) The current thinking of some nutritional epidemiologists is that it is not enough to estimate the effect of a food or nutrient on the risk of disease without giving due consideration to total energy intake [44]. For example, if high fat and energy intake were found to elevate the risk for colon cancer, then it is important to distinguish whether the apparent effect of fat intake on colon cancer actually acts through its contribution to the energy content (higher fat intakes results in higher energy content) or whether there is a specific effect of fat, independent of energy intake, on colon cancer. Statistically, what is needed is to estimate the association between fat intake and colon cancer adjusting for energy intake. Another justification for energy adjustment is that the same amount of a nutrient consumed will have less potency on a large person than on a smaller person (here, energy intake can be thought of as a surrogate for body size). Energy adjustment has also been advocated for micronutrients, such as vitamins and minerals, even though they have no appreciable energy content.

Not all nutritional epidemiologists agree with the need for energy adjustment in the estimation of nutrient-disease associations, and even though a variety of statistical methods have been proposed for energy adjustment, none is generally accepted as a standard. Indeed, energy adjustment is currently highly contentious [10, 17–19, 29, 30, 42, 44–46]. This section presents a brief sketch of the four proposed energy adjustment models. In these models, D denotes disease status, N denotes calories from the nutrient of interest, and T denotes total caloric intake. The exact specification of the regression model $M(\cdot)$ is not given, but the logistic and Cox **proportional hazards** models are the common choices.

Standard Model. $M(D) = \beta_{0S} + \beta_{1S}N + \beta_{2S}T + \varepsilon$, where the variables N and T are entered in the model simultaneously.

Residual Model. $M(D) = \beta_{0R} + \beta_{1R}R + \beta_{2R}T + \varepsilon$, where R is the **residual** from the linear regression model of N on T : $N = \alpha_0 + \alpha_1 T$.

Partition Model. $M(D) = \beta_{0P} + \beta_{1P}N + \beta_{2P}(T - N) + \varepsilon$, where the caloric intake is partitioned into calories from the nutrient of interest (N) and those from other sources ($T - N$).

Nutrient Density Model. $M(D) = \beta_{0N} + \beta_{1N}(N/T) + \beta_{2N}T + \varepsilon$, where the calories from the nutrient are divided by the total calories (N/T) to give the proportion of calories from the nutrient of interest.

The following identities show that the first three models are in fact equivalent when N and T are continuous. However, the models are not equivalent when either N or T or both are categorized and represented by indicator variables. Brown et al. [10] noted that the residual model is the most powerful and **robust** of the three models with categorized variables.

Relationship between standard and residual models:

$$\beta_{0S} = \beta_{0R} - \alpha_0\beta_{1R},$$
$$\beta_{1S} = \beta_{1R},$$
$$\beta_{2S} = \beta_{2R} - \alpha_1\beta_{1R}.$$

Relationship between standard and partition models:

$$\beta_{0S} = \beta_{0P},$$
$$\beta_{1S} = \beta_{1P} - \beta_{2P},$$
$$\beta_{2S} = \beta_{2P}.$$

Relationship between residual and partition models:

$$\beta_{0P} = \beta_{0R} - \alpha_0\beta_{1R},$$
$$\beta_{1P} - \beta_{2P} = \beta_{1R},$$
$$\beta_{2P} = \beta_{2R} - \alpha_1\beta_{1R}.$$

No one model appears clearly superior to another. The choice of model with continuous variables may be guided by the meaning of the parameters contained in each model. In the standard model, β_{1S} measures the effect on D of increasing N by 1 unit while keeping total calories constant, that is, the effect of substituting calories from sources other than N (denote by N') with calories from N. β_{2S} represents the effect on D of increasing T by 1 unit while

keeping N constant, that is, the effect of increasing calories from N'.

In the residual model, the above identities show that β_{1R} also measures the effect of substituting calories from N' with calories from N. The parameter β_{2R} represents the effect on D of increasing T by 1 unit while holding R constant. Recall that $R = N - \alpha_0 - \alpha_1 T$. Substituting $T' = (N + N') + 1$ into the equation, R is constant only when an increase of 1 unit in N' is matched with a concomitant increase in N of $\alpha_1/(1 - \alpha_1)$ units.

The partition model parameter β_{1P} measures the effect of increasing N by 1 unit while holding N' constant, that is, the effect on D of adding 1 calorie from N. By the identity with β_{2S}, β_{2P} represents the effect of increasing calories from N' by 1 unit.

The nutrient density model has a more complex structure that involves the reciprocal of caloric intake, making its coefficients rather difficult to interpret.

The partition model appears to have the parameters with the most straightforward interpretation, although it cannot be used to energy-adjust food or micronutrient intake. Pike et al. [29, 30] point out that the interpretation of β_1 in all four models is complicated by the fact that N' is itself made up of many dietary components. Suppose the nutrient of interest is fat. A β_{1S} of 0 would indicate that a substitution of 1 nonfat calorie with 1 fat calorie has no effect, that is, that calories from different sources have the same influence on the risk of D. This conclusion would be incorrect if calories from carbohydrate have a protective effect and calories from protein and alcohol have a direct effect on risk. The effect of calories from fat is being compared against the average effect of calories from the other components in these models.

Wacholder et al. [42] argue that it is not possible to distinguish the generic effect on the delivery of energy from the nutrient of interest and any specific effect of that nutrient. They point out that the true model of interest is

$$M(D) = \beta_0 + \beta_N N + \beta_{N'} N' + \beta_T T + \varepsilon,$$

which is a non**identifiable** problem because $T = N + N'$. All four models given above are special cases of this model, where one of the parameters is excluded. Therefore, the parameters in the energy adjustment models are confounded by the missing parameter and cannot clearly distinguish between a generic caloric effect and a specific nutrient effect. It is clear that when energy and nutrient intakes are too highly correlated, the variables measure nearly the same function (highly **collinear**), and their effects on D cannot be segregated. In this case, the residuals from the regression of N on T will have limited variability, as most of it will have been explained by calories, and should not be used to represent an independent exposure variable.

Energy adjustment methods can be used as a tool to investigate the joint effects of energy and individual nutrients on disease risk, but it is clear that much care must be taken in its application and interpretation.

Nutritional Exposure Measures

In all methods of measurement of nutritional exposure, some estimate of the weight of food consumed is required, and for the determination of nutrient or other food component intake, either an appropriate description for use with food tables is needed or a portion must be available for chemical analysis. Different methods are available to assess the weight of food, and they vary in accuracy, complexity, and cost [1, 5, 6]:

1. Food frequency questionnaires are designed to assess long-term habits, over months or years, and comprise a list of foods most informative about the nutrients or foods of interest [5]. The length of this list generally does not exceed 150 items. Various methods to assess portion sizes may be used, for example fitting average portion weights derived from other data to the respondents' chosen food and frequency selections. To assess the frequency of food consumption, accompanying the food list is a multiple response grid in which respondents attempt to estimate how often selected foods are eaten. Up to ten categories ranging from never, or once a month or less, to six times per day is a usual format. Because responses are standardized, food frequency questionnaires can be analyzed quickly and easily so that large numbers of individuals can be investigated relatively inexpensively. This method has been used particularly in **cohort studies**.
2. Diet history is usually conducted by trained interviewers, who obtain more detailed information on usual foods consumed, portion sizes, recipes, and frequency of food consumption over the recent past. The diet history is less commonly used in epidemiology but is frequently used in clinical dietetics.
3. Twenty-four hour recalls are based on interviews on written information about the previous day's intake, and the actual foods consumed are described, together with information on portion weights. This method is also more costly due to the variety of foods possibly consumed (at least 5000 different food items are available in most Westernized food suppliers), all of which require estimation of portion size and individual computer coding. This method is used in **surveillance** and **cross-sectional studies**, and potentially for nested case–control studies and validation studies.
4. Daily written records of the description and amount of food are kept at the time of consumption. In some studies, the consumer is asked to weigh food as it is served. The method requires substantial resources for data entry, but if records are kept for a sufficient length of time, this method has been generally used in research to assess the accuracy of other methods such as food frequency questionnaires, and for **nested case–control studies**. However, regression dilution may be considerably underestimated because of error correlation between the reference and test method [3, 4].
5. Checklists are precoded lists of foods for rapid data entry to be completed every day for several days [2]. The consumer is given one checklist per day, and asked to check off which foods are eaten from the list. Portion sizes and the list of foods are as for food frequency questionnaires, but errors in the estimation of frequency of consumption are avoided by this method.

Food frequency questionnaires or diet history methods are used in **case–control studies** to assess diet retrospectively prior to onset of symptoms. However, estimates of past dietary consumption are closely related to present consumption, and the discrepancy between actual and recalled past diet is greater the longer the period of recall attempted [5] (*see* **Recall Bias**).

Measurement errors can arise from food table databases, assessment of portion size, daily variation, inaccurate frequency categorization in food frequency questionnaires, and underreporting. All methods have different types of error structure, so that the magnitude of the error varies according to the method and may not be predictable. Relative **validation studies**, using biomarkers of intake as the reference method, suggest that regression dilution from written record methods is considerably less than with food frequency questionnaires [3]. All methods may

be subject to systematic **bias** from under- or overreporting.

Nyquist Frequency

While a **time series** $X(t)$ can often be thought of as having values for all real values of t for computation we must make recordings at discrete time points. Suppose we choose to digitize the record by taking values at time intervals Δt apart, giving $X(\Delta t), X(2\Delta t), \ldots, X(N\Delta t)$ to make inferences about the original $X(t)$.

The choice of time intervals is important since the digitizing, which samples the series, has two important consequences:

1. We have no information about phenomena which have frequencies above the *Nyquist frequency* or *folding frequency* of $1/2\Delta t$ cycles per unit time.
2. These missing effects may distort our perception of those cyclic phenomena which have frequencies below the Nyquist frequency. This effect is called *aliasing*.

Some definitions are given as follows: A function $g(t)$ is periodic if

$$g(t) = g(t \pm s) = g(t \pm 2s) = \cdots = g(t \pm ks) = \cdots,$$

and the smallest (nonzero) s value is called the period of the function. The frequency f is the number of periods per unit time; that is, $f = 1/s$ cycles per unit time. Thus, $\cos(2\pi t/s)$ has period s, while $\cos(2\pi ft)$ has frequency f. Our Nyquist frequency of $1/2\Delta t$ cycles per unit time will correspond to a minimum period of $2\Delta t$. Note that mathematicians like to work in angular frequencies $\omega = 2\pi f$ radians per unit time.

Sampling limits the frequency range because of the nature of periodic functions. Suppose $\Delta t = 1$ and the signal contains a function which is periodic; say, $g(t)$ with frequency 3/2, i.e. period 2/3. Then we observe in sequence

$$g(0), g\left(\frac{1}{3}\right), g\left(\frac{2}{3}\right) = g(0), g\left(\frac{1}{3}\right), g\left(\frac{2}{3}\right), \ldots,$$

a signal which repeats in steps of 3, giving an apparent frequency of 1/3. If we regard our periodic component $g(t)$, with period $f_b = k/2\Delta t + f_0$, $f_0 < f_N$, as being expressed in terms of complex exponentials $\exp(i2\pi f_b t)$, then, since $t = m\Delta t$, they become $\exp(i2\pi f_b m\Delta t) = \exp(i2\pi f_0)$. For an example see Figure 1.

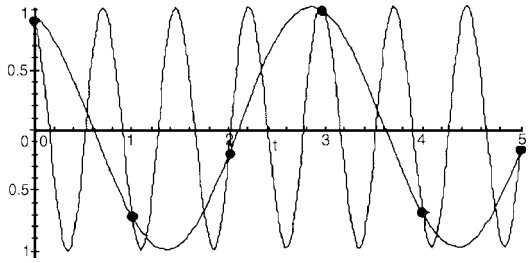

Figure 1 Alias of a signal after sampling

If the power spectrum of the original series (*see* **Spectral Analysis**) is $h(f)$, then we can show that the power spectrum of the observed, digitized, series $h_{\mathrm{d}}(f)$ is

$$h_{\mathrm{d}}(f) = \sum_{k=-\infty}^{\infty} h\left(f + \frac{k}{\Delta t}\right), \quad -\frac{1}{2\Delta t} < f \leq \frac{1}{2\Delta t}.$$

Our observed spectrum is thus the result of folding the original over the Nyquist range.

This means that the observed value of the power spectrum at f_0 is made up not only of $h(f_0)$ but also the values of the original spectrum at the aliases to f_0; that is, $f_0 \pm 1/\Delta t$, $f_0 \pm 1/2\Delta t$, $f_0 \pm 1/3\Delta t, \ldots$. So when you digitize a sequence it is vital that there are no components with appreciable power whose frequency lies outside the Nyquist range. Indeed, we can prove that if the power outside this range is exactly zero, then the original series can be reconstructed exactly from the digitized one.

Comprehensive accounts are given in [1] and [2].

G.J. JANACEK

Oblimin Rotation

Oblimin rotation is a general form of performing an **oblique rotation** of vectors comprising the matrix $\mathbf{V}$ of dimension $(p \times k)$ associated with **principal components** or factors in order to transform these quantities into new variables by the relationship $\mathbf{B} = \mathbf{V\Theta}$ [$\mathbf{B}$ is a matrix of dimension $(p \times k)$ and $\mathbf{\Theta}$ is a matrix of dimension $(k \times k)$] such that $\mathbf{B}$ will approximate **simple structure** (*see* **Rotation of Axes**). Oblimin rotation is similar in nature to the *Orthomax* **orthogonal rotation** procedure. Like Orthomax, the Oblimin rotations are also quartic solutions and are a general solution of the following expression:

$$Q = \sum_{g<j=1}^{k(k-1)/2} \left[p \sum_{i=1}^{p} b_{ij}^2 b_{ig}^2 - c \left(\sum_{j=1}^{p} b_{ij}^2 \right) \times \left(\sum_{i=1}^{p} b_{ig}^2 \right) \right],$$

where p is the number of original variables, k is the number of retained components or factors, b_{ij} are the coefficients of the vectors defining the rotation, and c is an arbitrary constant. Unlike the Orthomax procedure, Oblimin rotations require Q to be *minimized*.

The Oblimin expression includes a number of procedures that have been derived independently. *Covarimin* rotation [1, 7], which is obtained by setting $c = 1$, has been criticized by some as being too close to an orthogonal rotation. Similarly, setting $c = 0$ produces the *Quartimin* rotation [1, 6] which has been felt to be too oblique. As a compromise, Carroll [2] derived the *Biquartimin* rotation by setting $c = 1/2$. Standard errors for the vector coefficients produced by Oblimin rotation were given by Jennrich [4] and Clarkson [3].

There are several versions of these procedures. The expression above is referred to as *raw* Oblimin. In a manner similar to **Varimax rotation**, *normal* Oblimin may be obtained by dividing each b_{ij}^2 or b_{ig}^2 by the corresponding diagonal term of $\mathbf{VV}'$. The original Oblimin procedures involved both the primary and reference vectors. A later procedure, called *Direct Oblimin* [5, 6], simplified this by doing away with the reference vectors.

The direct Oblimin rotation is available in the SPSS software package (*see* **Software, Biostatistical**) [8]. Table 1 provides an example of the direct Oblimin solution with the original principal component characteristic vectors. This example deals with depression data collected in the Framingham Study. The principal components analysis is performed on a sample of 1660 subjects (*see* **Principal Components Analysis** for data description).

Table 1 Framingham depression data: characteristic and direct Oblimin rotated vectors

	Characteristic vectors			Direct Oblimin rotation		
	$\mathbf{v}_1$	$\mathbf{v}_2$	$\mathbf{v}_3$	$\mathbf{v}_1$	$\mathbf{v}_2$	$\mathbf{v}_3$
Effort	0.60	0.15	0.41	0.12	0.08	0.67
Restless	0.39	0.07	0.55	−0.06	−0.10	0.70
Depress	0.77	−0.13	−0.10	0.69	0.08	0.16
Happy	0.70	−0.23	−0.06	0.68	−0.05	0.15
Lonely	0.64	−0.23	−0.21	0.71	0.01	−0.02
Unfriend	0.35	0.67	−0.33	0.04	0.83	−0.06
Enjoylife	0.52	−0.27	−0.27	0.69	−0.03	−0.13
Feltsad	0.72	−0.23	−0.20	0.76	0.02	0.02
Disliked	0.34	0.72	−0.22	−0.06	0.83	0.06
Getgoing	0.58	0.20	0.47	0.04	0.10	0.73

In recent years, these solutions seemed to have lost favor to some two-stage procedures such as **Orthoblique** or Harris–Kaiser rotation, **Promax rotation**, and **Optres rotation**.

J. EDWARD JACKSON

Oblique Rotation

Given a matrix $\mathbf{V}$ of dimension $(p \times k)$ consisting of a set of k vectors, usually defining a set of **principal components** or factors, a new set of transformed variables may be obtained by a rotation of $\mathbf{V}$, namely $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$. $\mathbf{V}$ is often the **factor loading matrix** or factor matrix from the initial step in a principal components analysis or a **factor analysis**. Such a rotation is said to be **oblique** if the resultant rotated axes in the vector space are not at right angles to each other. Most rotation procedures are designed to approximate a **simple structure**. The matrix $\boldsymbol{\Theta}$ of dimension $(k \times k)$ defines the angles of rotation and the matrix $\mathbf{B}$ of dimension $(p \times k)$ defines the vectors determining the new variables obtained by rotation.

The purpose of using oblique rotation is to obtain a matrix $\mathbf{B}$ that exhibits a better pattern of simple structure than would be obtained by using an orthogonal rotation. This improvement towards a simple structure comes at the cost of loss of **orthogonality**. If the main purpose of rotation is to cluster groups of the original variables, then this may present no problem. As in the case of **orthogonal rotation**, there are many methods of obtaining oblique rotations and, again, there is a general quartic formula, the **Oblimin rotation**, which produces a number of these procedures. Unlike orthogonal rotation, the more popular oblique procedures are not members of this family and are generally two-stage procedures. Among these procedures are **Orthoblique** or Harris–Kaiser, **Promax**, and **Optres rotations**.

J. EDWARD JACKSON

Observational Study

An observational study is a study in which conditions are not under the control of the investigator, unlike an **experimental study**. In particular, the exposures or treatments of interest are not assigned at random to experimental units by the investigator (*see* **Randomization**). Thus, **associations** between exposure and health outcome, say, may result from **confounding** by factors associated both with exposure and outcome.

Epidemiologic studies of disease etiology in humans are almost always observational because it is unethical to allocate people to receive potentially harmful exposures (*see* **Ethics of Randomized Trials**). Although the investigator does not control the allocation of exposure in observational studies, it is possible to mimic experimental designs in many respects and, by proper collection of observational data, to examine critically the hypothesis that the exposure has a causal impact (*see* **Causation**) on health outcome. The process of causal induction from observational data was brilliantly described by Hill [1, 2] (*see* **Hill's Criteria for Causality**).

Observational data are particularly subject to confounding in studies of therapeutic effects because factors that cause a doctor or patient to select a particular treatment are also often strongly related to health outcome. Such confounding has been called 'confounding by indication' [3]. Whenever possible, an **experimental design**, the controlled **clinical trial**, should be used to evaluate such treatments.

MITCHELL H. GAIL

Observer Reliability and Agreement

Many measurements in medical practice and research are based on observations made by clinicians. As these measurements are prone to error, observer reliability and agreement are important issues in medicine. The terms "observer reliability" and "**agreement**" are often used interchangeably, but in theory they are different concepts. Reliability coefficients express the ability to differentiate among subjects. They are ratios of **variances**: in general, the variance attributed to the difference among subjects divided by the total variance [11, 12]. Agreement refers to conformity. Agreement parameters determine whether the same value is achieved if a measurement is performed twice, either by the same observer or by different observers [4]. In homogeneous populations one can imagine that reliability might be low while agreement is high; in a heterogeneous population, reliability and agreement measures will correspond well [13].

The parameters for assessment of observer reliability and agreement differ according to the scale of measurement. The possible scales of measurement are: categorical data on a **nominal** scale (e.g. the judgment of presence or absence of a sign or symptom); categorical data on an ordinal scale (e.g. judgment of the degree of severity of a lesion); and data on a continuous scale (e.g. the measurement of blood pressure). For each of these scales, reliability and agreement parameters will be presented and discussed. Table 1 summarizes several characteristics of the parameters.

Categorical Data

With a **binomial** outcome, the results of two observers rating N subjects or one observer rating N subjects twice, may be presented in a **two-by-two table** as shown in Table 2 [3]. The level of agreement is 50% (both positive scores) plus 20% (both negative scores). However, this measure does not discriminate between actual agreement and agreement which arises due to chance. A measure which attempts to correct for chance agreement is the **kappa** (κ) coefficient [4]. κ represents the extra amount of agreement observed above chance ($p_o - p_e$), divided by the amount of agreement which could maximally occur above chance ($1 - p_e$). In Table 2, the observed proportion of agreement (p_o) is the proportion of X-ray films agreed on by the two rheumatologists as being positive (50/100), plus the proportion agreed on as negative (20/100), i.e. 0.70. The expected proportion of chance agreement is calculated assuming independence of the observers: $65/100 \times 65/100 = 0.42$ of the X-rays would be scored positive and $35/100 \times 35/100 = 0.12$ would be scored negative by both observers: $p_e = 0.54.\kappa = (p_o - p_e)/(1 - p_e) = (0.70 - 0.54)/(1 - 0.54) = 0.35$. Usually, κ-values lie between 0 and +1, where 0 indicates only chance agreement and 1 indicates perfect agreement. However, κ-values can be negative, when there is less agreement than expected by chance (*see* **Kappa and its Dependence on Marginal Rates**).

Table 1 Characteristics of the presented parameters of agreement

Characteristics	κ	κ_w	ICC	Generalizability study	Limits of agreement
Scale	Categorical nominal	Categorical ordinal	Continuous	Continuous	Continuous
Measure of reliability or agreement	Agreement	Agreement	Reliability	Reliability	Agreement
Distinguish between random and nonrandom errors	No	No	No	Yes	Yes
Applicable to more than two observers	Yes	Yes	Yes	Yes	No
Expressed in metric unit of measurement	No	No	No	Yes	Yes

κ = kappa
κ_w = weighted kappa
ICC = intraclass correlation coefficient

Table 2 Agreement between two rheumatologists rating hand radiographs of 100 patients according to presence or absence of evidence of erosions [3]

	Rheumatologist B		
Rheumatologist A	Present	Absent	Total
Present	50	15	65
Absent	15	20	35
Total	65	35	100

In Table 3, an example is presented where both **random errors** and nonrandom errors in the measurements occur [3]. Two rheumatologists again show 70% agreement, but now rheumatologist A is more likely to score X-rays as positive (75%) than rheumatologist B (55%). The κ-value is 0.37, indicating a level of agreement which is slightly higher than for the example in Table 2.

The κ-coefficient can be extended for observations with more than two nominal categories [2]. If the number of categories increases, the opportunities for disagreement will increase, and consequently κ will tend to be lower.

In the situation of a scale with more than two classes with a logical sequence (ordinal scale), a weighted κ-coefficient (κ_w) has been proposed [5]. This reflects the fact that disagreements between adjacent categories are less serious than disagreements over more categories. κ_w adjusts for the seriousness of disagreement by assigning weights (between 0 and 1) to partial agreement cells, where 0 means total disagreement and 1 total agreement. Using quadratic weights in this calculation, κ_w becomes equivalent to the intraclass correlation coefficient [10] (*see* **Correlation**). This shows the similarity of reliability and agreement under specific conditions.

κ is the most widely accepted measure of agreement when considering categorical data. κ includes both random errors and nonrandom errors. However, the interpretation of κ is difficult. The practice of calculating a **confidence interval** for κ and assessing whether it differs statistically significantly from zero is of no use: the question is not whether an association is present or not, but how close to perfect the observer agreement is. Although proposals for interpretation of different κ-values have been made, the interpretation is not as straightforward as suggested [1, 9]. Several factors should be taken into account. First, κ is dependent on the number of classes. With more classes it is more difficult to classify the subjects correctly and lower κ-values are usually found. Secondly, κ is dependent on the **prevalence** of the attribute being measured. High underlying prevalences result in a high level of expected agreement, leaving less room for actual agreement. Supposing that the rheumatologists both scored 80% of the X-rays as positive, agreeing in 65% of the X-rays on positive scores and 5% on negative scores. In that case, the agreement would again be 70%, but the κ-value would only be 0.06. Thirdly, the κ-value also depends on differences in the marginals of the two observers, that is, in the presence of **bias**. In the case of bias, the κ-value can, paradoxically, become higher [7, 8]. A single κ-value does not differentiate between random and nonrandom errors. Therefore, presentation of the complete table together with the κ-value is very important. The table shows the prevalences of the scores, whether there is bias as well as random errors and, in the case of more classes, which classes are most difficult to distinguish. This information is indispensable for a proper interpretation of the κ-value and forms the basis for improvement of the observer agreement.

Table 3 Agreement between two rheumatologists rating hand radiographs of 100 patients for presence of erosions with bias in their evaluation [3]

	Rheumatologist B

Present	50	25	75
Absent	5	20	25
Total	55	45	100

Continuous Data

Intraclass Correlation Coefficient

The intraclass correlation coefficient (ICC) is a measure observer reliability designed for continuous variables, although it can also be used for ordinal data. The ICC is defined as the ratio of the **variance** of interest (often the variance between subjects) to the total variance [11, 12]. These variances are derived from **analyses of variance** (ANOVA). The structure of the ANOVA model depends, among other things, on whether the observers are drawn at random from a large population of observers (**random effects**) or whether they are the only observers of interest

(**fixed effects**), and on whether each observer rates each subject or not [11, 12]. These factors determine the appropriate ICC formula. The ICC includes both random errors and systematic differences. The ICC ranges from 0 with no agreement to +1 with perfect agreement.

The ICC avoids the problem of the Pearson correlation coefficient that a linear relationship is mistaken for agreement, but is, like other correlation coefficients, dependent on the range of the variables measured. With larger ranges, that is, in a more heterogeneous population, the value of ICC is higher. This reflects the fact that in heterogeneous populations subjects are easier to distinguish than in homogeneous populations. Although the ICC is designed to measure how well patients can be distinguished from each other despite measurement errors, the ICC is also used as a measure of agreement. In this case, caution should also be exercised by comparing ICCs between populations and by extrapolating results on ICCs to populations which differ with respect to heterogeneity [13]. The ICC is a ratio of variances and, therefore, difficult to interpret clinically. Presentation of its **variance components**, whose square roots are expressed in the metric units of measurement (*see* **Unit of Analysis**), would be more informative clinically.

Generalizability Studies

A more extensive analysis using ANOVA is proposed under the term "generalizability" studies [6]. In any measurement situation there are multiple sources of error variance. Besides intra-observer and inter-observer disagreements, variability among subjects may arise on different days, after different diets or in stressful situations. The error variance can be calculated for each source of error. By taking the square root of the error variances the **standard errors** of measurement (SEMs) are obtained, expressed in the dimension of the original measurement. An important goal of generalizability studies is to identify and measure variance components which contribute errors to a measurement. They provide a lot of information on observer reliability. They identify sources of error (e.g. intra-observer or inter-observer) and determine the relative importance of each component. This provides useful information for strategies to prevent or minimize errors. Moreover, the SEMs resulting from the analyses have direct use in clinical practice and research. Therefore, generalizability studies are powerful tools in assessing intra-observer and inter-observer reliability (*see* **Validity and Generalizability in Epidemiologic Studies**).

Example. In a three way **factorial experiment** (random effects model), 15 patients are rated by five different observers on three different days. Assuming that the patient characteristics being judged are stable over these days, the measurements at the three different moments can be used to assess the intra-observer reliability. The results of the ANOVA analysis are presented in Table 4. From an investigation of the variance components (σ^2), observations on different days (W: within observers) or in **interaction** of days with the other two main effects (P × W, B × W, P × B × W) appear to contribute little to the total variation. A greater proportion of variance is contributed by the different observers (B: between observers), and the largest by the inter-individual differences among the patients (P) and the patient−observer interaction (P × B). The variance components corresponding to the various facets of the measurement design are the major results of a generalizability study. The square root of these variance components equals the SEM. Hence, the generalizability studies identify the sources of error, assess the relative contribution to the measurement and provide direct usable clinical information.

Limits of Agreement

A simple method which measures agreement and distinguishes between random and nonrandom errors was proposed by Bland & Altman [2]. In order to assess whether there are systematic differences between two rheumatologists A and B, the scores of the two observers are subtracted (d) and plotted against the mean of the measurements (Figure 1) [3]. The confidence interval around $d(d \pm t_{n-1}SE)$ is calculated to assess whether statistically significant bias exists between the two rheumatologists. Furthermore, limits of agreement can be calculated, based on the mean difference between the rheumatologists (d) and the **standard deviation** of these differences. Approximately 95% of the differences will lie between $d - 2$ and $d + 2$ standard deviations, which are called the limits of agreement. These formulas hold if the differences are not dependent on the

Table 4 Fictitious example of ANOVA analysis of generalizability study

Facet	SS	df	MS	σ^2 : SEM^2	% σ^2
Patients (P)	14 000	14	1000	$\sigma^2_P = (MS_P - MS_{PW} - MS_{PB} + MS_{PWB})/n_B n_W = 58.67$	53.9
Inter-observer (B)	2400	4	600	$\sigma^2_B = (MS_B - MS_{BP} - MS_{BW} + MS_{PBW})/n_P n_W = 11.33$	10.4
Intra-observer (W)	200	2	100	$\sigma^2_W = (MS_W - MS_{WP} - MS_{WB} + MS_{PBW})/n_P n_B = 0.47$	0.4
P × B	4200	56	75	$\sigma^2_{PB} = (MS_{PB} - MS_{PBW})/n_W = 23.33$	21.4
P × W	1400	28	50	$\sigma^2_{PW} = (MS_{PW} - MS_{PBW})/n_B = 9$	8.3
B × W	160	8	20	$\sigma^2_{BW} = (MS_{BW} - MS_{PBW})/n_P = 1$	0.9
P × B × W	560	112	5	$\sigma^2_{PBW} = 5 = MS_{error}$	4.6

P = patients
B = between observers
W = within observers

MS = mean square
σ^2 = estimate of variance
SEM = standard error of measurement

value of the mean (e.g. larger differences with higher means). If this is not the case, **transformations** are required to make the differences independent of the mean.

The method of Bland & Altman [2] clearly visualizes systematic differences and random errors. Moreover, errors are expressed in terms of the scale of measurement (*see* **Measurement Scale**), which enables a direct clinical interpretation of the results. The minimum acceptable level of agreement depends on the clinical use and situation. Deciding whether errors are acceptable is always a question of clinical, not statistical, judgment.

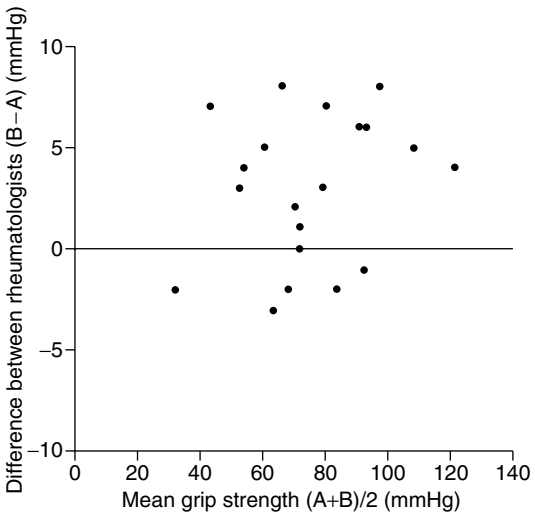

Figure 1 Difference between rheumatologist A and rheumatologist B's readings of grip strength measurements plotted against mean measurements for 20 patients [3]

Clinical Relevance

Assessing observer reliability and agreement is essential for interpretation of clinical observations both in research and in medical practice. Even more important than being aware of a suboptimal observer reliability or agreement is coping with or anticipating it. Tracing the sources and types (bias or random error) of the disagreements is the beginning of wisdom. For that purpose, presenting one single coefficient is insufficient and a visual presentation of the data is advisable. Generalizability studies, which aim to determine the origin of the variation and their relative contribution to measurement errors, are most valuable in this respect. Such studies are able to measure, among other things, the contribution of intra-observer and inter-observer variation to the total of measurement errors. The solutions for intra-observer and inter-observer disagreements have to be sought in standardization of the measurements and consensus meetings about clinical observations. Knowledge about the origins of the errors helps in this process. If the agreement cannot be improved by these

strategies, multiple measurements may be a solution. Depending on the major source of disagreement, these multiple measurements should be performed either by different observers or by the same observer. In medical research, increasing the sample size is also an option for coping with random errors. However, one should note that increasing sample size does not prevent bias. In general, improvement of observer reliability or agreement of clinical observations may have much impact on the **quality of health care**.

Occupational Epidemiology

Especially since the late 1970s, numerous epidemiologic studies have revealed elevated **risks** of cancer, cardiovascular disease, and neurologic and other disorders among various occupational groups [106]. Strong evidence that many disorders are work-related was unobtainable from the clinical experiences or **case reports** that used to be the basis for identifying occupational risks. The introduction of modern, rigorous principles for epidemiologic research and the integration of epidemiologic courses in **occupational health** training have played an important role in this development. Many textbooks on epidemiologic methods have appeared since the early 1980s, and some of these have specifically focused on occupational epidemiology [41, 75, 115]. The availability of computers and statistical packages also has facilitated the progress.

It is hardly possible to predict the directions in occupational epidemiology that will lead to the most important future achievements. Only the more general aspects and principles of occupational epidemiology can be illustrated here by examples drawn from the several different subject matter areas. The challenge in occupational epidemiology has been, and will be, to identify adverse agent(s) or processes rather than to associate health risks with occupational groups or titles, because successful prevention can only be based on the elimination or reduction of specific exposures. The difficulties in this respect are often considerable, however, as occupational exposures tend to be mixed, and lifestyle factors may interfere.

The refinements of methods in epidemiologic research [63] came long after the first few epidemiologic studies of occupational disorders. In 1843, **W.A. Guy** studied "pulmonary consumption" in letter press printers and identified a higher risk among compositors than among pressmen [99]. The observation in 1879 of an increased occurrence of lung cancer among Schneeberg miners [70], and the excess of bladder cancer among German aniline workers reported around the turn of the century [135], are other examples of early occupational epidemiology.

A more recent example of occupational epidemiology, from 1948, demonstrated a high **proportional mortality** of lung cancer among British workers exposed to inorganic arsenic [78]. A few years later an increased risk of lung cancer was demonstrated among gas workers [49] and also bladder cancer in rubber workers [39]. Important studies of the risk of lung cancer in asbestos workers [142] and in underground miners were published in the 1960s [164, 165]. Studies on chemically induced cardiovascular disease also appeared relatively early – for example, among workers exposed to carbon disulfide [76, 155].

There is now, in the twenty-first century, an increasing interest in the effects of work stress and psychosocial determinants of the risk of cardiovascular disease. Other recent studies concern neurologic disorders and their relationships to occupational exposures. Ergonomic risk factors and musculoskeletal disorders as well as reproductive hazards from occupational exposures are other aspects that have attracted interest since the 1980s. The health effects of electromagnetic fields have been among the most intriguing questions in occupational and **environmental epidemiology** during the 1990s [89, 141, 154], although the initiating study in this respect concerned cancer in children [166].

For the future, as for today, a central issue in occupational epidemiology will be the assessment of the effect of single as well as combined exposures. The recently developed tools of **molecular epidemiology** may increase the **power** of epidemiologic studies to detect risks at lower exposure levels and in smaller worker groups. These new tools are already being used in occupational epidemiology to define biomarkers of exposure or early effects [75, 161], to identify susceptible individuals and to specify cancers by their mutational patterns [13].

Defining Research Questions for Occupational Epidemiology

New ideas for occupational studies have come from a variety of sources. A clinical observation has often suggested a connection between a disease and an exposure; sometimes toxicologic data from animal experiments have indicated a possible health hazard. Suggestions for a study may also have originated from observations or suspicions among workers about an adverse health effect. Still other leads for study derive from an examination of death records

in various occupational groups (*see* **Occupational Mortality**) or from studies that link **census** data on job titles with cancer registry data or other **disease registries** or **causes of death**. Clues for new studies may also come from **case–control studies** that routinely tend to assess a number of exposures; should some unexpected **associations** appear, further studies are usually warranted.

The Role of Clinical Observations for Epidemiologic Research

The concerns about asbestos exposure as a cause of lung cancer and mesothelioma have probably generated more studies in occupational epidemiology than any other job-related health risk. The first suspicion of a lung cancer risk was raised by two case reports in 1935 [60, 102], and other such reports followed before the association between exposure and disease was clearly assessed in 1955, both in England [50] and California [32]. The risk of mesothelioma was not noticed until 1960; again the first suspicions arose from clinical observations [163].

The perception of possibly different risk patterns for the different types of asbestos may in part explain the numerous studies that have been conducted worldwide on asbestos exposure, but little gain in specific knowledge has been achieved in this respect. Indeed, between 1977, when the IARC (**International Agency for Research Against Cancer**) Monograph on asbestos exposure and cancer risk was published, and 1986, when this material was updated in the Monograph Supplement 7 [85], there was little new information regarding the effect of specific types of asbestos in spite of more than a doubling of the number of available studies. Several of these studies on asbestos in many countries have probably been motivated by the need to convince both the medical community and the authorities in each country with local studies on the health risk.

An even more clear-cut example of how a clinical observation initiated a large number of epidemiologic studies arose from the discovery of a cluster (*see* **Clustering**) of paranasal cancer cases among furniture workers in High Wycombe, UK [2, 104]. The many subsequent studies from various parts of the world have been convincingly consistent [85]. Similarly, a cluster of nasal cancers was traced to boot and shoe manufacturing [1], and again, this link was confirmed in many studies from several countries [85]. The rarity of this type of cancer certainly facilitated the recognition of a causal relationship (*see* **Causation**) to occupational exposures.

The report in 1974 of liver angiosarcomas among workers exposed to vinyl chloride provides still another example of how the observation of a cluster of cases of a rare tumor [46] gave rise to a number of further studies. Some of these included also other cancers and cardiovascular disease [51]. The first report on human liver angiosarcoma [46] referred to animal experiments that indicated the possibility of an oncogenic effect of vinyl chloride, but this knowledge seemed not to have reduced workplace exposures. A note added to the report on the human angiosarcomas described unpublished data showing liver angiosarcoma and other tumors in animals exposed to vinyl chloride. The consistent findings in humans and animals convincingly established the risk of liver angiosarcoma from exposure to vinyl chloride.

Studies of the association of phenoxy herbicides with soft tissue sarcomas and lymphomas represent another theme in occupational epidemiology that arose from clinical observations and a case series report [67]. In contrast to the vinyl chloride case, there has been no convincing experimental evidence of a cancer risk from phenoxy herbicides. However, in particular, the 2,4,5-trichlorophenoxyacetic acid was known to contain varying amounts of 2,3,7,8-tetrachlorodibenzodioxin and other dioxins, for which there was growing evidence of cancer risks from animal data from 1977 onwards [83, 159]. Although there has been some inconsistency among the ensuing studies, it seems that soft tissue sarcomas are mainly related to dioxin exposure, whereas the lymphomas, especially the non-Hodgkin lymphomas, might be caused by phenoxy herbicides themselves [68].

Clinical observations also have stimulated epidemiologic studies in other areas than cancer. Painters with severe neurasthenic or psychoorganic syndromes in the 1970s raised the question of a role for long-term solvent exposure. Following some initial case–control and **cohort studies** in Sweden and Denmark indicating an effect [17, 112, 119], further epidemiologic research has been conducted and essentially confirmed both acute effects and the

syndromes that may appear after long-term solvent exposure [30, 43, 160].

Animal Data Initiating Occupational Epidemiology

Sometimes the initial clue that precipitates epidemiologic research arises from animal studies. An example of strong animal evidence of a cancer risk preceding epidemiologic research concerns lung cancer among workers with exposure to chloromethyl methyl ether [54, 84]. The animal data existing in this case have apparently been so convincingly corroborating the epidemiologic findings that preventive actions were taken in many countries and few further human studies have followed.

Animal carcinogenesis studies of trichloroethylene also triggered epidemiologic investigations in the late 1970s [20, 156]. The early results were less convincing of a cancer risk, and only by aggregating the results from the later three most informative studies [5, 19, 150], and comparing the observed to expected numbers of liver and biliary tract cancers as well as non-Hodgkin's lymphomas, could an IARC Working Group conclude that there was limited evidence for a carcinogenic effect from trichloroethylene in humans [88].

Many epidemiologic studies also followed animal studies showing that formaldehyde caused cancer in the nasal cavity. An excess of nasal and nasopharyngeal cancers appeared as a fairly consistent finding in several of these ensuing studies [85]. Still, the IARC Working Group that evaluated this agent considered the available studies to provide only limited evidence for a carcinogenic effect in humans. This and the previous example indicate the problems and the latitude involved in trying to assess finally a cancer risk.

Animal data suggest carcinogenic risks from lead, cadmium, and beryllium, but epidemiologic findings have been relatively weak, although finally convincing enough for cadmium and beryllium to permit a conclusion about sufficient evidence for a carcinogenic effect also in humans [86]. A more recent meta-analysis suggests also a cancer risk for workers exposed to lead [57].

These examples notwithstanding, it is perhaps surprising that relatively few epidemiologic studies have been initiated in response to animal studies, especially in view of the large number of chemicals tested. For diseases other than cancer, there are even fewer examples of animal studies leading to epidemiologic investigations, but there is also a relative lack of animal studies about other effects than cancer. Furthermore, the principles of occupational epidemiology have been less developed for such other diseases.

Record Linkage Studies

Epidemiologists have linked mortality or cancer registry data with census or **death certificate** information on occupation (*see* **Record Linkage**) in efforts to discover new occupational health hazards. Even when there is an increased risk of some disorder in an occupational group, the imprecise measure of exposure in such linkage studies attenuates the effect, however. This dilution problem may explain why the associations found have usually been weak and have contributed relatively little new knowledge. **Census** data reflect the occupational status at a point in time (e.g. during a particular week), and are therefore inherently poor measures of the occupational exposure that may, or may not, have occurred over many years.

A source of potential **confounding** (see discussion later) in registry linkage studies is the geographic variation in disease incidence, which may be real or may reflect local preferences in diagnostic practice (*see* **Geographic Patterns of Disease**). A common job in an area with a high incidence of some disease may therefore be associated with an artifactually increased occupational risk of the disease. For example, the linkage of registry data in Sweden indicated an excess of brain cancer in glass workers, but further evaluation showed that there was also a locally increased risk for others living in the relatively small area where the glassworks were located [169].

These limitations do not imply that registry studies are futile, however. For example, a Nordic registry linkage study has contributed essential information regarding the risk of lung cancer in connection with silica exposure [103]. A **proportional mortality study** linking causes of death to job titles on the death certificates also suggested an occupational risk for leukemia from exposure to electric and magnetic fields [113]. Similarly, record linkage studies gave an early indication that multiple sclerosis was associated with solvent exposure [114] – a connection that now seems rather likely in the light of a recent meta-analysis [98].

Concerns of Workers and Others

Sometimes workers perceive adverse health effects and attract the interest of epidemiologists. For example, a group of men exposed to bromochloropropane, a pesticide for nematodes, noted that none of them had fathered any children. This risk was later confirmed in epidemiologic studies [167, 168]. In contrast, suspicions that work with video display units could cause spontaneous abortions have created considerable concern and many studies, but no consistent effect has been demonstrated [105]. There are probably many small-size negative or nonpositive studies relating to workers' anxiety about a health hazard that are unpublished and unknown but that nevertheless reassure the workers involved.

Sometimes media reports have initiated a study, as for example reports of a cluster of childhood leukemia and non-Hodgkin's lymphoma in the vicinity of the Sellafield nuclear plant in England (*see* **Leukemia Clusters**). A subsequent case–control study suggested that paternal exposure could have been the cause [59]; much controversy and other studies have followed, and the risks remain unclear. In general, however, there are surprisingly many observations that paternal exposures may play an important role for hazards affecting the next generation, especially perhaps for birth defects [45].

Options in Study Design

Cohort Studies

Cohort studies are often regarded as the most valid and informative type of epidemiologic study. Cohorts are defined by a common event for its members. This event is usually of a somewhat complex nature, involving employment during a defined period at a particular industry; exposure to a specific agent may preferably also be required. Employment records or trade union registers are almost always the starting point for defining an occupational cohort. **Cross-sectional studies** of specific exposures in the past or data gathered as a consequence of biological monitoring programs may also define suitable cohorts for follow-up. For example, cohorts can be defined based on surveillance programs for lead in blood or some solvent metabolite, such as trichloroacetic acid or mandelic acid in urine (reflecting exposure to trichloroethylene and styrene, respectively (*see* **Surveillance of Diseases**)).

The analysis of occupational cohorts may be based on either **cumulative incidence** or **incidence density**, and these rates can be compared between the exposed and unexposed in terms of a rate ratio (**relative risk**) or, more rarely, a rate difference. In countries with sound mortality statistics and cancer registries, the observed numbers of specific causes of death or cancer types in a cohort are usually compared to expected numbers as based on the general population rates. These expected numbers are calculated by the "**person-years** method" from the national (or regional) rates, and the relative risk in the exposed cohort, compared to the general (or regional) population, is expressed as the standardized mortality ratio, SMR [33, 58] (*see* **Standardization Methods**). In cancer incidence studies the corresponding measure of effect is usually referred to as SIR, i.e. the standardized incidence ratio.

Occupational cohorts are usually historical or retrospective in character (*see* **Cohort Study, Historical**) but may also include some prospective follow-up. Still, the accuracy of the exposure assessment is usually limited by that in the retrospective phase of the study. A purely prospective cohort study would permit more accurate exposure assessment in principle, but this design is rarely used because it may take decades to complete. Many cohort studies fail to address adequately the changes in the pattern of exposure over time. Inaccuracies in exposure assessment can therefore be severe for those individuals who change jobs and who acquire new exposures, which in combination with the earlier exposures may enhance multistage development of diseases such as cancer.

It may be difficult to trace individuals of an occupational cohort in countries without registries of the living population and of deaths, or because of restrictions in the use of identifying information. In many countries tracing may therefore rely on driving license registries, telephone directories, and writing and calling people with similar family names living in the vicinity of a factory at issue.

A successful follow-up includes 95% or more of the cohort, as is possible in countries with good registries. Emigrants are difficult but not impossible to trace in contrast to "guest workers", who often come from less developed countries without population statistics. If the follow-up requires health

examinations for assessing the health outcome, then a reference cohort usually needs to be established for sound comparisons; the participation rate may drop to 80% or less.

To account for a **latent period** between exposure and disease, especially in cancer studies, new cases and cumulative person-years may be ignored in the analysis for a certain period of time after the start of exposure. Alternatively, the cases and the person-years, along with the observed and expected number of cases, might be analyzed separately according to the time period since first exposure. Further aspects of the analysis of occupational cohort data are discussed below in connection with the healthy worker effect.

Cross-Sectional Studies

A traditional approach in occupational epidemiology has been the cross-sectional study, i.e. to examine an exposed and a nonexposed group at a particular point in time and to compare the **prevalence** of some disease or symptoms in the two groups according to degree of exposure. Cohort or case–control studies of incident disease are preferable, however, because they are not distorted by factors that influence survival or persistence of disease following disease onset. Nevertheless, many medically less serious health problems may be studied by a cross-sectional approach, especially as there is no other realistic possibility regarding, for example, lung or renal dysfunctions, neurobehavioral or neurophysiologic disturbances, or musculoskeletal and other nonlethal disorders. A problem with the cross-sectional design is, however, that the more severely affected workers might have left their jobs, resulting in an underestimate of the true health effects of a particular exposure.

Studies of pregnancy outcome, such as the occurrence of malformations or low **birthweight** may be regarded as cross-sectional. Also, the prevalence of pregnancies that terminate in spontaneous abortions may be compared between women with or without an exposure of interest. Similar to other cross-sectional studies in occupational epidemiology, the exposure information gathered in studies on reproduction may pertain to an entire period, e.g. pregnancy, or even before.

The prevalence **odds ratio** is sometimes used to measure risk in cross-sectional studies, but when the prevalence rate is large, as for abortions or musculoskeletal and other common disorders, the prevalence odds ratio poorly approximates the more intelligible **prevalence ratio**. Hence, when the prevalence rate is 10% in the unexposed and 40% in the exposed, the odds ratio is 6.0, whereas the prevalence ratio is only 4.0. Furthermore, a potentially confounding factor has different effects on the prevalence ratio than on the odds ratio. Thus, the use of **logistic regression** to adjust the odds ratio for confounding is of little utility in cross-sectional studies of common symptoms or disorders. Further details in this regard may be found elsewhere [16, 116, 170].

Cross-sectional studies in occupational health are usually applied also to data involving molecular markers such as DNA or protein adducts to indicate an early effect of an exposure or a sort of subclinical disorder. There are both shorter overviews and extensive conference proceedings on adduct studies with a variety of examples in occupational and environmental health [22, 73, 161]. Some further aspects of the use of molecular biological data are raised in the section "Use of Molecular Epidemiology in Occupational Health" below.

Case–Control (Case–Referent) Studies

Etiologic factors for rare diseases are usually best studied by case–control designs, unless exposures are very unusual (or extremely common). Except when the case–control study is nested in a cohort, the study population is open or dynamic in occupational case–control studies. Together with the time period involved, the **study population** forms the base for a study. An open base can be predetermined by defining the study population in geographic or administrative terms, but, alternatively, the boundaries may be secondarily laid down by the way the cases are recruited. That is, the study base can be either primary or secondary [110].

In a study with a primary base, all cases of the disease (or a representative sample of these cases) in an area are ascertained from cancer registries (or other disease registries when existent) or hospital files. The cases are compared in terms of various exposures with a sample of subjects from the study base, i.e. the **controls**. This approach implies that the general population is the reference for estimating the odds ratio. If the study base is secondary, then one would have to recruit the controls similarly to

the cases, such as by taking patients with other diseases in a hospital to serve as controls for the cases with the disease of interest from that hospital [109] (*see* **Case–Control Study, Hospital-based**). Results obtained from a secondary base tend to be less reliable than those derived from a primary base.

Especially since the 1980s, the case–control study has become widely used in occupational health for studying the effects of exposures that are not confined to any particular industry, as, for example, in studies of cancer risks from pesticide use in farming and forestry. The risk of exposure to a particular industrial process or agent can also be studied by locating the case–control study to a restricted population living in the area where a particular factory is located. Examples include studies of lung cancer risk from exposure to arsenic in copper smelter workers as well as in the general population [18, 127]. As an alternative to a cohort design, a **case–cohort study** may be useful by allowing multiple case–control comparisons against a common control group.

When other disease entities are used as controls, there is the possibility that these may be associated with exposure. In this case, the exposure frequency of the diseased controls does not reflect the exposure frequency in the base population and the risk ratio is **biased** (*see* **Bias in Case–Control Studies**). If a mix of other disorders are intended to be used as the controls, then some disease entities may be associated with the exposure and should therefore be excluded. Should unrelated disorders be misjudged and also excluded, no bias in the estimated rate ratio (odds ratio) would result, as the relation of exposed to nonexposed among the remaining, properly selected, controls is not affected. Appropriate exclusions may easily be misunderstood and lead to skeptical comments, however, unless clear arguments are given for leaving out some disorders from the control series. Since more than one occupational exposure might be of interest as influencing the occurrence of a disease, a refinement might be necessary in the selection of control disorders because some conditions might be related to some but not all exposures under consideration.

Nested Case–Control (Case–Referent) Studies

A nested case–control study is obtained if the cases as well as the sample of controls are drawn from a closed population, that is, within a cohort. The nested case–control study is usually applied to gather information on exposures and confounders not assessable for all cohort members in the main study. For example, the combined effect of an industrial exposure and smoking (or other exposure) might be of interest. Then, if the distribution of smoking is not known for the cohort members, smoking status need be determined only for the cases and for a sample of the base population, that is, a sample of the cohort members; see, for example, the nested case–control study of lymphohematopoietic cancer in a cohort of workers manufacturing styrene-butadiene rubber [140].

Proportional Mortality Studies and Mortality Odds Ratio Studies

As already mentioned, the proportional mortality study has been applied in occupational epidemiology for many years [78] and may be seen as a kind of cross-sectional study at the time of death, even though the deaths considered are not simultaneous. The principle is to calculate the proportion of deaths from a particular disease out of all deaths and calculate the ratio of the proportions of cause-specific deaths for exposed and nonexposed individuals, the proportional mortality ratio (PMR). **Stratifications** and standardizations for age and other factors may be applied. Another possibility is to use national or regional proportions of specific causes of death for comparisons. The proportional mortality study tends to be somewhat insensitive because any excess mortality would not only affect the numerator but also increase the denominator.

Proportional mortality data may also be analyzed by a case–control approach – sometimes more specifically referred to as a mortality odds ratio study. Analogously to a hospital-based case–control study, other deaths than those from the disease of interest are used as controls [8, 111]. Thus, the ratio of odds of the cause of death of interest to the other deaths for the exposed and nonexposed, respectively, namely the mortality odds ratio, can be estimated as the exposure odds ratio for the cases and for the other deaths. Control diseases should be excluded if they are suspected to be related to the exposure as in case–control studies with hospital controls. The aforementioned copper smelter study may illustrate this approach as comparing various types of cancer and cardiovascular deaths against a common control group of deaths unlikely to be related to the exposure [18].

Correlational Studies

With a continuous census over time in an open study base, a comparison could even be made with regard to incidence rates in regions with a more or less concentrated representation of the type of industry and exposure under consideration. Although studies of this type have been presented in the field of occupational epidemiology, this design cannot be recommended because of the lack of information on exposures and confounders at the individual level and because of the dilution with nonexposed individuals. The design, also called an **ecologic study**, is perhaps more useful in environmental epidemiology, for example in studying health effects of air or water pollution.

Character of Exposed Populations and the Healthy Worker Effect

Being able to work usually requires good health, which means that there is some selection regarding who will enter a particular job as well as who is expelled from it. More skilled jobs tend to recruit workers with different lifestyles from workers in less skilled jobs, and health-related departures from the labor force may be concentrated among low socioeconomic groups [47]. A particular group of workers is therefore likely to be healthier than the general population and also tends to differ from other workers. This health-related selection process, called the "healthy worker effect" [107], makes it difficult to find proper comparison groups and explains why various worker groups often enjoy better health outcomes and have smaller risks than expected [6, 44].

One can distinguish between a healthy worker effect in the period shortly after hire and a healthy worker survivor effect operating on a long-term basis. The latter may cause cumulative exposure to become associated with good health among the long-term employees and have a tendency to depress the upper end of an exposure–response curve.

Cohort Studies

In cohort studies, the healthy worker effect is usually evidenced by a total mortality of about 90% or less than expected. A decrease in cardiovascular deaths tends to contribute most to the healthy worker effect, but other causes of death may also be below expected levels. Sometimes the observed number of deaths is as low as only about 50%–60% of the expected, as, for example, in some studies for cardiovascular disease [121], other noncancer deaths [24], as well as cancer [157].

When the healthy worker effect is strong, the comparison with expected numbers based on national or regional rates is questionable, but often there is no alternative reference population. One should be cautious, however, in concluding that there is no risk when national or regional rates are taken as the reference. Even with an appropriate reference, studies showing no effect should be looked upon as essentially uninformative or "nonpositive" rather than "negative" unless there is a large number of cases [4, 74]. If a cohort is large enough, then internal comparisons regarding exposure–response relationships might offer the better comparability, but often there is no unexposed reference group in such studies. Regarding the early period of follow-up, preemployment measures such as health exams create strong selection for a healthy worker effect; a further concern is that cases might have been selectively lost to follow-up – for example, due to sorting out of deceased individuals from company registries.

The healthy worker effect has been relatively weak in many cohort studies from the Nordic countries. Possibly the low unemployment rate that prevailed for a long period of time made it necessary for employers to recruit even people with a marginal health prognosis. In contrast, a more pronounced healthy worker effect may occur in countries and time periods characterized by a high unemployment rate. Usually the healthy worker effect is greater in the younger age groups in a cohort and in the early phase of follow-up [125].

In many studies, the higher risk ratios have appeared among workers with short-time employment rather than among those who have been employed for a long time, and risk may decrease with increasing duration of employment and exposure. The reason for the poor health outcome in short-time employees is usually sought in certain lifestyle characteristics. Part of the explanation may also be that only those workers remaining healthy stay on the job long enough to achieve a higher degree of exposure measured as years of employment or as a product of exposure concentration and time. Allowing for a time

lag following initial employment tends to reduce this healthy worker survivor effect.

Adjustment for length of follow-up and employment status (if associated with the disease, independently of the exposure) may also reduce bias from the healthy survivor effect [55, 123, 151]. Computer programs are available that can provide appropriate person-time data for such adjustments [124]. Arrighi & Hertz-Picciotto [6] compared methods to deal with the healthy worker survivor effect in a study of exposure to arsenic on lung cancer risk. The so-called G method of Robins et al. [136] was thought to be most appropriate, but a lagged analysis worked relatively well except for diseases with a short induction-latency time.

Cross-Sectional Studies

A recent study of symptoms of the respiratory tract, lung function and airway responsiveness in relation to occupational and smoking histories in underground bituminous coal miners and nonmining controls illustrates selection problems in cross-sectional studies [131]. Miners with the longest duration of work at the coal face responded less often to methacholine than miners who had never worked at the coal face, and miners who responded to methacholine were less likely to have worked in dusty jobs than miners not responding. It was concluded that these findings probably resulted from health-related job selection. Similarly, a cross-sectional study of animal feed workers revealed a decreasing prevalence of most chronic respiratory symptoms with increasing years of exposure to dust and endotoxin [144]. Thus, the healthy worker effect may lead to underestimation of risk in cross-sectional studies and even obscure a risk altogether.

Case–Control Studies

The healthy worker effect can also influence the results of case–control studies if exposed individuals tend to be healthier than other members of the population constituting the study base. A more subtle, reversed, and less obvious healthy worker effect can occur in hospital-based case–control studies. If the working population with the exposure of interest is healthier than others in the study base, then the controls would less often be exposed, as many of them come from the unexposed part of the study population with less good health. The result of the healthy worker effect in such case–control studies using hospital (or deceased) controls would therefore be an exaggerated rate ratio (odds ratio). The same reasoning applies to proportional mortality studies. Park et al. [122] have presented parallel analyses showing that mortality odds ratios (MORs) and proportional mortality ratios (PMRs) were higher than standardized mortality ratios (SMRs) for some causes of death; it seems likely that "the truth" might be somewhere between the different estimates obtained. In case–control studies this reverse healthy worker effect is avoided when population controls are enrolled.

A related phenomenon in case–control studies may arise when controls are recruited by **random digit dialing**. Subjects answering the telephone are less likely to be working or to have an exposed job, especially if exposure is associated with a job that demands long working hours. Thus, the exposure frequency in the study base might be underestimated, resulting in an exaggerated estimate of the effect of the exposure.

Assessment of Exposure

Conferences held in the early 1990s reflect the efforts made to improve exposure assessment in occupational epidemiology [15, 72, 77]. Specific knowledge is required for preventive measures to reduce or eliminate hazardous agents or processes from the work environment. The proper assessment of exposure is therefore a key issue in any study of work-related adverse health effects. There are conceptual difficulties in defining exposure and dose, and further problems in accurately measuring or classifying the exposure. Errors in this regard can also affect adjustments for confounding.

Records showing the specific job tasks of the workers are available in many companies and usually form the basis for cohort studies, but can also be used for exposure assessment in case–control and proportional mortality studies. Case–control studies often rely on questionnaire information or interviews, however, and may therefore be subject to **recall bias** or **interviewer bias** (observer bias).

Measures of Exposure

Measures of exposure are usually either exposure intensity, exposure duration, or cumulative exposure. For acute diseases, peak exposure intensity is often

particularly relevant. Cumulative exposure measured as duration or as time-integrated intensity are often used in studies of chronic disease. With ionizing **radiation** as the paradigm, cumulative exposure is commonly taken as a proper determinant of risk for genotoxic and carcinogenic agents, and there are specific arguments in support of such a measure [134]. These arguments are based on an assumption of linear kinetics in the metabolism. However, a literature survey on cancer studies has shown that intensity measures of exposure often yielded larger relative risks than duration of exposure, and intensity measures also often yield monotonically increasing exposure–response curves [26].

Furthermore, in a **pharmacokinetic** study relating cumulative exposure to tissue dose for insoluble, respirable dust particles and toxic metabolites of a nonpolar organic solvent, Smith [146] found no linear relationship between cumulative exposure and tissue dose. It was suggested that this observation could explain why a disproportionally high risk of pulmonary effects is commonly seen for workers with relatively short but intense dust exposures. Specific measures of exposure that result in large apparent risks and clear **dose–response** relationships have been suggested for particular diseases, such as silicosis [40].

Job–Exposure Matrices

Occupations or job tasks are easier to recall and report correctly than exposures to specific agents like metals, solvents, or pesticides. Hoar [79] proposed a **job–exposure matrix** to translate job task histories into estimates of exposure to specific agents. A job–exposure matrix consists of jobs on one axis and specific exposures to substances or other agents on the other, with the matrix elements describing the likelihood of an individual's exposure to a specific substance in a given job, either in **binary** or **polytomous** categories. A matrix may also dichotomize exposure on a probability basis [29].

However, it is necessary to adapt the job–exposure matrix to the country or region and the type of industry where it is to be used. A population-specific job–exposure matrix may therefore be preferable to general job–exposure matrices developed elsewhere. Such a matrix can be constructed from the results of in-depth interviews of a job-stratified sample of cohort members [97].

Ronneberg [138] used a job–exposure matrix in a study of Norwegian aluminum smelter workers. Jobs held by cohort members were identified from personnel records; work tasks and their locations were determined for all jobs, and information was gathered about changes in exposure conditions over time. Then the jobs were combined into categories thought to represent similar exposure conditions, and time-weighted average exposures were estimated on a relative scale.

A specific job–exposure matrix for chlorinated solvents assigned semiquantified estimates of the probability and intensity of exposure to each four-digit job category of the Standard Industrial Classification and Standard Occupational Classification codes in the US [61]. The matrix was also designed to account for the changing patterns of use of these solvents by decade from the 1920s to the 1980s. An algorithm was applied to assign each study subject a unique lifetime probability of exposure and an estimated score of cumulative exposure for each of the solvents. An important goal of the matrix was to reduce the number of **false positive** exposure assessments.

The latter principle is corroborated by a study of astrocytomas and exposure to methylene chloride showing that the odds ratios increased with increasing **specificity** of the exposure assessment [53]. The risk estimate more than tripled compared with the risk estimate obtained without taking probability of exposure and exposure by decades into account and coding for industries and occupations.

There have been many comparisons and evaluations of the validity of the various approaches to assess exposure. Structured questionnaire information is commonly used, but underreporting of exposure remains a problem [90, 128]. On the basis of a large-scale study from Canada [143], Dewar et al. [48] found that the assessment of exposure by an expert team was more efficient than the use of a job–exposure matrix. This may explain why interviews resulted in several increased odds ratios in a study of mental retardation and parental occupation, whereas the use of a job–exposure matrix did not [137].

Men and women with the same job title may have different exposure patterns, indicating a need for gender-specific job–exposure matrices [108]. A comparison of information on exposure to dusts, gases,

and fumes from a job–exposure matrix with questionnaire data indicated a better agreement in men than in women and suggested that men had a more accurate recollection of exposure – especially well-educated men [80]. Smoking habits had no effect on the perception of exposure. For women, the perception of exposure did not vary significantly according to respiratory symptoms. In men, however, subjects without chronic cough or chronic bronchitis even had a significantly higher perception of exposure than the others, but no difference was shown for wheezing, dyspnoea, or asthma.

Stengel et al. [152] compared the performance of experts vs. job–exposure matrices in studies of glomerulonephritis and bladder cancer. Categories of exposure as obtained from both experts and job–exposure matrices were dichotomized, using different cutoff points for exposure and nonexposure. **Sensitivity** of the job–exposure matrices vis-à-vis the experts was low (23%–63%), whereas **specificity** was rather high (87%–98%). Assuming an odds ratio of 3 and an exposure prevalence of 10%, and taking the experts' classification of exposure to be completely correct, the use of a job–exposure matrix led to attenuation of the odds ratio by a factor of 1.5–2.1, and to a loss of power equivalent to a reduction in the number of subjects by a factor of 5–10. On the other hand, the job–exposure matrix performed better than self-reported exposure in discriminating high-risk subgroups in a study of lung cancer and asbestos exposure among construction workers [56].

Job–exposure matrices have also been applied to assess physical exposures such as electric and magnetic fields [21, 91] as well as to study aspects of work organization such as work control, social support, and psychological and physical job demands [92, 65]. Also, a kind of job-exposure matrices have recently been elaborated for assessing exposure to carcinogens in some European countries [93, 94].

Some Other Aspects on Exposure Assessment

Data from biological monitoring programs may be helpful for exposure assessment in cohort studies. For example, when animal studies indicated a cancer risk from trichloroethylene in the late 1970s, existing data from routine monitoring of the metabolite trichloroacetic acid in urine could be used for defining cohorts for follow-up with regard to cancer [20, 156]. Although trichloroacetic acid in urine clearly indicated exposure, the proper measure of exposure (e.g. peak values or simple averages) was not evident.

Hygienists are needed not only for judgments about whether a particular exposure is likely to have occurred, but also to evaluate documents on previously measured exposures. Measurement strategies and methods of sampling and analysis have varied over the years. It is especially important to consider the sampling strategies when hygienists' measurements are used for epidemiologic purposes [158]. The reason is that such measurements usually have been made for control of the work environment after changes in an industrial process for hygienic or technical reasons and therefore tend to underestimate the average daily exposures.

Considerable differences in exposure may occur between workers from the same factory and with the same job titles [96]. Only one-quarter of some worker groups had individual **mean** exposures within a two-fold range for 95% of the individuals. Furthermore, about one-third of the worker groups had a greater than 10-fold range for 95% of the individuals. There were also large day-to-day variations, especially for outdoor workers and when the process was intermittent. Indoor work in a continuous process led to more homogenous exposures. Others have reported similar observations regarding exposure variation [36, 126] and a suggested approach to deal with the problem of retrospective exposure assessment by Bayesian methods has lead to some discussion [37, 133].

Uncertainties are likely to affect any exposure assessment, causing some individuals to be taken as more exposed and others as less exposed than they really are. In principle, one should emphasize the need for a positive **predictive value** rather than sensitivity of a job-exposure matrix or a questionnaire for assessing exposure to agents of interest [132]; the reverse is true for confounding factors, however.

Sometimes the presence of recall bias or observer bias in case–control data can be revealed by comparing the odds ratio for those with and without reported exposure but within job categories with potential exposure. If the latter, who report no exposure, show a decreased risk in comparison to those in clearly unexposed jobs, it is likely that an increased odds ratio for those reported exposed reflects some bias in the assessment of exposure [9].

If there are no systematic influences on the exposure assessment, then the result is **nondifferential error**, which usually leads to risk estimates that are

biased towards the null value (*see* **Misclassification Error**). Nondifferential misclassification makes it difficult to discover adverse health effects by attenuating the risk estimates. However, even in the presence of nondifferential error, chance sometimes may lead to exaggerated risk estimates. Little attention has been paid to this possibility in reporting of study results, but it has been well illustrated by computer **simulations** [148]. Dosemeci et al. [52] showed that discretizing continuous exposure data can lead to biases away from the null if nondifferential error acts on the continuous exposure measurement.

Assessment of exposure in limited time windows may yield particular insights. A time-window approach that is sensitive to recent exposures may enable one to detect a late stage effect for cancer or other diseases. For example, exposure to radon and radon progeny in mines in the 5–15 years before lung cancer seems to have had an important effect on risk [25].

Confounding in Occupational Epidemiology

Determinants of risk that are associated with the exposure under consideration can spuriously increase the apparent risk from this exposure. Such determinants are called "**confounders**". Confounders can also obscure an effect, either when the confounding risk factor tends to be more common in absence of the exposure or when it is protective. In principle, confounding may explain all or part of an association of a disease with an exposure, either because the control of a known confounding factor is incomplete, or because the confounder has not been identified. Mismeasurement or nondifferential misclassification of a confounder can lead to poor control for confounding [3, 132]. However, as long as the exposure under study has a quite strong effect, incomplete control of confounding is not too deleterious for risk estimation [14, 62].

Often the concern about confounding in occupational epidemiology has been focused on lifestyle factors such as smoking and alcohol use or socioeconomic class. Even for a strong risk factor like smoking for lung cancer, the confounding influence is quite modest because smoking tends to be nearly equally prevalent among the occupationally exposed and the unexposed [7, 14].

The most important confounders to consider in occupational epidemiology are other work-related exposures and factors [42]. For example, it is difficult to investigate the role of welding fumes on lung cancer risk because asbestos has often been used in protective equipment in the welding process, and there is also considerable exposure to magnetic fields from electric arc welding, which may or may not be a risk factor. Likewise, in the artistic glass industry, there has been exposure to many different and potentially carcinogenic metals or metallic compounds, but again, asbestos has also been present to protect from the warm glass [86].

Sometimes various exposures are inextricably linked. For example, some phenoxy herbicides have contained impurities of chlorinated dibenzodioxins as a result of the manufacturing process. The association between exposures of this kind is so tight that there is no way to control properly for confounding of one compound to find out the effect of another. Instead, one has to consider the effect of these exposures en bloc [7]. Similarly, occupational job titles might sometimes have to be viewed as blocs of exposures. The best possibilities for prevention occur, however, when specific exposures or processes can be identified as hazardous.

Since a worker may be exposed to a complex array of occupational and other agents of physical or psychosocial character, there is considerable potential for some mutually confounding effects in occupational studies. For this and other reasons, it has become increasingly common to consider many exposures, especially in case–control studies. For example, Blair et al. [27] considered some 150 occupations and about as many industrial categories in a study of lymphoma. When a great number of exposures are analyzed, **false positive** findings may result from the play of chance in the many comparisons. There is also the possibility that confounding from one or more of the exposures associated with increased risk may explain some other positive associations as well. More interest should probably be devoted to this possibility than to the consequences of **multiple comparisons** because exposures for consideration in a study are not randomly selected but are usually included on the basis of some evidence or suspicion of an adverse effect.

Interaction of Exposure Effects

When multiple exposures occur in occupational settings it would be useful to know whether synergistic

or antagonistic **interactions** are present (*see* **Synergy of Exposure Effects**). Not many examples in this respect were found in a literature survey [10], but, for example, combined exposure to vinyl chloride and arsenic increased the risk of respiratory cancer, and the combined exposure to phenoxy herbicides and solvents seemed to increase the risk of lymphoma. This latter interaction has also been recently confirmed by other data in which the combination of phenoxy herbicides and solvent exposure gave an odds ratio of 8.6 vs. 2.6 and 1.4, respectively, for the two exposures alone [130]. Exposure to plastic and rubber chemicals resulted in an odds ratio of 2.2, which increased to 4.8 in the presence of solvents.

As in these examples, the sample sizes available for assessing such occupational interactions are usually small, resulting in considerable uncertainty in the estimates. A background of differently combined exposures may explain inconsistent findings obtained in different studies on the same agent, as can interactions with factors outside the work environment. In the latter respect, the strong synergistic effect of smoking and asbestos exposure on the risk of lung cancer is a classical example [66]. Arsenic and smoking also act synergistically to increase the risk of lung cancer [129]. A synergistic effect of smoking and exposure to radon progeny seems likely as well, although the results differ to some extent between studies [25].

Use of Molecular Epidemiology in Occupational Health

The great achievements in molecular biology over the past decade have also influenced occupational epidemiology [71, 73, 147, 161]. Chemical adducts to deoxyribonucleic acid (DNA) or various proteins like hemoglobin and albumin have been used as either markers of exposure or taken as early adverse health effects. A somewhat later development has involved attempts to evaluate exposure effects in relation to metabolic **polymorphism** and to detect mutations, for example in the p53 **gene**. Specific mutations in the p53 gene in squamous skin cancers have been associated with UV-light exposure [31] and in liver tumors with widespread exposure to aflatoxin B_1 and hepatitis B virus [34, 81], and, by analogy, it is likely that characteristic mutations may result also from occupational exposures to carcinogens.

Studies involving adducts are usually of a cross-sectional design and tend to reflect rather recent exposures due to the turnover of cells and proteins in blood. There is a similarity in this respect to investigations based on chromosomal aberrations, sister chromatid exchanges or micronuclei. These latter type of studies became common in the late 1970s and early 1980s [149]. It has been unclear to what extent chromosomal damage implies any serious effect, but a cohort follow-up indicates that chromosomal aberrations might be predictive of cancer development [64]. The relation to known exposures to carcinogens remains uncertain, however [28] In an evaluation of the cancer risk to humans from styrene exposure, an IARC Working Group took into special account the many studies indicating chromosomal damage [87]. Even so, there now seems to be a decreasing enthusiasm to use chromosomal damage as an outcome measure.

The case–control design is well suited to detecting exposures that can lead to mutations in oncogenes or tumor suppressor genes [147]. The cases are divided into subentities defined by some mutational characteristic, and each such subentity of cases is compared with controls regarding exposure. For example, Taylor et al. [153] compared 62 cases of acute myeloid leukemia with 630 controls. The 10 leukemia patients who were positive for *ras*-mutation were found to have worked more often in high risk occupations. Odds ratios between 1.9 and 7.2 were obtained for the various exposure categorizations made. In contrast, the odds ratios for the *ras*-negative cases ranged from 0.6 to 0.9.

The case–control design is also useful for studying the impact of the genetically determined polymorphism of enzymatic activity and metabolic capacity that determines the susceptibility to risk from an occupational exposure. For example, individuals with one form of the polymorphic CYP1A1 gene appeared to be more susceptible to risks from smoking and occupational exposures such as asbestos than those with other alleles [38, 100]. Although these results have not been confirmed, the applied epidemiologic design used in these studies defines a valid approach for studying metabolic activity and occupational exposures as well as smoking. Efforts to identify individuals at increased occupational risk for bladder cancer because of a glutathione-S-transferase M1 deficiency can serve as another example of this type of study [35].

Glutathione-S-transferase polymorphism may also influence the susceptibility to nonmalignant asbestos-related disease [145].

Occupational exposures may even increase the risk for a clearly inherited disorder. Few individuals with the genetic trait for familial amyloid polyneuropathy develop the disease, suggesting that some other factors might have been involved in the clinically overt cases. In a case–control study of this disorder, solvent exposure appeared as a fairly strong risk factor, with an 11-fold risk for the more heavily exposed [69].

More time is needed to evaluate the role of **molecular epidemiology** for identifying health risks in the workplace. The complexity and the costs involved in these studies will remain a major hindrance for future development, even though some interesting and important results are likely to appear. Identification of genetically determined susceptibility to occupational exposures raises ethical concerns because persons without elevated susceptibility may be selected for employment. Instead, the proper goal should be to create a safe work environment even for those individuals who are more susceptible.

The Etiologic Contribution of Occupational Exposures

The proportion of disease burden attributable to specific exposures or jobs is rather substantial. In Germany, for example, about 250 asbestos-associated lung cancers and 400 mesotheliomas have been recognized and compensated for each year [23]. Lung cancer claims among the underground uranium mine workers in Thuringia and Saxony ranked second to asbestos. Lung cancers related to silicotic scar tissue and to chromium (VI) and arsenic compounds and other chemicals were also subject to compensation.

Estimates of the etiologic contribution of occupational exposures to morbidity or mortality may be obtained by calculating the so-called population **attributable risk** or etiologic fraction. Any particular occupational exposure is quite rare in the general population, however, and can therefore cause only a limited proportion of disease. The overall burden of diseases related to various occupational exposures may nevertheless be considerable. A study of lung cancer in Norway indicated a population attributable risk of 22%–35% for occupations with definitely hazardous exposures [95]. The estimate rose to 37%–47% when jobs with "possibly exposed" categories were also included. Asbestos exposure was the main single risk factor. Attributable risks may add up to more than 100% due to interaction between risk factors. Not surprisingly, therefore, the contribution from smoking could still be estimated to be 82%. Quite similar estimates have more recently been reported also from Sweden and Finland [12, 117].

The quantitative impact of working conditions on cardiovascular diseases in Denmark has been suggested to account for 16% of the premature cardiovascular mortality in men and 22% in women [118]. Including sedentary work as an occupational risk factor, the etiologic fractions rose to 51% and 55% for men and women, respectively. Monotonous high-paced work and shift work were considered the most important single factors, whereas the impact of rather rare chemical exposures to carbon disulfide, nitroglycol, lead, arsenic, carbon monoxide, and other agents was marginal.

Estimates of attributable risk for musculoskeletal and neurologic disorders can be calculated as well. Olsen et al. [120] estimated the population attributable risk for coxarthrosis, a degenerative condition of the hip joint, as 40% for physical workload on the job, 55% for sports, and 15% for excess weight. Overall these three risk factors could account for about 80% of the "idiopathic" coxarthrosis. Landtblom et al. [98] reviewed 10 studies of multiple sclerosis and found relative risks near two for exposure to solvents. Assuming the frequency of relevant solvent exposure to be in the range of 10%–20% in an industrialized country, one would estimate a population attributable risk of about 10% or more. These few examples indicate that the contribution of occupational exposures to cancer as well as other disorders is not negligible.

Concluding Remarks

Identification of risks from occupational exposures and quantification of the associated burden of diseases should lead to prevention efforts. Mandated and voluntary changes in the work environment and proper supervision to ensure compliance with regulations may be as beneficial to health as attempts to change personal habits and lifestyle. Continuous

epidemiologic surveillance is important to obtain information about the long-term impact of preventive measures.

When an epidemiologic study indicates a health risk associated with an industrial process, required changes in the production process may be costly. Workers and the management often hold different views of the balance between the costs and health benefits of preventive measures. It is not unusual, however, that an improvement in the work environment also improves productivity; even so there is usually considerable resistance from an industry to accept epidemiologic evidence of a risk and to improve the work environment.

The method of presenting epidemiologic results is critical to a successful prevention strategy when serious health effects are indicated, such as excess cancer deaths or malformations. When the study pertains to a particular plant or company, it is advisable first to inform the management as well as the employees or their representatives. Mass media may be interested as well, but untimely information through the media can create controversy and hostility towards occupational health research. Press conferences in the presence of management and worker representatives can be useful for limiting negative publicity for a company, because, eventually, the mass media will get access to the information when a scientific report is published. It is therefore advisable to provide information in a more controlled manner [11].

In view of the technical difficulties of conducting epidemiologic studies and a natural reluctance to accept that an industrial process may be harmful, it is not surprising that interpretations of data may differ and serious controversies arise. For example, in 1966 Hueper [82] reconsidered his early warnings, in view of the European experiences, of lung cancer risk from exposure to radon progeny, and accused government officials of having impeded studies of this health hazard among uranium miners in the US. By 1966, Hueper's suspicions had been confirmed by the first report on an excess of lung cancer among these miners [164]. As late as 1971, B. MacMahon wrote in the preface to a comprehensive report on lung cancer in uranium miners [101]:

> The epidemic now in progress among American uranium miners could readily have been – and indeed was – predicted on the basis of past experience in other parts of the world. Less predictable was the extent of the scientific, legal and political controversy that the American experience would engender. Although ... few medical experiences have been so carefully documented, diametrically opposite opinions are still held and expressed not only regarding the interpretation of the facts that have emerged but as to the nature of the facts themselves.

When epidemiologic study results are weak or inconsistent it is indeed difficult to come up with a tenable judgment on the health risk involved. Some subjectivity is unavoidable in such situations, but decision makers may get some guidance from ethical considerations. Hence, it seems reasonable to give the benefit of the doubt to those suffering the risk [4], and in balancing benefits against risk one has to be clear about who takes the risk and who has the benefit. In occupational health, the situation is more complicated than in medical treatment, where the risk of adverse side-effects might be weighed against benefits for the same individual [162]. A comprehensive discussion of the ethical guidelines in occupational health can be found elsewhere [139].

OLAV AXELSON

Occupational Health and Medicine

Occupational health is an activity organized to protect the health of employees from harmful consequences arising out of their work. It includes industrial medicine and occupational medicine which also provides medical **surveillance** services. The aims are to reduce the frequency and severity of occupational diseases, i.e. diseases caused or exacerbated by the occupational environment, and hence to reduce premature death and disability. The prevention or reduction of occupational disease is emphasized, and this involves changes in the occupational environment that may be achieved by those practicing occupational hygiene. The importance given to occupational health is dependent on the social attitudes of the population in which it is based, and many of the occupational health questions now considered would have seemed of trivial concern a few decades ago. Occupational health includes safety, sometimes emphasized by the use of the term "health and safety", which is concerned with the reduction of accidents in the workplace.

Important elements are first the identification of adverse health effects of occupational exposure to a pollutant (*see* **Occupational Epidemiology**) and, secondly, the implementation of measures to reduce exposure and hence the frequency or severity of adverse health effects. This second step may involve standard setting, i.e. the setting of exposure limits predicted to lead to minimal adverse health effects. The setting of such limits may utilize **dose–response** data but also takes into account practicality and the milieu in which employers and workers interact.

Historical Development

The Italian physician, Bernardino Ramazzini (1633–1714), has been referred to as the "father of occupational medicine" [13]. He was professor of medicine at the Universities of Modena and Padua. He stressed the importance of direct examination of workers and introduced the concept of the taking of an occupational history. He described diseases associated with a wide range of occupations and their causes [24], including diseases caused by the inhalation of dusts and gases and those caused by poor ergonomic practices. Ramazzini's publications were the main source on illnesses caused by work for over a century [18]. Popper [22] drew the distinction between "occupational diseases" and "workers diseases", the former restricted to diseases caused directly by some intrinsic feature of the occupation, such as exposure to a chemical, while the latter also includes diseases occurring for socioeconomic reasons associated with the occupation. Ramazzini had noted that breast cancer was more prevalent in nuns than other women, and attributed this to celibacy.

In the eighteenth century there was a growing concern on the effects of industrialization. **Guy** [10] analyzed the proportion of deaths due to pulmonary consumption in broad occupational groupings and attributed an excess of such deaths to poor conditions, such as inadequate drainage and ventilation, an inadequate water supply, and overcrowding, in both dwellings and workshops. **William Farr** (1807–1883), the first compiler of Abstracts in the General Register Office of England and Wales, introduced a classification of occupations in 1851 that was used for the analysis of **occupational mortality** from official **vital statistics.** Later, **Hill** [12] used national insurance statistics to examine sickness absences of printers, cotton weavers, and spinners. From about this time, and particularly after the end of World War II, there was increasing attention to research into the extent and causes of occupational diseases, and this research necessitated the application of statistical concepts and methods into the design and analysis of studies.

Types of Study

The relationship between the occupational environment and health has been studied in a variety of ways. Insofar as occupational diseases may be caused by industrial pollutants, then basic studies of the interaction between pollutants and biological systems have been carried out in toxicology, by *in vitro* experiments, and by animal experimentation.

Studies of humans have involved experimentation, looking at acute effects, but such studies are infeasible, and unethical, for chronic effects. Such effects have been studied by epidemiologic investigations

(*see* **Observational Study**). The outcome variables include mortality, the occurrence or presence of a disease, and the value of a variable that measures some function of health (*see* **Health Status Instruments, Measurement Properties of**). For example, measures of lung function, such as the forced expiratory volume, are indicators of health but do not indicate disease unless grossly abnormal. Disease outcomes include diseases specific to occupational exposure, e.g. the pneumoconioses are caused by the inhalation of dust or fibers. They also include nonspecific diseases, the incidence of which may be increased by occupational exposure. For example, the frequency of lung cancer is increased by exposure to asbestos and a number of chemicals, but it occurs also in the absence of such exposures.

The main study designs employed have been:

1. **Cross-sectional study** – a study examining the relationship between disease, or a measure of health, and occupational conditions at a given time.
2. **Cohort study** – a study in which subjects are selected and followed-up over time to observe their mortality, morbidity, or changes in some functional measure of health, and to relate these to the exposure within the occupation. Cohort studies have been used particularly in the study of cancer, and frequently are *historical cohort studies* in which the cohort is defined in terms of existing historical data, such as records of employees. Follow-up is then from some time in the past – often many years or decades – to the present (*see* **Cohort Study, Historical**).
3. **Case–control (case-referent) study** – A study in which cases of disease are identified and noncases are chosen as **controls** or referents. The previous occupational exposure history of cases and controls are then ascertained and compared to give estimates of the **association** between the occupational environment and the disease. Case–control studies may be nested within a cohort study so that the cohort study is used to identify cases of disease in an occupational population and the case–control study is used to obtain more detailed information on exposure on a smaller number of cases and controls than would be practical for all members of a large cohort (*see* **Case–Control Study, Nested**) [16, 14].

Landmark Studies

One of the earliest controlled **clinical trials** took place in the area of occupational health. J. Lind, a naval surgeon on the *Salisbury*, divided a group of 12 seamen suffering from scurvy into six groups of 2. One of the treatments was two oranges and a lemon a day, and the "most sudden and visible good effects" were observed in the two seamen receiving this treatment. Regrettably it took another 50 years before lemon juice was supplied as a dietary supplement on British naval vessels [15; 21, pp. 14, 15].

The association between exposure to occupational environments and cancer has been a constant theme. The first malignant disease to be associated with a particular occupation was cancer of the scrotum in chimney sweeps, described by Percivall Pott [23]; see [20] and [27]. Härting & Hesse [11] reported an excess of respiratory cancers in underground metal miners, later shown to be due to radon daughters. This was the first association between an external agent and an internal cancer. The studies of Doll [6] on lung cancer amongst gas-workers, and of Case et al. [2] on bladder cancer and exposure to chemicals, were important studies, not only with respect to the identification of occupational carcinogens, but also in the early use of historical prospective cohort studies and the use of the **person-years at risk** method of mortality analysis. The risk of exposure to asbestos in producing lung cancer has been identified and confirmed using historical prospective studies [7, 25, 19], and the strong link between asbestos exposure and mesothelioma has been evaluated using similar studies following the identification of the link by Wagner et al. [26].

Particular Statistical Concepts, Problems, and Techniques

Most of the statistical methods used in occupational health are not unique to that area. Problems of potential **bias** due to **confounding** are often present in epidemiologic studies since the workers in groups to be compared may differ systematically in other characteristics. The confounding effect of smoking in studies on occupational respiratory diseases is a particular problem because of the large effect on health of the smoking habit (*see* **Smoking and Health**). A particular type of bias, which may be

considered as due to confounding, but is more usefully considered separately, is the "healthy worker effect", which may arise in any epidemiologic study in which a workforce is compared with the general population or different workforces are compared with one another. A second problem is that due to the *latency* of occupational cancers, i.e. an excess of cancer due to occupational exposure does not occur until many years after the exposure (*see* **Latent Period**). Related to this, during a follow-up study of current workers the extent of exposure is constantly changing during the period of follow-up when adverse health effects are being noted. This makes the linking of the extent of exposure to the health effect difficult. A full account of many of the statistical methods used in occupational health is given by Checkoway et al. [3].

Healthy Worker Effect

Studies of occupational health are carried out in groups of workers who select themselves, and are selected by employers, into particular occupations. These selection processes lead to the "healthy worker effect", which occurs because they are likely to eliminate the most unhealthy from entering the workforce and also may mean that those developing ill health are less likely to remain in the job. As noted by McMichael [17], these selection effects lead to lower mortality rates than would be expected. Fox & Collier [9] noted that the healthy worker effect consisted of three components, which they attributed to selection (*see* **Selection Bias**), survival, and length of follow-up. They found that the effect was particularly marked in the first 10 years after the start of employment in which there was exposure to vinyl chloride. The consequence of the healthy worker effect is that comparisons of mortality between employed groups and the general population may be biased unless workers are followed-up after they have left the employed group and unless comparisons take account of time since the start of employment. Methods of analysis using internal comparisons may take account of the initial selection criteria provided that these were applied similarly to the groups under comparison.

The Analysis of Mortality – External Comparisons

One method of analysis of follow-up studies where the outcome is mortality consists of the comparison of the observed number of deaths due to all or specific causes with the number that would be expected taking into account the age distribution of the cohort studied, the period during which follow-up occurred, and the varying lengths of follow-up of the different subjects in the study. The indirect method of standardization is the basis of the method, referred to as the *person-years* method (*see* **Standardization Methods**). This method was first used by Doll [6] and has been commonly applied in occupational mortality studies. The total follow-up period is divided into periods, usually of 5 years, and within each of these periods the ages of those persons followed within that period of time are similarly subdivided, again usually into 5-year groups. The expected number of deaths is calculated by multiplying the person-years at risk in each of the age–period intervals by the age- and period-specific death rates of a standard population. The standard population is a national or regional population for which death rates are available. The usual measure of effect is the ratio of observed to expected deaths which, in analogy with indirect standardization, is often referred to as an SMR.

The method has usually been applied to single groups or descriptively to a few subgroups, but may be extended to take account of other variables recorded for the persons followed-up using **Poisson regression** [1].

The Analysis of Mortality – Internal Comparisons

A disadvantage of the person-years method is the implicit assumption that the death rates in the occupational group would be the same as in the standard population except for factors within the occupational environment. While this assumption is not strictly necessary, the healthy worker effect has to be taken into account in the interpretation of the results. The method does assume that the death rates in the occupational group and the standard population are in a fixed proportion in all the age–period groups, i.e. that the standard death rates apply to the occupational group at least proportionally. The approach may be modified by working internally within the occupational group and avoiding the use of a standard population for comparison. This leads to internally calculated SMRs, and comparison of more than two of these depends on **proportional hazards** of the subgroups across the age-period strata. This problem may be overcome by the use of directly

standardized rates, which leads to the *standardized rate ratio* (SRR).

All these methods involve **stratification** and become imprecise when there are several variables to take into account. Stratification can be avoided by using the most general method, i.e. Poisson modeling (*see* **Poisson Regression**).

As it is often required to assess the mortality of an occupational group in the context of the population of which the workers are a part and also to assess dose–response relationships within the occupational group, or to compare subgroups within the whole occupational group, a combination of external and internal methods is appropriate. For example, Checkoway et al. [4], in a study of workers employed in the mining and processing of diatomaceous earth, compared the mortality due to lung cancer in the whole group. The methods of analysis included comparison with US national death rates using the SMR and internal analyses using Poisson regression to examine the trend with duration of employment. The combination of methods led to the conclusion that there was an excess of deaths due to lung cancer in the workforce, compared with the US population, and that this excess was associated with duration of employment in dust-exposed jobs.

Time-Related Exposure and Covariates

A measure of exposure to an occupational agent that may be used is cumulative exposure, i.e. the intensity of exposure accumulated to give a time-weighted cumulative measure. Clearly this measure will continue to increase as long as exposure is occurring. Methods of analysis relating health outcomes to exposure have to take this into account, not only with respect to the appropriate exposure to link with the outcome event, but also, equally importantly, to allocate the earlier years, when the event did not take place, to the lower cumulative exposure; failure to do this results in biased results [8]. Other variables that may be included in the analysis as **covariates** (confounders) may also be time-dependent (*see* **Time-dependent Covariate**) – for example, smoking and age. One way of dealing with this problem is through a proportional hazards model [5] with time-related variables. Another way when there are no covariates is to use the person-years method, or corresponding internal methods, with each individual transferring from one cumulative exposure category to the next when the cumulative exposure reaches the appropriate values.

Latency

Many diseases do not occur until some time after the exposure that has caused the disease. In particular, occupational cancers usually do not occur, i.e. they cannot be diagnosed, until at least 10 years after exposure. This feature should be incorporated into the analysis since, otherwise, very recent exposure, that cannot be relevant to the disease, is included as if that exposure were relevant. One method of dealing with this problem is to begin the follow-up after an interval, of say 10 years, since the start of exposure, and to ignore deaths and person-years at risk within this interval. This method does not allow regression-type methods including cumulative exposure but may be extended for this situation by defining a lagged cumulative exposure; for example, the lagged cumulative exposure relevant to the disease risk of a 45-year-old worker would be the cumulative exposure at age 35.

Allowing for latency also helps to reduce the influence of the healthy worker effect.

Future Developments

The perceived importance of occupational diseases is dependent on societal attitudes. The major occupational effects of early industrialization have been eliminated, and the large excess death rates due to exposure to asbestos and other occupational pollutants have been identified and preventive measures taken, although the **excess mortality** continues to occur because of the long latency effects. Concern has moved to the possibility or suspicion of smaller effects. Methods will need to be developed to identify small effects of occupational pollutants. As the estimation of small effects may not be achievable by epidemiologic studies, there is likely to be an increasing emphasis on biological methods and on the translation of biological findings into meaningful **risk assessments** for exposed populations.

The concept of individual susceptibility to disease has been a long-standing concept, but there has been insufficient knowledge for most occupational diseases on how to identify those who would be most susceptible to occupational exposure. This means

that it has not been practical to screen out of the exposed workforce those most likely to develop disease due to exposure to a pollutant. Advances in **molecular epidemiology** may contribute to this area by leading to the possible identification of susceptible individuals, who could be advised to avoid employment in particular industries.

Occupational Mortality

The study of occupational mortality involves the systematic tabulation of mortality by occupational groups or by socioeconomic groups (*see* **Social Classifications**) when these are defined by occupation. Three main methods are used to conduct these studies.

The first method, **cross-sectional studies**, utilizes the number of deaths occurring to persons in a given occupation during a given time period divided by the number of persons in that occupation in the middle of the period. The source for the numerator is usually **death certificates**; the denominator is usually based on the **census**. As the age distribution varies considerably between the occupational groups, an age **standardization** is needed in order to compare the mortality of different occupational groups. In the cross-sectional studies, the comparative mortality figure (CMF, direct standardization) or the standardized mortality ratio (SMR, indirect standardization) are used as summary measures of an occupational group's relative mortality.

The second method, death certificate studies, involves the distribution of deaths by cause for a given occupational group compared with the distribution for a total population without regard to occupation. Such studies are often sex-specific or limited to the male population. Here **proportional mortality ratios (PMRs)** are used as summary measures for each occupational group's relative mortality from a given cause of death.

The third method, follow-up studies (*see* **Cohort Study**), is based on individually matched records and typically on census data. A census population is followed up for deaths and emigrations, and maybe also for new census data, which allows separate analyses of persons who stayed in an occupation from one census to the next. In these studies various methods are used for the matching of individual records (*see* **Record Linkage**). In the UK, for example, the study population is flagged in the National Health Service Central Register; whereas in the Nordic countries the matching is based on the personal identification numbers used in both censuses and death and emigration registrations. In the follow-up studies, the CMFs and SMRs are often used as summary measures for an occupational group's mortality. However, each individual in these studies has a record containing the census characteristics, the number of **person-years at risk**, and the eventual **cause of death**. It is therefore possible to use these data sets also for internal comparisons of the mortality between occupational groups; for example, controlled for sex, age, marital status, and region.

Cross-Sectional Studies

The study of occupational mortality is closely linked to procedures developed in England and Wales, where the first cross-sectional study was published in 1855 [37]. Since then, occupational mortality studies have been published every ten years; no other country has a similar record. The potentials and limitations of cross-sectional studies are therefore best illustrated by this series of data.

It was realized in England in the late 1840s that

> if the age of the various classes of society ... are abstracted from the census returns ... and if the deaths are abstracted in the same classes ... the relative mortality ... can be satisfactorily deduced ... and much light will be thrown upon the causes which really influence the health and well being of the working, middle and higher classes [36].

Farr used this method to tabulate the mortality for 1851 by occupation, and commented that

> the professions and occupations of men open a new field of inquiry, on which we are now prepared to enter, not unconscious, however, of the peculiar difficulties that beset all inquiries into the mortality of limited, fluctuating, and sometimes ill-defined sections of the population [37].

The methodological problems entailed in occupational mortality studies were thus realized from the very beginning. In 1851, miners, bakers, butchers, and inn and beershop keepers experienced the heaviest rates of mortality.

CMFs were first calculated for the 1880–1882 data. The 1900–1902 data showed a variation in the CMF from 600 or below for clergyman, priest, minister; gardener, nurseryman, seeds-man; gamekeeper; and farmer, grazier, farmer's son, etc.; to 1800 or above for inn-, hotel-servant; costermonger, hawker; tin miner; and general laborer [38].

In the 1910–1912 decennial supplement, Stevenson "included for the first time an attempted grading of the male working population into eight social

classes as determined by occupation", where "I represented as far as possible the middle and upper classes ... III skilled labour, and V unskilled labour" [46]. The social classes II and IV were intermediate classes, and textile workers, miners, and agricultural workers formed separate classes. **Infant mortality** showed a steep gradient from 76 deaths per 1000 births in social class I to 153 in social class V. The CMFs for men aged 25–65 for the classes I–V were 88, 94, 96, 93, and 142. Commercial clerks with an CMF of 108 formed 28% of class I and thus inflated the overall CMF for class I. This gave rise to a discussion about criteria for grouping of occupations into social classes, a discussion which has persisted ever since.

The changing composition of the labor force made it necessary to shift from an industry based classification to one in which it was "no longer necessary to assign the head of a tinplate etc. works to the same social class as his labourers" [39]. In 1921–1923, the relative mortality for occupations and social classes were presented both by the CMFs and by summary measures similar to SMRs. The CMFs for social classes I–V were 821, 942, 951, 1007, and 1258; and the SMRs were 82, 94, 95, 101, and 125. The two methods of calculation gave similar results, illustrating a subsequently often observed **robustness** of occupational mortality data.

From a previous holistic view of occupation as encompassing both occupational risks and living conditions, an interest in separating the two aspects emerged in the 1930s. To address this question, the 1930–1932 decennial supplement added tables on the mortality of married women by the social class of their husbands. Similar gradients of SMRs from social classes I–V were found; for men 90, 94, 97, 102, and 111; and for women 81, 89, 99, 103, and 113; and it was concluded "that the contribution made by actual work done to men's social mortality gradient from all causes must be small compared with the contribution made by the accompanying environmental, economic and selective factors" [47].

The 1951 classification included 600 occupations. However, the more detailed classification increased the risk for discordance between numerators and denominators. There was a tendency for people to be given more prestigious occupational titles on death certificates than they had in the census: in 1949–1953, for example, 1443 deaths were registered among company directors compared with only 98 expected deaths based on the number of company directors registered at the census and the mortality rates for all men. As a supplement to the SMRs for deaths in persons aged 20–64, PMRs were therefore presented for deaths in persons aged 65–74 to avoid the problem of discordance between the numerators and denominators. The post-war concern about equity was reflected in systematic tabulations of trends in social class differences in the 1949–1953 decennial supplement. The SMRs for men from social classes I–V were 98, 88, 101, 104, and 118 [40], showing that the English society still had a disadvantaged social class V. The relatively high SMR for social class I was partly due to **misclassification** [24]. A new observation was that the social class gradient of some diseases changed as they became more frequent. The mortality from lung cancer almost tripled in men under 65 years from 1921–1923 to 1930–1932, and the social class gradient changed from an excess risk in social class I in 1921–1923, to equal risks across social classes in 1931–1932, and to a clear excess risk in social class V in 1949–1953. Coronary heart disease increased rapidly in men after the war. In 1930–1932 it was a disease of "the better classes" [11], with an SMR gradient from 237 in social class I to 67 in social class V, but the gradient in 1949–1953 was from 150 in social class I to 89 in social class V.

"The most disturbing feature of the [1959–1963 decennial supplement] when compared with earlier analyses [was] the apparent deterioration in social class V" [41]. The SMRs for the five social classes were 76, 81, 100, 103, and 143. A new and shorter occupational classification was used in 1960, but the results for social class V remained "even when the rates were adjusted to the 1950 classification" [41]. The social class gradient in lung cancer had become even steeper, with SMRs of 53 in social class I and 148 in social class V. The change in the social distribution of coronary heart disease had continued, and the SMRs were now 98 for social class I and 112 for social class V.

When it came to results for specific occupations in 1959–1963, the concern about discordance between numerators and denominators clearly influenced the interpretation. Following a review of occupational cancers, Adelstein wrote that "although the exercise known as occupational mortality is not a useful tool as an early warning system, it remains a valuable analysis of mortality of groupings of occupations

as a back-up and reference system" [1]; a modest aim compared with the expectations a hundred years earlier.

The social class III was in 1970–1972 divided into nonmanual and manual workers. The SMRs for men over the six social classes were 77, 81, 99, 106, 114, and 137. Similar patterns were seen for women and for stillbirths, and mortality of infants and children. Gradients across social classes showed, for example, that social class V had an almost fourfold risk of respiratory diseases but the same risk of pancreatic cancer as social class I. Some occupations stood out with high risks for specific diseases; for example, butchers with cancer of the lung and maxillary sinus, and electro- and dip platers with cancer of the lung [33].

The 1972 smoking rates for men by occupational order showed a high positive **correlation** with the lung cancer mortality. Under these circumstances the previous concern about the influence of living conditions on occupational mortality became a concern about "life-styles of persons" [33]. In a paper on "work or way of life", Fox & Adelstein found that only 18% of the variation in mortality between occupational orders remained when the mortality was standardized for social class [12].

In 1979–1983, the social gradient in mortality for men went from an SMR of 66 in social class I to 165 in social class V; the official comment being that "these data are subject to serious bias and do not represent usable estimates of mortality by social class" [34]. However, aggregated into nonmanual workers (social classes I, II, and IIIN) and manual workers (social classes IIIM, IV, and V), where a serious misclassification would not be expected, the data showed "an overall fall in all-cause mortality from 1970–1972 to 1979–1983 for both manual and nonmanual occupational classes, but the rate of decline [had] been greater in nonmanual groups. Thus the social gap [had] widened" [26].

As a consequence of concern about biases, the 150 year old practice of combining census and death certificate data was abolished with the next decennial supplement, that for 1990.

Cross-sectional studies of occupational mortality were undertaken in several other countries – for example, in France in 1907–1908 [19], and in the US in 1930 [50] and 1950 [14–16, 20] – but in no other country did these studies have the same importance for the social debate as in England and Wales.

Death Certificate Studies

At the time of the 1990 decennial supplement for England and Wales, advancement in technology had rendered the cross-sectional method obsolete, as the overall mortality of an occupational group could now be estimated from the individually matched records of a follow-up study known as the Longitudinal Study (see below). However, the death certificate data were used for search of specific associations between detailed occupations and causes of deaths using only PMRs. This analysis included 1.8 million deaths from 1979–1980 and 1982–1990. New observations were, for example, an excess risk of leukemia, lymphoma, aplastic anemia, and agranulocytosis in teachers, "suggesting a possible hazard from exposure to childhood infections" [8].

In the US, large-scale death certificate studies started in the 1970s. The first study was from Washington State and covered deaths from 1950 to 1971 [27]. An update included deaths from 1950 to 1979. The systematic tabulation of PMRs for detailed occupation and cause of death revealed, for example, an increased risk of leukemia in workers exposed to electric and magnetic fields and a deficit of multiple sclerosis among outdoor workers [28].

Similar studies were undertaken in California [35], Massachusetts [10], Utah [3], and Rhode Island [21]. A detailed analysis of the large number of solvent exposed jewelry workers from Rhode Island revealed an excess mortality from mental disorders, kidney diseases, liver, and kidney cancer [9].

A standardized reporting, coding, and registration scheme for occupation on death certificates from 12 states started in the US in 1984. A PMR analysis for broad groups has been published for the 270 000 deaths occurring in 1984 for persons above the age of 20 [42]. Data from death certificates from 1985 to 1991 are available on public-use data tapes [31].

Follow-Up Studies

That the numerator/denominator bias in cross-sectional studies could be overcome in follow-up studies of census populations was realized as early as the 1920s in the Nordic countries, among others [7]. It was, however, 50 years later that such studies started to emerge. The earliest studies were a 4 month follow-up of the 1960 census population from the

US [22], a 5 year follow-up of the Norwegian 1960 census population [48], a 17 year follow-up of a sample of the French 1954 census population [5], and a 10 year follow-up of the Swedish 1960 census population [45].

The 1970 censuses were used for follow-up studies of the national populations In Denmark [2, 4], Finland [25, 44], and Norway [23], and a joint analysis was made of the occupational mortality in Norway, Sweden, Finland, and Denmark for the 10 year period 1971–1980 [32]. The Longitudinal Study from the UK is a follow-up study of a 1% sample of the 1971 census population, where the sample is, in addition, continuously supplemented with 1% of births and immigrations [13]. A 6 month follow-up of the Italian 1980 census population was published in 1995 [43]. In addition to sex, age, and occupation, these studies often also include other census variables such as marital status, housing conditions, region, family composition, etc.

Some important and fairly consistent observations have been made from the follow-up studies of census populations, such as:

1. All marginal groups of the labor market have an excess overall mortality compared with the working population. In the Nordic countries in 1971–1980, the SMR for economically inactive men was 233, when the economically active men were used as the standard. The SMR for economically inactive women, the majority being housewives, was 151 [32]. In England and Wales in 1971–1975, the SMRs for unemployed men or men with an inadequately described occupation were 306 and 185, respectively, when all men were used as the standard [13].
2. There is a social class gradient in the overall mortality. The SMRs for men in England and Wales in 1971–1975 varied from 80 in social class I to 115 in social class V [13]. The short follow-up of the US 1960 census showed for white men aged 25–64 a mortality ratio of 0.92 for white-collar workers and of 1.07 for blue-collar workers, when the mortality of all men was used as the standard [22].
3. Farmers have a low overall mortality in many countries. The mortality ratio for white male agricultural workers was 0.76 in the US study [22], the SMR for farmers in the Nordic countries was 87 [32], and farm workers in Italy had a 20% deficit in overall mortality compared with all economically active men [43].
4. When studied, the social class gradient in mortality seems to have widened. In Finland in 1971–1983, the overall mortality for men aged 35–49 declined for all occupational classes, but in 1984–1990 it increased for workers and farmers while declining further for white-collar employees [49]. In France, the overall mortality for men aged 35–60 decreased by 28%–30% for professionals, foremen, and salaried employees, but by only 7%–12% for skilled, unskilled, and farm workers from 1955–1959 to 1975–1980 [6].

The follow-up studies of census data are often criticized for lack of information on personal habits, especially tobacco smoking. Such data are available in a follow-up study of 300 000 US veterans who were interviewed about their smoking habits in 1954 and 1957. A follow-up study of this cohort provides smoking adjusted **relative risks** [17, 18], but the number of deaths for a given combination of occupation and cause of death is often small.

However, data from smaller cohorts with a broad range of recorded variables may often provide useful supplementary information to the census studies. Data from the Longitudinal Study have shown, for example, that men unemployed at the time of the census have an excess mortality in the subsequent years [30]. Very useful supplementary data came from the British Regional Heart Study, where unemployed men had an excess mortality even when controlled for age, town, social class, smoking, alcohol intake, and pre-existing diseases [29].

However, at present follow-up studies of census populations provide the most comprehensive data on overall mortality by occupational groups in unselected populations.

ELSEBETH LYNGE

Odds Ratio

If two events, E_1 and E_2, have respective probabilities $\Pr(E_1)$ and $\Pr(E_2)$, the odds ratio comparing E_1 with E_2 is $[\Pr(E_1)/\{1-\Pr(E_1)\}]/[\Pr(E_2)/\{1-\Pr(E_2)\}]$, namely the ratio of the **odds** of E_1 to the odds of E_2.

MITCHELL H. GAIL

Odds

If an event E has probability $\Pr(E)$, the odds of the event is defined as $\Pr(E)/\{1 - \Pr(E)\}$.

MITCHELL H. GAIL

Office for National Statistics (ONS) (formerly OPCS)

The Office for National Statistics (ONS) lies at the centre of the UK Government Statistical Service, which aims to "provide Parliament, Government and the wider community with the statistical information, analysis and advice needed to improve decision making, stimulate research and inform debate". The Director is also the Head of the Government Statistical Service and Registrar General for England and Wales. He has a leading international role as a member of the UN Statistical Commission and of the Board of EUROSTAT, the statistical office of the European Union. The ONS was formed in 1996 as a result of the merger of the two major statistical agencies in the UK, the Office of Population Censuses and Surveys and the Central Statistical Office. These two government departments had long and distinguished histories [1, 2]. The new organization employs approximately 3000 people, spread between its offices in London, Newport, Southport, and Titchfield. The merger brought together the main collection, processing, analysis, and publication of social and economic statistics into a single organization. The Registrar General also has responsibility for the administration of the vital registration of births, marriages, and deaths and for the running of the National Health Service Central Register for England and Wales (*see* **Vital Statistics, Overview**).

In partnership with other government departments ONS aims to provide, for the UK, "the main statistical advisory service for policy formulation, resource allocation, planning, and research on the number, characteristics and health of the population. It collects and analyses data from a wide variety of sources, and publishes and interprets the statistics. Major customers are government, business, researchers and the general public." Its main outputs, increasingly available on the web [3], are:

1. regular publications, including the quarterly *Population Trend*s and *Health Statistics Quarterly*;
2. large-scale databases covering mortality, fertility, cancer incidence and survival, congenital anomalies, morbidity in general practice, and longitudinal data from the ONS Longitudinal Study; and
3. advice and interpretation of recent patterns and trends.

It conducts a significant fraction of its work in the health field on a commissioned basis, with the Department of Health for England and the National Health Service (NHS) as principal customers. ONS also plays a key role in providing a service to government covering the main **survey** collections. In recent years, this has included surveys on children, psychiatric morbidity, health and nutrition, dental health and disability, carried out for the Department of Health, as well as the regular General Household Survey.

The UK Government Statistical Service is distributed among the constituent countries of the UK. The Registrars General for Scotland and Northern Ireland have similar responsibilities for **censuses**, the administration of vital registration, and associated statistical activities to those held by the Registrar General for England and Wales. The Government Statistical Service also supports the Chief Medical Officers for England, Scotland, Wales, and Northern Ireland, supports the NHS in each of these countries, and provides policy advice to ministers. Statisticians in different policy departments in government take the lead on infectious diseases (Public Health Laboratory Service; *see* **Communicable Diseases**), **occupational health** (Health and Safety Executive), transport, and home accidents (Departments of Transport and Trade and Industry, respectively), health in prisons (Home Office), and the health of the armed forces (Ministry of Defence).

Oncology

The subject of statistical methods applied to oncology covers a wide range of applications. Accordingly, the subject is considered here in three separate areas:

1. biostatistics in cancer epidemiology;
2. methods for cancer **clinical trials**; and
3. tumor modeling.

The three areas are interrelated, the most ubiquitous connecting factor being the seminal work of Mantel & Haenszel [30] on **relative risk** estimation in **case–control studies**. From this single paper, an enormous body of methodologic work has followed, and innumerable studies in the field have made use of the **Mantel–Haenszel** technique or of adaptations thereof.

Biostatistics in Cancer Epidemiology

Definitions

Although epidemiology of a kind which entails at least a basic application of scientific method has been intermittently apparent for centuries, biostatistics has only made a formal contribution since the twentieth century. The role of biostatistics has included advances in the methodology of study design as well as in analysis of data, and it is timely to define the three major design categories used in cancer epidemiology.

First, there is the prospective **cohort study**, in which a cohort of healthy individuals have certain characteristics recorded and are subsequently monitored for incidence of or mortality from a particular cancer. The aim of the study is to assess whether the characteristics recorded at recruitment are predictive (*see* **Prediction**) of subsequent disease. A characteristic which is related to incidence of disease is usually referred to as a **risk** factor. Related to this is the **prevention trial** in which healthy individuals are randomized (*see* **Randomization**) to receive or not to receive a particular intervention (for example, vitamin supplementation), and are subsequently followed up for the cancer in question to assess whether the intervention has a preventive effect.

Secondly, and most commonly in cancer epidemiology, there is the **retrospective** case–control design. In a study of this design, a series of cancer patients (cases) is compared with a series of subjects who do not have the cancer in question (controls), with respect to retrospectively assessed potential risk factors. This type of study has the advantage of being relatively quick to perform, but is more prone to **biases**, for example from differential recall between cases and controls (*see* **Recall Bias**), than the prospective cohort study [40].

Finally, there is **descriptive epidemiology**. This is not, strictly speaking, a design at all, being the practice and methodology of analysis of routinely collected national or regional figures on cancer incidence or mortality, to determine differences in morbidity or mortality by time or by geographic area.

To understand the landmark developments in statistical methods in epidemiology, it is necessary to define the fundamental measure of epidemiology, the **relative risk** (RR). Let D denote the event of disease occurring, $RF+$ denote the presence of a certain risk factor, and $RF-$ its absence. Let Pr denote probability. The relative risk is defined as

$$RR = \frac{\Pr(D|RF+)}{\Pr(D|RF-)}.$$

Historical Development

The first study of cancer epidemiology with a substantial biostatistical input was the Lane–Claypon case–control study of breast cancer [26]. This innovative study was the first rigorous case–control study addressing multiple risk factors and using a large cases base. Its findings included relationships of high parity with lowered breast cancer risk, late marriage with increased risk, miscarriage with increased risk and a family history of cancer with increased risk. This very much set the scene for later research, indicating a concentration on factors related to fertility and parity.

In a retrospective case–control study, the relative risk is not directly estimable but it may be approximated by the **odds ratio** (OR). This quantity is invariant to the design of the study. Suppose that the number of subjects with and without the disease and the risk factor are as in Table 1.

The odds ratio is defined as

$$OR = \frac{ad}{bc}.$$

Table 1 Symbolic tabulation of disease status by risk factor status

Risk factor	Disease present	Disease absent
Present	a	b
Absent	c	d

This is sufficient for the case in which there is only one risk factor of interest and it is assumed unrelated to other risk factors. In the case in which other factors are related both to disease risk and to the risk factor under study (such factors are known as **confounders**), it is clear that some amendment or complication of the formula is necessary. For this purpose, one of the most important developments has been the proposed estimate of **Mantel & Haenszel** [30]. A simple example of confounding arises in the assessment of the effect of alcohol drinking on lung cancer risk. It is known that smoking has a strong predisposing effect, and that heavy drinkers are more likely to be smokers than the rest of the population. How do we adjust our estimate of the effect of excessive drinking on lung cancer for the common association of disease and risk factor with smoking?

Let i denote smoking status, $i = 0$ representing nonsmokers and $i = 1$ representing smokers and suppose that we have a case–control study with data as in Table 2.

Thus there are two **two x two tables**, one for nonsmokers and one for smokers. A solution which intuitively recommends itself is a weighted average of the odds ratios calculated in each table separately. Mantel & Haenszel suggested weights $b_i c_i / N_i$, where $N_i = a_i + b_i + c_i + d_i$. This approximates weighting by inverses of the variances and gives the Mantel–Haenszel estimate familiar to epidemiologists

$$OR_{\mathrm{MH}} = \frac{\sum((a_i d_i)/N_i)}{\sum((b_i c_i)/N_i)}.$$

Table 2 Symbolic tabulation of lung cancer by heavy drinking and smoking

Heavy drinker	Lung cancer cases	Controls
Present	a_i	b_i
Absent	c_i	d_i

An accompanying **chi-square test** similarly adjusted for stratum was also developed. The original development of this estimate had no particularly strong theoretic backing, but the estimate has subsequently proved very **robust** and useful, and has been shown to possess various desirable properties, in particular its equivalence to the OR estimate from **conditional logistic regression** in the case of a matched study (see below). The disadvantage of the estimate is the lack of a universally applicable **variance** estimate. Different variance formulas apply depending on the sparseness of the data [18].

A copious amount of research has built on the Mantel–Haenszel estimate. For a review, see Gail [20]. The range of applications includes adaptations of the estimate for use in randomized trials, prospective **cohort studies**, **meta-analyses**, and studies in which risk factors are measured with error (*see* **Measurement Error in Epidemiologic Studies**).

Other landmarks in biostatistics as applied to cancer epidemiology include the development of **generalized linear models**. This revolutionized statistical analysis in many fields but was of particular benefit in epidemiology, enabling estimation of relative risks and odds ratios in a **regression** framework, notably **logistic regression** and **Poisson regression** [6, 7]. This made it considerably easier to adjust for confounding variables in analysis of **observational data**.

Current Approaches and Ongoing Problems

Other major developments include the evolution of methods to deal with mismeasurement of risk factors, beginning with Bross's [8] definition of the problem, with approaches including simple **likelihood**-based methods [15], imputation (*see* **Multiple Imputation Methods**), and regression methods [39] and, more recently, stochastic estimation [38] and **structural equations models** [25].

The development of computer software and hardware since the 1960s has gone hand in hand with the development of statistical models, in particular software for fitting generalized linear models. There are now several computer packages available which perform logistic regression for unmatched case–control studies, Poisson regression for cohort studies and conditional logistic regression for matched case–control studies (*see* **Software, Biostatistical**).

The advent of generalized linear models has also been influential in changing the approach to descriptive epidemiology [18]. Poisson regression has proved useful in providing simple estimates of changes in disease rates over time (see, for example, Lee et al. [29]). Recent methodologic work has included **Bayesian methods** for smoothing changes over time or area [3], the latter having a specific application in cancer mapping (*see* **Geographic Epidemiology**) [10], techniques for identifying clusters (*see* **Clustering**) [4] and methods for prediction of future incidence or mortality [24].

Likely Future Developments

Problems of measurement error are of particular interest because of the perceived need to ascertain the effect of dietary factors (*see* **Nutritional Exposure Measures**) on cancer risk. This is especially relevant to the ongoing series of cohort studies of diet and cancer [37]. In cancer epidemiology there is also interest in other variables which are often impossible to measure definitively, such as history of exposure to electromagnetic fields. In this case, approaches involving measurement by several different methods are likely to be productive [25].

The growth of **genetic epidemiology** [1] raises particular methodologic problems. These are likely to stimulate considerable statistical research in the future.

Another area of particular interest at the moment is in descriptive epidemiology, in terms of analysis and prediction of incidence and mortality rates. Because of recent changes in therapy or the introduction of preventive or **screening** policies, public health departments are particularly interested in modeling changes in rates, contemporaneously with, or following upon, changes in policy. Techniques of interest include linear modeling [24], the use of **excess mortality** models [27], and Bayesian prediction [10].

Methods for Cancer Clinical Trials

Definitions and Historical Development

Whether for cancer or any other complaint, the basic principle of a clinical trial is the same: a comparative study in which one group (the **control** group) receives a traditional regime or a placebo and another group receives a new regime or treatment (study group). There are, however, methodologic features which tend to dominate in cancer clinical trials. First, time to a given event – for example, death or recurrence – is usually the primary outcome variable of a trial in cancer treatment, rather than a dichotomous "cure" result or a posttreatment **cross-sectional** measure of a continuous attribute. Secondly, the nature of the disease, in particular the tendency of cancers at certain anatomical sites to recur after a period of remission, renders long-term success of therapy relatively difficult to achieve. Thus, full evaluation of the effect of the new therapy may involve prolonged follow-up. Another corollary of this difficulty in achieving long-term success is that fairly small differences in prognosis may be considered worth pursuing.

The seminal papers in the field are therefore methodologic papers on **survival analysis** [11, 35] and discursive works on the design and analysis of survival studies [34, 35]. Both have proved very useful in clinical trials both within and outside the discipline of oncology. The two survival analysis methods which have gone into widespread use are the **logrank test** [33], which is another adaptation of the Mantel–Haenszel method, and **Cox regression** [11]. The latter is a method which assumes a constant proportional effect (of treatment, prognostic feature, and so on) on the instantaneous hazard of death or recurrence, but assumes no distributional form for the survival probability (*see* **Proportional Hazards, Overview**).

Following from the work on the methods of survival analysis, considerable effort has gone into the calculation of **sample sizes required for clinical trials** in general and cancer trials in particular; see, for example, Freedman [19].

Current Approaches and Ongoing Problems

Due to the necessity of establishing treatment effects which may be small in absolute terms, the necessity for large clinical trials has long been appreciated in oncology [34]. For this reason, **multicenter trials** and overviews of separate clinical trials are a regular feature of cancer treatment research (*see* **Meta-analysis of Clinical Trials**) [14, 32].

Another factor in cancer therapeutic research is the need for timely results. Chemotherapies often have toxic effects, and patients should not be subjected to potentially harmful experimental treatments for any

longer than is absolutely necessary. On the other hand, the wider patient population is anxious for effective new therapies to be introduced as soon as possible. Consequently, a considerable amount of research on stopping rules has been conducted (*see* **Sequential Analysis**) [44].

In conjunction with developments in cancer prevention, the methodology of disease prevention trials is an ongoing issue. In a trial of a preventive measure, the ultimate aim is to assess the effect of the measure on future disease incidence or mortality in currently healthy individuals. Thus a small number of disease/death events will occur in a large number of subjects. For this reason, research has focused on methods of reducing the numbers of patients required, shortening the observation period and simplifying the organizational aspects. Strategies include use of **surrogate endpoints** for reducing the size and period of the trial [36], and cluster randomization (*see* **Group-randomization Designs**) to reduce complexity [21, 43].

Likely Future Developments

Bayesian methods are becoming more common in trial design and analysis [41], with particular progress in terms of monitoring (*see* **Data and Safety Monitoring**) and early stopping. This trend is likely to continue.

Pressure on resources combined with the need to assess preventive measures give an impetus to research on efficient designs of preventive measures. In particular, surrogate outcomes are likely to be more frequently adopted in trials of cancer screening regimens [13]. Another potentially useful strategy is the **factorial design** in which more than one intervention is assessed in the same trial [5].

Tumor Modeling

Definitions and Historical Development

Traditionally, there has been a need to devise mathematical models of tumor initiation and development, first to understand better epidemiologic observations of exposure and subsequent disease and, secondly, to model realistically the results of animal experiments in carcinogenesis and tumor promotion (*see* **Tumor Growth**; **Tumor Incidence Experiments**). The seminal works on the subject are the multistate models of Armitage & Doll [2] and Day & Brown [12] (*see* **Multistage Carcinogenesis Models**). Mathematical forms for tumor development models include **exponential, Weibull**, and Gompertz (*see* **Parametric Models in Survival Analysis**) models. For a review, see Gart et al.[22, Chapter 6].

Current Approaches and Ongoing Problems

In recent years, a major aim of tumor modeling has been to describe and estimate the parameters of tumor development in humans and its arrest by early detection and treatment. This is necessary to understand how programs of screening for cancers have worked in the past and for ongoing monitoring of such programs in the future. Although the ultimate aim of screening is to reduce mortality from the disease in question, it is desirable to have early indicators of whether this is likely to be achieved or whether changes are necessary to the screening regime before results on mortality are available.

Although the methods developed are applicable to screening for a variety of diseases, their primary application has been in screening for breast cancer and cervical cancer [42], cancers for which the effect of screening has been demonstrated, researched and documented over a long period of time. With recent interest in screening for colorectal cancer, modeling of the cancer process at this anatomical site is becoming a target for research [28].

Probably the most commonly used model is the **Markov chain** with discrete state space [42]. Such a model divides the development of the tumor into stages – for example, no disease, lymph node negative, and lymph node positive – with exponentially distributed times spent within the stages. These have been used to predict the effect of different screening regimes for breast cancer [31].

One reason for use of the Markov chain model is the mathematical tractability of the exponential distribution of time spent in each state which is implicit in the Markov model. It is possible, however, to use other distributions for time spent in states. Other models used in the past include the Weibull [17] and **nonparametric** models [9].

Likely Future Developments

Computer programming and estimation from complex biologic models are likely to become easier with the development of theory, practice, and

software in Gibbs sampling (*see* **Markov Chain Monte Carlo**) [23]. Gibbs sampling has already been used to estimate screening **sensitivity** and the average time spent in the preclinical screen-detectable period for colorectal cancer (*see* **Screening, Sojourn Time**) [28].

With the possibility of chemoprevention of various cancers [5], a new application for mathematical models is likely to be the modeling of the biologic processes underlying the chemoprevention strategies. Another possible new application is in modeling of early detection in circumstances in which a randomized trial of screening is not considered appropriate, such as in screening of **gene** carriers for breast cancer.

STEPHEN W. DUFFY

Operations Research, Simulation

Introduction

Simulation is a versatile problem-solving methodology that involves the abstraction of a real-life system into a symbolic model format and provides an alternative to a purely mathematical analytical solution. A **Monte Carlo** simulation generates random number values (in a process similar to spinning a wheel of fortune), which can be interpreted as actual real-life circumstances or discrete events (*see* **Pseudo-random Number Generator**). Using a computer, a large number of possible combinations of circumstances can be generated to replicate the uncertainties in a real-life scenario, and their impact on selected outcome variables can be evaluated. One can manipulate and experiment with such a model to produce information about the behavior of the real-life scenario over time.

Simulation models can provide estimates of a system's performance measures, for example, the length of a queue in a system with customers waiting for service, the time spent by those customers in the queue, as well as the total time spent in the system. Simulation techniques can also be used to provide financial estimates in the area of investment appraisal, for example, the overall net present value (NPV) for a capital-budgeting investment decision; the likelihood of competitors entering a market and the effect of those competitors on market share. In addition to these performance estimates, simulation models can provide a vehicle to evaluate the effect of changes to a system's input parameters or changes to various operating strategies in a system, for example, changes to the number of staff serving customers, changes in the arrival rates or service rates of customers, changes in future interest rates or discount rates included in an investment decision analysis, and changes in future revenues and costs.

A simulation model must be developed in a way that accurately captures the real-life variation that exists in the system. It must also be systematically verified and validated before it is implemented to provide valuable insight for a decision maker. Such a model becomes a powerful tool for decision makers, often helping to reduce the time needed to evaluate decisions and saving significant costs when good alternatives or solutions are identified. Experimenting with such a model can be less expensive and less disruptive than experimenting with the real-world system. The decision maker can evaluate alternatives in the "safe" environment of a symbolic model.

The Simulation Process

The following stages are part of any simulation study:

(1) Problem Statement
(2) Information Gathering and Data Preparation
(3) Model Conceptualization
(4) Model Implementation
(5) Analysis and Interpretation
(6) Verification and Validation
(7) Implementation and Documentation.

Problem Statement:

Any real-life system tends to be "messy" in terms of its structure and the risk and uncertainty of the system parameters. At the beginning of any simulation study, one must first understand the problems or opportunities that exist in the system. What are the user's stated and unstated goals? Is there a gap between the current situation and the desired one? What information do we need and what criteria will be used to evaluate the decisions?

This first stage is accomplished when we have a complete description of the problem scenario including a problem statement, objective criteria for evaluation, and an understanding of the data that will be needed to represent the real-life system in a simulation model format.

Information Gathering

In this stage of a simulation study, information about the real-life system definition and operation must be gathered. Accurate data are needed to build the simulation model. What are the relevant data needed to abstract the real-life system? What are the uncertainties that exist in these data? Can we assess probability distributions for these uncertainties and how will this happen? What measures of effectiveness are appropriate to analyze these data?

The output from this stage is an understanding of all relevant data and the key factors needed to build a simulation model that accurately represents the real-life scenario.

Model Conceptualization

The art or craft of model building is the abstraction of the real-life scenario into a symbolic model of variables and relationships. This art requires a simplification of the real-life situation that both captures sufficient detail to be acceptable to decision makers yet does not become prohibitively complex. A balance must be struck between keeping the model understandable and representing a reasonable abstraction of the real-life complexity. One big advantage of simulation modeling over analytical models is the number and scope of complexities that can be included. Mathematical models used in optimization are often very limited by their assumptions and therefore applicable to only very simple circumstances. Simulation models can capture much greater complexity in most situations (*see* **Model, Choice of**).

For example, if the simulation model is built to capture a process flow, for instance, a hospital emergency room or an obstetrics–gynecology clinic, one can capture the real-life routing logic that represents various types of arrivals to the system as well as various service patterns and interventions that might occur in the system. If the model is built to capture a capital-budgeting decision, for example, a 10-year cash flow projection for a new ambulatory care facility, one can capture the relevant resource costs, utilization factors, and revenues over a defined window of time. In either case, this stage requires the conceptualization of performance measures that will be used to evaluate effectiveness as well as identification of the key relationships among the inputs and the performance measures.

Model Implementation

In this stage of a simulation study, the conceptual model is translated into the requirements of a chosen computer software package. Although general-purpose languages can be used to program simulation logic, special purpose simulation packages are available that are flexible, inexpensive, and user friendly. The advantages of these packages include the ability to represent **random variables** with probability distributions, the ability to control iterations of the model, and the automatic generation of output statistics, risk profiles, and **sensitivity** and scenario results. Simulation packages are available in several categories. For the simulation of discrete event processes, software such as GPSS/H, Simscript, ARENA, and Process Model are widely used [2, 4–6]. For static simulation models such as the simulation of financial spreadsheet projections, @RISK and Crystal Ball products are available [3, 7].

Analysis and Interpretation

The execution of a simulation model using a computer is designed to replicate all of the combinations of variation that exist in the input parameters of a real-life scenario. The simulation model will produce statistical estimates or probability distributions for all of the outcome variables, based on the variation in the multiple input factors (*see* **Estimation**). This is accomplished by repetitively executing the model generating different sets of inputs and saving the output results. For each execution or iteration of the model, each random input variable is sampled from its defined probability distribution. With a set of sampled input values, the model is evaluated in terms of the outcome variables and these results are saved.

For a discrete event process flow model such as a hospital emergency room, the input variables might represent types of patients arriving with different types of demands for care, arrival time intervals, types of available resources, and service times. The outcome variables might be an estimate of the time an arrival occurred, the time that service started, and the time that service is completed. From these data, estimates of the wait time, server idle time, and queue length can be determined.

For a cash flow financial projection model such as a capital-budgeting investment analysis, the input variables might represent the types of costs, the types of revenues, the growth rates or projections for growth rates, the presence of competitors, and market share. The outcome variables might be yearly after-tax cash flows and net present value for the time frame analyzed.

During each model iteration, a new set of random variables is sampled and a new set of outcome variables are saved. Upon a predetermined number of iterations or a predetermined termination point, all of the outcome variables can be summarized in terms of statistics (e.g. **means**, **standard deviations**, minimum and maximum), risk profiles, sensitivity results, and scenarios.

Once the model is producing outcome measures, it is important to determine which input variables have

the greatest impact on these measures. One needs to pay attention to this type of information as the most sensitive inputs should be modeled with the greatest care. Sensitivity analysis allows the analyst to explore how changes to the input variables impact the output measures. Some typical types of sensitivity analyses would explore the choice of a probability distribution for a particular input or the choice of a particular parameter value. If the number of input factors is small, sensitivity may be explored changing one variable at a time or the **interactions** of changes to two or more variables simultaneously.

Verification and Validation

The output from a simulation model must be checked for accuracy (verification) and reasonableness (validity). Completing these requirements can be time consuming but are critical, requiring the analyst to carefully check all of the inputs and relationships to ensure that the process of developing the conceptual model as well as the process of translating the conceptual model into a computer model was done accurately. Initially, one should take steps to ensure that the conceptual model makes sense to a group of participants (conceptual model validity). Once the conceptual model is agreed to, its translation into the computer model should be verified for accuracy. Finally, in order to validate the computer model, the analyst should ask whether the model results resemble the real-life output or expected output (face validity)? Do the results make sense? Are the results consistent with how the participants perceive the system should behave? (*See* **Model Checking**.)

It is essential that a user have confidence that a simulation model is credible before decisions can be made on the basis of the model. One should design the process of verification and validation to ensure that confidence.

Implementation and Documentation

Once the model has been developed, verified, and validated, simulation experiments may be executed, analyzed, and documented. A simulation study is considered successful when its results have been understood, accepted, and acted upon. Documenting all assumptions, conceptual logic, programmed model logic, and data results in a way that is readable and understandable by both an analyst and the user will enable future modification to the model as well as provide a foundation for future simulation modeling.

Conclusion

One creates simulation models in order to provide valuable insight to decision makers by replicating real-life decision scenarios and providing more complete information about the risks and uncertainties in those environments. Once a model has been verified and validated as accurately representing the real-world environment, many "what if" questions about the system can be posed.

Simulation models have been an indispensable tool for decision makers in many different public and private environments. Several excellent models in the area of health care are illustrative. Rossi describes the use of a simulation model to forecast short- and medium-term projections of HIV/AIDS epidemic indicators for evaluating prevention campaigns, alternate health care strategies for AIDS patients, and drug supply needs [11]. This model also estimates the number of intravenous drug users and the number of AIDS cases that are not appropriately tracked by surveillance and monitoring systems. On the website, `www.informs-cs.org`, an annual conference of simulation practitioners publishes proceedings with complete texts of articles relating to a wide variety of applied simulation models. In the Health Care Track for the Winter 2003 Conference, papers on emergency management of critical incident response, mobile examination centers, a geriatric center, and patient care processes in an ambulatory care center, to name a few, present applied simulation models that enhance decision making in health care settings [1, 8–10]. Past conference papers are also available demonstrating the widespread application of simulation methods to the health care environment.

Operations Research

Operations research methods have been applied widely to improve efficiency and effectiveness in health service delivery, as well as to assist managers and policy-makers in planning and implementation. The conceptual framework used in operations research to assist managers in solving their decision problems has several key attributes:

1. There is an identified decision-maker who is expected to use the results from an operations research analysis.
2. Essential elements of the manager's decision or problem can be mathematically modeled, including constraints on alternatives or options.
3. Measurable indicators of the decision-maker's goals or preferences can be applied to identify optimal solutions.

The focus on decision-making, measurable objectives, constrained decision-making, and opportunity costs are common to most operations research applications. With the growth in high-speed personal computing, plus user-friendly software, many operations research models can now be used directly by managers, clinicians, and their staffs.

Operations research methods have been applied in several areas of health care:

1. The efficient allocation of resources (infrastructure) to meet health care needs of patients or a defined population.
2. Structuring the care processes to ensure that the flow of patients and resources is efficient.
3. Information systems support and patient classification systems to assist managers in understanding the relationship of patient characteristics (e.g. diagnosis, service types, care setting) to resource requirements and costs.

These tools have applications in the design and management of large managed care organizations and integrated delivery systems, as well as in the management of physician group practices and community health center clinics (*see* **Health Services Organization in the US**). A significant barrier to the application of operations research methods has been the timely availability of relevant data at reasonable cost. With advances in health management information systems and their application in hospitals and physician offices, this is becoming less of a barrier than ever before. Advances in medical informatics are making it possible to integrate complex patient care and management data (*see* **Administrative Databases**) in support of clinical and management decision-making.

Operations research models to support decision-making can be categorized in several ways. Models may be either deterministic or stochastic, depending on the importance of random variability in the problem and its solution (*see* **Model, Choice of**). Making a decision regarding the numbers of hospital beds needed in a community may use a deterministic model to predict demand and market characteristics, while an appropriate model to schedule hospital admissions and operating rooms optimally would need to incorporate the effects of random arrivals of emergency admissions and variations in operating time from patient to patient.

Another classification of operations research models concerns whether the model is designed to provide optimal solutions (*see* **Optimization and Nonlinear Equations**) or has a more limited capability to predict and compare the outcomes from decision alternatives or trends (e.g. a **simulation** model). One may want a decision model to determine the optimal number of operating rooms on the basis of a known future demand for surgery. However, a model would be needed to estimate future demand for inpatient vs. outpatient surgery on the basis of trends in population and market characteristics, and in surgical technologies. Since there will be uncertainty about future demand, the predictive model might be used to estimate high, average, and low future scenarios. These estimates would be used in the optimization model to determine what impact, if any, uncertainty of future demand would have on the optimal number of operating rooms. Analysis of the sensitivity (*see* **Sensitivity Analysis**) of optimal solutions due to uncertainty is a standard part of the application of operations research methods. Alternatively, one might not seek an optimal decision but employ simulation modeling to estimate the numbers of operating rooms that would be needed under alternative demand projections. Simulation modeling is frequently easier to learn and to apply than many optimization models, and may be appropriate when the assumptions underlying the optimization model cannot be satisfied.

Operations research models may operate over different time horizons in different decision-making environments. Real-time decision-making is needed when scheduling elective hospital admissions or deciding when specific pharmaceuticals should be reordered to avoid being out of stock when a prescription needs to be filled. These models are generally embedded in computer information systems so they can be updated continually (*see* **Database Systems**). This contrasts with models used in strategic and capital investment planning, which may be updated and used annually or less frequently.

What distinguishes operations research from related fields of biostatistics and economics is the focus on a decision-maker, constraints on alternative choices, the emphasis on tools that can provide the decision-maker with optimal solutions, and the explicit consideration of opportunity cost. However, the methods used by operations researchers are drawn from statistics, economics, computer science, and other areas of applied mathematics and behavioral sciences. Models used to find optimal solutions include **linear programming**, **decision theory**, and a range of nonlinear optimization methods (e.g. dynamic programming, quadratic programming). Optimization models may incorporate stochastic models or stochastic models may be used independently of optimization to predict system performance under alternative assumptions. Some frequently used stochastic models are queuing and Markov models (*see* **Markov Processes**), inventory control, and quality control models.

Health workforce models are used to determine the efficient allocation of health care personnel for meeting the health care needs of patients or a defined population. Such models can be used to predict future physician requirements, or to determine optimal staffing in individual health care facilities.

Decision-making occurs at all levels of the US health care system, ranging from Congress and corporate boards to physician offices and pharmacies. Operations research provides methods that can support decision-making at all these levels. The **Analytic Hierarchy Process** is a method for strategic planning that uses hierarchical methods to elicit utilities and preferences. These methods have been used by corporate boards of directors in strategic decision-making. Physicians and other health care providers need to make decisions regarding the best care for individual patients. Decision analysis models allow the provider to compare alternative treatments in terms of expected outcomes and costs (e.g. medical management vs. surgery). Bayesian decision analysis models can help to quantify the level of uncertainty and its relationship to individual patient risk factors (*see* **Bayesian Methods**; **Bayesian Decision Models in Health Care**).

One of the most widely used operations research optimization technique is linear programming. This technique has been applied extensively in industrial management, but less so in health care management. As health care is becoming a more highly organized and vertically integrated service industry, applications of linear programming are increasing.

Operations research has contributed to the development of patient classification methodologies that can be used to predict patient care resource requirements and costs. **Diagnosis Related Groups (DRG)** is a methodology using diagnoses, surgical procedures, and patient characteristics for estimating the cost of inpatient care. DRGs are widely used as the basis for paying for inpatient hospital care, and also as a measurement of a hospital's "output" that can be used with operations research techniques.

All of the applications and techniques of operations research share a common focus on the needs of the decision-maker for making better decisions. The complexity inherent in the provision of health care services has limited the easy translation of operations research applications from other services industries. Where successful health care applications have been developed, their impact has been substantial. DRGs, physician requirements modeling, and applications of decision analysis are probably the most notable examples of widely used and highly successful operations research applications.

DONALD STEINWACHS

Ophthalmology

Ophthalmology is a branch of medical science concerned with the structure, functions, and diseases of the eye; and *optometry* is an art or occupation consisting of the examination of the eye for defects and faults of refraction, and prescription of correctional lenses and exercises which does not include the use of drugs or surgery. The eye has a wide variety of structures in which both physical and functional defects can have serious consequences regarding the ability to perform in everyday life, and in particular in occupations and professions.

The history of ophthalmology dates from ancient times and documents many issues pertinent to modern ophthalmology. While many of the technical details involved with today's surgical procedures differ from those of the past, many basic strategies for combating eye disease (such as "couching cataracts" which dislodges an opacified lens, or using a magnet to remove foreign ocular bodies) have their roots in antiquity. Indeed, some of the diseases described thousands of years ago, such as trichiasis (inverted eyelashes rubbing against the eye), diplopia (double vision), and night blindness, still constitute significant ophthalmologic problems today.

Johannes Kepler (1571–1631), pioneered the physics of vision and refraction, and shifted the perception of the "organ of vision" from the lens to the retina. During the seventeenth and eighteenth centuries, cataracts were known to occur in the lens, Daviel's extraction of lenses was used in place of the older "couching of cataracts", and spectacles, used since the thirteenth century, were prescribed for patients following lens removal. The nineteenth century brought new advances in anatomy and physiology, including early attempts at corneal transplants, a description of "diabetic retinopathy" (a condition which currently is one of the leading causes of blindness in the Western world), and the invention of the ophthalmoscope, enabling observation of the inner eye.

The twentieth and twenty-first centuries have brought further advances in technology (e.g. tonometers to measure intraocular pressure, lasers to treat a variety of retinal abnormalities, and echography or ultrasound to aid in diagnosis and management), and the application of modern scientific knowledge: the agent of trachoma, a conjunctival infection, was discovered in China; strabismus surgery to correct misaligned eyes increasingly addressed functional, rather than cosmetic, issues; and **genes** associated with certain eye disorders have been identified. Despite these advances, eye disorders are still of major concern.

Types of Data Collected

There are many types of data from ophthalmic research: some are direct measures of visual function and others are more descriptive of certain characteristics associated with visual conditions. Data related to visual function can be related to *central vision* and/or *peripheral vision*. Central vision is the sharp, clear vision that most people use when looking directly at an item or object, such as reading or driving, while peripheral vision is the progressively less clear vision found at further distances from the point of fixation. Tests of central vision include tests to measure visual acuity, contrast sensitivity, reading speed, and others.

Peripheral vision is often quantified and described using perimetry tests such as with visual field analyzers. Tests of either central or peripheral visual function depend on the ability of the person being tested to focus the test object on to the retina and for that image to be correctly interpreted by the brain.

Refractive error is a measure of the amount of optical correction needed to focus an image precisely on the retina. The measure is a combination of three components (sphere, cylinder, and axis) that are often summarized into a spherical equivalent measurement: sphere $+\frac{1}{2}$ cylinder. Subjective refraction is performed by presenting various lenses to an individual and asking which makes the vision clearer. Retinoscopy is an objective measurement of the refractive error that uses a streak of light to determine the needed refractive correction. When performed by a skilled examiner, it is extremely accurate, but the measurement of refraction can often be more generally measured subjectively. Combinations of objective and subjective measurements are also possible. Refractive error measurements are usually performed before further visual function testing and corrective lenses matching the refractive error can be worn by the person during the later tests of visual function to determine, for example, the "best corrected visual acuity" or the "best corrected reading

speed". The change in refractive error over time is an important issue in any surgery involving the cornea, but there has been little development in the analysis of refractive error measurements.

Visual acuity (VA) is a common measure of visual function and generally consists of a "Snellen fraction" of two numbers based on a measurement taken at 6 m (20 ft) from the testing object. The first number indicates the distance separating the test object from the test subject; the second indicates the distance at which the object subtends an angle of 5 minutes. The largest symbol used in the US subtends an angle of 5 minutes at a distance of 200 ft (60 m). An individual being tested is asked to read the smallest symbol on the chart that they can clearly see. Therefore, if a person is 6 m from the visual acuity chart and they can clearly read the line on the chart that subtends the desired angle at 6 m, then the visual acuity of that person would be recorded as 6/6. If they are unable to read the letters on that line but are able to read the largest symbol, their vision would be recorded as 6/60. If the individual is unable to recognize the largest test symbol, the distance at which he recognizes it is recorded (i.e. if it was seen at 3 m the vision would be recorded as 3/60). Whenever an individual is unable to recognize any symbol, then VA is recorded as one of the following measurements (in order of increasing poor visual acuity): distance at which he can count fingers (CF), distance at which hand motion can be detected (HM), light projection ability (being able to project the direction from which light is entering the eye from a small penlight), light perception ability (LP), or no light perception ability (NLP). The **World Health Organization** defines blindness as a VA less than 3/60, and in the US blindness is legally defined as a VA less than 20/200.

A variety of methods have been suggested for computing the **mean** of a set of VA measurements, all of which are expressed in fractional (Snellen) notation: (i) treat the VA as a fraction, convert to decimals, compute the mean, then express the result as a fraction with a numerator of 6 m (or 20 ft); (ii) if all VAs are all measurable at the same distance (or convertible to $6/X$ or $20/X$), then compute the mean of denominators and report the average VA as a fraction with 6 (or 20) in the numerator; and (iii) convert the VA fraction to decimals, average the logarithms of the decimals, take the antilogarithm of the resulting mean, and report the average VA as a fraction with 6 (or 20) in the numerator. This latter method of calculating the mean VA is most consistent with the geometric progression of VA used in the newer standardized VA charts recommended for visual research. The logarithm of the Snellen fraction is approximately the logarithm of the minimal angle of resolution (logMAR) and the new charts provide a step of 0.1 logMAR units for each higher line on the chart. An additional feature of the newer charts is the uniformity in the number of letters on each line of the chart. Earlier visual acuity charts had more smaller letters on lower lines of the charts and fewer, larger letters on higher lines, while the newer charts have a standard five letters per line. Hence, the precision is constant over all levels of measured acuity. Scores are computed from 0.1 logMAR units for each complete line correctly read plus 0.02 units for each additional letter.

Calculating a mean of a set of VA values with both chart-measurable (Snellen fraction) and nonchart measurable (CF, HM, LP, and NLP) visions is more difficult and less standardized because there is no universally agreed upon numerical equivalent for the nonchart measurable (coded) visions. Arbitrary Snellen fractions can be assigned for these coded values; however, it is usually preferable to report the **median** VA or describe the data categorically. To compute the change of vision among VA measurements with a mixed continuous and categorical scale, one is forced either to assign scores or describe the change among category percentages.

Contrast threshold, another measure of visual function, reflects the degree of contrast (darkness) needed to distinguish an item from its underlying background. Some disorders such as optic neuritis may not affect VA (which is usually tested under high-contrast conditions) but may affect the amount of contrast needed to perform tasks such as reading. There are varying tests to measure contrast threshold, with the most common being the Pelli–Robson chart that consists of triplets of letters at decreasing contrast levels. The "log contrast sensitivity" is determined by the faintest triplet of letters for which two of the three letters were correctly identified, although newer methods of scoring have been proposed. The data are reported either as log contrast sensitivity which ranges from 0.00 (the darkest segment) to 2.25 (the lightest segment) or as contrast threshold, which is equal to the reciprocal of the antilog of the contrast sensitivity.

A whole spectrum of other measures of visual function exist. For example, special cards of various sizes test reading rates; and measurements of ability to distinguish different colors can be done using the Farnsworth–Munsell 100-hue test, the Ishihara test, or Hardy–Rand–Rittler plates – the latter two contain dots of primary and secondary colors which test whether an individual can distinguish a particular pattern among the colors. There are tests to determine if the individual is able to fuse correctly the images from both eyes into a single image. Goldmann and Humphrey visual field tests determine the location and extent of peripheral vision or the lack of peripheral vision, which is one of the complications of glaucoma. Instruments for measurement of vision-related **quality of life** have recently become popular with the development of instruments such as the Activities of Daily Vision Scale (ADVS), the VF14, the National Eye Institute Visual Function Questionnaire (NEI-VFQ), and the Refractive Status and Vision Profile (RSVP). These instruments measure the impact of eye disease on the functioning in activities of daily life.

Other commonly occurring ocular measurements are derived from external physical examination of the cornea, iris, lens, retina, and other parts of the eye either during clinical examinations or from photographs, or fluorescein angiography. Retinal photographs and angiography aid in documenting the pathology of retinal vasculature, retinal pigment epithelium, and some aspects of choroidal vasculature. These methods require a trained observer to quantify the features of the disease. A common method of evaluating photographs or angiograms for the presence of particular characteristics is to use numerical scales or grading systems which assign scores that reflect the relative severity of a characteristic. Often, the grades are determined by comparing the characteristics with a set of "standard" photographs or angiograms chosen to represent the severity of the characteristic with a numerical score. Two common examples of these methods include: (i) grading of the degree of nuclear opacity of the lens for classifying cataracts using the four-step Lens Opacity Classification System II (LOCS II) or the decimal LOCS III scales via photograph or slit lamp examination; and (ii) grading of diabetic retinopathy from stereoscopic color fundus photographs using the modified Airlie House classification schemes or from fluorescein angiograms as developed for the Early Treatment Diabetic Retinopathy Study.

Unfortunately, time and space limit the description of the types of ophthalmologic data, and although many have been listed or described, many more have remained unmentioned. But more important than the type(s) of data is the fact that the data from the two eyes of an individual may differ. Some diseases or conditions are *bilateral* (affecting both eyes) and other conditions are *unilateral* (affecting only one eye). Furthermore, bilateral conditions may occur at different times or to different extents. Some treatments may be eye-specific, while others are systemic or affect the person and both eyes. All of these features make analyzing ophthalmologic data more challenging to statisticians.

Common Statistical Issues

The field of ophthalmology and vision research provides a rich source for both the application and the development of statistical theory and methodology. It is safe to say that one could find an application of nearly every major statistical method to the wide array of ophthalmologic data discussed above.

Because of the natural pairing of eyes within individuals, however, ophthalmology has provided particular inspiration for the development of methods for paired, correlated data (*see* **Correlated Binary Data**). Interest in providing designs and analyses that "correctly" estimate and/or account for the associations inherent in paired data have both contributed to and benefited from the increased research in methods for analyzing correlated data over the past decade. Ederer's oft-quoted 1973 paper [2] with the title "Shall we count numbers of eyes or number of subjects?" lays the foundation for interest in this area. In this article, Ederer notes that paired measurements are usually correlated, and explains the consequence of this correlation: positively correlated observations provide *less* statistical information than uncorrelated data when data analysis concerns the *average* of paired measurements, but they provide *more* information than uncorrelated data when the analysis concerns the *difference* of the paired measurements. Thus, using an experimental example, if one is investigating two treatments, where one of the two is applied to each patient (and thus both eyes simultaneously), then the **variance** of the mean

treatment difference using data from both eyes of N patients may not be as small as if $2N$ independent patients provided only one eye observation each. Conversely, if each person receives one treatment in their right eye and the other treatment in their left eye, then the variance of the mean treatment difference using both eyes may be smaller than if using one eye of $2N$ patients. Ederer's article does not go into additional detail, but it provides the basis for subsequent work that treats the eye as the fundamental **unit of analysis**. Thus, the correlation between eye measurements becomes a component in the analysis. This correlation may be a **nuisance parameter** that is required to obtain the "correct" **standard errors**, or it may be the parameter of scientific interest.

It is important to note that it is often useful to consider the patient as the fundamental unit of analysis. Obviously, there are a number of ophthalmologic-related outcomes that can only be obtained on the "person level" instead of the "eye level"; for example, quality of life. For the evaluation of some systemic or bilateral treatments for ocular disease (such as gangcyclovir for CMV retinitis), summarization to a person-level outcome is necessary. For some studies, it is impractical or unethical to observe outcomes on both eyes of patients. For example, with some highly experimental surgical procedures, it may be desirable not to treat one eye of a patient in the event that complications occur or the procedure fails, thereby not risking the loss of vision in at least one eye (although the risk of vision loss from surgery may be lower than the risk associated with no treatment). Eye-specific selection criteria for entry in some studies may also result in patients providing only one eye meeting **eligibility criteria**.

Even when observations specific to each eye are collected, it may be easier to conduct analyses on either a subset of the data or to transform the eye-specific responses to person-specific responses and then apply statistical methods that are appropriate for independent data. Obvious subsets include analyses based on only left eyes, right eyes, or one eye chosen at random. These analyses can suffer from lower efficiency and can possibly provide discordant results [4]. Transformations to person-level responses include using only the worse or better eye of patients, the average of left- and right-eye responses, or a "composite response" approach, which is similar to using the worse eye of each patient but creates additional ordinal steps by treating patients with identical values in both eyes as having a severity score one step greater than patients having worse vision in one eye [3]. Thus, for example, a patient with retinopathy scores of "30" in each eye is assigned a composite response of "30/30", while a patient with retinopathy scores of 30 and 10 is classified as "30/<30", one step lower on the composite response scale. Therefore, if each eye were measured on a scale of (10, 20, 30, 40), the corresponding ordinal composite response index would be (10/10, 20/<20, 20/20, 30/<30, 30/30, 40/<40, 40/40).

The primary advantage of these transformation methods is that they allow one to use standard statistical techniques for analysis. However, there are several problems with these approaches. From a **regression** viewpoint, only models relating person-specific **covariates** can be appropriately constructed for person-level outcomes. To relate eye-specific covariates, some **transformation** of the covariates must be obtained (e.g. the average covariate value). This is a clear example of the **error-in-variables** or exposure **misclassification** problem that will result in estimated effects which are biased relative to the true relationship. In addition, the direct clinical interpretation of an estimated relationship can be lost when using these techniques. It has been shown that the relationship of a person-level covariate to a composite response score can be biased by up to 33% relative to the relationship to the original eye score, with the bias a function of the **correlation** between outcomes [3]. The interpretation of a relationship becomes less clear when based on the average of two eye-specific covariates [4], depending on the goal of the analysis.

In cases in which eye-specific outcomes are collected, it is generally better to construct a statistical model or test which incorporates the relationship between eye responses. When data can be assumed to be from a **multivariate normal distribution**, regression models and testing methods date back to the earliest interest in **multivariate analysis**. Two influential papers by Rosner [8, 9] detail regression models for **bivariate normal data**, with specific application to problems in ophthalmology. These models are flexible enough to allow the response of each eye to be modeled as a function of covariates that are specific to the individual (e.g. gender) and covariates that are specific to the eye (e.g. intraocular pressure). Standard **maximum likelihood** methods are used for estimating and testing parameters.

The single correlation parameter in the standard bivariate normal distribution that, in our context, represents the correlation between left and right eye responses, is often referred to as the *intraclass correlation*. While the models of Rosner detail maximum likelihood estimates of this parameter in conjunction with regression modeling of the bivariate expectations, several other methods have been proposed to estimate this parameter.

When the data cannot be assumed to have a multivariate normal distribution, such as with **binary** and categorical data, different strategies need to be used because of the dearth of an overall multivariate distribution for categorical responses with interpretable parameters. If the scientific questions concern only testing an hypothesis, **nonparametric methods** have been developed for correlated data. For constructing the association between covariates (risk factors and treatment assignments) and ocular outcomes, there has been a tremendous interest in bivariate and more general multivariate models for correlated categorical data that are directly applicable and often inspired by ophthalmologic data. In particular, the papers by Rosner [8, 9] also detail models for **binomially distributed** data. In the context of strategies for correlated binary data, these methods can be classified as *conditional* models, since they model the probability of an outcome in an eye conditional on the outcome of the fellow eye in addition to the covariates of interest. The interpretation of the regression parameters from these models can then be viewed as the effect of a covariate after controling for the outcome status in the fellow eye, and can be viewed as extensions of **beta-binomial** methods. Building upon these models, Rosner & Milton [10] consider significance testing (*see* **Hypothesis Testing**) while Donner [1] and others have proposed alternate approaches based upon adjusting standard **chi-square** statistics.

By contrast to the conditional approaches, many other strategies and models for correlated binary data have been suggested. In particular, methods which model the marginal outcome probability, such as the **generalized estimating equations** methods, have been extensively developed and applied to ophthalmologic problems [7]. The interpretation of the regression parameters from these models is different from the conditional approach in that the parameter represents the effect of a covariate *not* adjusting for the outcome in the fellow eye. Because of the variety of methods that have been proposed, several papers [4, 6] have made comparisons among the approaches with specific application to ophthalmology problems. The key results from these papers have highlighted the inadequacy of ignoring the correlation between ocular outcomes, and have emphasized the difference between conditional and marginal approaches.

The above methods are appropriate when investigating factors associated with the prevalence or incidence of disease outcomes from two eyes. Other scientific questions might concern the factors associated with the time to a particular event, such as the time from enrollment in a clinical trial to a visual acuity worse than 20/200. A variety of methods have been developed for this type of "survival" or "failure time" outcome that occurs from paired eyes, including those that extend the popular **proportional hazards** (**Cox regression**) models.

Ophthalmologic data have also provided inspiration for the investigation of a wide range of biostatistical problems beyond regression models for correlated data. A particularly interesting area is the measurement of visual field function throughout the central retina (the "visual field"). Automated perimetry has gradually become more accepted as the **gold standard** for determining field loss. Individuals are asked to fixate on a central point while flashes of light of varying brightness are presented to the individual at varying locations. The patient then presses a button when the flash is seen. Computerized analysis packages and pre-programmed test patterns have made the standardization of visual field tests much more effective, and produce much more reliable and reproducible results. The result of the test is to produce a grid that maps the ability to detect light across the visual field. Several papers [5] have described methods for analyzing this type of data for the purposes of diagnosis. However, detecting changes over time has proven a formidable task because of the high degree of variability within and between tests, particularly in field areas of damage.

Other ophthalmologic problems have motivated biostatistical research. These include, for example, models and methods for time to visual loss, determining numerical scales and schemes for clinical outcome grading, studying the spatial pattern of retinal structures, estimating **agreement** in binocular data, and interim analyses of clinical trials (*see* **Data and Safety Monitoring**) with long response times or correlated outcomes. It is certain that the field will

continue to provide interesting problems and inspire further methodologic developments in biostatistics.

Optimal Design

Informally, an *optimal design* is one which makes best use of the experimental resources available. We need to define what is meant by "best", to see which designs are best and to see if different definitions of best give markedly different designs (*see* **Experimental Design**).

Models and Parameter Estimates

The aim of any experiment is to estimate the parameters in some model as accurately as possible. Thus, it is natural to define best in terms of the **variance** of the parameter estimates for a **regression** model, and in terms of the variance of estimable **contrasts** of treatment effects in an experimental design model. For either situation we need to specify the model for which parameter estimates are required and the *design region*, the region in which it is possible to experiment.

Let the vector of observed responses be denoted by $\mathbf{y}$ and let the model be given by $\mathrm{E}(\mathbf{y}) = \mathbf{X}\boldsymbol{\beta}$, where we assume that the errors in the observations are independent and have a constant variance denoted by σ^2.

In **simple linear regression**, for example, we have $\boldsymbol{\beta}' = (\beta_0, \beta_1)$ and all the entries in the first column of $\mathbf{X}$ would be 1 and the entries in the second column of $\mathbf{X}$ would be the x values at which the responses were observed. Thus, for each observed y we would have $\mathrm{E}(y) = \beta_0 + \beta_1 x$.

In a design model, $\mathbf{X}$ is the usual design matrix. For a completely randomized design to compare t treatments, for example, we have $\mathrm{E}(y_{ij}) = \mu + \tau_i$, $\boldsymbol{\beta}' = (\mu, \tau_1, \tau_2, \ldots, \tau_t)$ and $\mathbf{X}$ has $t + 1$ columns. If the first n_1 responses are those associated with treatment 1, the next n_2 with treatment 2 and so on, then the first column of $\mathbf{X}$ has all entries equal to 1, the second column has the first n_1 entries equal to 1 and the remainder equal to 0, the third column has the first n_1 entries equal to 0, the next n_2 equal to 1 and the remainder equal to 0, and so on. A **simulation** study comparing 15 designs for 12 models is given in [14].

In regression models it is usually the case that the parameter estimates are unique and we can show that $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$. Thus, $\mathrm{var}(\hat{\boldsymbol{\beta}}) = \sigma^2(\mathbf{X}'\mathbf{X})^{-1}$ and the matrix $X'X$ is called the **information matrix**. If we are interested in predicting the response at some point $\mathbf{x}$ in the design region we would have $\hat{y}(\mathbf{x}) = \mathbf{x}'\hat{\boldsymbol{\beta}}$, with $\mathrm{var}(\hat{y}(\mathbf{x})) = \sigma^2\mathbf{x}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}$. Then we say that a design is *optimal* if it minimizes $\mathrm{var}(\hat{y}(\mathbf{x}))$ or some other function of $\mathrm{var}(\hat{\boldsymbol{\beta}})$. A case study comparing the estimates obtained using a 10-point data set with those obtained from smaller, optimally chosen, subsets appears in [12].

Optimality Criteria

The four most frequently used optimality criteria are A, D, E, and G optimality. In all cases the expressions are given in terms of the **eigenvalues**, $\lambda_1, \lambda_2, \ldots, \lambda_p$ of the information matrix $\mathbf{A} = \mathbf{X}'\mathbf{X}$.

A design is said to be *A-optimal* if the sum of the variance of the parameter estimates is minimized. Thus, we seek to minimize $\mathrm{tr}(\mathbf{A}^{-1}) = \sum_i \lambda_i^{-1}$.

A design is said to be *D-optimal* if the generalized variance of the parameter estimates is minimized. Thus, we seek to minimize $\det(\mathbf{A}^{-1}) = \prod_i \lambda_i^{-1}$.

A design is said to be *E-optimal* if it minimizes the variance of the least well-estimated normalized contrast. Thus, we seek to minimize the largest eigenvalue of $\mathbf{A}^{-1}$; that is, we aim to minimize the largest value of λ_i^{-1}.

A design is said to be *G-optimal* if it minimizes the maximum variance of a predicted value over the design region (*see* **Minimax Theory**).

Other optimality criteria may be preferred; see, for instance, [7] and [10].

It is important to realize that the optimum design is dependent on the postulated model. For example, in a simple linear regression $\mathrm{var}(\hat{\beta}_1) = \sigma^2 / \sum_i (x_i - \overline{x})^2$, where $\overline{x} = \sum_i x_i / N$. Then, with a, perhaps coded, design region $-1 \le x \le 1$, the variance of $\hat{\beta}_1$ is minimized by having half the responses at $x = -1$ and half at $x = 1$. If, however, the initial assumption is incorrect and the response is really quadratic, say, then it will be impossible to detect it with this optimum design. This is why various authors recommend that modifications of optimal designs be used in practice (see, for example, [1], [9], and [16]).

Optimality and Block Designs

In design models the estimates of the elements of $\boldsymbol{\beta}$ are not, in general, unique, but some functions

of them, such as the difference of two treatment estimates, are uniquely estimated. Such functions are called *estimable functions* and can be represented by $\mathbf{c}'\boldsymbol{\beta}$. As we are interested in the design setting, in the treatment parameter estimates and not in the block parameter estimates, we need to use a modified information matrix.

We are only interested in *connected* designs; that is, designs in which every pairwise difference of treatment effects is estimable. Assume there are t treatments and b blocks. Let $Y_{ij} = \tau_i + \beta_j + E_{ij}$, $1 \leq i \leq t$, $1 \leq j \leq b$, although some treatments may not appear in some blocks so the corresponding Y_{ij} do not exist. (*see* **Randomized Complete Block Designs**) It should be noted here that we have assumed that the block and treatment effects do not interact. This is the usual assumption in the literature on blocks designs, and if this is not the case then the conclusions that are drawn from the experiment may be invalid. It can be helpful to test for nonadditivity; Read [13] gives a test and a discussion. Let $\mathbf{N}$ be a $t \times b$ incidence matrix in which the (i,j)th position is the number of times that treatment i is in block j. Let $\mathbf{R}$ be a diagonal matrix with the treatment replication numbers on the diagonal and let $\mathbf{K}$ be a matrix with the block sizes on the diagonal. Then the *information matrix* $\mathbf{A}$ is defined by $\mathbf{A} = \mathbf{R} - \mathbf{N}\mathbf{K}^{-1}\mathbf{N}'$. Let $\mathbf{T}$ be the vector of treatment totals and let $\mathbf{B}$ be the vector of block totals. Then the *reduced normal equations* are given by $\mathbf{A}\hat{\boldsymbol{\tau}} = \mathbf{q}$, where $\mathbf{q} = \mathbf{T} - \mathbf{N}\mathbf{K}^{-1}\mathbf{B}$. We now need an expression for $\hat{\boldsymbol{\tau}}$. In any block design, $\mathbf{A}$ is not of full rank and so no inverse exists. However, it can be shown that in a connected design the rank of $\mathbf{A}$ is $v - 1$. Hence, to get an expression for $\hat{\boldsymbol{\tau}}$ we need to calculate a generalized inverse for $\mathbf{A}$, $\boldsymbol{\Omega}$ say. A *generalized inverse* of $\mathbf{A}$ is a matrix $\boldsymbol{\Omega}$ such that $\mathbf{A}\boldsymbol{\Omega}\mathbf{A} = \mathbf{A}$. One way to get $\boldsymbol{\Omega}$ is to calculate the eigenvalues and corresponding **eigenvectors** of $\mathbf{A}$. Suppose that λ_i is an eigenvalue of $\mathbf{A}$ with corresponding eigenvector $\mathbf{z}_i$. These eigenvectors can be normalized so that $\mathbf{z}_i'\mathbf{z}_m = 0$, unless $i = m$, when it equals 1. Then we can write $\mathbf{A}$ in canonical form as $\mathbf{A} = \sum_i \lambda_i \mathbf{z}_i \mathbf{z}_i'$, and a generalized inverse of $\mathbf{A}$ is $\boldsymbol{\Omega} = \sum_i \lambda_i^{-1} \mathbf{z}_i \mathbf{z}_i'$, where this summation is over the nonzero eigenvalues only. Then $\hat{\boldsymbol{\tau}} = \boldsymbol{\Omega}_q$ and the **covariance matrix** of $\hat{\boldsymbol{\tau}}$ is $\sigma^2\boldsymbol{\Omega}$. Note that the variance of estimable functions of the treatment parameters is independent of the particular generalized inverse used. The previous definitions of optimality can now be used with $\boldsymbol{\Omega}$ replacing $\mathbf{A}^{-1}$ throughout.

Efficiency

The final topic that we will discuss is that of *efficiency*. This is the ratio of the optimality value of the optimal design to that of the proposed design. Clearly, the efficiency of the optimal design is 1, and so all other designs have a lower efficiency. The higher the efficiency, the better the design.

There are other efficiency measures that are unique to designed experiments. For blocked experiments the variance of the pairwise differences of treatments (*see* **Paired Comparisons**) is compared with the variance that would be obtained in a completely randomized design with the same replication as the blocked experiment for each of the treatments. In a completely randomized design with equal replication r, say, for each of the treatments, we see that $\text{var}(\hat{\tau}_i - \hat{\tau}_m) = 2\sigma^2/r$. For a block design in which each treatment is replicated r times, the *pairwise efficiency factor* is the ratio of $2\sigma^2/r$ to $\text{var}(\hat{\tau}_i - \hat{\tau}_m)$. The ratio of $2\sigma^2/r$ to the average variance of the treatment differences is the *average efficiency factor*.

For **balanced incomplete block designs**, we get $\boldsymbol{\Omega} = k/\lambda v(\mathbf{I} - \mathbf{J}/v)$ and so each pairwise efficiency factor is $\lambda v/rk$ and hence so is the average efficiency factor. For **partially balanced incomplete block designs** with two associate classes (PBIBD (2)) a similar result can be obtained. In this case, there are two pairwise efficiency factors, one for comparing first associates and one for comparing second associates. The values are given for the designs tabulated by Clatworthy [4], as well as the general expressions for any PBIBD (2).

Bounds on the efficiency factors of pairwise comparisons may be found in [8]. **Algorithms** for constructing designs such as GENDEX [6] and the algorithm given by Paterson et al. [11] look for designs which are close to the upper bound for efficiency.

Other Topics

Optimal designs for bivariate **logistic regression** appear in [7]. Optimal design of LD50 bioassay (*see* **Biological Assay, Overview**) is discussed in [10] and references cited therein. Optimal design of **validation studies** is considered in [15]. Optimal design of **Phase II clinical trials** is discussed in [5]. An introduction to the issues involved in the design of

optimal **crossover trials** is given in [3]. A package to construct optimal designs for a batch reaction catalyzed by a soluble enzyme where the activity of the enzyme decays with time is described in [2].

Optimization and Nonlinear Equations

Optimization means finding that value of $\mathbf{x}$ which maximizes or minimizes a given function $f(\mathbf{x})$. The idea of optimization goes to the heart of statistical methodology, as it is involved in solving statistical problems based on **least squares**, **maximum likelihood**, posterior mode (*see* **Bayesian Methods**), and so on.

A closely related problem is that of solving a nonlinear equation,

$$\mathbf{g}(\mathbf{x}) = \mathbf{0}$$

for $\mathbf{x}$, where $\mathbf{g}$ is a possibly multivariate function. Many algorithms for minimizing $f(\mathbf{x})$ are in fact derived from algorithms for solving $\mathbf{g} = \partial f/\partial \mathbf{x} = \mathbf{0}$, where $\partial f/\partial \mathbf{x}$ is the vector of derivatives of f with respect to the components of $\mathbf{x}$.

Except in linear cases, optimization and equation solving invariably proceed by iteration. Starting from an approximate trial solution, a useful algorithm will gradually refine the working estimate until a predetermined level of precision has been reached. If the functions are smooth, a good algorithm can be expected to converge to a solution when given a sufficiently good starting value.

A good starting value is one of the keys to success. In general, finding a starting value requires heuristics and an analysis of the problem. One strategy for fitting complex statistical models, by maximum likelihood or otherwise, is to progress from the simple to the complex in stages. Fit a series of models of increasing complexity, using the simpler model as a starting value for the more complicated model in each case. Maximum likelihood iterations can often be initialized by using a less efficient moment estimator (*see* **Method of Moments**). In some special cases, such as **generalized linear models**, it is possible to use the data themselves as starting values for the fitted values.

An extremum (maximum or minimum) of f can be either *global* (truly the extreme value of f over its range) or *local* (the extreme value of f in a neighborhood containing the value); see Figure 1. Generally it is the global extremum that we want. (A maximum likelihood estimator, for example, is by definition the global maximum of the likelihood.)

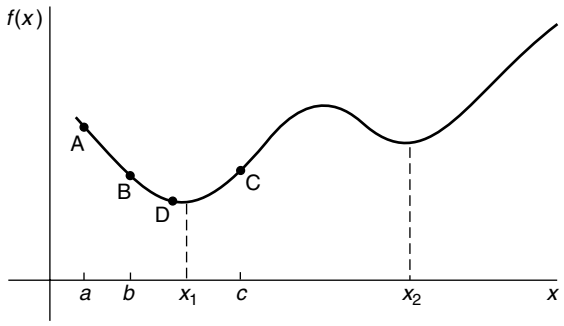

Figure 1 The function $f(x)$ has a local minimum at x_2 and a global minimum at x_1. The points $\mathrm{A} = [a, f(a)]$, $\mathrm{B} = [b, f(b)]$, and $\mathrm{C} = [c, f(c)]$ bracket the global minimum. The next point tried by a golden section search would be D

Unfortunately, distinguishing local extrema from the global extremum is not an easy task. One heuristic is to start the iteration from several widely varying starting points, and to take the most extreme (if they are not equal). If necessary, a large number of starting values can be randomly generated. Another heuristic is to perturb a local extremum slightly to check that the **algorithm** returns to it. Two relatively recent types of algorithms, simulated annealing and genetic algorithms, are often used successfully on problems where there are a large number of closely competing local extrema. Simulated annealing handles multiple minima by introducing a stochastic element into the interaction, which allows it to escape from local extrema by temporarily increasing the objective function. Genetic algorithms handle multiple minima by remembering at each iteration a set of candidate parameter estimates instead of just one.

This article discusses *unconstrained optimization.* Sometimes, however, $\mathbf{x}$ must satisfy one or more constraints. An example is some of the components of $\mathbf{x}$ being known a priori to be positive. In some cases the constraints may be removed by a suitable transformation ($x_i = \mathrm{e}^{z_i}$, for example), or by use of Lagrange multipliers.

One must choose between algorithms which use derivatives and those which do not. In general, methods which use derivatives are more powerful. However, the increase in speed does not always outweigh the extra overheads in computing the derivatives, and it can be a great convenience for the user not to have to program them.

Algorithms are also distinguished by the amount of memory they consume. Storage requirements are typically order N or order N^2, where N is the dimension of $\mathbf{x}$. In most biostatistical applications, N is not usually so large that storage becomes an issue.

If you can calculate first and second derivatives of f, then the well-known *Newton's method* is simple and works well. It is crucially important, though, to check the function value $f(\mathbf{x})$ at each iteration, and to implement some sort of backtracking strategy, to prevent the Newton iteration from diverging to distant parts of the parameter space from a poor starting value. If second derivatives are not available, then *quasi-Newton* methods, of which Fisher's method of scoring is one, can be recommended. General-purpose quasi-Newton algorithms build up a working approximation to the second-derivative matrix from successive values of the first derivative. If computer memory is very critical, then *conjugate gradient* methods make the same assumptions as quasi-Newton methods but require only order N storage [8, Section 10.6]. If even first derivatives are not available, the Nelder–Mead *downhill simplex* algorithm is compact and reasonably robust. However, the slightly more complex *direction-set* methods or Newton methods with finite difference approximations to the derivatives should minimize most smooth differentiable functions, with fewer function evaluations. Whilst all the above comments apply generally, the one-dimensional problem is something of a special case. In one dimension, once one can provide an interval which contains the solution, there exist efficient "low-tech" algorithms robust enough to take on all problems.

A practical introduction to root finding and optimization is given in Chapters 9, 10, and 15 (Sections 15.5 and 15.7) of *Numerical Recipes* [8]. More specialist texts are Dennis & Schnabel [2], Fletcher [3], and Gill et al.[4]. A classic but technical text on solving nonlinear equations is Ortega & Rheinboldt [6]. A survey of available software is given by Moré & Wright [5].

One Dimension

The case where x is one-dimensional is qualitatively simpler than the multidimensional case. This is because a solution can be trapped between bracketing values, which are gradually brought together. A root of $g(x)$ is bracketed in the interval (a, b) if $g(a)$ and $g(b)$ have opposite signs. A minimum of $f(x)$ is bracketed by a triplet of values, $a < b < c$, if $f(b)$ is less than both $f(a)$ and $f(c)$.

The simplest and most robust method for finding a root in a bracketing interval is *bisection*. That is, we evaluate the function g at the midpoint of (a, b) and examine its sign. The midpoint then replaces whichever end point has the same sign. After k iterations, the root is known to lie in an interval of length $(b - a)/2^k$.

The equivalent method for function minimization is the *golden section search*. Given a bracketing triplet of points, the next point to be tried is that which is a fraction 0.38197 of the way from the middle point of the triplet to the farther end point (Figure 1). One then drops whichever of the end points is farthest from the new minimum. The strange choice of step size ensures that at each iteration the middle point is always the same fraction of the way from one end point to the other (the so-called golden ratio). After k iterations, the minimum is bracketed in an interval of length $(c - a)0.61803^k$.

Bisection and golden section search are linear methods, in that the amount of work required increases linearly with the number of significant figures required for x. There are a number of other methods, such as the *secant method*, the *method of false position, Muller's method*, and *Ridder's method*, which are capable of *superlinear convergence*, wherein the number of significant figures liberated by a given amount of computation increases as the algorithm converges. The basic idea is that g should be roughly linear in the vicinity of a root. These methods interpolate a line or a quadratic polynomial through two or three previous points, and use the root of the polynomial as the next iterate. They therefore converge more rapidly than bisection or golden search when the function g is smooth, but can converge slowly when g is not well approximated by a low-order polynomial. They also require modification if they are not to risk throwing the iteration outside the bracketing interval known to contain the root.

It is an advantage to use one of the higher-order interpolating methods when the function g is nearly linear, but to fall back on the bisection or golden search methods when necessary. In that way a rate of convergence at least equal to that of the bisection or golden section methods can be guaranteed, but higher-order convergence can be enjoyed when it is

possible. Brent [1, 8] has published methods which do the necessary bookkeeping to achieve this, and which can be generally recommended for root finding or minimizing in one dimension. Brent's algorithms do not require the derivatives of f or g to be supplied. However, the method for minimizing a function can be easily modified to make use of the derivative when it is available [8].

Newton's Method

The most celebrated of all methods for solving a nonlinear equation is *Newton's method*, also called *Newton–Raphson*. Newton's method is based on the idea of approximating $\mathbf{g}$ with its linear Taylor series expansion about a working value $\mathbf{x}_k$. Let $\mathbf{G}(\mathbf{x})$ be the matrix of partial derivatives of $\mathbf{g}(\mathbf{x})$ with respect to $\mathbf{x}$. Using the root of the linear expansion as the new approximation gives

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \mathbf{G}(\mathbf{x}_k)^{-1}\mathbf{g}(\mathbf{x}_k)$$

(see Figure 2).

The same algorithm arises for minimizing $f(\mathbf{x})$ by approximating f with its quadratic Taylor series expansion about $\mathbf{x}_k$. In the minimization case, $\mathbf{g}(\mathbf{x})$ is the derivative vector (gradient) of $f(\mathbf{x})$ with respect to $\mathbf{x}$ and the second derivative matrix $\mathbf{G}(\mathbf{x})$ is symmetric. Beware, though, that Newton's method as it stands will converge to a maximum just as easily as to a minimum.

If f is a log **likelihood** function, then $\mathbf{g}$ is the score vector and $-\mathbf{G}$ is the observed **information matrix**. Newton's method for maximizing the likelihood is based on the same quadratic expansion which underlies asymptotic maximum likelihood theory.

Newton's method is powerful and simple to implement. It will converge to a fixed point from any sufficiently close starting value. Moreover, once it starts to home in on a root, the convergence is quadratic. This means that, if the error is ε, the error after one more iteration is of order ε^2. In other words, the number of significant places eventually doubles with each iteration. However, its global convergence properties are poor. If $\mathbf{x}_k$ is unlucky enough to occur near a turning point of $\mathbf{g}$, then the method can easily explode, sending the next estimate far out into the parameter space (Figure 3). In fact, the set of values for which Newton's method does and does not converge can produce a fractal pattern [8].

The problems with Newton's method are: (i) an inability to distinguish maxima from minima; and (ii) poor global convergence properties. Both problems can be solved effectively through a *restricted step* suboptimization [3]. Suppose we want to minimize $f(\mathbf{x})$. A condition for a minimum is that $\mathbf{G}(\mathbf{x})$ be positive definite. We therefore add a diagonal matrix to $\mathbf{G}$ to ensure that it is positive definite:

$$\mathbf{x}_{k+1} = \mathbf{x}_k - [\mathbf{G}(\mathbf{x}_k) + \lambda_k \mathbf{I}]^{-1}\mathbf{g}(\mathbf{x}_k).$$

It is always possible to choose λ_k sufficiently large so that $f(\mathbf{x}_{k+1}) < f(\mathbf{x}_k)$. A simple algorithm then is to choose λ_k just large enough to ensure a descent step. As the iteration converges to a minimum, λ_k can be decreased towards zero so that the algorithm enjoys superlinear convergence. This is the algorithm of choice when derivatives of f are available.

Solving $\mathbf{g}(\mathbf{x}) = 0$, when $\mathbf{g}$ is not the gradient of some objective function f, is slightly more difficult.

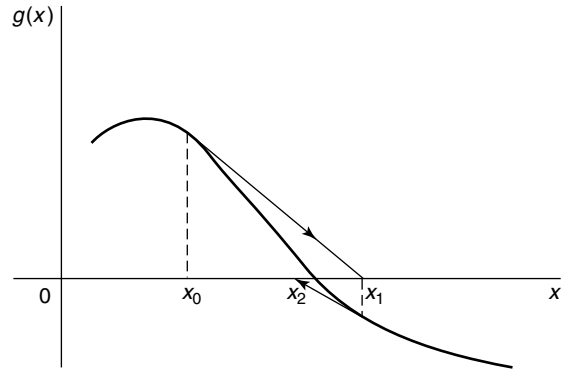

Figure 2 Newton's method converges quadratically from the starting value x_0

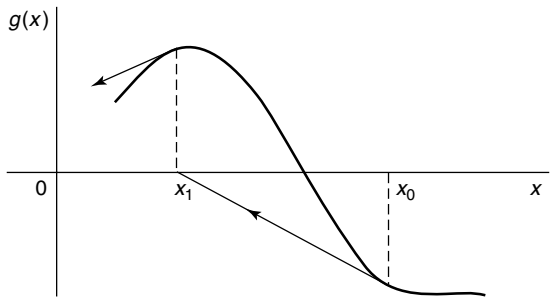

Figure 3 Newton's method diverges from the starting value x_0

One can manufacture a stand-in objective function by defining

$$f(\mathbf{x}) = \mathbf{g}(\mathbf{x})^{\mathrm{T}}\mathbf{g}(\mathbf{x}).$$

Then the root of $\mathbf{g}$ occurs at a minimum of f. Note, however, that $\mathbf{g}$ is not the derivative of f, so that the above restricted step strategy is not available. In this case we can replace the Newton step with the *line search* strategy,

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha_k \mathbf{G}(\mathbf{x}_k)^{-1}\mathbf{g}(\mathbf{x}_k),$$

where $0 < \alpha_k < 1$. It is always possible to choose α_k sufficiently small that $f(\mathbf{x}_{k+1}) < f(\mathbf{x}_k)$. The line search idea is to implement a one-dimensional suboptimization at each step, minimizing $f(\mathbf{x}_{k+1})$ approximately with respect to α_k.

Both the restricted step and the line search algorithms have global convergence properties. They can be guaranteed to find a local minimum of f and a root of $\mathbf{g}$ if such exist subject only to some standard regularity conditions such as differentiability.

Quasi-Newton Methods

One of the drawbacks of Newton's method is that it requires the analytic derivative $\mathbf{G}$ at each iteration. This is a problem if the derivative is very expensive or difficult to compute. In such cases it may be convenient to iterate according to

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \mathbf{A}_k^{-1}\mathbf{g}(\mathbf{x}_k),$$

where $\mathbf{A}_k$ is an easily computed approximation to $\mathbf{G}(\mathbf{x}_k)$. For example, in one dimension, the *secant method* approximates the derivative with the difference quotient

$$a_k = \frac{g(x_k) - g(x_{k-1})}{x_k - x_{k-1}}.$$

Such an iteration is called a *quasi-Newton* method. If $\mathbf{A}_k$ is positive definite, as it usually is, an alternative name is *variable metric* method.

One positive advantage to using an approximation in place of $\mathbf{G}$ is that $\mathbf{A}_k$ can be chosen to be positive definite, ensuring that the step will not be attracted to a maximum of f when one wants a minimum. Another advantage is that $\mathbf{A}_k^{-1}\mathbf{g}(\mathbf{x}_k)$ is a descent direction from $\mathbf{x}_k$, allowing the use of line searches.

The best known quasi-Newton method in statistical contexts is Fisher's method of scoring, which is treated in more detail below. Among general purpose quasilikelihood algorithms, the best is probably the *Broydon–Fletcher–Goldfarb–Shanno* (BFGS) algorithm. BFGS builds upon the earlier and similar *Davidon–Fletcher–Powell* algorithm. BFGS starts with a positive-definite matrix approximation to $\mathbf{G}(\mathbf{x}_0)$, usually the identity matrix. At each iteration it makes a minimalist (rank two) modification to $\mathbf{A}_k^{-1}$ to gradually approximate $\mathbf{G}(\mathbf{x}_k)^{-1}$. Both DFP and BFGS are robust algorithms showing superlinear convergence.

Statisticians might fall into the trap of thinking that the final approximation $\mathbf{A}_k^{-1}$ is a good approximation to $\mathbf{G}^{-1}(\mathbf{x}_k)$ at the final estimate. Since $\mathbf{A}_k$ is chosen to approximate $\mathbf{G}(\mathbf{x}_k)$ only in the directions needed for the Newton step, it is useless for the purpose of providing standard errors for the final estimates.

Fisher's Method of Scoring

Of frequent interest to statisticians is the case where $f(\mathbf{x})$ is a log likelihood function and $\mathbf{x}$ is the vector of unknown parameters. Then $\mathbf{g}$ is the score vector and $-\mathbf{G}$ is the observed information matrix. For many models (curved **exponential families** are the major class), the Fisher **information**, $\mathcal{I}(\mathbf{x}) = \mathrm{E}[-\mathbf{G}(\mathbf{x})]$, is much simpler in form than $-\mathbf{G}(\mathbf{x})$ itself. Furthermore, since $\mathcal{I}(\mathbf{x}) = \mathrm{var}[\mathbf{g}(\mathbf{x})]$, $\mathcal{I}(\mathbf{x})$ is positive definite for any parameter value $\mathbf{x}$ for which the statistical model is not degenerate. The quasi-Newton method which replaces $-\mathbf{G}(\mathbf{x})$ with $\mathcal{I}(\mathbf{x})$ is known as *Fisher's method of scoring* [7, Section 5g]. Fisher scoring is linearly convergent, at a rate which depends on the relative difference between observed and expected information [10].

Consider the special case of nonlinear least squares, in which context Fisher scoring has a very long history and is known as the *Gauss–Newton* algorithm. The objective function is

$$f(\boldsymbol{\beta}) = \sum_{i=1}^{n} [y_i - \mu(\mathbf{t}_i, \boldsymbol{\beta})]^2,$$

where the y_i are observations and μ is a general function of covariate vectors $\mathbf{t}_i$ and the vector of unknown parameters $\boldsymbol{\beta}$. Write $\mathbf{y}$ for the vector of y_i, $\boldsymbol{\mu}$ for the vector of $\mu(\mathbf{t}_i, \boldsymbol{\beta})$, and $\dot{\boldsymbol{\mu}}$ for the derivative

matrix of $\boldsymbol{\mu}$ with respect to $\boldsymbol{\beta}$. The Fisher scoring iteration becomes

$$\boldsymbol{\beta}_{k+1} = \boldsymbol{\beta}_k + (\dot{\boldsymbol{\mu}}^{\mathrm{T}}\dot{\boldsymbol{\mu}})^{-1}\dot{\boldsymbol{\mu}}^{\mathrm{T}}(\mathbf{y} - \boldsymbol{\mu}),$$

where all terms on the right-hand size are evaluated at $\boldsymbol{\beta}_k$. The updated estimate is obtained by adding to $\boldsymbol{\beta}_k$ the coefficients from the multiple regression of the residuals $\mathbf{y} - \boldsymbol{\mu}$ on the derivative matrix $\dot{\boldsymbol{\mu}}$. Gauss–Newton therefore solves the nonlinear least squares problem by way of a series of linear regressions.

The Gauss–Newton algorithm can be speeded-up considerably in the special case that some of the $\boldsymbol{\beta}$ appear linearly in μ. For example, if

$$\mu(t_i; \boldsymbol{\beta}) = \beta_1 \exp(-\beta_3 t_i) + \beta_2 \exp(-\beta_4 t_i),$$

then β_1 and β_2 are linear parameters. In such cases, the Gauss–Newton iteration can be restricted to the nonlinear parameters, β_3 and β_4. This idea is known as *separable* least squares; see, for example, Seber & Wild [9, Section 14.7]. Smyth [10] discusses the same principle in the context of maximum likelihood estimation.

Perhaps the most important application of Fisher scoring is to generalized linear models (GLMs). GLMs extend the idea of nonlinear regression to models with nonnormal error distributions, including **logistic regression** and **loglinear** models as special cases. GLMs assume that y_i is distributed according to a probability density or mass function of the form

$$p(y; \theta_i, \sigma^2) = a(y, \sigma^2) \exp\left\{\frac{1}{\sigma^2}[y\,\theta_i - b(\theta_i)]\right\}$$

for some functions b and a (a curved exponential family). We find that $\mathrm{E}(y_i) = \mu_i = b'(\theta_i)$ and $\mathrm{var}(y_i) = \sigma^2 v(\mu_i)$, where $v(\mu_i) = b''(\theta_i)$. If the mean μ_i of y_i is as given above for the nonlinear least squares, then the Fisher scoring iteration for $\boldsymbol{\beta}$ is a slight modification of the Gauss–Newton iteration:

$$\boldsymbol{\beta}_{k+1} = \boldsymbol{\beta}_k + (\dot{\boldsymbol{\mu}}^{\mathrm{T}}\mathbf{V}^{-1}\dot{\boldsymbol{\mu}})^{-1}\dot{\boldsymbol{\mu}}^{\mathrm{T}}\mathbf{V}^{-1}(\mathbf{y} - \boldsymbol{\mu}),$$

where $\mathbf{V}$ is the diagonal matrix of the $v(\mu_i)$. The update for $\boldsymbol{\beta}$ iteration is still obtained from a linear regression of the residuals on $\dot{\boldsymbol{\mu}}$, but now the observations are weighted inversely according to their variances.

Classical GLMs assume a link-linear model of the form

$$h(\mu_i) = \mathbf{x}_i^{\mathrm{T}}\boldsymbol{\beta}$$

for some link function h. In that case the Fisher scoring update can be reorganized as

$$\boldsymbol{\beta}_{k+1} = (\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{z},$$

where $\mathbf{z}$ is a working vector with components $z_i = h'(\mu_i)(y_i - \mu_i) + h(\mu_i)$ and $\mathbf{W}$ is a diagonal matrix of working weights $1/[h''(\mu_i)^2 v(\mu_i)]$. The updated $\boldsymbol{\beta}$ is obtained from weighted linear regression of the working vector $\mathbf{z}$ on $\mathbf{X}$. Since $\mathbf{X}$ remains the same throughout the iteration, but the working weights change, this iteration is known as *iteratively reweighted least squares* (IRLS).

When the observations y_i follow an exponential family distribution, observed and expected information coincide, so that Fisher scoring is the same as Newton's method. For GLMs this is so if h is the *canonical link*. We can conclude from this that IRLS is quadratically convergent for logistic regression and loglinear models, but linearly convergent for binomial regression with a probit link, for example (*see* **Quantal Response Models**). In practice, rapid linear regression is difficult to distinguish from quadratic convergence.

Nonderivative Methods

The Nelder–Mead *downhill simplex algorithm* is a popular derivative-free optimization method. It is based on the idea of function comparisons amongst a simplex of $N + 1$ points. Depending on the function values, the simplex is reflected or shrunk away from the maximum point. Although there are no theoretical results on the convergence of the algorithm, it works very well on a range of practical problems. It is a good choice if a once-off solution is required with minimum programming effort or if the function to be minimized is not differentiable.

If you are prepared to use a more complex program and if the function to be optimized is smoothly differentiable, the best performing methods for optimization without derivatives are quasi-Newton methods with difference approximations for the gradient vector. These programs require only the objective function as input, and compute difference approximations for the derivatives internally. Note that this is different from computing numerical derivatives and inputting them as derivatives to a program designed to accept analytic derivatives. Such a strategy is unlikely to be successful, as the numerical derivatives

are unlikely to show the assumed analytic behavior.

Close competitors to the finite-difference methods are *direction set methods*. These methods perform one-dimensional line searches in a series of directions which are chosen to be approximately *conjugate*, i.e. orthogonal with respect to the second derivative matrix. The best current implementation is given by Brent [1].

EM Algorithm

The **EM algorithm** is not an optimization method in its own right, but rather a statistical method of making optimization easier. The idea is the possibility that the log likelihood $\ell(\mathbf{y};\boldsymbol{\theta})$ might be easier to maximize if there were additional observations or information. Let $\mathbf{z}$ be the completed data, and let $\ell(\mathbf{z};\boldsymbol{\theta})$ be the log likelihood for $\mathbf{z}$. Maximizing the *incomplete* likelihood $\ell(\mathbf{y};\boldsymbol{\theta})$ is equivalent to maximizing the conditional expectation of the *complete* likelihood given $\mathbf{y}$, $\mathrm{E}[\ell(\mathbf{z};\boldsymbol{\theta})|\mathbf{y})$. In most cases, the EM is applied when the complete likelihood can be maximized in one step. However, the conditional expectation changes with the updated estimate of $\boldsymbol{\theta}$. So the optimization proceeds by alternate steps of expectation and maximization – hence the name "EM".

The EM algorithm is linearly convergent, at a rate which depends on the proportion of observed to unobserved Fisher information. Let ρ be the fraction of the Fisher information for a particular parameter in the complete log likelihood $\ell(\mathbf{z};\boldsymbol{\beta})$ which is not actually observed. Then the error in the estimate for that parameter after each iteration is $\varepsilon_{k+1} \approx \rho\varepsilon_k$. The proportion ρ can in applications be very close, or even equal, to one for some parameters, so that convergence can be very slow. On the other hand, the EM algorithm normally converges even from poor starting values. The iteration can often be speeded up by *Aitkin acceleration*, which attempts to convert linear convergence into quadratic convergence [8, p. 92].

Software

Optimization software is included in the commercial subroutine libraries IMSL and NAG, and in many statistical programs such as SAS, **S-PLUS, R**, MATLAB, and Gauss (*see* **Software, Biostatistical**). Publicly available software can be obtained by searching the NETLIB online library at `http://www.netlib.org/`. The guides and software provided by the Optimization Technology Center at the Argonne National Laboratory at the URL, `http://www.ece.northwestern.edu/OTC`, are also worth considering. Less elaborate programs suitable for user modification can be found in *Numerical Recipes* [8].

Optres Rotation

Optres rotation [2, 3] is a nonquartic method of performing an oblique rotation of a matrix $\mathbf{V}$ of dimension $(p \times k)$ made up of vectors associated with **principal components analysis** or **factor analysis** in order to transform these quantities into new variables by the relationship $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$ such that $\mathbf{B}$ will approximate a **simple structure**. The matrix $\mathbf{B}$ is of dimension $(p \times k)$ and the matrix $\boldsymbol{\Theta}$ is of dimension $(k \times k)$ (*see* **Rotation of Axes**). Optres rotation is essentially an enhancement of a conventional **oblique rotation**. The principle feature of Optres rotation is that it requires, for each vector, a specification of the variables (called *salient* variables) whose rotated coefficients should be maximized and the nonsalient variables whose coefficients should be minimized. This specification is done by means of an algorithm applied to the results of another oblique rotation such as **Promax**. The Optres rotation then produces a new rotation subject to the constraints associated with the identified variables. Since Promax, itself, requires an orthogonal rotation, such as **Varimax**, for its starting approximation, Optres rotation is a three-step procedure.

The Optres procedure is based on the following criterion:

$$Q_j = M({v_{j(\mathrm{s})}}^2) - cM({v_{j(\mathrm{ns})}}^2) = \max,$$

where $M({v_{j(\mathrm{s})}}^2)$ is the mean of the squared loadings of the salient variables of component or factor j (*see* **Factor Loading Matrix**), $M({v_{j(\mathrm{ns})}}^2)$ is the mean of the squared loadings of the nonsalient variables of component or factor j, and c is a constant designed to give equal importance to these two quantities. Hakstian recommended $c = 50$, but Cureton [1] felt that $c = 100$ was more appropriate.

For the Decathlon example given in the article **Rotation of Axes**, the Optres solutions for $c = 50$ and $c = 100$ are given in Table 1 along with the original principal component characteristic vectors (*see* **Eigenvector**).

Order Statistics

The order statistics of a collection of data or **random variables** are their ordered values. More precisely, if $X_1, \ldots, X_n$ is a collection of random variables with ordered values

$$X_{(1)} \leq X_{(2)} \leq \cdots \leq X_{(n)},$$

then their rth order statistic is the rth smallest among them, $X_{(r)}$. Thus $X_{(1)}$ and $X_{(n)}$ are, respectively, the sample minimum and maximum. Clearly the order statistics are not independent. In principle the order statistics are certain to be unequal when the underlying data are continuous, but in practice this depends on the degree of rounding to which they are subject.

The order statistics are widely used as the basis of estimators and assessment of fit, but they have many other uses. Simple statistics based on them include:

1. The sample **median**,

$$\text{median}_j X_j = \begin{cases} X_{((n+1)/2)}, & n \text{ odd}, \\ \frac{1}{2}(X_{(n/2)} + X_{(n/2+1)}, & n \text{ even}. \end{cases}$$

2. The α trimmed mean,

$$\frac{1}{n-2r} \sum_{j=r+1}^{n-r} X_{(j)}, \tag{1}$$

where r is the integer part of αn, which gives the sample average when $\alpha = 0$ and is interpreted as the median when $\alpha = 0.5$ (*see* **Trimming and Winsorization**).

3. The median absolute deviation (MAD),

$$\text{median}_i |X_i - \text{median}_j X_j|.$$

4. The interquartile range (IQR), $X_{(m_2)} - X_{(m_1)}$, where m_2 and m_1 are the integer parts of $\frac{3}{4}n$ and $\frac{1}{4}n$.
5. The **range**, $R = X_{(n)} - X_{(1)}$.

The first two of these are estimates of the location of the sample, while the last three can be used to estimate its dispersion. The median, trimmed mean, interquartile range, and MAD are little affected by **outliers**, while the range is badly affected by them because it depends on the most extreme observations in the sample. The median, trimmed mean, interquartile range, and range are linear combinations of order statistics, a class of quantities called L statistics.

Linear interpolation between adjacent order statistics is often used in small samples; an example is provided by the median above.

For illustration, consider the following data, which show the differences between the numbers of attacks of angina pectoris that were suffered by 12 patients, each of whom was given two different treatments [4, p. 16]:

$$-25 \quad 2 \quad 2 \quad 3 \quad 5 \quad 7 \quad 7 \quad 7 \quad 9 \quad 14 \quad 19 \quad 42.$$

Their median is 7, their 25% trimmed mean 6.33, their interquartile range 7, their MAD 4.5, and their range 67. If the lowest difference of -25 is replaced by -125, than the values of the first four are unchanged, but the range becomes 167. The average and sample standard deviation for the original data are 7.67 and 15.11; for the modified data they are -0.67 and 40.69. Statistics such as the average, sample standard deviation, and range are sensitive to the values of extreme observations, and for this reason *robust estimates* of location and scale are often based on combinations of nonextreme order statistics (*see* **Robustness**). In this example the rounding is severe enough to give a number of ties.

Exact Distributions

Suppose that $X_1, \ldots, X_n$ are independent identically distributed continuous random variables with cumulative distribution function (cdf) F and probability density function (pdf) f. Then the rth order statistic, $X_{(r)}$, has cdf

$$\Pr(X_{(r)} \leq x) = \sum_{i=r}^{n} \binom{n}{i} F^i(x)[1 - F(x)]^{n-i} \tag{2}$$

and pdf

$$\frac{n!}{(n-r)!(r-1)!} F^{r-1}(x)[1 - F(x)]^{n-r} f(x). \tag{3}$$

Eq. (2) follows because the event $X_{(r)} \leq x$ occurs if and only if at least r of X_j are less than or equal to x, and these events are independent and

each has probability $F(x)$. Expression (3) is obtained on differentiating (2). When the distribution F is discrete, the possibility of ties among the $X_1, \ldots, X_n$ makes the corresponding formulas messy.

If F is known, then expressions for the mean, variance, and other moments of $X_{(r)}$ can be established from (3). For example, if the X_j have the **exponential** pdf $f(x) = \lambda \exp(-\lambda x), x > 0$, then it is fairly straightforward to show that for $r = 1, \ldots, n-1$ the differences of order statistics $X_{(r+1)} - X_{(r)}$ are independent exponential variables with means $\lambda^{-1}/(n-r)$. Consequently

$$\lambda \mathrm{E}(X_{(r)}) = e(r, n) = \sum_{j=1}^{r} (n + 1 - j)^{-1}.$$

The quantities $e(r, n)$, sometimes called exponential scores, are useful in assessing the fit of the exponential distribution. In a plot of the order statistics against the $e(r, n)$, a straight line indicates perfect fit of the distribution to the data, with the slope giving an estimate of λ^{-1}, while departures from exponentiality will show as different types of curvature. Probability plots such as this are widely used for assessing fit. The best known of them is based on **normal scores**, and is used to check normality of a sample of data. In such plots it often suffices to replace the rth expected order statistic by $F^{-1}[r/(n+1)]$, which is an approximation to the r/n **quantile** of F, though in particular cases better approximations are sometimes available.

The joint pdf of any subset of order statistics can be written down in a form that generalizes (3), and expressions for their covariances and other properties obtained. For example, the expected value of the range of $n = 12$ independent normal variables with variance σ^2 is 3.26σ, so for the sample above an estimate of σ based on the range is $R/3.26 = 20.55$. Estimates such as this are easy to calculate and hence are widely used in quality control, where the sample size may be tiny, but their sensitivity to outliers makes them too unreliable for general use.

The exact joint distribution of order statistics is also useful in testing for outliers. For example, if $X_1, \ldots, X_n$ is thought to be a sample from the exponential distribution, except that the largest observation may be an outlier, then a standard test rejects the null hypothesis of no outlier for large values of $T = X_{(n)} / \sum X_j$. The statistic T has a **beta distribution** when there is no outlier, so exact calculation of the significance level is straightforward. Barnett & Lewis [3] is a compendium of such tests, many of which rely on order statistics.

The cdf (2) is the basis for a simple nonparametric **confidence interval** for the p quantile of F, i.e. the value x_p such that $F(x_p) = p$; we suppose that $f(x_p) > 0$, so x_p is unique. Suppose that we choose s and r so that as nearly as possible,

$$\Pr(x_p \le X_{(s)}) = \alpha, \qquad \Pr(X_{(r)} \le x_p) = \alpha;$$

$(X_{(s)}, X_{(r)})$ is then an approximately equi-tailed $1 - 2\alpha$ confidence interval for x_p. Since $x_p = F^{-1}(p)$, we should take the values of r and s so that

$$\sum_{j=0}^{s-1} \binom{n}{j} p^j (1-p)^{n-j} \doteq \alpha;$$

$$\sum_{j=r}^{n} \binom{n}{j} p^j (1-p)^{n-j} \doteq \alpha.$$

For illustration, suppose that a confidence interval is required for the median $x_{0.5}$ of the population of differences underlying the sample given above. In this case $n = 12$, and with $p = 0.5$ we find that $s = 3$ and $r = 10$ gives endpoints (2,14) for a 96% confidence interval for $x_{0.5}$.

Approximate Distributions

The exact formulas (2) and (3) for the pdf and cdf of the rth order statistic can be difficult to work with. Fortunately, there is a simple approximation for the pdf of a central order statistic. Suppose that r is the integer part of pn, where $0 < p < 1$, and let x_p denote the p quantile of F. As before, we suppose that $f(x_p) > 0$. Then in large samples the approximate distribution of $X_{(r)}$ is

$$X_{(r)} \dot{\sim} \mathrm{N}\left[x_p, \frac{p(1-p)}{n f^2(x_p)}\right]. \tag{4}$$

Thus the sample median can be used to estimate the median of the population from which the sample is drawn, and other order statistics can be used to estimate their corresponding quantiles. The result (4) shows that the limiting distribution of the median of a sample of size n from the $\mathrm{N}(\mu, \sigma^2)$ distribution is normal with mean μ and variance $\pi\sigma^2/(2n)$,

and that for such a sample the IQR and MAD have expected values 1.35σ and 0.675σ; thus IQR/1.35 and MAD/0.675 are the corresponding robust estimates of σ.

One consequence of (4) is that although nonparametric estimation of a population quantile is straightforward, it is much harder to give an accurate statement of its uncertainty in small samples. For we see from (4) that the problem of estimating the variance of $X_{(r)}$ is tantamount to estimating the density $f(\cdot)$ at x_p, and accurate **density estimation** needs large samples because nonparametric density estimators converge only slowly.

Under mild conditions on F, (4) extends to any fixed number of central order statistics. Consider $X_{(r_1)} \leq \cdots \leq X_{(r_k)}$, where r_j is the integer part of np_j, and $0 < p_1 < \cdots < p_k < 1$, and for $j = 1, \ldots, k$ let $x_{p_j} = F^{-1}(p_j)$ and suppose that $f(x_{p_j})$ is positive and finite. Then the joint limiting distribution of $X_{(r_1)}, \ldots, X_{(r_k)}$ is **multivariate normal** with means $x_{p_1}, \ldots, x_{p_k}$ and covariances given by $p_i(1 - p_j)/[nf(x_{p_i})f(x_{p_j})]$, where $j \geq i$. This implies, for example, that the IQR has a limiting normal distribution, because it is a difference of the two approximately bivariate normal random variables obtained by taking $p_1 = 0.25$ and $p_2 = 0.75$.

These limiting distributions do not apply to an order statistic $X_{(r)}$ for any fixed r, since in that case $r/n \to 0$ as $n \to \infty$, corresponding to $p = 0$. In this situation the approximate distributions that apply are those for extreme values, and it is possible to show that if there are sequences a_n and b_n such that $Y_{(n+1-r)} = a_n(X_{(n+1-r)} - b_n)$ has a nondegenerate limiting distribution as $n \to \infty$, then the pdf of $Y_{(n+1-r)}$ must have the form

$$\frac{1}{\tau(r-1)!}\left[1 + \kappa\left(\frac{y-\eta}{\tau}\right)\right]^{-r/\kappa - 1} \times \exp\left\{-\left[1 + \kappa\left(\frac{y-\eta}{\tau}\right)\right]^{-1/\kappa}\right\},$$
$$-\infty < \eta, \kappa < \infty, \tau > 0,$$

where the range of y is such that $1 + \kappa(y - \eta)/\tau > 0$. Such distributions are useful in a wide range of applications, more details of which are given in the article on **extreme values**, and in [8] and [10].

L statistics such as (1) are widely used, but appropriate distributional approximations are not immediate from the discussion above because they depend neither on extreme values nor on a fixed number of order statistics. Such a linear combination can be written as

$$T = n^{-1}\sum_{r=1}^{n} w\left(\frac{r}{n}\right) X_{(r)},$$

where $w(u)$ is a function of u, for $0 \leq u \leq 1$, which ascribes weights to the order statistics. For the α trimmed mean, for example,

$$w(u) = \begin{cases} 1, & \alpha \leq u \leq 1 - \alpha, \\ 0, & \text{otherwise.} \end{cases}$$

Then under mild conditions on $w(\cdot)$ and F, a general result [12] is that T has an approximate normal distribution with mean and variance

$$\int w[F(x)]x \, \mathrm{d}F(x),$$
$$\frac{2}{n}\int_{-\infty}^{\infty} \mathrm{d}x \int_{x}^{\infty} \mathrm{d}y \, w[F(x)]w[F(y)]F(x)[1 - F(y)]. \tag{5}$$

This result is theoretically useful because the conditions are mild and easy to verify for particular choices of $w(\cdot)$, and because estimates of the variance in (5) can form the basis of uncertainty statements for the estimator T.

Bibliography

The huge literature on order statistics to 1981 is surveyed by David [5], with a more recent book-length treatment by Arnold et al. [2]. David [6] gives a brief survey, while Galambos [7] is a somewhat longer fairly mathematical account. Reiss [10] focuses particularly on approximate distributions useful in nonparametric statistics, while Resnick [11] discusses extreme-value approximations. Arnold & Balakrishnan [1] give a compendium of order statistic approximations. References to order statistics of the more common continuous distributions are given by Johnson et al. [9].

Ordered Alternatives

In experiments to determine whether a particular chemical causes cancer in laboratory animals, the dose response is an important indication of possible carcinogenicity. If the test chemical is a carcinogen, then in general the higher the dose the more animals develop cancer. The dose response in toxicity assays is an important example of ordered alternatives.

Do children tend to lie more as they grow older? Here we would like to known if the lying tendency is related monotonically to age. Does drinking during pregnancy increase the risk of congenital malformation? Are younger cancer patients more prone to multiple malignancies? These are some illustrative examples of ordered alternatives in biostatistics.

Let $d_1 < d_2 < \cdots < d_{k-1} < d_k$ denote ordered values associated with k groups. There may, for instance, be k levels of chemical dose in toxicity assays. They may represent k age groups. The values are not necessarily quantitative but can be ordinal values such as $1, 2, \ldots, k$, denoting unquantifiable k values. We assume that the increasing d value also increases the outcome value under the **alternative hypothesis**, generating ordered alternatives.

Ordered Alternative in Binomial Probabilities

Suppose that n_i animals are assigned to the d_i dose group, and that $n_i\mu_i$ animals are expected to develop a particular type of tumor, where μ_i is an unknown probability of developing the tumor during the study period. We are interested in testing the **null hypothesis** that $\mu_1 = \mu_2 = \cdots = \mu_k$ against the ordered alternative that $\mu_1 \le \mu_2 \le \cdots \le \mu_k$ with at least one strict inequality. Let Y_i denote the number of animals developing the tumor of interest in the d_i dose group. Y_i is a **binomial** random variable. We would like to determine whether the higher dose increases the risk of the tumor. For such an analysis, the usual **chi-square test** with $k-1$ **degrees of freedom** is inappropriate, because it is directed toward finding if μ_is are different rather than if μ_is increase with increasing dose. The χ^2 statistic is given by $\sum n_i(\hat{\mu}_i - \hat{\mu})^2/\hat{\mu}(1-\hat{\mu})$, where $\hat{\mu}_i = y_i/n_i$ is the observed proportion of animals developing the tumor of interest and $\hat{\mu} = \sum y_i / \sum n_i$ is the overall observed proportion of animals developing the tumor.

An appropriate test statistic for the ordered alternative is

$$Z_{\mathrm{L}} = \frac{\sum d_i Y_i - \hat{\mu} \sum n_i d_i}{\left[\hat{\mu}(1-\hat{\mu}) \sum n_i (d_i - \overline{d})^2\right]^{1/2}},$$

where $\overline{d}$ is $\sum n_i d_i / \sum n_i$ (*see* **Trend Test for Counts and Proportions**). If $Z_{\mathrm{L}} \ge z_{1-\alpha}$, then the null hypothesis is rejected and the chemical is considered to cause the tumor. Here, $z_{1-\alpha}$ is the upper α cutoff point of the standard **normal distribution**. In applying the Z_{L}, it is assumed that μ_i is related to d_i linearly, i.e. $\mu_i = a + bd_i$. When such an assumption is improper, we can apply

$$Z_{\mathrm{M}} = \frac{\sum i Y_i - \hat{\mu} \sum i n_i}{\left[\hat{\mu}(1-\hat{\mu}) \sum n_i (i - \overline{i})^2\right]^{1/2}},$$

where $\overline{i} = \sum i n_i / \sum n_i$. If $Z_{\mathrm{M}} \ge z_{1-\alpha}$, then the null hypothesis is rejected in favor of the ordered alternative. Both Z_{L} and Z_{M} statistics are considered **nonparametric** [1], while the Z_{M} statistic is applicable to broader ordered alternatives than the Z_{L} statistic.

Ordered Alternative in Poisson Means

The test statistic based on $\sum d_i Y_i$ or $\sum i Y_i$ is applicable to ordered alternatives in means of k **Poisson** distributions. Let Y_i be a Poisson random variable with mean $w_i\mu_i$ for $i = 1, \ldots, k$, where w_i is a known weight variable and μ_i is an unknown parameter which is ordered under the alternative hypothesis, namely $\mu_1 \le \mu_2 \le \cdots \le \mu_k$ with at least one strict inequality. For example, suppose that Y_i is a binomial random variable with sample size n_i and probability $\mu_i = p(d_i)$, and that $p(d_i)$ is an unknown function of given dose $d_i, d_1 < d_2 < \cdots < d_k$. Furthermore, assume that μ_i is very small. Then Y_i is considered a Poisson random variable with mean of $n_i\mu_i$.

We know that $(Y_1, \ldots, Y_k)$ is a **multinomial** vector with $(N, w_1\mu_1/\sum w_i\mu_i, \ldots, w_k\mu_k/\sum w_i\mu_i)$, conditional on $N = \sum Y_i$. Lee [6] showed that both the $\sum d_i Y_i$ and $\sum i Y_i$ statistics are applicable to testing the null hypothesis against the ordered alternative, although $\sum i Y_i$ is more broadly applicable than

$\sum d_i Y_i$. For given N and w_is, we can obtain exact distributions of $\sum d_i Y_i$ and $\sum i Y_i$ statistics under the null hypothesis that μ_is are constant for all i. For notational convenience assume that $\sum w_i = 1$ and that $\sum w_i \mu_i = 1$. Under the null hypothesis, $T_{\mathrm{M}} = (\sum i Y_i - n \sum i w_i)/\{N[\sum i^2 w_i - (\sum i w_i)^2]\}^{1/2}$ is an asymptotic standard normal random variable, and thus if N is large and $T_{\mathrm{M}} \geq z_{1-\alpha}$, then the null hypothesis is rejected. We can apply $T_{\mathrm{L}} = (\sum d_i Y_i - n \sum d_i w_i)/\{N[\sum d_i^2 w_i - (\sum d_i w_i)^2]\}^{1/2}$ to testing somewhat narrower ordered alternatives [6].

In testing ordered alternatives in Poisson means, we can apply the best asymptotic normal **(BAN)** estimation method [4]. For a small to moderate sample size, the BAN estimation method can fail [7]. Furthermore, test statistics $\sum i Y_i$ and $\sum d_i Y_i$ are asymptotically **efficient** [10].

Ordered Alternative in Multinomial Probabilities

Let $(Y_1, Y_2, \ldots, Y_k)$ be a k-variate multinomial vector with sample size N and probabilities $(w_1\mu_1, w_2\mu_2, \ldots, w_k\mu_k)$, where $\sum w_i \mu_i = 1$ and $\sum w_i = 1$. Under the null hypothesis, $\mu_i = \mu_j$ for $i \neq j$, and under the alternative, $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_k$, with at least one strict inequality. We can apply $\sum i Y_i$ to testing the ordered alternative. Examples of ordered alternatives in multinomial probabilities can be found in [5] and [6].

Nonparametric Tests for Ordered Alternatives in Means of Continuous Distributions

Suppose that Y_{ij} is an independent random variable with distribution function $F(y_{ij} - \mu_i)$ for $i = 1, \ldots, k$ and $j = 1, \ldots, n_i$. This is a one-way **analysis of variance** situation where the form of the underlying distribution is unknown. Under the null hypothesis, $\mu_i = \mu_{i'}$ for $i \neq i'$, and under the alternative, $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_k$ with at least one strict inequality. If $k = 2$, then we can apply the **Wilcoxon–Mann–Whitney** two-sample test statistic. For $k > 2$, we compute the Mann–Whitney version of the Wilcoxon–Mann–Whitney statistic for every pair of $1 \leq i < i' \leq k$, and sum $k(k-1)/2$ Mann–Whitney statistics. This statistic was proposed for testing the ordered alternative by Jonckheere [3].

Let $I(a < b) = 1$ if $a < b$, 0 if $a > b$, and $\frac{1}{2}$ if $a = b$. For $i < i'$, let $U_{ii'} = \sum_{u=1}^{n_i} \sum_{v=1}^{n_{i'}} I(y_{iu} < y_{i'v})$. The Jonckheere statistic is given by $J = \sum_{i=1}^{k-1} \sum_{i'=i+1}^{k} U_{ii'}$. The exact null distribution of J for $k = 3, 4, 5, 6$ and small n_is is available [2]. Under the null hypothesis, $\mathrm{E}_0(J) = (N^2 - \sum_{i=1}^{k} n_i^2)/4$ and $\mathrm{var}_0(J) = [N^2(2N+3) - \sum_{i=1}^{k} n_i^2(2n_i+3)]/72$, where $N = \sum n_i$. For a large $\min(n_i, i = 1, \ldots, k)$, if $[J - \mathrm{E}_0(J)]/[\mathrm{var}_0(J)]^{1/2} \geq z_{1-\alpha}$, then the null hypothesis is rejected in favor of the ordered alternative at significance level α. When some blocks are incompletes because of missing observations, see the methods presented in [9].

When observations are collected in n blocks of size k, we cannot apply the Jonckheere test because of the possible block effect. k is the number of treatment groups. In this case, the Page statistic [8] is a relatively simple and easy to use method to test the ordered alternative. Suppose that Y_{ij} is an independent random variable with distribution function $F(y_{ij} - \mu_i - \theta_j)$ for $i = 1, \ldots, k$ and $j = 1, \ldots, n, \theta$ is a block effect, and the parameter of interest is μ, the treatment effect. Under the null hypothesis, $\mu_i = \mu_{i'}$ for $i \neq i'$, and under the alternative, $\mu_1 \leq \mu_2 \leq \cdots \leq \mu_k$ with at least one strict inequality.

Let r_{ij} be the **rank** of y_{ij} among $(y_{1j}, y_{2j}, \ldots, y_{(i-1)j}, y_{ij}, \ldots, y_{kj})$, k observations of the jth block. Let $R_i = \sum_{j=1}^{n} r_{ij}$. The Page statistic for testing the ordered alternative is given by $L = \sum_{i=1}^{k} i R_i$. Exact cutoff points for given significance levels of 0.001, 0.01, and 0.05 are given for $k = 3, \ldots, 8$ for small to moderate n [2]. Under the null hypothesis, $\mathrm{E}_0(L) = nk(k+1)^2/4$ and $\mathrm{var}_0(L) = n(k^3 - k)^2/144(k-1)$. For a large n, if $[L - \mathrm{E}_0(L)]/[\mathrm{var}_0(L)]^{1/2} \geq z_{1-\alpha}$, then the null hypothesis is rejected in favor of the alternative hypothesis at the given significance level α. When some blocks are incomplete because of missing observations, see the methods presented in [9].

Ordered Categorical Data

The methodology considered herein complements general methodology for categorical data analysis (*see*, for example, **Categorical Data Analysis**; **Contingency Table**; **Loglinear Model**), but it differs from the general methodology in that a natural ordering is assumed for one or more of the categorical variables of interest. Ordered categorical data are ubiquitous in the medical and health sciences, and research into methodology for the analysis of such data has been vigorous over the past 20 or so years.

An observed variable that is ordered categorical may arise as the result of **categorizing a continuous variable**, or it may be an inherently categorical measurement. It is routine medical practice to classify patients as being at various degrees of risk for developing a disease or condition according to specified ranges on risk factors (*see* **Prognostic Factors for Survival**). In cardiovascular disease, for example, important risk factors are serum cholesterol and blood pressure levels. These variables are intrinsically continuous, but for some purposes, such as classifying patients into groups or levels of risk, it is useful to analyze them as ordered categorical variables; see, for example, [49]. However, in classifying levels of pain relief attained with a treatment it is often only possible to arrive at subjective categorizations, such as "no relief", "some relief", "considerable relief", or "complete relief". Likewise, clinical assessments of mental health status are sometimes based on a numerical scoring system for one or more functional items or tasks (*see* **Scores**), and at other times according to a subjective clinical evaluation. Even when the observed data arise from the subjective assignment of an observed response into a category on an ordered scale, it might be assumed that there does indeed exist an underlying continuous random variable for which the discrete classification is an imperfect measure. The issue of whether the observed variable or the underlying continuous variable is of primary interest sparked a contentious debate between **Karl Pearson** [50] and **G. Udny Yule** [58, 59] in the early part of this century. Those issues will not be revisited here, but rather I cover methodology developed from both points of view.

It should be noted that methodology developed for categorical data in general can be applied to the analysis of ordered categorical data. There are, however, important advantages to using models and methodology developed to explicitly take account of the ordinal structure of the categories. In particular, models for ordered categorical data tend to be more **parsimonious** than their more general counterparts, thus resulting in more **efficient** inferences and facilitating interpretation of parameters and economical presentation of results. The ability to focus hypothesis tests on restricted alternatives specific to the ordinal structure of the data often results in tests that are substantially more **powerful** (for the alternatives of interest) than those that cover omnibus alternatives; see, for example [3, pp. 269, 282–283] (*see* **Isotonic Inference**).

The models and methodology outlined herein focus on two general areas of statistical analysis: (i) **association** and (ii) **regression**. The study of **correlation** and **linear regression** are central to any development of models and methodology for the analysis of continuous variables, and the situation is no different for categorical variables. Many of the models, measures, and parameters that I consider here have analogous counterparts in **general linear models** for continuous data, e.g. in ordinary linear regression and in the **analysis of variance**. There are, of course, important issues particular to the analysis of ordered categorical data, and those are the primary focus of this article.

Models for the analysis of association are the first topic I consider. The **odds ratio** serves as the focus of much of the modern analysis of **binary data**, and the models I consider for the analysis of association build on that work by focusing also on the use of odds ratios in summarizing associations. Regression models for the analysis of an ordered categorical response are covered subsequently. The approach taken is to focus on models that generalize (extend) **logistic regression** modeling of a binary response. I conclude with a brief discussion of recent developments and ongoing lines of research on the analysis of ordered categorical data.

It is impossible to cover all approaches to the analysis of ordered categorical data here. It is inevitable that some topics are omitted, intentionally or otherwise, or not covered as fully as some others. For example, ordinal probit models (*see* **Quantal Response Models**) are mentioned only briefly. In such cases, I have attempted to provide citations to papers and books that will assist the interested reader in exploring those areas.

Models for Association

The correlation coefficient is the standard measure for the assessment of (linear) association between two continuous variables, and the parameters in a classical linear regression are readily related to it. The odds ratio plays the parallel role in the modeling and analysis of categorical data. Here, I work within the context of two-way contingency tables; citations to literature on multivariate generalizations are given subsequently. Continuous variables are introduced in the subsequent section on regression-type models. There are immediate connections between models for odds ratios and regression models for categorical data, just as there are immediate connections between partial correlations and regression coefficients in ordinary linear regression.

Odds Ratios for $I \times J$ Contingency Tables

Let π_{ij} denote the probability associated with the cell in row i and column j of the $I \times J$ table $(i, = 1, \ldots, I; \quad j = 1, \ldots, J)$, and let n_{ij} denote the corresponding observed count. The letters R and C are used to denote the row variable and the column variable, respectively. A loglinear representation of the saturated model (i.e. the only constraints placed on the cell probabilities follow from the axioms of probability) is

$$\ln \pi_{ij} = \lambda + \lambda_i^{\mathrm{R}} + \lambda_j^{\mathrm{C}} + \lambda_{ij}^{\mathrm{RC}},$$

where the λ terms are parameters to be estimated from the data. The model of statistical independence is the reduced model where $\lambda_{ij}^{\mathrm{RC}} = 0$ for all pairs (i, j). The association between R and C is captured by the $\lambda_{ij}^{\mathrm{RC}}$ terms, and contrasts of the $\lambda_{ij}^{\mathrm{RC}}$ terms are readily interpreted in terms of log odds ratios for 2×2 subtables of the complete table, i.e.

$$\ln\left(\frac{\pi_{ij}\pi_{i'j'}}{\pi_{ij'}\pi_{i'j}}\right) = \lambda_{ij}^{\mathrm{RC}} - \lambda_{ij'}^{\mathrm{RC}} - \lambda_{i'j}^{\mathrm{RC}} + \lambda_{i'j'}^{\mathrm{RC}}.$$

All possible local log odds ratios may be completely characterized by a set of $(I-1)(J-1)$ local log odds ratios, and the model of independence for the complete table is equivalent to independence in all $(I-1)(J-1)$ subtables. When at least one of the variables is ordered, there are parsimonious models between statistical independence and the saturated model that have been found to be extremely useful in empirical work for characterizing the pattern of association.

Loglinear Models of Association

Goodman [29] and Haberman [35] considered simple loglinear models for the association in contingency tables having ordered categories. Goodman specified models in terms of the basic set of local odds ratios $\theta_{ij} = (\pi_{ij}\pi_{i+1,j+1})/(\pi_{i,j+1}\pi_{i+1,j})$, and in particular the models of *uniform association, row effects association, column effects association*, and row + column *effects association* are:

$$\begin{aligned}
\text{uniform} &: \theta_{ij} = \theta, \\
\text{row effects} &: \theta_{ij} = \theta_i, \\
\text{column effects} &: \theta_{ij} = \theta_j, \\
\text{row + column effects} &: \theta_{ij} = \theta_{1i}\theta_{2j},
\end{aligned}$$

where $i = 1, \ldots, I-1$, $j = 1, \ldots, J-1$. The uniform association model takes the local association, as characterized by local odds ratios, to be constant throughout the table. The row effects association model summarizes the local association in terms of $I-1$ odds ratios θ_i, and, likewise, the column effects association model summarizes the local association in terms of $J-1$ local odds ratios θ_j. The row + column effects model allows for additive variation of the local log odds ratios. Corresponding loglinear models for the cell probabilities restrict the $\lambda_{ij}^{\mathrm{RC}}$ parameters by assigning scores to the categories of one or both of the variables cross-classified. For example, in the uniform association model $\lambda_{ij}^{\mathrm{RC}} = \beta u_i v_j$, where the u_i are equally spaced and the v_j are equally spaced. Note that $\ln\theta = \beta[(u_{i+1} - u_i)(v_{j+1} - v_j)]$, and that there is no loss in generality in assuming the scores $u_i = i$ and $v_j = j$. This model is also known as the model of linear-by-linear association [3, 35] when the scores, or the distances between them, are fixed but not assumed to be equally spaced. Inferences are necessarily sensitive to the choice of scores [34], but these simple loglinear models provide a useful starting point for exploring associations between ordered categorical variables.

Example 1: Association Between Mental Health Status and Socioeconomic Status

In a now classic study of mental health in Manhattan, New York, Srole et al. [53] explore the relationship,

among others, between mental impairment and parents' socioeconomic status. Table 1, from that study, has been used extensively (see, for example [3, 23, 29, 32], and [33]) to illustrate the utility and application of models for ordered categorical data.

Residual degrees of freedom and deviance statistics for loglinear association models applied to this table are reported in Table 2. Note that under the assumption of multinomial sampling for the n_{ij} a deviance statistic equals minus two times the log likelihood ratio statistic, with an asymptotic **chi-square distribution** under the assumed model, for testing model **goodness of fit** (*see* **Likelihood Ratio Tests**). The hypothesis of statistical independence between mental health status and parents' socioeconomic status is rejected, both by the omnibus test of goodness of fit (deviance = 47.42, on 15 df) and by the more focused test of independence versus uniform association (deviance = 47.42 − 9.90 = 37.52, on 1 df). The uniform association model provides an excellent fit to these data (deviance = 9.90, on 14 df), and likelihood ratio comparisons of uniform association to the row effects, column effects, and row + column effects association models do not yield evidence of departures from uniform association in favor of these more general models. The **maximum likelihood** estimate $\hat{\beta}$ of β under uniform association is 0.09, with an estimated asymptotic **standard error** of 0.015. Hence, there is strong evidence that mental health status and parents' socioeconomic status are positively associated (i.e. higher socioeconomic status is associated with better mental health), but the strength of that association is quite small, i.e. an approximate 95% **confidence interval** for the uniform local odds ratio is (1.06, 1.13), as compared with the value 1.00 for independence.

Table 1 The Midtown Manhattan Study: mental health and parents' socioeconomic status

Parents' socioeconomic status	Mental health status			
	Well	Mild symptom formation	Moderate symptom formation	Impaired
A (high)	64	94	58	46
B	57	94	54	40
C	57	105	65	60
D	72	141	77	94
E	36	97	54	78
F (low)	21	71	54	71

Table 2 Models summary for Table 1

Model	Degrees of freedom	Deviance
Independence	$(I-1)(J-1)=15$	47.42
Uniform association	$(I-1)(J-1)-1=14$	9.90
Row effects	$(I-1)(J-2)=10$	6.83
Column effects	$(I-2)(J-1)=12$	6.28
Row + column effects	$(I-2)(J-2)=8$	3.05

All of the above models are appropriate when both variables are ordered, but assuming fixed scores does have limitations. Assigning fixed scores to a variable implies a specified ordering and spacing to the categories. That may not be desirable or realistic for some ordered variables, and it is inappropriate for a nominal variable. The row effects (column effects) model does not assume fixed scores for the row (column) categories, and hence it can be used to estimate row (column) scores, and to analyze nominal–ordinal (ordinal–nominal) cross-classifications of counts; see, for example, [1], and [23]. The row + column effects model includes both fixed and estimated scores for both variables.

RC and Quasi-Symmetric RC Models

The preceding loglinear models are immensely useful, but they cannot be used to describe all data sets encountered in practice. An intrinsically nonlinear model that is a simple generalization of the linear-by-linear association model is

$$\ln(\pi_{ij}) = \lambda + \lambda_i^{\mathrm{R}} + \lambda_j^{\mathrm{C}} + \beta\mu_i\nu_j,$$

where the μ_i and ν_j are scores to be estimated from the data [11, 29]. Hereafter, we refer to this model as the *RC association* model. Setting $\Delta_i^{\mathrm{R}} = \mu_{i+1} - \mu_i$ and $\Delta_j^{\mathrm{C}} = \nu_{j+1} - \nu_j$, the local log-odds ratios are of the form

$$\ln(\theta_{ij}) = \beta\Delta_i^{\mathrm{R}}\Delta_j^{\mathrm{C}}.$$

The row effects and column effects models are special cases of the RC model where one of the two sets of scores are constrained to be equally spaced.

There are many instances in biostatistical practice where there is a one-to-one correspondence between the categories of two, or more, ordered categorical variables. It is frequently the case in

this situation that questions arise regarding issues of symmetry, be they in terms of the joint distribution of the variables, the marginal distributions of the variables, or in the association as summarized by local odds ratios. Models that exhibit symmetric marginal distributions are said to satisfy marginal homogeneity, and models of symmetric association are said to exhibit **quasi-symmetry**. Quasi-symmetry corresponds to symmetry in the association, but asymmetry in the joint distribution. The special case of the RC association model where the row and column scores are constrained to be equal (i.e. $\mu_i = \nu_i$, $i = 1, \ldots, I$) is a restricted form of quasi-symmetry. Models of this type have been considered by Agresti [2], Becker [17], and Goodman [29, 32], among others. Note that the uniform association model is the special case of the quasi-symmetric RC model where the scores are assumed to be equally spaced. Introducing the constraint $\lambda_i^{\mathrm{R}} = \lambda_i^{\mathrm{C}} (i = 1, \ldots, I)$ along with symmetric association results implies a symmetric joint distribution, and hence marginal homogeneity. In general, symmetry in the joint distribution is equivalent to marginal homogeneity and symmetric association holding simultaneously.

The RC association model is not a loglinear model or **generalized linear model**, and as such it is not readily estimated with standard computer programs for fitting generalized linear (or loglinear) models (*see* **Software, Biostatistical**). **Algorithms** that can be used to fit the model, as well as some generalizations of it, are described in Goodman [29], Becker [18], and Haberman [36]. It is also possible to program in some statistical packages, such as GLIM and SAS, to fit the RC association model; see, for example [1, Appendix D].

Example 2: Reliability of Self-Reported Passive Smoking Histories

Exposure to passive **smoking** has been studied as a possible risk factor for lung cancer, and hence reliable measures of exposure to passive smoking are required. The data I consider here are from a study of the reliability of passive smoking histories [51]. A sample of 177 controls from a case–control study of lung cancer were interviewed on two different occasions with respect to exposure to occupational and residential passive smoke. Subjects were to indicate the number of regular smokers with whom they had resided. The results for the residential histories are given in Table 3.

Table 3 Exposure to passive smoking in the residence: number of smokers resided with

First interview	Second interview			
	0	1	2	3+
0	19	7	1	2
1	2	15	18	10
2	1	5	5	6
3+	1	4	3	18

Table 4 Models summary for Table 3

Model	Degrees of freedom	Deviance
Independence	9	69.02
Uniform association	8	24.41
Row effects	6	13.47
Column effects	6	17.02
Row + column effects	4	10.05
RC	$(I-2)(J-2) = 4$	10.36
Quasi-symmetric RC	$(I-2)(J-1) = 6$	10.59

Residual degrees of freedom and deviance statistics for both loglinear association models and RC-type models are presented in Table 4. Again, there is strong evidence of a departure from statistical independence (deviance = 69.02, on 9 df), but in this case models more general than uniform association are better suited for summarizing the degree to which the first and second interview responses are associated. The conditional test of quasi-symmetric RC association vs. RC association provides a direct means for testing the assumption of homogeneous scores; there is no reason to reject the null hypothesis that the scores are homogeneous (deviance = $10.59 - 10.36 = 0.23$, on 2 df). In addition, the quasi-symmetric RC model provides a reasonable summary of these data (deviance = 10.59, on 6 df). The $\hat{\Delta}_i$, $i = 1, 2, 3$, scaled for direct comparison to the uniform distances equal 1, are (1.67, 0.36, 0.97), and $\hat{\beta} = 0.88$. The interested reader is referred to Becker [14] for discussion of how the estimated scores from the fit of the quasi-symmetric RC model may be used to measure and characterize the reliability of the residential passive smoking histories within the framework developed by Darroch & McCloud [26] for analyzing observer agreement (*see* **Agreement, Measurement of**). Comments

Models for local association provide a useful starting point for the analysis of two-way cross-classifications where at least one of the variables cross-classified is ordered categorical. These models are not predicated on the assumption of an underlying continuous distribution for the ordered categorical variable(s), but there are close connections between some of the models and the **bivariate normal distribution** for continuous data [15, 30, 39]. Generalizations of the RC model to accommodate more general association structures have been developed (see, for example, [17, 20, 32], and [33]), as have generalizations for higher-way contingency tables (see, for example, [6, 16, 20, 22, 28, 29], and [33]).

In the case of the doubly ordered contingency table, global cross-ratios [24] provide an alternative odds-ratio measure of association. Models for global cross-ratios have been considered by Dale [25], Heagerty & Zeger [37], Molenberghs & Lesaffre [48], and Williamson et al. [57], among others. All of these authors also consider the joint modeling of the marginal distributions (*see* **Marginal Models**) and the association structure, which can be extremely useful for some purposes. Global cross-ratio models also do not require the assumption of an underlying continuous bivariate distribution, but certain models can be motivated in terms of a multivariate Plackett distribution [25, 48]. The joint modeling of marginal distributions and local association structure is considered by Lang & Agresti [43]. Multivariate probit models [10, 13, 41, 44, 46] (*see* **Quantal Response Models** for a definition of the univariate probit) are an approach to the analysis of ordered categorical that do assume an underlying continuous distribution conditional on covariates, the **multivariate normal**. In all of these papers the authors also specify regression models for the (univariate marginal) response distributions, and so now we turn to the modeling of ordered categorical responses.

Regression Models for an Ordered Categorical Response

Logistic regression is a regression model for a binary response variable. The link between the response, "success" or "failure", to a set of predictor variables or covariates is through a linear regression model for the log-odds for success versus failure. That is, let $\pi(\mathbf{x}_i)$ denote the probability of success for subject i, or for a group of n_i subjects, with covariate vector $\mathbf{x}_i$. Let logit $(\mathbf{x}_i)] = \ln\{\pi(\mathbf{x}_i)/[1 - \pi(\mathbf{x}_i)]\}$ denote the so-called logit for observation i. Then the standard logistic regression model is

$$\text{logit}[\pi(\mathbf{x}_i)] = \beta_0 + \beta'\mathbf{x}_i,$$

where β_0 is the intercept term.

In moving from the case of a binary response to an ordered categorical response there are multiple approaches to defining logits for the response. The three logits that figure most prominently in the biostatistics literature are adjacent-categories logits, continuation-ratio logits, and cumulative logits. For the purposes of exposition we take the number of categories for the response to be J, and hence for each set of logits it is necessary to construct $J - 1$ logits. Let $\pi_j(\mathbf{x}_i)$ denote the probability of response category j, given the covariate vector $\mathbf{x}_i$, and let $\gamma_j(\mathbf{x}_i) = \sum_{k=1}^{j} \pi_k(\mathbf{x}_i)$. Then the respective logits are defined as follows:

Adjacent-categories logits:

$$L_j(\mathbf{x}_i) = \ln\left[\frac{\pi_j(\mathbf{x}_i)}{\pi_{j+1}(\mathbf{x}_i)}\right], \quad j = 1, \ldots, J-1.$$

Continuation-ratio logits:

$$L_j(\mathbf{x}_i) = \ln\left\{\frac{\pi_j(\mathbf{x}_i)}{[1 - \gamma_j(\mathbf{x}_i)]}\right\}, \quad j = 1, \ldots, J-1.$$

Cumulative logits:

$$L_j(\mathbf{x}_i) = \ln\left\{\frac{\gamma_j(\mathbf{x}_i)}{[1 - \gamma_j(\mathbf{x}_i)]}\right\}, \quad j = 1, \ldots, J-1.$$

The definitions of the adjacent-categories logits and the cumulative logits are invariant with respect to reversing the ordering of the response categories, but the high-to-low ordering of the categories gives a different set of continuation ratio logits than are obtained with the low-to-high ordering. The decision of which set of logits to use, and which ordering in the case of continuation-ratio logits, should be based on the substantive questions of interest that are to be addressed in the statistical analysis.

Given a set of logits $L_j(\mathbf{x}_i)$, a general logit linear regression model is of the form

$$L_j(\mathbf{x}_i) = \beta_{0j} + \beta_j'\mathbf{x}_i.$$

Note that there is a separate intercept β_{0j} for each logit. The interpretation of the regression coefficients is specific to the form of the logits modeled. Models where the vectors of regression coefficients β_j are constrained to be equal for all $j = 1, \ldots, J-1$ are referred to as **proportional-odds models**. It is most common to see the proportional-odds assumption used with cumulative logits, and McCullagh [45] has been highly influential in promoting the use of proportional-odds cumulative logit models.

In general, adjacent-categories linear logit models can be estimated using software for fitting loglinear or generalized linear models, and continuation-ratio linear logit models can be estimated using software for fitting logistic regression models. Fitting cumulative linear logit models under the proportional-odds assumption requires specialized software, such as that documented in Stokes et al. [54]. The interested reader is referred to Agresti [3] for discussion of how standard statistical software can be used to fit certain ordered categorical linear logit models.

Example 3: Evaluation of Treatment Effects for Relief of Arthritis Pain, by Gender

It is common in clinical trials of treatments for **pain** relief to record an ordered categorical response variable with categories ranging from no relief to substantial or complete relief. The data used in Table 5 to illustrate and compare the results obtained with the three types of logits are from a clinical study comparing an active treatment to a placebo treatment for arthritis pain [42]. There are three response categories for the degree of pain relief.

Table 5 Response to therapy for arthritis pain

		Response to treatment		
Gender	Treatment	Marked	Some	None
Female	Active	16	5	6
Female	Placebo	6	7	19
Male	Active	5	2	7
Male	Placebo	1	0	10

Table 6 reports the deviance statistics and estimated regression coefficients for each of the three types of logits under the proportional-odds assumption. The models were fit using the lower levels of pain relief as the numerators in odds, and the continuation-ratio logits were formed going from "none" to "marked". That is, the continuation-ratio logits were constructed for the comparisons "none" vs. "some + marked", and "some" vs. "marked". The adjacent-categories logits compare "some" vs. "marked" and "none" vs. "some", and the cumulative logits make the comparisons "none" vs. "some + marked" and "none + some" vs. "marked". The gender variable was coded 0 for "female" and 1 for "male", and the treatment variable was coded 0 for "active" and 1 for "placebo".

The data are congruent with proportional odds for all three types of logits in this case. That is, all three deviance statistics are consistent with good fits to the data, and test statistics for testing the proportional-odds assumption (not reported here) fail to reject it. In general, it is possible that proportional odds will be supported for a subset of the adjacent-categories logits, continuation-ratio logits, and cumulative logits, but not all three. The estimates of $\hat{\beta}_{\text{gender}}$ are all significantly greater than zero (e.g. evaluate $\hat{\beta}_{\text{gender}}/se(\hat{\beta}_{\text{gender}})$ relative to the distribution of a N(0,1) random variable), suggesting that females tended to achieve a greater degree of pain relief. The estimates of $\hat{\beta}_{\text{treatment}}$ are all significantly greater than zero, suggesting that subjects on the active treatment achieved higher levels of pain relief.

Comments

There are close connections between adjacent-categories logit models and the association models of the section on models for association. The connections between the two approaches to modeling ordered categorical data parallel those for loglinear models and logit models for a binary response [21]. Goodman [31] focuses on regression formulations

Table 6 Models summary for Table 5

Logits	Deviance	$\hat{\beta}_{\text{gender}}$ (se)	$\hat{\beta}_{\text{treatment}}$ (se)
Adjacent-categories	3.36	0.741 (0.325)	1.076 (0.293)
Continuation-ratio	4.42	0.997 (0.460)	1.551 (0.409)
Adjacent-categories	2.71	1.319 (0.529)	1.797 (0.473)

of loglinear association models, and Anderson [12] considers a family of models that can be viewed as generalizations of the regression formulation of an RC association model. Anderson's stereotype ordered regression model, is equivalent to

$$\ln\left[\frac{\pi_j(\mathbf{x}_i)}{\pi_{j+1}(\mathbf{x}_i)}\right] = \beta_{0j} + \phi_j \beta^t x_i,$$

where the ϕ_j are ordered and $j = 1, \ldots, J-1$. Note that the stereotype model follows from the general logit linear model when the regression coefficient vectors are assumed to be parallel, i.e. $\beta_j = \phi_j \beta$. In addition, just as RC models can be motivated in terms of multivariate normality, Anderson provides a motivation for stereotype models in terms of ordered multivariate normal distributions. It is, however, important to recognize that neither log multiplicative association models nor stereotype regression models are reliant on normality assumptions. Rather, the point is that the models are also appropriate in those cases where the assumption of latent normality is assumed or reasonable.

The discussed papers by Anderson [12] and McCullagh [45] provide good background on issues that arise in the analysis of an ordered categorical response, and the theoretical perspectives that can be used to motivate the different logit formulations. Among the issues discussed in both papers are: (i) the utility of the models in data analysis; (ii) theoretical results for statistical inference; (iii) the computation of **maximum likelihood** estimates; and (iv) the stochastic ordering of response distributions.

Concluding Remarks

The development and application of models to the analysis of ordered categorical responses continues to be an area in which important contributions are being made. It was noted in concluding the section on models for association that there have been recent developments along the lines of the simultaneous modeling of ordered categorical responses and the association between them. An overlapping area in which there has been much recent activity is the analysis of repeated measures data (*see* **Longitudinal Data Analysis, Overview**) in the form of an ordered categorical response. Such data arise, for example, in longitudinal studies, **crossover** experiments, and studies of families or sibships (*see* **Generalized Linear Models for Longitudinal Data**). General approaches to the analysis of repeated measures data have been applied to such problems, including methodology based on **generalized estimating equations** [37, 40, 55] and methodology based on incorporating **random effects** into the models [8, 27, 38, 40]. The vast majority of this work builds on the models and literature summarized herein.

This entry has focused on models for the analysis of ordered categorical data, emphasizing the study of association and the formulation of regression relationships. There are many important issues that can not be covered here due to space limitations. A few examples include methods for **exact inference** (see, for example, [5]), measures (rather than models) of association (*see*, for example, [1] and [23] and **Association, Measures of**), and inference for association model scores under order restrictions [9, 52] (*see* **Isotonic Regression**).

MARK P. BECKER

Orders of Magnitude

It is often useful to compare the limiting behavior of a function $f(x)$ with some known simple function $g(x)$ as x tends to L:

1. If $f(x)/g(x)$ remains bounded as x tends to L, then we say that $f(x)$ *is at most of the order of g(x)* and we write $f(x) = O[g(x)]$ as $x \to L$.
2. If $f(x)/g(x)$ tends to zero, then we say that *f(x) is of a smaller order than g(x)*, and we write $f(x) = o[g(x)]$ as $x \to L$.
3. If $f(x)/g(x)$ tends to 1 as x tends to L, then we say that $f(x)$ *is asymptotically equal to g(x)*, and we write $f(x) \sim g(x)$ as $x \to L$.

Note that $O(1)$ stands for any bounded function, $o(1)$ stands for any function tending to zero, and $O(x)$ stands for any function which is at most of order x, as x tends to ∞. The above definition can be applied to any sequence a_n by considering $a_n = f(n)$, for $n \in N$.

Listed below are some simple rules for asymptotic calculations:

1. If $f_1(x) = O[g_1(x)]$, and $f_2(x) = O[g_2(x)]$, then $f_1(x) + f_2(x) = O[g_1(x) + g_2(x)]$.
2. $f(x) = o[g(x)]$ implies that $f(x) = O[g(x)]$.
3. If $f_1(x) = O[g_1(x)]$ and $f_2(x) = o[g_2(x)]$, then $f_1(x) f_2(x) = o[g_1(x) g_2(x)]$.
4. The order of magnitude of a sum of a finite number of terms is the largest order of magnitude of the summands.

Example: $o(1) + O(n^{-1/2}) + O(n^{-1}) = o(1)$.
Example: Let $f(x) = \log(1 + x)$. By the Taylor expansion of f at $x = 0$, we have

$$f(x) = x + o(x) = O(|x|) \quad \text{as } x \to 0.$$

Example: $n \log(1 + n^{-1}) = n[n^{-1} + o(n^{-1})] = 1 + o(1)$.

For further examples, see [1]

Ornstein–Uhlenbeck Process

The Ornstein–Uhlenbeck process (OUP) is a diffusion process (*see* **Brownian Motion and Diffusion Processes**) – a continuous-time **stochastic process** which satisfies the strong Markov property and has continuous sample paths – which has a drift, towards some mean taken to be zero without loss of generality, which is proportional to its displacement from that mean, i.e. the process has instantaneous mean $-\beta X$ when at X, where $\beta > 0$, and constant instantaneous variance σ^2.

If the process is denoted by $\{X(t), t \in \mathbb{R}\}$, then the conditional distribution is of the form

$$X(s+t)|X(s) = x \sim \mathrm{N}\left\{\exp(-\beta t)x, [1-\exp(-2\beta t)]\frac{\sigma^2}{2\beta}\right\}.$$

The limiting distribution of $X(t)$ is $\mathrm{N}(0, \sigma^2/2\beta)$, and if

$$X(t) \sim \mathrm{N}\left(0, \frac{\sigma^2}{2\beta}\right) \tag{1}$$

for some t, then the process is **stationary** and (1) holds for all t.

The OUP is the only diffusion process that is both stationary and Gaussian.

The stationary process has autocovariance function

$$\gamma(t) = \exp(-\beta t)\frac{\sigma^2}{2\beta}$$

and hence **autocorrelation function**

$$\rho(t) = \exp(-\beta t).$$

The OUP can be obtained as the solution to the following stochastic differential equation:

$$\mathrm{d}X = -\beta X\,\mathrm{d}t + \sigma\,\mathrm{d}W,$$

where $W(t)$ is a Wiener process.

The process generalizes to two or more dimensions; then the conditional distribution is of the form

$$\mathbf{X}_{(s+t)}|\mathbf{X}(s) = \mathbf{x} \sim \mathrm{N}(\exp(\mathbf{B}t)\mathbf{x}, \mathbf{\Lambda} - \exp(\mathbf{B}t)\mathbf{\Lambda}\exp(\mathbf{B}'t)),$$

where $\mathbf{\Lambda}$ and $\mathbf{B}$ are matrix constants, $\mathbf{B}$ is stable [i.e. $\exp(\mathbf{B}t) \to 0$ as $t \to \infty$, or equivalently the **eigenvalues** of $\mathbf{B}$ all have negative real parts], and the limiting distribution is

$$\mathbf{X}_{(t)} \sim \mathrm{N}(\mathbf{0}, \mathbf{\Lambda}).$$

Genesis

The OUP arose originally [27] as a model for the velocity of a particle suspended in a fluid and undergoing Brownian motion. The particle's velocity is assumed to be affected by collisions with the molecules of the fluid, resulting in both random fluctuations and an overall frictional effect. The process representing the position of a particle which has velocity given by an OUP will be referred to as the integrated OUP. The integrated OUP improves on the Wiener process as a model for Brownian motion, in that the Wiener process has nowhere-differentiable sample paths, and hence undefined velocity.

The OUP also arises as the limiting diffusion approximation to certain urn models. In the Ehrenfest urn model, there are $2N$ balls divided between two urns, A and B. At each time step of the process, one of the balls is selected (completely at random) and moved to the other urn. Thus if at time t there are i balls in A, and hence $2N - i$ in B, then at time $t+1$ there are $i-1$ balls in A with probability $i/2N$ and $i+1$ balls in A with probability $1 - i/2N$. As $N \to \infty$ and the interval between steps becomes small, the process converges to an OUP. Details are given in, for example, [9]; Jacobsen [7] gives some alternative urn models leading to the OUP, as part of a historical account of the origins of the OUP.

Applications

Neural Models

An important application of the OUP is in modeling the activity of individual nerve cells. Stein's [23] model assumes that membrane potential in a nerve cell changes discontinuously at random times due to excitatory (positive) and inhibitory (negative) inputs, with exponential decay of the potential between inputs; when the potential exceeds some threshold, the neuron fires. If the individual inputs are small but frequent, then the behavior of the membrane

potential in the Stein model can be well approximated by an OUP. This diffusion approximation has become a basic model in the study of nerve-cell activity (e.g. [14]); Tuckwell [26] gives a self-contained introduction to stochastic models in this area, and describes results for the OUP model. The importance of the interspike interval, the time taken for the potential to reach the level that triggers activity, has led to particular interest in first-passage time problems for the OUP.

Velocity Models

The original use of the OUP, as a model for the velocity of a particle, continues in a number of fields. Stokes et al. [24], for example, consider cell motility effects in physiological processes. They present a model in which an individual microvessel endothelial cell follows an integrated OUP, with parameters dependent on the biochemistry of the medium in which it is moving.

Heubach & Watkins [6] model the rotational velocity of a white blood cell. They show that, in the limit as the number of receptors on the cell becomes large, and in a uniform concentration of chemoattractant, the rotational velocity follows an OUP.

Movement Models

The OUP can also be used for the direct modeling of movement (rather than velocity). Dunn & Gipson [3], for example, use a bivariate OUP to represent the location over time of an animal exhibiting home range behavior as a model with which to interpret data from radio tracking. They also use a higher-dimensional form to model simultaneously the movements of multiple animals. Worton [28] reviews some applications and refinements.

Population Models

The OUP arises as a limiting diffusion approximation in many population processes. Andersson & Djehiche [1] consider a stochastic spatial epidemic model (*see* **Epidemic Models, Spatial**). They show that the differences between their model and its deterministic approximation converge, as the number of subpopulations increases, to an OUP.

Kämmerle [8] and Möhle [18] consider bisexual versions of the Moran and Wright–Fisher models, respectively, and show that in each case the backward process – the number of ancestor-pairs of a given generation – converges when suitably normed to an OUP (*see* **Population Genetics**).

Other Biological Models

Martins [17] uses an OUP to represent the change in (mean) phenotype within a species, under stabilizing selection. Properties of the OUP can thus be used to describe the behavior over time of between-species variability in the phenotype.

Taylor et al. [25] analyze serial CD4 T-cell measurements from the Multicenter **AIDS** Cohort Study. They use the integrated OUP as part of their model, to incorporate **correlation** between measurements in a way that allows the testing of immunologic theories about the dynamics of CD4 cell numbers.

Newell et al. [19] describe an experiment in which individual human subjects, of various age groups, stood still on a platform equipped to measure the downward pressure exerted. The authors found that the dynamics of the center of pressure could be modeled adequately by an OUP, with parameters dependent upon the age group of the subject.

Statistical Applications

In the applications mentioned so far, the OUP is used directly as a model for some process of interest, or emerges as a limiting case or approximation to some such model. Alternatively, the OUP may be a limiting approximation to a statistical quantity.

For example, in **genetic mapping** of quantitative trait loci (QTL), Lander & Botstein [13] consider the LOD score or **likelihood ratio** $Z(t)$ at all locations t in the genome simultaneously. In the limit as the **genetic markers** become dense and the number of individuals tested becomes large, under the **null hypothesis** of no QTLs, the random process $Z(t)$ converges to the square of an OUP. Thus knowledge of the **extreme-value** behavior of the OUP enables testing of that hypothesis. Lander & Botstein assume a normal distribution for the phenotype of interest; Kruglyak & Lander [10] give a nonparametric version of the test, based on the Wilcoxon rank-sum statistic, in which the OUP plays essentially the same role.

Inference

Parameter estimation for an OUP is typically by **maximum likelihood**; we assume for this section that the mean parameter, denoted by μ, is unknown.

If the process is observed continuously over some interval $[0, s]$, say, then the variance parameter σ can be calculated exactly as

$$\sigma^2 = s^{-1} \lim_{n\to\infty} \sum_{j=1}^{2^n} \{X(js2^{-n}) - X[(j-1)s2^{-n}]\}^2.$$

The likelihood for the drift parameter, β, and for the mean, μ, can then be written down – see, for example, Tuckwell [26] or Guttorp [5] – and we can thus obtain maximum likelihood estimates:

$$\hat{\mu} = \left\{ [X(s) - X(0)] \int_0^s X^2(t)\,\mathrm{d}t - \frac{1}{2}[X^2(s) - X^2(0) - \sigma^2 s] \int_0^s X(t)\,\mathrm{d}t \right\} \times \left\{ s \int_0^s X^2(t)\,\mathrm{d}t - \left[\int_0^s X(t)\,\mathrm{d}t \right]^2 \right\}^{-1}$$

and

$$\hat{\beta} = \left\{ [X(s) - X(0)] \int_0^s X(t)\,\mathrm{d}t - \left(\frac{s}{2}\right)[X^2(s) - X^2(0) - \sigma^2 s] \right\} \times \left\{ s \int_0^s X^2(t)\,\mathrm{d}t - \left[\int_0^s X(t)\,\mathrm{d}t \right]^2 \right\}^{-1}.$$

Alternatively, given discrete observations $X(t_1), \ldots, X(t_n)$ on the process, the conditional density for each observation is

$$X(t_i)|X(t_{i-1}) = x \sim \mathrm{N}(\nu_i + \exp[-\beta(t_i - t_{i-1})]x, \phi_i), \quad i = 2, \ldots, n,$$

where

$$\nu_i = \{1 - \exp[-\beta(t_i - t_{i-1})]\}\mu$$

and

$$\phi_i = \{1 - \exp[-2\beta(t_i - t_{i-1})]\}\frac{\sigma^2}{2\beta},$$

and so the log likelihood is of the form

$$\sum_{i=2}^{n} \left(-\frac{1}{2}\ln(\phi_i) - \frac{1}{2}\{x_i - \nu_i - \exp[-\beta(t_i - t_{i-1})]x_{i-1}\}^2/\phi_i \right).$$

If, rather than conditioning on $X(t_1)$, it is assumed that the process is in equilibrium at time t_1, then there is an additional term in the log likelihood

$$-\frac{1}{2}\ln\left(\frac{\sigma^2}{2\beta}\right) - (x_1 - \mu)^2\frac{\beta}{\sigma^2},$$

and the information contained in $X(t_1)$ may be much greater than in other observations. The likelihood can be maximized numerically; if *regular* discrete observations are available, then the relationship with the AR(1) process (see below) may be exploited, and estimation techniques from the **time series** literature are available.

Dunn & Gipson [3], Dunn & Brisbin [2], and Worton [28] consider inference based on the likelihood for discrete observations in higher-dimensional cases, the latter investigating the performance of estimation based on the OUP likelihood in the case where the true model is not an OUP, and using **bootstrapping** to obtain **standard errors**.

Polson & Roberts [20] describe **Bayesian** model selection techniques for diffusions, which allow comparison between an OUP, say, and an alternative diffusion model.

As an alternative to likelihood-based approaches, Kutoyants [11] and Kutoyants & Pilibossian [12] use minimum distance estimation, based on the L_2 and L_1 norms, respectively.

Further Properties

First Passage Times

The first passage time of a stochastic process from x_0 to $a > x_0$, say, is

$$T = \inf_{t\geq 0}\{t : X(t) \geq a | X(0) = x_0\},$$

with the obvious change if $a < x_0$. A time-varying threshold $a(t)$ can also be considered.

The first passage time of the OUP to a fixed threshold is of particular interest since it represents the interspike interval in neural models (see above). Ricciardi & Sato [22] consider the first passage time for the OUP, and Giorno et al. [4] consider the asymptotic case for the OUP and related diffusions. Lefebvre considers the two-dimensional case [16] and the integrated OUP [15].

Related Processes

An OUP $X(t)$ is related to the Wiener process $W(t)$ by

$$X(t) = \exp(-\beta t)W[\exp(2\beta t)],$$
$$W(t) = t^{1/2}X\left(\frac{\ln t}{2\beta}\right).$$

An OUP observed at regular discrete time intervals (of length 1, without loss of generality) is of the form

$$X_{t+1} = \exp(-\beta t)X_t + \varepsilon_t,$$

where the ε_ts are independent $\mathrm{N}(0, [1\exp(-2\beta)]\ \sigma^2/2\beta)$ random variables, and so the process is just a Gaussian first-order autoregression or AR(1) process (*see* **ARMA and ARIMA Models**).

A spatial discretization of the (integrated) OUP, in which velocity, and hence position, is restricted to integer values, is developed by Renshaw [21].

PAUL G. BLACKWELL

Orthoblique Rotation

Orthoblique or *Harris-Kaiser Rotation* [1, 2] is a nonquartic method of performing an **oblique rotation** of a matrix $\mathbf{V}$ of dimension $(p \times k)$ made up of vectors associated with **principal components analysis** or **factor analysis** in order to transform these quantities into new variables by the relationship $\mathbf{B} = \mathbf{V\Theta}$ such that $\mathbf{B}$ will approximate a **simple structure**. The matrix $\mathbf{B}$ is of dimension $(p \times k)$ and the matrix $\mathbf{\Theta}$ is of dimension $(k \times k)$ (*see* **Rotation of Axes**). The principal feature of Orthoblique rotation is that the solution is obtained from the product of a number of orthogonal matrices which are either diagonal or orthonormal. One of these matrices is the solution of an **orthogonal rotation** such as **Varimax**, making this a two-step rotation. Another is a diagonal matrix made up of the characteristic roots (*see* **Eigenvalue**) associated with the retained characteristic vectors (*see* **Eigenvector**). This latter matrix is raised to a power which essentially affects the normalization of the original vectors. A power of zero implies a model where the clusters are independent and will be a definite oblique rotation. Higher powers will approach an orthogonal rotation. At various times, **Quartimax**, Equimax, and Varimax have each been suggested for the initial rotation, but Hakstian & Abell concluded that the effect of this choice is far outweighed by the choice of power.

For the Decathlon example given in the article, **Rotation of Axes**, the Orthoblique solutions for powers of 0.35 and 0.75 are given in Table 1 along with the original principal component characteristic vectors.

Orthogonal Designs

In the design of experiments, the term *orthogonal* is used widely and in different contexts. Orthogonal *designs* is a term generally used by statisticians in the context of experiments in which a number of treatments (with or without a **factorial** structure) are to be compared and in which it is desirable to eliminate the variability due to nuisance factors such as blocks, rows, columns, etc. This term, in a very different context, has been used, for example, by Geramita & Wallis [1].

Orthogonal Designs in Comparative Experiments

In comparative experiments two factors (say, treatments and blocks) are said to be *orthogonal* if and only if the condition of *proportional frequency* is satisfied. This condition can be explained as follows. Suppose the two factors involved are A and B, where A has a levels and B has b levels. Furthermore, let n_{ij} be the number of times level i of A appears with level j of B, let $n_{i\cdot}$ be the number of times level i of A appears in the whole design, and let $n_{\cdot j}$ be the number of times level j of B appears in the whole design: $i = 1, \ldots, a$; $j = 1, \ldots, b$. Then A and B are orthogonal if and only if the condition $n_{ij} \propto n_{i\cdot} n_{\cdot j}$ holds for all values of i, j. In particular, if each level of A appears equally often with each level of B, the condition trivially holds. The simplest examples of orthogonal design are **randomized complete blocks designs**, where each of the v treatments under comparison appears precisely once in each block.

An advantage of this type of orthogonality is that if A and B are orthogonal, then under a standard **additive model**, the *best linear* **unbiased** *estimator* of any **contrast** among the levels of A is uncorrelated with the best linear unbiased estimator of any contrast among the levels of B. As a consequence, the sums of squares due to A and B in the **analysis of variance** can be partitioned orthogonally.

Similar properties hold for higher order layouts, involving more than two factors. For example, in the case of **Latin square designs** with s treatments, each treatment appears in each row and each column precisely once. The three factors – treatments, rows, and columns – are mutually orthogonal; that is, treatments are orthogonal to each of rows and columns, and the rows are orthogonal to columns.

Latin squares can be generalized to **Graeco–Latin squares**. Two $s \times s$ Latin squares are said to be orthogonal if, when one of the squares is superimposed on the other, each of the s^2 ordered pairs of symbols from the two separate squares appears once in the superimposed arrangement, called a Graeco-Latin square. In a Graeco-Latin square, any pair of the factors, rows, columns, symbols of the first square, and symbols of the second square are orthogonal.

A set of Latin squares of the same order is said to form a set of mutually orthogonal Latin squares if each pair in the set is orthogonal. If a set of mutually orthogonal Latin squares contains three or more squares, then by superimposing these one over the others, a generalization of Graeco-Latin square is obtained, which may be called a hyper-Graeco-Latin square. A further generalization is provided by orthogonal arrays. An orthogonal array of size N, s symbols, k constraints, and index t is an $k \times N$ array having s symbols with the property that in any $k \times t$ subarray, every s^t ordered t-plets occurs equally often (say, λ times each) as a column. The integer λ is called the *index* of the array. It is easily seen that a Latin square of order s is equivalent to an orthogonal array of size s^2, s symbols, three constraints, strength two and index unity. In general, one can convert an orthogonal array to an orthogonal multifactor design by identifying the rows of the orthogonal array with the factors of the design.

Orthogonality in Response Surface Designs

In **response surface** experiments, it is often assumed that the expected response to the quantitative input variables is a smooth function; say, a polynomial. In particular, suppose that the expected response to the quantitative variables $x_1, x_2, \ldots, x_p$ is a linear function of p unknown parameters. A design for fitting this function is said to be orthogonal if the columns of the matrix of input variables are mutually orthogonal. In an orthogonal response surface design, the **least squares** estimators of the parameters of the surface are mutually uncorrelated. Furthermore, the least squares estimator of any parameter depends only on the values in that column of the matrix of **explanatory variables** and the data.

Orthogonal Factorial Structure

In experiments where the treatments have a factorial structure (*see* **Factorial Experiments**), it is often desirable to have designs in **incomplete blocks** such that the usual least squares estimators of factorial effects belonging to different main effects and interactions are mutually uncorrelated. Such designs are called designs with orthogonal factorial structure. Details on these are available in Gupta & Mukerjee [2].

Other Orthogonal Designs

Geramita & Wallis [1] define an orthogonal design of order n and type $(s_1, \ldots, s_t)$, where the s_is are positive integers, as an $n \times n$ matrix A with entries from the set $\{0, \pm x_1, \ldots, \pm x_t\}$, the x_is being commuting indeterminates, such that

$$AA' = \left(\sum_{i=1}^{t} s_i x_i^2\right) I_n,$$

where A' is the transpose of A and I_n is an identity matrix of order n. These orthogonal designs can be regarded as generalizations of Hadamard matrices. For a review on Hadamard matrices, see Hedayat & Wallis [3].

Orthogonal Rotation

Given a matrix $\mathbf{V}$ of dimension $(p \times k)$ often consisting of a set of k vectors defining a set of principal components or factors, a new set of transformed variables may be obtained by a rotation of $\mathbf{V}$; namely, $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$. $\mathbf{V}$ is often the **factor loading matrix** or factor matrix from the initial step in a **principal components analysis** or a **factor analysis**. Such a rotation is said to be *orthogonal* if the resultant rotated axes in the vector space are at right angles to each other (*see* **Orthogonality**). Most rotation procedures are designed to approximate **simple structure** (*see* **Rotation of Axes**). $\boldsymbol{\Theta}$, a matrix of dimension $(k \times k)$, defines the angles of rotation and the resulting matrix, $\mathbf{B}$, of dimension $(p \times k)$, contains the new rotated vectors defining the transformed variables.

A great many of the orthogonal rotation schemes belong to a class called *Orthomax* rotation. These start with the general expression:

$$Q = \sum_{j=1}^{k} \left[\sum_{i=1}^{p} b_{ij}^4 - \frac{c}{p} \left(\sum_{i=1}^{p} b_{ij}^2 \right)^2 \right],$$

where p is the number of original variables, k is the number of retained components or factors, b_{ij} are the coefficients of the vectors defining the rotation, and c is an arbitrary constant. As the concept of a simple structure requires the b_{ij} to be as large or small as possible, these rotation methods are designed to determine the b_{ij} such that Q is maximized. These are sometimes referred to as *quartic* solutions since they involve fourth powers of the coefficients.

If $c = 1$, then the resulting solution is called **Varimax rotation** in which the sums of squares of $\mathbf{B}$ are maximized *columnwise*. **Quartimax rotation** is obtained by setting $c = 0$ and maximizes the sums of squares of $\mathbf{B}$ *rowwise*. A compromise, *Equimax*, which maximizes the sums of squares across both rows and columns is obtained by setting $c = k/2$. Standard errors for the vector coefficients produced by Orthomax rotations were given by Archer & Jennrich [1].

A method not related to Orthomax is the Minimum Entropy Solution [3], which minimizes:

$$H = -\sum_{i=1}^{p} \sum_{j=1}^{k} b_{ij}^2 \ln(b_{ij}^2).$$

A method of obtaining a single rotation to simultaneously obtain a simple structure for two sets of vectors was obtained by Hakstian [2].

Orthogonality

In the study of a system in which several factors contribute to a net "effect" it is convenient, though not always possible, to consider the contribution of each factor independently of the others. Coordinate geometry is a trivial example – any point on a plane can be specified in terms of its x and y coordinates, and if we move a point around by varying its x coordinate, its y coordinate is unaffected. This is because movement in the x direction is *orthogonal* to that in the y direction. The orthogonality (Greek *orthos* = straight; erect) of two entities implies that they are, in some sense to be described below, perpendicular to each other. In applied statistics, orthogonality may loosely be regarded as a descriptive term for the ability to disentangle individual effects.

We start with a brief overview of the relevant formal mathematical notions; this provides a basis for referral in later sections. The reader wishing to skip the mathematical detail in the next few paragraphs may find that the subsequent section "Orthogonal Vectors and Matrices" helps to fix ideas in a geometrical context. The section "Orthogonality in Experimental Design" is undoubtedly the most important one from a biostatistical viewpoint; other sections outline more peripheral material which may be encountered in the literature.

Mathematical Definition

Orthogonality arises most naturally in the context of inner product spaces. An inner product is a suitably-behaved scalar (and possibly complex) valued, linear operation (usually denoted by $\langle \cdot, \cdot \rangle$) between pairs of elements in a vector space $\mathcal{V}$. Elements x and y are said to be *orthogonal*, with respect to the space $\mathcal{V}$ and inner product $\langle \cdot, \cdot \rangle$, if $\langle x, y \rangle = 0$.

It is natural to think of elements of $\mathcal{V}$ as having a "size" or "length". This is achieved by defining a *norm* on the space, which has length-like properties. The norm of x is usually denoted by $||x||$: we are solely interested in that defined by $||x|| = \langle x, x \rangle^{1/2}$. If x and y are orthogonal and both have unit length, they are called *orthonormal*.

A subset $\mathcal{S}$ of elements of $\mathcal{V}$ is called a *subspace* of $\mathcal{V}$ if $\mathcal{S}$ is itself an inner product space with the same addition and scalar multiplication defined as in $\mathcal{V}$. The set of elements of $\mathcal{V}$ which are orthogonal to every element of $\mathcal{S}$ is denoted by $\mathcal{S}^{\perp}$. A fundamental result (the *projection theorem*) says that if x is in $\mathcal{V}$ and $\mathcal{S}$ is a subspace of $\mathcal{V}$, then x can be uniquely written as $x = x_1 + x_2$, where $x_1 \in \mathcal{S}$ and $x_2 \in \mathcal{S}^{\perp}$. x_1 is the *orthogonal projection* of x onto $\mathcal{S}$, and satisfies $||x - x_1|| = \inf[||x - y|| : y \in \mathcal{S}]$. Furthermore, the mappings $x \mapsto x_1$ and $x \mapsto x_2$ are linear.

An *orthonormal basis* for $\mathcal{V}$ is a (possibly infinite and uncountable) collection $\{e_i\}$ of elements of $\mathcal{V}$ which are mutually orthonormal and which *span* $\mathcal{V}$ (in other words, every element of $\mathcal{V}$ can be expressed as a linear combination of the $\{e_i\}$). If $\{e_i\}$ is such a basis, define $\hat{a}_i(x) = \langle x, e_i \rangle$ for all $x \in \mathcal{V}$ [so that $x = \sum_i \hat{a}_i(x) e_i$], and denote by $\overline{\hat{a}_i(x)}$ the complex conjugate of $\hat{a}_i(x)$. Then the *Parseval relation* states that, for $x, y \in \mathcal{V}$,

$$\langle x, y \rangle = \sum_i \hat{a}_i(x) \overline{\hat{a}_i(y)}. \tag{1}$$

In particular,

$$||x||^2 = \sum |\hat{a}_i(x)|^2. \tag{2}$$

The latter result is especially important because it offers a means of assessing the relative contributions of each e_i to the magnitude of x; alternatively, it provides a decomposition of the magnitude of x into individual effects arising from each of its components.

Our discussion of inner product spaces ends here; it is necessarily brief and details have been omitted in order to present the most relevant results clearly and concisely. Thorough treatments may be found in the many available texts on real and complex analysis, e.g. [12].

Orthogonal Vectors And Matrices

The theory of inner product spaces is most easily visualized in terms of standard k-dimensional Euclidean space. Let $\mathbf{u} = (u_1, \ldots, u_k)'$ and $\mathbf{v} = (v_1, \ldots, v_k)'$ be vectors in $\mathbb{R}^k$, and define their inner product to be the standard vector product

$$\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}'\mathbf{v} = \sum_{i=1}^{k} u_i v_i. \tag{3}$$

The norm is thus defined by

$$||\mathbf{u}|| = \left(\sum_{i=1}^{k} u_i^2 \right)^{1/2}, \qquad (4)$$

which justifies our thinking of it as a measure of "length". With this inner product, two vectors are orthogonal if they are perpendicular to each other. The most obvious orthonormal basis for $\mathbb{R}^k$ is the Cartesian one; the Parseval relation, (2), is then Pythagoras's theorem in k dimensions.

An *orthogonal matrix* is a square matrix whose columns, considered as vectors in Euclidean space, are mutually orthonormal. Orthogonal matrices can be regarded as rotations and/or reflections of axes in Euclidean space, as they map any one set of mutually perpendicular vectors into another. Orthogonal matrices play an important role in multivariate analysis (*see* **Multivariate Analysis, Overview**), because any set of n measurements on each of k ordinal variates may be represented as an $n \times k$ data matrix $\mathbf{X}$, regarded as a set of n points in k-dimensional space. Often interest centers on finding a subspace of dimension $p < k$ which contains most of the information in $\mathbf{X}$; this amounts to finding an appropriate set of axes on which to plot the data, or alternatively to finding an orthogonal matrix, of dimension $k \times k$, which will map the data points to their positions within the coordinate system defined by these axes. Perhaps the most important tool for such purposes is the *singular value decomposition*, which allows any matrix to be factorized into orthogonal components. Statistical applications of this decomposition are discussed in [5].

In experimental design, a design matrix $\mathbf{X}$ (*see* **Analysis of Variance**) which is not square is usually described as being orthogonal if its columns are mutually orthogonal; alternatively, $\mathbf{X}$ is orthogonal if $\mathbf{X}'\mathbf{X}$ is either a diagonal matrix or block diagonal with blocks corresponding to submodels of interest.

Random Variables

Here we consider a **random variables** with finite second moments. An inner product may be defined as

$$\langle X, Y \rangle = \mathrm{E}(XY)$$

under which the norm of a random variable is its root mean square. X and Y are orthogonal if $\mathrm{E}(XY) = 0$. If $\mathrm{E}(X)$ or $\mathrm{E}(Y)$ is zero, then orthogonality equates to lack of **correlation**; hence, if X and Y are uncorrelated, then the random variables $X^* = X - \mathrm{E}(X)$ and $Y^* = Y - \mathrm{E}(Y)$ are orthogonal. Some authors describe uncorrelated random variables as being orthogonal regardless of whether or not either of them has zero mean; although this is technically incorrect according to the definition given above, the practice is sufficiently widespread that the point is worth mentioning to avoid confusion.

Regression and Conditional Expectation

Suppose we wish to approximate one random variable, Y, by a linear function of k others, say $X_1, \ldots, X_k$. Denote by $\mathcal{S}$ the space of all linear functions of the $\{X_i\}$, i.e. $\mathcal{S} = (Z : Z = \sum_{i=1}^{k} a_i X_i, a_1, \ldots, a_k \in \mathbb{R})$. Suppose $\tilde{Y}$ is the orthogonal projection of Y onto $\mathcal{S}$; then, by the projection theorem, $\tilde{Y}$ minimizes $||Y - \tilde{Y}||$ (alternatively, $||Y - \tilde{Y}||^2$), so it is the linear predictor with the *minimum* **mean square error** (MMSE). If one of the predictors is a constant ($X_1 \equiv 1$, say), then, because $Y - \tilde{Y}$ is orthogonal to all the predictors, we must have $\mathrm{E}[1 \times (Y - \tilde{Y})] = 0$, so the prediction error is a zero-mean random variable.

A similar interpretation can be given to the idea of conditional expectation. Here the aim is to approximate Y by *any* function of the $\{X_i\}$, not just linear functions; so now we are seeking our predictor in the subspace $\mathcal{T} = [Z : Z = h(X_1, \ldots, X_k), h : \mathbb{R}^k \mapsto \mathbb{R}]$. In this case, the function yielding the MMSE predictor is the conditional expectation of Y given $X_1, \ldots, X_k$.

A useful introduction to these ideas is given in [7].

Orthogonal Processes

In **time series analysis**, reference is frequently made to *orthogonal processes* (or *processes with orthogonal increments*). Orthogonal processes are **stochastic processes** in continuous time, $W(t)$, say, such that when I_1 and I_2 are disjoint intervals on the real line,

$$\mathrm{cov}\left[\int_{I_1} \mathrm{d}W(t), \int_{I_2} \mathrm{d}W(t) \right] = 0. \qquad (5)$$

Note that this definition uses the "uncorrelated" interpretation of orthogonality of random variables

rather than its strict definition. The Wiener process (*see* **Brownian Motion and Diffusion Processes**) is an example of such a process. Orthogonal processes arise in the specification of continuous-parameter time series models and in the Spectral Representation Theorem (*see* **Spectral Analysis**). The ideas generalize straightforwardly to spatial processes.

Orthogonality in Experimental Design

For the applied statistician, the most important role orthogonality has to play is in isolating effects due to different factors (*see* **Experimental Design**). To explore this, we start by examining linear regression, as this is perhaps the easiest scenario to visualize. Some points related to the analysis of variance and to **factorial experiments** are then discussed, and finally the ideas are extended to general likelihood-based estimation.

Linear Regression

Suppose we have a dependent variate y, which we wish to regress on p covariates $x_1, \ldots, x_p$ (*see* **Multiple Linear Regression**). A sample of n observations on each variate is taken; the x-data are assembled into an $n \times p$ data matrix $\mathbf{X}$ (the *design matrix*), and the y-data are put into a $n \times 1$ vector $\mathbf{y}$. The regression model is

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon},$$

where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ is a vector of parameters to be estimated, and $\boldsymbol{\varepsilon}$ is a vector of uncorrelated errors with equal variance. If $\tilde{\mathbf{y}}$ denotes the fitted value of $\mathbf{y}$, then the standard technique for fitting the model (*see* **Least Squares**) is to minimize the residual sum of squares $\sum(y - \tilde{y})^2 = (\mathbf{y} - \tilde{\mathbf{y}})'(\mathbf{y} - \tilde{\mathbf{y}}) = ||\mathbf{y} - \tilde{\mathbf{y}}||^2$, if the vectors are considered as points in $\mathbb{R}^n$ and the norm and inner product are the standard Euclidean ones defined in (3) and (4). Columns of $\mathbf{X}$ also represent points in $\mathbb{R}^n$, and the span of all linear combinations of these columns is a subspace, $\mathcal{S}$ say, which is a hyperplane of dimension equal to the rank of $\mathbf{X}$. Each value of $\boldsymbol{\beta}$ defines a point in this subspace.

Now consider the Normal equations (*see* **Multiple Linear Regression**) for the estimation of the parameter vector $\boldsymbol{\beta}$:

$$(\mathbf{X}'\mathbf{X})\hat{\boldsymbol{\beta}} = \mathbf{X}'\mathbf{y}. \tag{6}$$

If the matrix $(\mathbf{X}'\mathbf{X})$ is diagonal, then (6) has the trivial solution

$$\hat{\beta}_j = \frac{\sum_{i=1}^{n} x_{ij} y_i}{\sum_{i=1}^{n} x_{ij}^2}, \quad j = 1, \ldots, p. \tag{7}$$

In this case no element of $\hat{\boldsymbol{\beta}}$ depends on any other; hence, if we decide to hold one or more β values fixed, then estimates of the others are not affected. Furthermore, the information matrix for $\boldsymbol{\beta}$ is diagonal (*see* **Information Matrix**), so that individual parameter estimates are uncorrelated, and tests of the significance of individual parameters are independent of the values taken by other parameters. See [13, Section 3.5] for more detail on the advantages that accrue from an orthogonal design matrix in linear regression.

It is instructive to link this with concepts introduced earlier. In a geometrical context, $(\mathbf{X}'\mathbf{X})^{-1}$ will be a diagonal matrix if and only if its columns, regarded as n-dimensional vectors, are mutually orthogonal. The Parseval relation then gives us

$$||\mathbf{y}||^2 = \sum_{j=1}^{p} \hat{\beta}_j^2 ||\mathbf{x}_j||^2 + ||\mathbf{e}||^2, \tag{8}$$

where $\mathbf{e}$ is the vector of residuals from the fitted model, and $\mathbf{x}_j$ is the jth column of $\mathbf{X}$. This is just a decomposition of the sum of squares into individual model components and residuals.

There is also a close parallel with the ideas discussed earlier in the section "Random Variables", for we have

$$\mathbf{x}_j'\mathbf{x}_k = \sum_{i=1}^{n} x_{ij} x_{ik} = n\hat{\mathrm{E}}(X_j X_k),$$

the notation $\hat{\mathrm{E}}(\cdot)$ being used to denote a sample estimate of the expectation. The space considered here is thus effectively the sample version of that considered previously. In particular, if a constant term is included as a linear predictor (giving rise to a column of ones in $\mathbf{X}$) and the linear predictors are mutually orthogonal, then all nonconstant predictors must have zero mean and the sample correlation matrix must be diagonal.

It is unusual to find an example of linear regression where the design matrix is orthogonal. It may be possible to find a set of orthogonal linear combinations of the original variables (using **principal components analysis**, for example), but this is generally only useful in modeling if the principal components themselves have some physical interpretation. One exception to this general rule is in **polynomial regression**, where terms of successively higher degree in a predictor variable X may be parameterized in such a way as to ensure that columns of the design matrix corresponding to each power of X are mutually orthogonal. We seek a sequence $[f_p(\cdot) : p = 0, 1, 2, \ldots]$ such that f_p is a polynomial of degree p and

$$\sum_{i=1}^{n} f_p(x_i) = 0, \quad p = 1, 2, \ldots,$$

$$\sum_{i=1}^{n} f_p(x_i) f_q(x_i) = 0, \quad p \neq q.$$

Setting the coefficient of x^p in $f_p(\cdot)$ to be unity, we obtain a set of simultaneous equations for the coefficients in each $f_p(\cdot)$. For example, we have

$$\begin{aligned} f_1(x) &= x - \overline{x}, \\ f_2(x) &= x^2 + a_{21}x + a_{20}, \end{aligned} \tag{9}$$

where

$$a_{21} = \frac{\sum x_i^2(\overline{x} - x_i)}{\sum x_i^2 - n\overline{x}^2},$$

$$a_{20} = -\left(a_{21}\overline{x} + n^{-1}\sum x_i^2\right).$$

Further discussion of orthogonal polynomials in this context may be found in [13, Section 8.2].

We now present an example to clarify the ideas presented so far. Figure 1 is a scatterplot showing a clear linear relationship between energy requirement and body weight for a sample of 64 grazing sheep in Australia. Let us fit constant, linear and quadratic models to the data, using both a "naive" and an orthogonal parameterization. Denoting by y_i the energy requirement for the ith individual, and by x_i its body weight ($i = 1, \ldots, 64$), the two parameterizations are:

$$y_i = \beta_0^{(1)} + \beta_1^{(1)} x_i + \beta_2^{(1)} x_i^2 + \varepsilon_i, \tag{10}$$

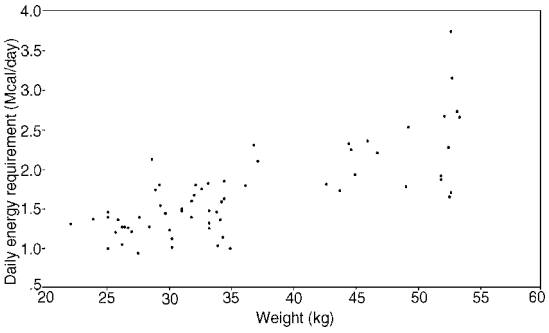

Figure 1 Daily energy requirement versus body weight for a sample of 64 sheep. This is data set no. 241 from [6]. The mean energy requirement is 1.69 Mcal/day, and the mean weight is 35.94 kg

$$\begin{aligned} y_i = \beta_0^{(2)} &+ \beta_1^{(2)}(x_i - 35.9359) \\ &+ \beta_2^{(2)}(x_i^2 - 78.2152x + 1430.4947) + \varepsilon_i. \end{aligned} \tag{11}$$

(the coefficients in the second parameterization being obtained using Eq. (9)). The fitted constant, linear and quadratic models under each parameterization are shown in Table 1, together with P values for each parameter. Notice the following:

1. The parameter estimates, and assessment of the significance of model components, differ under the first parameterization, depending on which model is fitted. In particular, for the quadratic model no components are significant, so the misspecification of the model has serious consequences. Under the second parameterization there is no such ambiguity, and individual parameter estimates are unchanged by the inclusion of other terms in the model. This is convenient for computation, as we only need to estimate each parameter once.
2. The equation of the fitted model is the same in both cases. This is because of the uniqueness of the least squares predictor, as guaranteed by the projection theorem.

The full benefits of orthogonality here result from the appearance of the quantity $\mathbf{X}'\mathbf{X}$ in the normal equations (6), which itself is a consequence of the least squares approach to the estimation. It is clear that these same properties of an orthogonal design will continue to hold as long as estimation is carried

Table 1 Parameter estimates and significance levels for models fitted to sheep data

	Parameterization 1		Parameterization 2	
Model	Estimate	P value	Estimate	P value
Constant	$\hat{\beta}_0^{(1)} = 1.693$	$<5 \times 10^{-5}$	$\hat{\beta}_0^{(2)} = 1.693$	$<5 \times 10^{-5}$
Linear	$\hat{\beta}_0^{(1)} = 0.133$	0.4640	$\hat{\beta}_0^{(2)} = 1.693$	$<5 \times 10^{-5}$
	$\hat{\beta}_1^{(1)} = 0.0434$	$<5 \times 10^{-5}$	$\hat{\beta}_1^{(2)} = 0.0434$	$<5 \times 10^{-5}$
Quadratic	$\hat{\beta}_0^{(1)} = 0.941$	0.3257	$\hat{\beta}_0^{(2)} = 1.693$	$<5 \times 10^{-5}$
	$\hat{\beta}_1^{(1)} = -7.779 \times 10^{-4}$	0.9879	$\hat{\beta}_1^{(2)} = 0.0434$	$<5 \times 10^{-5}$
	$\hat{\beta}_2^{(1)} = 5.650 \times 10^{-4}$	0.3895	$\hat{\beta}_2^{(2)} = 5.650 \times 10^{-4}$	0.3895

out by least squares or weighted least squares (so that the quantity $\mathbf{X}'\mathbf{X}$ is replaced by $\mathbf{X}'\mathbf{W}\mathbf{X}$, where $\mathbf{W}$ is a diagonal matrix). However, most inferential procedures (such as hypothesis testing) rely on **likelihood**-based estimation rather than least squares methods. For simple linear regression, the two methods coincide and an orthogonal design matrix gives rise to a diagonal information matrix; it is the information matrix that plays a central role in likelihood estimation. We shall return to this point after discussing the role played by orthogonality in the analysis of variance.

Analysis of Variance

We have just seen that in linear regression, an orthogonal design matrix enables us to estimate the effect of each covariate individually, regardless of which other covariates are included in the model. The same is true of the analysis of variance, for ANOVA model parameters are estimated by least squares, and the same geometrical argument applies – see, for example, [10, Chapter I.4]. However, for ANOVA models we have the additional advantage that, for certain types of experiment, it is possible to obtain an orthogonal design matrix in a relatively straightforward manner. A simple example illustrating this is given by [4, Appendix C].

Unfortunately, much of the literature on analysis of variance and experimental design is extremely unclear as to exactly what is meant by orthogonality in this context; the term is often used in a descriptive rather than a mathematical sense, and the justifications for its use are varied. The various strands may be connected as follows: suppose we fit an ANOVA model to data, by least-squares estimation of a parameter vector $\boldsymbol{\theta}$ (which is typically a vector of treatment effects), and that $\boldsymbol{\theta}$ can be partitioned into two subvectors $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$. Let us also fit a model containing only those parameters in $\boldsymbol{\theta}_1$ – we refer to this as the *reduced model*. Then the design of the experiment is orthogonal for $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$ if either of the following equivalent conditions are satisfied:

1. The sums of squares attributable to parameters in $\boldsymbol{\theta}_1$ are the same in the ANOVA table for the reduced model as in that for the full model.
2. The least-squares estimate of $\boldsymbol{\theta}_1$ is the same in the reduced model as in the full model.

These conditions result from an orthogonal design matrix, as outlined previously; however, either one of them is often cited as a definition of orthogonality, even in situations where there is no explicit mention of a design matrix. Perhaps the most helpful interpretation of such a "descriptive" view of orthogonal design (*see* **Orthogonal Designs**) is that an underlying design matrix exists, whose columns corresponding to $\boldsymbol{\theta}_1$, regarded as vectors, are orthogonal to those corresponding to $\boldsymbol{\theta}_2$. Note that a design can be orthogonal only for certain parameter combinations.

In the analysis of variance, frequent use is made of *orthogonal* **contrasts** for making treatment comparisons simultaneously. Suppose there are a total of t treatments in an experiment; any contrast is a linear combination of at least two of them whose coefficients sum to zero, and represents a comparison of treatments. The contrasts themselves may be regarded as vectors in $\mathbb{R}^{(t-1)}$, and are defined to be orthogonal if these vectors are orthogonal. If the contrasts are orthogonal and each treatment is applied to the same number of observational units, then it can be shown (see, for example, [10, p. 85]) that the design matrix corresponding to the contrasts (rather than to

the original treatments) is orthogonal, and hence their effects can be assessed independently.

Schemes giving rise to orthogonal designs for the analysis of variance include randomized block designs (*see* **Graeco–Latin Square Designs**; **Latin Square Designs**; **Randomized Complete Block Designs**). These may all be regarded as special cases of *orthogonal arrays*, which provide the combinatorial framework within which a particular orthogonal design may be generated. Orthogonal arrays are used extensively in Taguchi design; a useful introduction and extensive reference list appears in [8].

Orthogonality in Likelihood Theory

A brief account is now given of the role of orthogonality in more general parameter estimation settings. Let $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_k)'$ be a model parameter vector to be estimated, and let $l(\boldsymbol{\theta})$ be its log likelihood. Then parameters θ_i and θ_j are said to be orthogonal if $\mathrm{E}(\partial^2 l/\partial\theta_i \partial\theta_j) = 0$. The implication is that, in the large-sample normal distribution theory for the **maximum likelihood** estimator $\hat{\boldsymbol{\theta}}$, the estimators $\hat{\theta}_i$ and $\hat{\theta}_j$ are asymptotically independent. Furthermore, the standard error of $\hat{\theta}_j$ remains the same whether θ_i is regarded as known or unknown. If all k parameters are mutually orthogonal, then the information matrix is diagonal and we have a clear parallel with the linear regression case explored previously.

Now suppose that θ_i and θ_j are two parameters, and that θ_i is given. It has been shown [2] that, as θ_i is varied, the maximum likelihood estimate of θ_j changes much more slowly when the two parameters are orthogonal than otherwise. The most important consequence of this is that, for large samples, fixing θ_i has a minimal effect upon inference regarding θ_j, providing it is fixed close to its maximum likelihood estimate.

Ideally, of course, we would like the estimate of θ_j to be completely unaffected by changes in θ_i. Examples of distributions for which this is possible are given by [1, Chapter 9] – an important class is the **exponential family** with θ_i as part of the canonical parameter and θ_j as the complementary part of the expectation parameter.

These ideas have particular relevance in a generalized linear modeling framework, where the parameters represent effects of different predictor variables. The information matrix for a **generalized linear model** takes the form $\mathbf{X}'\mathbf{W}\mathbf{X}$, where $\mathbf{X}$ is the design matrix and $\mathbf{W}$ is a diagonal matrix. Thus, if $\mathbf{X}$ is orthogonal then the information matrix is diagonal and the discussion in the preceding paragraphs applies. When the maximum likelihood estimate can be obtained directly by weighted least squares, we can assess the effect of each predictor individually as though it were the only one in the experiment; otherwise, fixing one parameter at a "sensible" value (i.e. close to its maximum likelihood estimate) will have an effect on other parameter estimates, but the effect will be smaller than if the design matrix were not orthogonal.

Orthogonal Functions

Inner products may be defined on $L^2(\mathbb{R})$, the collection of complex-valued square-integrable functions on the real line: for two functions f and g in this class, the most commonly-used inner product is given by

$$\langle f, g\rangle = \int_{-\infty}^{\infty} f(x)\overline{g(x)}\,\mathrm{d}x,$$

where $\overline{g(\cdot)}$ denotes the complex conjugate of $g(\cdot)$. The function space is infinite-dimensional, and any orthonormal basis for the space must have an infinite number of elements. One such basis is the collection of complex exponential functions $[e_\omega : e_\omega(x) = (2\pi)^{-1}\exp(-i\omega x), \omega \in \mathbb{R}^+]$ used in Fourier theory. For any function f which is in $L^2(\mathbb{R})$ (and satisfies certain other regularity conditions), the quantity $\langle f, e_\omega\rangle = G(\omega)$, say, is the *Fourier coefficient* at frequency ω. The Parseval relation, (2), becomes

$$\int_{-\infty}^{\infty} |f(x)|^2\,\mathrm{d}x = \int_{-\infty}^{\infty} |G(\omega)|^2\,\mathrm{d}\omega,$$

so that the basis $\{e_\omega\}$ effects an orthogonal decomposition of the variation in f into cyclical components at each frequency $\omega \in \mathbb{R}^+$.

Applications in Distribution Theory

Orthogonal functions have an important role to play in distribution theory, and give rise to methods for characterizing and approximating distributions, establishing their properties, and also for finding distributions which satisfy certain requirements. For

example, the **characteristic function** of a continuous random variable is just its expansion in terms of the Fourier basis above. Other choices of basis underlie methods such as the Edgeworth expansion. A good account of the application of such methods in distribution theory is given by [11]; see also [9].

Applications in Time Series Analysis

Any realization of a time series (discrete or continuous parameter) may be regarded as a function defined on some interval and may thus, providing it is suitably well-behaved, be expressed as a linear combination of functions which are orthogonal over that interval in exactly the same way as if it were deterministic (the only difference is that the coefficients in the linear representation are random variables rather than constants). This is the underlying idea behind the **spectral analysis** of time series. Wavelet techniques (see [3], for example) are another example using different basis functions. In some situations, there may be a physical reason for wishing to decompose a time series into orthogonal components (spectral analysis was originally developed as a means of detecting periodicities in noisy data); in others, statistical properties (such as approximate uncorrelatedness) of the coefficients in the orthogonal representation may be useful in their own right.

Concluding Remarks

Orthogonality has applications throughout mathematics and statistics; the topics covered here are merely those which have some relevance in biostatistics. Recurring themes include the Parseval relation, which simultaneously forms the basis for an extension of Pythagoras's theorem and for variance decomposition, and the projection theorem, asserting the existence of a unique least squares linear predictor, for example, which is orthogonal to the prediction error (this property is called the *orthogonality principle* by some authors). In closing, we emphasize that orthogonality is best exploited in *linear* systems (a consequence of the linearity of a vector product in the underlying mathematical framework).

Given the enormous range of subjects within which the notion of orthogonality may be usefully employed, the references below have been chosen to provide a broad (and, where possible, recent) overview of the relevant ideas. Most contain extensive bibliographies for more detailed reading.

Otorhinolaryngology

Otorhinolaryngology (ORL) is a speciality in medicine dealing with diseases of the ears, nose, and throat (ENT). The practice of ORL continues to change and expand, as does research in this field. It covers areas such as audiology, immunology, **oncology**, microbiology, facio-plastic surgery, implantation of advanced medical technologies, **genetics**, and communicative development [8].

Modern otorhinolaryngology has expanded so much over the past few decades that subspecialities have developed, including pediatric ORL, head and neck surgery, and otology. ENT surgeons care for with patients of all age groups with a focus on children (upper airway infections, middle ear diseases) and elderly people (deafness).

As most of the diseases dealt with by otolaryngologists interfere with communication skills (hearing, speech), the consequences for individual quality of life and for society are tremendous. This is especially true because many of the diseases in ORL are highly **prevalent**, for example:

1. Seventy percent of children experience one or more episodes of acute otitis media before the age of 3 years [17]. Middle ear effusion that is associated with hearing loss is present in 20–40% of all ears of preschool children, dependent on the season [20].
2. ENT operations (adeno-tonsillectomy, tympanostomy tubes) are by far the most common surgical procedure in Western societies [5].
3. Around 10% of all people older than 65 years possess a hearing aid [4].

In addition to these highly prevalent diseases, the otorhinolaryngologist can be faced with several relatively rare but life-threatening diseases, such as acute airway obstruction, congenital syndromes with craniofacial malformations, and malignant tumors of head and neck.

In many respects, research in ORL follows the same lines as in other specialities, including the biostatistical aspects of these studies. Some landmark studies on selected areas are:

1. A randomized **clinical trial** of the Veterans Affairs Study Group comparing combinations of surgery, chemotherapy, and radiotherapy in patients with laryngeal cancer with respect to survival rate and other outcomes. Statistical analyses are straightforward comparing **Kaplan–Meier** curves of patients' survival and disease-free interval by **logrank tests** [18] (*see* **Survival Analysis, Overview**).
2. A newly developed PCR assay (polymerase chain reaction, a gene amplification method) for *Streptococcus pneumoniae* is compared with classic bacterial culture of the middle ear fluid. The assay is to be used for the etiological diagnosis of acute otitis media [19]. **Sensitivity** and **specificity** of the PCR method were assessed in 180 middle ear fluid samples of 125 children with acute otitis media. Standard statistical procedures (**chi-square test** and **McNemar test**) were applied to the data.
3. Triggered by the high incidence of permanent sensorineural hearing loss among US soldiers returning from World War II, many studies (human and animal experiments) have been published on noise-induced hearing loss [6]. Typical of these kinds of studies is the graphical presentation of **mean** and **standard deviation** threshold shifts (TS) for exposed and unexposed groups. Such permanent or temporary TSs [expressed in decibel (dB) loss] are measured by pure tone audiometry at frequencies ranging from 500 Hz to 8000 Hz. For statistical testing many authors compare the mean of three frequencies (1000 Hz, 2000 Hz, and 4000 Hz, important for discrimination of speech) for each exposure group.
4. Typical for pediatric infectious diseases in ORL is the favorable natural course. As a result, the effect of treatment in clinical practice seems large. In randomized clinical trials, however, only modest effects are demonstrated, underscoring the importance of this type of study. An example of this phenomenon is a three-way trial in 177 children with recurrent episodes of throat infection that met the US standards for tonsillectomy or adino-tonsillectomy [12]. Children were randomized to either a tonsillectomy group, an adino-tonsillectomy group, or a control group and followed for three years. The authors assumed a Poisson distribution for comparing mean rates of occurrence of episodes of throat infection using a generalized linear model.

As ORL diseases are so diverse and ORL research touches so many disciplines, including laboratory, clinical, and epidemiologic research (*see* **Observational Study**), all study designs and statistical procedures are applied in this field. Some specific characteristics of ORL bear consequences for biostatistics.

Specific Statistical Issues in ORL Research

Dependency

In principle each patient in an ORL study provides the investigator with one nose, one throat, and two ears. The ears do not act independently, but neither do they perform in perfect concert. Analyses of data on hearing, middle ear function, and morphology of the ear have to cope with this partial dependency. This feature of paired, dependent organs is not confined to ORL. Other medical disciplines such as **ophthalmology**, orthopedics, and **nephrology** share this feature. With a view to the **power** of the study, it is tempting to analyze the data as if they are independent. This will lead to **confidence intervals** (CI) that are too narrow. Until recently, conservative solutions for this problem were found in selecting just one ear for each patient, but this led to considerable loss of information. The construction of a 95% CI for the prevalence of middle ear disease with the ear as the unit of analysis, accounting for the dependency in pairs of ears, is given below.

Let θ denote the true probability for an ear to have middle ear disease and let γ denote the true **conditional probability** that one ear is affected when the other ear is also affected. Suppose a sample of n pairs of ears ($2n$ single ears) is drawn. Let n_{l} denote the number of left ears and n_{r} the number of right ears that are affected. Denote by n_{lr} the number of pairs where both ears are affected. The **maximum likelihood** estimates for the prevalence of θ and the conditional probability γ are given by

$$\hat{\theta} = \frac{n_{\mathrm{l}} + n_{\mathrm{r}}}{2n}, \qquad \hat{\gamma} = \frac{2n_{\mathrm{lr}}}{n_{\mathrm{l}} + n_{\mathrm{r}}}.$$

An approximate 95% CI for θ is then given by

$$\hat{\theta} \pm 2\left(\frac{\hat{\theta}(1-\hat{\theta}) + (\hat{\theta}\hat{\gamma} - \hat{\theta}^2)}{2n}\right)^{1/2}.$$

When both ears are independent ($\hat{\theta} \approx \hat{\gamma}$) the 95% CI reduces to the conventional confidence interval for θ from $2n$ Bernoulli trials with success probability θ. If there is positive dependency, $\hat{\gamma} > \hat{\theta}$, then the width of the correct CI is on average larger than the conventional CI.

More advanced methods for the analyses of correlated ears with the possibility to include **covariates** are described by Rosner [15], Dallal [3], and Le & Lindgren [10]. The outcome variables in the models given by Rosner are **normally distributed** (**multiple linear regression**) or **binomially** distributed (**logistic regression**). Dallal modifies the assumptions of the logistic regression model of Rosner. Le & Lindgren give another logistic model for the analysis of correlated ears (*see* **Correlated Binary Data**).

Random effect logistic models for indistinguishable data are another possibility to model the dependency between ears and to include covariates. In these models, the probability θ that an ear is affected does not only depend on the covariate values but also on extra random variation. Let θ_i denote the probability for each ear in the ith pair to be affected. The θ_i is modeled by

$$\mathrm{logit}(\theta_i) = \ln\left[\frac{\theta_i}{(1-\theta_i)}\right] = \mathbf{z}_i'\boldsymbol{\beta} + \sigma\mathbf{u}_i.$$

In this expression $\mathbf{z}_i$ is the covariate vector for the ith pair, $\boldsymbol{\beta}$ the vector of the regression parameters, $\mathbf{u}_i$ a realization of a standard normal distribution, and $\sigma > 0$.

The issue of dependent ears also provides elegant potential for within-person trials. Maw [11] became famous for his trials on surgical treatment for persistent middle ear disease in children. The design of the trial allowed the child to act as his or her own control, in that only one of the bilaterally affected ears was treated with a ventilation tube. The unoperated ear in the group of children not receiving surgery either to the adenoids or tonsils allowed documentation and examination of the natural history of the untreated condition over a long period (*see* **Crossover Designs**; **Unit of Analysis**).

Fluctuating Natural Course

Many infectious diseases in ORL have a very fluctuating, and usually favorable natural course, that is,

episodes of disease in different degrees of severity are followed by episodes without the disease and vice versa in an apparently random order. A typical example is the occurrence of otitis media with effusion (OME) in children. There are four states for characterizing a middle ear with respect to OME based on tympanometry measurement of the compliance of the tympanic membrane at different levels of external air pressure:

A. Normal (aerated) ear: no effusion present in the middle ear cavity. A middle ear pressure corresponding to ambient air pressure. Maximal compliance at ambient air pressure.
B. OME ear: middle ear cavity filled with fluid. No compliance of the tympanic membrane.
C1. Intermediate: slight negative pressure in the middle ear. Fluid in some instances. Maximal compliance at pressures below ambient air pressure.
C2. Intermediate: moderate negative pressure in the middle ear, fluid in approximately half of the cases. Maximal compliance at pressures below ambient air pressure.

A typical pattern for the development of the disease is from type A to type B via type C1 and type C2, followed by the same sequence in reverse order. It takes at least several weeks to develop OME and to recover from it. Short episodes (1 or 2 months) are common, in many cases not even reaching the type B state. Some children's ears, however, have persistent middle ear effusion (type C2 and B) that may have long-term consequences for hearing and language development.

A description of the natural course of OME is very important as a first step in identifying those children who will have persistent disease and therefore need treatment. As there is no simple model that fits the empirical data on the natural history of OME, most statistical techniques fail in this description. For instance, **Markov** models were explored but gave no valid descriptions. Instead we used several graphical techniques [22]. A useful technique describing dichotomized data (type B vs. the other types) on ears measured by tympanometry nine times in a period of 2 years is shown in Figure 1. It gives some insight into **cumulative incidence**, rate of improvement, and rate of recurrence. Unfortunately, these graphical techniques are not suitable for studying determinants of natural course, nor do they provide precision parameters.

Simplified models and survival analytic techniques are more suitable when the focus is on duration of OME episodes. Let X denote the duration of an OME episode. Suppose X has an **exponential distribution** with density $a\exp(-ax)$, $a > 0$, and X is measured in months. If after 3 months 50% of the patients have recovered from OME, the monthly rate of recovery is given by the solution of the equation $\exp(-3a) = 0.5$. The proportion of patients still diseased after x months is then given by $\exp(-ax)$. Such a simple model does help to describe natural course (with an appealing effect on public awareness) but might fail proper fit [21].

An extension of the **life table** to repeating and changing events described by Hoover [7] can be used to model the cumulative episodes of middle ear disease. Tests for changes in the number of episodes within age intervals and differences between individuals are possible.

Dynamics of Disease Over Time

Some typical ORL diseases now very prevalent, such as OME, seemed rare in the past. Other diseases, such as acute mastoiditis, have become less frequent over time. These patterns are subject to **bias** as concepts and classification of disease also change over time [2]. Until the nineteen nineties, OME was considered a sterile inflammation of the middle ear, distinct from but correlated with acute otitis media and upper airway infections. Nowadays, the general belief is that OME is just one of several expressions of infections of the upper respiratory system. This idea is supported by **principal components analysis** of data on signs and symptoms of a large number of patients [16].

In addition, demographic trends such as aging of the population and improving socioeconomic conditions and changes in disease management lead to changes in frequency of diseases or its sequelae [23]. Societal views on **quality of life** are also major issues in ORL research [14]. For instance, utilities for technology-supported hearing programs (cochlear implants) or radical head and neck surgery (vs. radiotherapy in case of advanced laryngeal carcinoma) may vary over time and between groups of patients. One should recognize these differences in the analysis and interpretation of descriptive statistics on ORL diseases and/or frequency of treatment options.

Dynamics of Management Over Time

ORL is a medical discipline that has experienced large changes in the popularity of treatment options over time. These were partly the result of the dynamics of the disease itself, partly a result of newly developed techniques or drugs (note that antibiotics have only been available since World War II). Some changes, however, are due to new scientific insights into the effectiveness of specific treatments. A typical example of this in the field of ORL is the practice of tonsillectomy, alone or in combination with adenoidectomy [2, 5, 11]. In the 1950s and 1960s it was almost routine to remove the tonsils and/or adenoids. During the 1970s and 1980s the belief in the effectiveness of these surgical procedures disappeared, leading to a one-third reduction of their frequency [5]. Since the late 1980s there has been some revival of the tonsillectomy and/or adenoidectomy for specific indications [12]. In the same period the rate of surgery with ventilation tubes has risen quite rapidly, with stabilization in recent years.

The practice of ORL in general is considered sensitive to the results of epidemiologic research, bearing consequences for medical practice. Despite a high standard of international scientific communication in journals and at conferences, large international differences do occur. For instance, European countries still prefer surgical treatment of middle ear disease, while US physicians (most of them pediatricians) prefer medical treatment (e.g. antibiotics or steroids) [23]. To a certain extent these international differences provide opportunities for **ecologic studies**. Medical audit and formal assessment of cost–effectiveness or cost–benefit ratios of medical procedures and technologies is also expanding into the field of otolaryngology [1, 9] (*see* **Health Economics**). Alongside standard statistical procedures, techniques like **factor analysis**, uncommon in this

medical field, are being introduced. An example is the Glasgow Benefit Inventory as a measure of patient benefit from ORL interventions [13]. With a principal components analysis of patient responses to five such interventions, subscales for different types of benefit are developed. The use of these and other evaluation instruments will assist evaluation research as well.

Concluding Remarks

Biostatisticians entering the field of ORL are confronted with large numbers of patients and a diversity of diseases and treatment options. Most of the statistical procedures used are similar to those used in other branches of medicine. Special features are the potential of each patient having two ears, the fluctuating course of many of the common ORL diseases, and the diversity of management options.

ANNE G.M. SCHILDER

Outcome Measures in Clinical Trials

Clinical trials are an important source of information used by health care decision makers to establish health policy, and to make judgments about prescribing treatments for specific patients. In recent years, the clinical evaluation of therapeutic interventions has moved beyond simple measures of safety and efficacy to include measures of symptom improvement, **quality of life**, and cost-effectiveness (*see* **Clinical Epidemiology**; **Health Economics**). This has resulted in more complex experimental designs using multiple response variables to address multiple objectives (*see* **Multiplicity in Clinical Trials**). The purpose of this article is to address the statistical considerations used to select the outcome measures in clinical trials. Issues relating to clinical endpoints, quality of life assessments, and economic evaluations are discussed.

Clinical Endpoints

Primary Outcomes

In regulated environments evaluating pharmaceutical interventions, it is recommended that clinical trials have a single primary objective. In confirmatory trials, this typically includes **hypothesis testing** about the comparative efficacy of the therapies under study. The hypothesis may be one of superiority of one treatment compared to a placebo or other control, or it may be the **equivalence** of two treatments. The primary outcome variable or endpoint is the measure capable of providing the best evidence directly related to the primary objective of the trial.

It is readily agreed that the most clinically relevant outcomes are those directly relating treatment to the patient's health status. In studies of serious or life-threatening diseases, this may be an important clinical event (e.g. mortality or myocardial infarction), measured either as a **binary** outcome or by the time from **randomization** to the event. In some trials, health status may be measured according to disease rating scales, usually with ordered categories of severity (*see* **Ordered Categorical Data**) (e.g. the New York Heart Association classification of congestive heart failure). When study variables are continuous (e.g. blood pressure or serum cholesterol) the effect of treatment is usually based on a comparison of change or percent change from baseline. Response data are often collected on a repeated basis at several time points during the trial. Also, patients may experience several primary events during the period of observation. These data can be analyzed using models for recurrent events or using the time to the first event.

It is important that the primary outcome variable be measured without **bias** in a reliable manner using validated instruments with adequate **sensitivity** to detect real change in a patient's health status. These assessments should be made prior to initiation of the trial, using experience gained from previous trials or from the published literature. The **power** and **sample size for the trial** should be based on the primary outcome variable.

Surrogate Endpoints

There are situations in which short-term measures of response to treatment may provide reliable indicators of long-term patient outcome. The presence of serum antibody at protective levels following vaccine administration is one example. In the area of cardiovascular disease, it has been shown using **meta-analysis** [20], and with long-term clinical endpoint trials, that lipid-lowering by diet or drugs does confer the benefits of a reduced risk of coronary heart disease [36, 37] and increased survival [36]. This suggests that serum cholesterol levels may be a viable **surrogate endpoint** marker.

The use of surrogate endpoints also has its drawbacks [14]. Pocock [33] notes that their use has been a "deceptively attractive pursuit" in many areas of clinical trials research. His view was formed in part by HIV research, with a reliance on CD4 counts as a potential surrogate that could hopefully shortcut the need for long-term trials. However, the Concorde trial [5] of immediate and deferred use of zidovudine failed to show a difference in clinical outcomes, despite a significant change in CD4 cell counts.

The statistical methodology needed to explore surrogate endpoints has undergone considerable development in recent years. Prentice [35] proposed a definition and operational criteria for surrogate endpoints. Fleming et al. [15] discussed data analysis methods.

Responder or Threshold Variables

Investigators may want to re-express continuous or ordinal variables into categorical or dichotomous response variables (*see* **Categorical Data Analysis**). These are often called responder or threshold analyses since they are usually specifications of a positive clinical result. A typical example may be a reduction in serum LDL-cholesterol to a level below the recommended levels established by the National Cholesterol Education Program [31]. When using these types of variables, it is important to recognize that the loss of information can result in a loss of power for the study, and **regression to the mean** effects can introduce bias when the underlying variables are subject to **measurement error** [4].

Composite Variables

Constructed variables which are composites of multiple measurements or endpoints are sometimes used to provide a single summary response. At the individual level, this involves combining the univariate responses in some clinically sensible manner. This technique is often used in quality of life assessments. Composite endpoints can also be formed from multiple clinical event data. For example, clinical trials of antiretroviral therapy for patients infected with HIV may use the combined clinical endpoint of any new or recurrent AIDS defining event or death. Composite endpoints of heart disease or death have also been used for cardiovascular clinical trials. Composite variables may offer advantages in terms of increased statistical power due to the reduction in dimensionality of the multiple endpoints, or to the increased incidence of the composite event when the incidences of the individual events are low. However, this advantage is offset if the treatment does not affect each endpoint consistently. Also, the clinical interpretation of the constructed variables can be difficult.

Secondary Outcomes

Secondary outcome variables are either supportive measures to help interpret the primary results, or response variables, related to secondary objectives or hypotheses. Trials may also include **explanatory variables** to be used for generating hypotheses to be tested in future studies.

Compliance

Although difficult to measure, it is well known that patient noncompliance can dramatically impact estimates of treatment effect in trials (*see* **Compliance Assessment in Clinical Trials**). In a study comparing two treatment programs to reduce levels of serum LDL-cholesterol, Oster et al. [31] showed that patient compliance differed between programs and, not surprisingly, noncompliance affected the likelihood of patients achieving their target levels. Efron & Feldman [13] proposed a compliance–response **regression** to measure the relationship between the treatment effect and compliance using data from a primary **prevention trial** of a cholesterol lowering drug (*see* **Noncompliance, Adjustment for**).

Multiplicity Considerations

Inclusion of **multiple endpoints** in a trial raises concern about an increased probability of drawing a **false positive** conclusion. This is the principal reason that studies subject to regulatory review use only a single primary endpoint, or use appropriate multiplicity adjustments in those situations in which multiple hypotheses are being tested. Cook & Farewell [6] take a less restrictive viewpoint in allowing studies to consider a few well-chosen, important clinical outcomes and computing a marginal ***P* value** for each. This position recognizes the P value as providing a measure of the strength of the evidence against the **null hypothesis**, rather than as a decision making criterion wherein the type I error rate α (*see* **Hypothesis Testing**) is interpreted as a rejection rate.

Understanding the distinction between multiple endpoints and multiple hypotheses is particularly important in circumstances in which the underlying disease may be measured across a number of meaningful dimensions. One such example is described by Gormley et al. [19], who studied the effect of finasteride in men with benign prostate hyperplasia (BPH). They recognized BPH as a multifaceted disease and evaluated the effect of treatment on a biochemical variable, dihydrotestosterone, on physiologic measures, prostate size, and urinary flow rate, and on a subjective assessment of BPH symptoms using a validated questionnaire. If evidence of a treatment effect depends on any single variable being impacted by treatment, then attention focuses on the most extreme P value, and a **Bonferroni**-type adjustment

(see, for example, [22]) is appropriate (*see* **Multiple Endpoints, *P* Level Procedures**). If evidence of a treatment effect requires that each of the variables is affected by treatment, then no adjustment to the individual P values is necessary. Tests of a global hypothesis proposed by O'Brien [30] can also be performed using the individual analyses to help interpret the results (*see* **Multiplicity in Clinical Trials**).

Quality of Life

Patient perceptions of health-related **quality of life** have recently received a higher priority in clinical trials. This is due in part to the broadened definition of health proposed in 1947 by the **World Health Organization** as "a state of complete physical, mental, and social well being, and not merely the absence of disease and infirmatory" [40]. One of the first clinical applications of quality of life was by Karnofsky & Burchenal [27], who outlined the basic criteria necessary for evaluating chemotherapeutic agents. These included measures of survival, but also subjective variables, such as performance status, symptom status, mood, and well-being. There are several important statistical considerations in the design, analysis, and interpretation of quality of life studies. Fletcher et al. [16] and Cox et al. [7] offer recommendations on how to keep quality of life evaluations simple.

Measurement Characteristics

The most important statistical consideration in using quality of life questionnaire instruments in clinical evaluations is an assessment of its measurement characteristics (*see* **Health Status Instruments, Measurement Properties of**). Quality of life (QoL) is by definition a multidimensional construct. A typical instrument consists of components or dimensions which usually include a number of individual questions or items. The scoring of an instrument begins with a response scale for each item. Scores are usually provided for each dimension and an overall score is sometimes provided. Although controversial, the scoring scheme may sometimes use weights based on individual patient preferences [38], or data analytic techniques based on **factor analysis** or **discriminant analysis**.

Quality of life scales used in clinical trials should have demonstrated reliability and validity, and be responsive to changes in health status. Reliability is assessed through examination of the internal consistency at a single administration of the instrument, using **Cronbach's alpha**. The test–retest properties of the scales can be evaluated using the concordance **correlation** coefficient, or the intraclass correlation. The correlation coefficient is not an appropriate measure of agreement in assessing reliability [2].

Face validity is a subjective judgment of whether the instrument appears to cover its intended topics clearly and unambiguously. It can be maximized by including individuals of diverse backgrounds, including both patients and healthcare providers, among the developers. Construct validity is a formal measure of the association between the QoL scores and other objective and subjective measures of health status.

Responsiveness checks the ability of a scale to detect clinically meaningful changes in health status. It is the most difficult property to assess prior to its use in a trial. Responsiveness is usually assessed through measuring the longitudinal association of changes in QoL scores with changes in other measures of health status. Jaeschke et al. [24] defines a minimal important difference as the change from baseline in QoL score associated with a patient perceived change in health status based on a global rating.

Selection of Instruments

The choice of dimensions to use in a trial depends on the nature of the disease and the candidate treatments. For example, symptomatic conditions such as asthma or rheumatoid arthritis are likely to have a negative impact on a patient's quality of life that may potentially be offset with therapy. Alternately, for patients with high blood pressure or high levels of serum cholesterol, interest focuses on the adverse experiences associated with therapy, or on the reduction in both quality and length of life associated with coronary heart disease.

Most clinical trials use standard questionnaire instruments. These are generally categorized as generic or disease-specific. Generic instruments cover a broad range of quality of life dimensions and are particularly useful when there is uncertainty regarding the appropriate dimensions, or when there is not much known about the therapeutic effects. They are also useful for making comparisons among

different diseases, which is sometimes necessary when establishing health policy. The disadvantage of generic instruments is that their responsiveness to changes in health status is reduced. Health indices are meant to provide an overall measure of a patient's quality of life by using a continuum from 0 (death) to 1 (perfect health). Health states with diminished quality are scored less than 1. The clinical usefulness of health indices is limited unless individual component scores are also made available.

Well-known examples of generic instruments include the MOS 36-item short form health survey (SF-36) [39], the Sickness Impact Profile [1], and the Nottingham Health Profile [23]. The Quality of Well-Being (QWB) index [26] is a health index that is an additive combination of three function scales (mobility, physical activity, and social activity), and a scale for symptoms and health problems. Fryback et al. [17] provides a quantitative link between the eight subscales of the SF-36 and the QWB as a means of providing a single health utility summary score representative of the SF-36 profile.

The quality adjusted life year (QALY) method of analysis [38] accumulates the 0 to 1 quality scores over the lifetime of individuals to combine the concepts of quality and length of survival. The number of QALYs gained is often used as a measure of health benefit in cost–effectiveness analysis (*see* **Health Economics**). A related method measures TWIST (Time WIthout Symptoms of disease and Toxicity of treatment) and Q-TWIST provides a quality adjustment to TWIST [18] (*see* **Quality of Life and Survival Analysis**). While conceptually attractive, both the QALY and Q-TWIST have limitations in interpretation, since separate evaluations of quality and survival are usually of interest.

Disease-specific instruments focus only on relevant dimensions of quality of life that impact patients with the underlying target illness. As such, they have greater responsiveness and a higher level of patient acceptance. Disease-specific quality of life is most applicable with symptomatic disease, where patients are able to detect changes in their health status due to therapy. For example, Juniper et al. [25] evaluated the measurement properties of an asthma QoL instrument developed for use in clinical trials. The 32-item instrument included dimensions for activities, symptoms, emotions, and exposure to environmental stimuli, and was developed through an item-generation and item-reduction process involving adult asthmatics.

Disease-specific QoL evaluations may have limited usefulness in guiding health policy decisions involving multiple diseases and therapeutic interventions. Fletcher et al. [16] recommends using both a generic and a disease-specific instrument in trials. This approach assures the focus needed to identify the QoL impact of changes in health status, and yet allows the possibility of detecting unexpected effects, and may allow a comparison with other diseases.

Analysis

Special considerations in the analysis of QoL data in a clinical trial are related to the multidimensional aspect of both the concept and the instrument. Cox et al. [7] recommend simplicity in the scoring and weighting schemes used. The analysis should also evaluate the sensitivity of the results to alternate scoring and weighting schemes. Fletcher et al. [16] recommend that scores can be expressed as the percentage out of the maximum achievable, to facilitate the interpretation of aggregated dimension scores.

The separate dimension mean scores, dimension-by-treatment mean scores, and the overall treatment mean scores are the key values for interpretation. The possibility of a dimension-by-treatment qualitative interaction (*see* **Treatment-covariate Interaction**) should be explored, since a drug may have a positive impact on some dimensions and a negative impact on others. A complete interpretation of the trial results needs to consider the multivariate character of the data. This raises issues of **multiplicity**, which can be addressed by a protocol specification of a limited number of dimensions thought to be impacted by therapy. An overall summary score can be derived, but limits the clinical utility of the analysis. Bonferroni and modified Bonferroni-type procedures [22] based on the ordered P values can be used if the researcher is to treat the multiple dimensions as separate multiple hypotheses. Tests of significance of departures from a global null hypothesis of treatment equivalence can be undertaken using the methods of O'Brien [30]. Global tests and overall summary scores are more applicable for evaluating disease-specific QoL, since there is less possibility of an interaction.

Effect Size

Two forms of effect size are available to help interpret the magnitude of changes observed in a trial. Deyo et al. [8] consider the difference in **means** relative to the **standard deviation** at baseline. This approach transforms the change score into a standardized unit of measurement that can be compared to other instruments. The index of responsiveness [21] considers the pre-minus-post mean changes relative to the within-patient standard deviation during a stable period. This allows differences to be measured against changes that individuals experience in normal day-to-day variability. Fletcher et al. [16] note that, for an individual patient, a treatment effect of one to two units of responsiveness is probably important. When considering average treatment effects for a randomized group, it is likely that effects that are larger than one-third of the between-patient standard deviation are noticed by individual patients. The availability of estimated effect sizes for established therapies is useful in providing a benchmark for interpreting the results of trials involving experimental therapies.

Economic Analysis

Economic endpoints are becoming an increasingly important part of clinical trials. Data on individual patients' use of health care resources can be collected and combined with cost data, relevant to the trial perspective, to perform cost comparisons or cost–effectiveness analysis (*see* **Health Economics**).

There has been considerable debate on the appropriateness of randomized trials to support valid conclusions about economic endpoints [34]. Drummond & Davis [11] discuss some of the methodologic issues. There is no consensus on the most relevant choice of outcome measure, clinically important effect sizes [12], or the analytic method to be used in comparing treatments on the basis of cost–effectiveness [3, 29]. Dudley et al. [10] note the complexity of analyzing cost data that are subject to **censoring**.

Advances in the methodology are being made, as a number of trials have recently been completed that have included economic evaluations. Pedersen et al. [32] collected data on hospitalization and coronary revascularization procedures, as part of the Scandinavian Simvastatin Survival Study. They concluded that simvastatin therapy, to reduce levels of serum cholesterol, has the potential for significant cost offsets, in addition to reducing mortality and morbidity. Mark et al. [28] supplemented data from the one-year Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial with projected **life expectancy** data and hospital cost data, to evaluate the cost–effectiveness of thrombolytic therapy with tissue plasminogen activator (t-PA) compared to streptokinase for the treatment of acute myocardial infarction. Using cost–effectiveness analysis, they concluded that the added costs of t-PA therapy were consistent with other well-accepted medical technologies, when evaluated relative to the benefits of therapy. Similarly, the Diabetes Control and Complications Trial (DCCT) Research Group [9] examined the cost–effectiveness of aggressive approaches to the management of insulin-dependent diabetes mellitus. They used a **Monte Carlo simulation** model, based on the clinical outcome results of the DCCT, supplemented with other clinical, epidemiologic, and cost studies.

These three examples illustrate innovative ways of utilizing clinical and health care utilization data, collected as part of randomized trials, to perform cost–effectiveness analysis. In each case, the researchers were able to overcome certain limitations in the trial with supplemental data and modeling techniques.

JOSEPH F. HEYSE

Outcomes Research

The multidisciplinary field of study that seeks to understand and improve the end results of particular health care practices and interventions is now broadly and commonly known as outcomes research [9]. The US Agency for Healthcare Research and Quality defines such end results to include not only survival and other biomedical endpoints, but also such patient-reported outcomes as symptom status, functional status, and experiences with the health care system [1]. At the US National Cancer Institute, outcomes research "describes, interprets, and predicts the impact of various influences, especially (but not exclusively) interventions on 'final' endpoints that matter to decision makers: patients, providers, private payers, government agencies, accrediting organizations, and society at large" [20, p. III-4]. In cancer, these final endpoints (outcomes) include not only survival and disease-free survival (*see* **Survival Analysis, Overview**), but health-related **quality of life**, patient perceptions of and satisfaction with health care, and economic burden. Final outcomes are to be distinguished from a variety of "intermediate" outcomes, for example, smoking quit rates, colorectal cancer screening rates, tumor shrinkage rates. While these latter are central to evaluating the proximate success of a particular prevention, screening, or treatment intervention, the pivotal question in almost every instance is whether improvement in the intermediate outcome increases the likelihood of improvement in one or more final outcomes.

Outcomes research, so defined, and **quality-of-care** research are not synonymous, but are closely linked. Indeed, much of the logic and vocabulary of outcomes research can be traced to Donabedian's seminal work on assessing and assuring the quality of health care [12, 13]. His paradigm usefully distinguishes three components of health care: "structure" (the nature and quantity of the physical, human, and financial resources available for providing care); "process" (the health care services and products delivered to individuals and populations), and "outcome" (the resulting impact on health and well-being). The paradigm posits a fundamental functional relationship among the components (see Figure 1). The structure of care feeds into and supports the production of the processes of care, and structure and process together influence outcomes. While, as Donabedian notes, this tripartite typology is a simplifying abstraction of the complex reality of healthcare delivery, it offers what has become an enduring framework for defining and analyzing the quality of care. Specifically, quality may be measured by the appropriateness of structure (e.g. was the physician specialty certified?), process (e.g. was the service or procedure performed consistent with evidence-based practice guidelines?), or outcome (e.g. did the patient have improved length of life or quality of life?).

While the valued end product of the healthcare system is good outcomes, it is not always easy or even feasible to judge quality by outcomes alone. For example, the 40-year old hypertensive who begins pharmacological and behavioral therapy to reduce blood pressure can expect to see major "final outcome" benefits only years later, when (all else being equal) she will be at lower risk than otherwise for heart disease, stroke, and microvascular problems. Moreover, all else might not be equal. If this individual later develops adult onset diabetes, she may yet suffer similar target organ damage even if her blood pressure is controlled. In cases like this (and they are numerous in the chronic disease domain), when the outcomes of interest cannot be immediately observed or else might be influenced by myriad systematic and random factors, the focus of quality-of-care assessment shifts to process or structure variables. In particular, quality is frequently measured by the extent to which the processes of care *that are expected to produce valued outcomes* are performed. In the example above, reducing this individual's blood pressure may be judged good quality care because substantial evidence exists that, on average, it will eventually lead to improvements in final outcomes that matter to her.

For outcomes research to achieve its potential to improve health care quality, progress must continue on three broad fronts, leading specifically to: (1) valid, reliable, appropriately responsive, and feasible outcome measures, (2) sound evidence about the impact of interventions on the outcomes of interest (*see* **Evidence-based Medicine**), (3) the capacity and commitment by research investigators and sponsoring organizations to translate findings into information useful to patients, providers, and other decision makers [18].

1. There has been significant progress in recent decades to develop, test, and use measures of patient-reported health outcomes, largely in research studies but sometimes also in clinical practice. These include

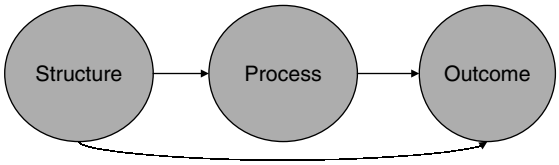

Figure 1 Components of health care

measures of health-related quality of life, at several levels: generic (non-disease-specific) indexes of functional status (*see* **Quality of Life and Health Status**), such as the SF-36 [32] or the Sickness Impact Profile [5]; disease-specific measures, such as the FACT G [8] in cancer or the VF-14 [30] for vision assessment; and even disease-subtype-specific measures such as the FACT-B [28], which combines the FACT G items with additional questions targeted for breast cancer. There are scales measuring patient report of symptom frequency and bother [10]. Measures of global well-being may be preference-based [14, 17] or psychometrically derived (*see* **Psychometrics, Overview**). For evaluating patient perceptions of and satisfaction with healthcare, the CAHPS (Consumer Assessment of Health Plans survey) instrument is being increasingly applied [16]. While there are few standardized instruments for measuring the economic burden of disease, the guiding principle in most applications is the same: capture the explicit or implied monetary value of the resources consumed by disease and its treatment.

Descriptions and analyses of a wide variety of quality-of-life measures are available in [6, 25, 29]. A comprehensive evaluation of the state of the science in cancer outcomes assessment has been completed by the Cancer Outcomes Measurement Working Group, a 35-member task force appointed by the National Cancer Institute [19]. Key findings from the working group underscore the importance of modern psychometric approaches, such as item-response theory modeling (*see* **Rasch Models**), for improving the technical quality and feasibility of patient-reported outcomes assessment. Throughout, this working group was guided by the evaluation criteria recommended by the Medical Outcomes Trust [21].

2. The central inferential problem in outcomes research can be summarized symbolically as: $O = f[P, S, X, E]$, which says that outcome (O) is a function of process (P) and structural variables (S), additional factors (X) such as patient characteristics and **risk factors**, and **random error** (E); it is understood further, that S may influence P, but at a point in time, both may potentially influence O (Figure 1). The approaches available for understanding the impact of P and S on O, while adjusting for X and taking account of E, are of course the standard strategies for scientific inference. These include randomized control trials (*see* **Clinical Trials, Overview**) [7] and a variety of **observational study** designs, ranging from retrospective [4] and prospective **cohort studies** [26], to **case–control studies** [27], to systematic expert judgment and synthesis (e.g. through a Delphi-type process) [22]. Observational studies are increasingly employing techniques such as **instrumental variables** [24] and **propensity scores** [11] in an effort to compensate or correct for **selection biases** arising because patients are not randomized to interventions.

An important motivating concern in outcomes research is whether there is an unexplained or unwarranted variation across population groups in valued health outcomes. In terms of the variables defined above, does O vary systematically with X? If so, does the impact of P and S on O also vary with X (that is, should there be **interaction** terms allowing for the possibility that the observed effectiveness of interventions may vary across population groups)?

While most such analyses are still conducted by individual investigators or small teams, there is a growing trend towards larger collaborative projects conducted by multidisciplinary groups comprising clinicians, statisticians, psychometricians, economists, behavioral scientists, and others [3, 23].

3. The challenges in translating the findings of outcomes research into knowledge useful to decision makers have been underscored by a recent US government report examining "The Outcomes of Outcomes Research" [31]. The report framed its analysis around a four-tiered pyramid (see Figure 2) depicting the levels of impact that outcomes research might have. In ascending the pyramid, one moves from research that largely adds to the knowledge base (level 1), to research that affects medical practice policy (level 2), to research that affects medical care delivery (level 3), to research that changes health outcomes (level 4). The report concludes that most of the federally funded outcomes research it reviewed represented level 1 studies that contributed to understanding the **epidemiology** of disease, the impact of specific interventions, or methodological issues (such

Figure 2 Outcomes research levels of impact [31]

as **meta-analysis** or other inferential techniques). There were only a few examples where outcomes research had been incorporated into policy practice or clinical decision making, or where interventions had then been shown to improve patient outcomes [31]. In response, there has been a heightened focus in the first half of this decade on initiatives to enhance the dissemination, diffusion, and adoption of evidence-based interventions (e.g. [2, 15]). At the same time, much (level 1) work remains, to understand better the behavioral, social, economic, and environmental factors that jointly determine whether, and how rapidly, any given evidence-based intervention scales the "outcomes pyramid."

In sum, the central tasks of outcomes research are measurement, inference, and translation into practice. The central aim is to improve outcomes important to decision makers, most typically through efforts to enhance the quality of care.

Outliers

Outliers are an important issue in data analysis. Since a single undetected outlier can destroy an entire analysis, analysts should worry about the origins, relevance, detection, and correct handling of outliers.

Intuitively, an outlier is an observation so discordant from the majority of the data as to raise suspicion that it could not plausibly have come from the same statistical mechanism as the rest of the data. Apparent discordancy is what distinguishes an *outlier* from a *contaminant* – an observation that did not come from the same mechanism as the rest of the data but was generated in some other way. A contaminant may appear ordinary (and not outlying), while an outlier could be, but is not necessarily, a contaminant.

Outliers can arise in several ways.

- They may be contaminants generated by some other statistical mechanism. For example, if the seeds used in a plant growth experiment contain some foreign seed, then the plants produced from the foreign seed will be contaminants and may be outliers.
- They may result from procedural errors in data gathering. For example, misreading an instrument will produce a contaminant that may be outlying. It is generally accepted that several percent of even high-quality data are wrong, and some of these errors may be outlying.
- The analyst may have a misconception of the true model (*see* **Misspecification**). For example, if an instrument is thought to produce **normally distributed** readings, but actually produces **Cauchy-distributed** readings, then some valid correct readings will be severe outliers *relative to the wrongly assumed normal model*.
- In structured data such as **multiple regression** or **analysis of variance** data, they may be a symptom of some other model failure. Heteroscedasticity (*see* **Scedasticity**) and nonlinearity, as well as nonnormality, may cause what appear to be isolated outliers.

Different possible origins of outliers call for different resolutions. Where the outliers are caused by imperfect modeling, the model should be refined so that they are accommodated. Where the outliers result from errors of execution, the primary concern is to minimize the damage they do to the analysis. Where the outliers result from mixtures of distributions or other types of contamination, there may be interest in identifying the outliers and (in the mixture case) estimating the characteristics of the mixture components. It is not always clear in applications what caused the outliers, and so "one size fits all" recipes for dealing with outliers are inappropriate.

Here, we concentrate on methods of *identifying* outliers – that is, of deciding whether observations really are implausibly discordant. This has two parts – deciding which of the observations are most discordant from the majority; and measuring their discordancy.

The first task – locating the most discordant observations – seems trivial at first glance, but is so only in the simplest case of univariate **random samples**. Here, it is only the largest and the smallest of the data that could be potentially discordant. Locating the most discordant observations, however, can be very difficult in "structured" data sets such as **time series**, analysis of variance, multiple regression, and **multivariate** data. Here, simple **diagnostics** like regression **residuals** cannot be relied upon to locate discordant observations.

Estimating the parameters of a model without risk of serious damage from outliers is addressed by the techniques of *robust estimation* (*see* **Robustness**), the most familiar example of which may be the box and whisker plot with its outlier identification rules (*see* **Graphical Displays**). The objectives of robust estimation and outlier identification are logically connected – if the potential outliers are located, then removing them from the sample and fitting the model to the remaining data will neutralize them and so provide robust estimates. Similarly, sturdy estimates of unknown parameters will provide a good picture of the model fitting the majority of the data, thereby helping locate potential outliers. The details of both approaches are less simple than they seem though, and the connection is not enough for either technology to supersede the other.

Likelihood Models for Outliers

Outliers may be flagged and investigated in varying degrees of formality. For example, making a normal probability plot (*see* **Normal Scores**) of residuals from a multiple regression and labeling as outliers any cases that seem visually too far from the line

is a method of flagging questionable cases. Being informal though, it suffers from dependence on perceptions of how large a deviation is too large and may be criticized for having no obvious theoretical basis. More formal statistical models for outliers remove the subjective element and are valuable even if used only as benchmarks to assess other less formal models. A general framework that permits the modeling of data sets that might contain outliers is the "parameter shift" model. Each "good" (scalar or vector) observation $\boldsymbol{X}_i$ in the sample is modeled as following a specified statistical model with unknown parameter vector $\boldsymbol{\theta}$

$$\boldsymbol{X}_i \sim g_i(., \boldsymbol{\theta}).$$

There may also be one or more contaminating observations $\boldsymbol{X}_i$ with distribution

$$\boldsymbol{X}_i \sim g_i(., \boldsymbol{\theta}, \alpha_i),$$

where the parameter α_i drives the contaminant's displacement, and is most conveniently parameterized so that a contaminant with $\alpha_i = 0$ has the same distribution as a "good" value. Commonly, different contaminants are modeled as having different α_i, but in some settings, a common α for all is sensible. Contaminants with sufficiently extreme α_i values will be outlying and so potentially identifiable; those with less extreme α_i values will be indistinguishable from the good observations. This model is less restrictive than it might seem. An outlier that resulted from a recording error of transposing digits would not plausibly be explained by this parameter shift model, but since a good choice of α_i could be fit to the data, this conceptual failing is arguably unimportant. For example, a transposition error of writing 84 for X_i instead of 48 is exactly the same as adding $\alpha_i = 84 - 48$ to the value actually generated by the model.

This distributional approach to describing outliers is attractive for those who like to work with formal models, as it allows much of the processing of outliers to be formalized and codified. Using say **maximum likelihood** to estimate the parameters $\boldsymbol{\theta}$ and α_i automatically gives a robust estimate of $\boldsymbol{\theta}$, and the **likelihood** gives a formal outlier test through a test of the **null hypothesis** $\alpha_i = 0$.

The likelihood model describes contaminants, not outliers. Contaminants that are not outlying are undetectable; however, since they are undetectable precisely because they behave like "good"observations, their invisibility means that failing to detect them usually does not have serious bad consequences.

Computational Issues

Fitting the model is less trivial than it might seem as it requires looking at all possible partitionings of the data into the "good" and the "potentially suspect" subsets. In the simplest cases, this can be done by inspection. For a single sample from a normal distribution with mean-shift contamination, it is easy to show that the highest likelihood results when the extreme **order statistics** of the sample are labeled as "potentially suspect". This means that no other types of partitioning need be studied.

In multiple regression, it would be equally intuitive that the cases most likely to be outliers would be those with the largest residuals, or the largest **studentized** residuals. Here though intuition is misleading: a pair of outliers can so distort the regression line that both have small residuals. This is called "masking". They may also make the residual of a "good" case large – this is termed "swamping". Thus, the most discordant observations need not necessarily have large (or even nonzero) residuals. Reliable identification of potentially suspect cases in multiple regression requires the substantial computational exercise of looking at all possible partitioning of the cases into "good" and "potentially suspect" subsets, selecting the partition with the largest likelihood.

"High-breakdown" methodologies do indeed guarantee locating even large numbers of outliers, however badly they may be placed, provided enough computation is done. These methodologies are inherently **computer-intensive** as the guarantee of locating the outliers requires potentially investigating all partitions of the data into an "inner half" and an "outer half". After this exhaustive search, all outliers along with some inliers can be expected to be in the outer half where using some cutoff rule should distinguish the outliers from the more extreme inliers.

A much lighter computation is required for "sequential identification" methods. In these, the single observation from the whole sample whose deletion would lead to the greatest increase in likelihood is flagged as potentially suspect, and temporarily removed from the sample. The single observation in the remaining sample whose deletion would lead to the greatest improvement in model

fit is then identified as another potentially suspect observation, and is also temporarily removed from the sample. This stripping of observations continues until some stopping rule is reached.

Sequential identification methods are of two types. In **"forward selection"**, a discordancy measure is calculated as each new potentially suspect observation is identified and the process stops when it first fails to find an observation sufficiently discordant to be called an outlier. In "backward elimination" a preset number of potentially suspect observations is identified in one pass, and then in a second pass, each of them is tested sequentially to see whether it really is sufficiently discordant to be called an outlier. A case that is not discordant is then reincluded with the "good" observations and the testing of the remaining potentially suspect observations repeated.

Both theoretical reasoning and practical experience show that backward elimination is much better than forward selection, which can miss arbitrarily severe outliers. This is because the masking effect may cause the outlier diagnostics of all the outliers to appear modest so that forward selection stops before all outliers have been located.

Intuitive though sequential identification is, an even more intuitive approach is one-pass identification of all cases whose outlier diagnostics are large. Because of masking and swamping though, this approach is much worse than even forward selection and should not be used at all. This leaves backward elimination as the most reliable approach with low computational requirements.

Another "backward elimination" method starts with some small subset of the data that is outlier-free, and then sequentially adds observations that appear not to be discordant, reestimating parameters as each new apparently concordant observation is added. Success with this approach depends on finding a starting subset of cases that is not only outlier-free but also informative enough to correctly distinguish the inliers from the outliers in the not-yet-classified group. Starting with a high-breakdown estimate gives reliable results, but at high computational cost. Methods using full-sample estimates – for example, the cases with the smallest absolute residuals from a full-sample **least squares** regression fit – may succeed, but come with no guarantees.

Even high breakdown methods are not completely bulletproof: see the example in Hawkins and Olive [5] in which even high breakdown regression methods saw nothing surprising about men less than an inch tall, but whose head circumference was some five feet.

The second phase, of deciding whether to label a suspect case outlying, may be based on a **likelihood ratio** or a case diagnostic such as a studentized residual. Two different philosophies on outlier labeling are to use fixed cutoff values; and to use **multiple comparison** tests. An example of the first approach is to flag as outlying any cases whose regression residual exceeds 2.5 standard deviations regardless of sample size. This rule will delete a fixed percentage of the *cases* in data sets consisting of only good data. A sound multiple comparison method is the **Bonferroni** approach of testing the externally studentized residual ("outlier t", or RSTUDENT) of a regression against the α/n **quantile** of a **Student's *t* distribution**, where n is the sample size and α a significance **level**. In this approach, a fixed proportion of good *data sets* will have one or more observations wrongly labeled outliers.

Particular Cases

The easiest situation is mean-shift outliers from a univariate normal distribution, with inliers distributed as $N(\mu, \sigma^2)$, both parameters unknown, contaminated by one or more $N(\mu + \alpha_i, \sigma^2)$ outliers. The scaled deviations from the mean, $(X_i - \overline{X})/s$, where $\overline{X}$ is the sample mean and s the standard deviation, are effective for both identifying and testing a single outlier. Multiple outliers can be found using sequential identification either by starting with the full sample and stripping one suspect observation at a time, or by starting with the easy-to-find "inner half" of cases and adding concordants.

Outliers in the univariate normal can also be modeled by scale contamination, where the outliers are $N(\mu, \sigma^2(1 + \alpha))$. This (with a common α) can be thought of as mixing the mean-contamination model's displacements over a $N(0, \alpha\sigma^2)$ distribution, and is effective for outliers occurring symmetrically to the left and the right of the inliers.

Flagging and testing for outliers from a **chi-square distribution** use the scaled quantities $X_i/\overline{X}$. Cochran's test for the largest such ratio is classical, but outlier tests can also be performed on the smallest such ratios.

In homoscedastic normal linear modeling (both linear regression and analysis of variance), a general-purpose approach to outlier identification and testing is by variance analysis. Let S_0 with ν degrees of freedom denote the residual sum of squares from a fitted model using some set of cases. Write S_1 for the residual sum of squares obtained after deleting a suspect observation. Then, the pseudo-F ratio

$$F = \frac{(\nu - 1)(S_0 - S_1)}{S_1} \tag{1}$$

may be compared with the fractiles (Bonferroni-corrected or fixed) of an ***F* distribution** with 1 and $\nu - 1$ **degrees of freedom** to decide whether the suspect case is or is not within plausible limits. This F ratio is the square of the "outlier t" statistic that software often produces as a case diagnostic.

In analysis of variance with replicates, fitting the ANOVA model on the full sample and after removal of individual readings leads to tests for individual outliers. A different model is the "slippage" model in which all the replicate readings in some cell are displaced by the same amount. Reducing the original data to cell means and taking these means as the basic data to which to apply outlier screening methods addresses the slippage model.

Multivariate outliers are commonly modeled by the **multivariate normal distribution** $N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ with unknown mean vector and **covariance matrix**. The mean contamination model holds that the outliers are $N(\boldsymbol{\mu} + \boldsymbol{\alpha}_i, \boldsymbol{\Sigma})$, and mixing the outlier displacements over a zero-mean normal distribution leads to the scale-contamination model in which the outliers are $N(\boldsymbol{\mu}, \boldsymbol{\Sigma} + \boldsymbol{\Gamma})$. With this baseline model, if the sample mean vector and covariance matrix are written as $\overline{X}$ and S respectively, then the discrepancy of a single case X_i can be measured by its squared **Mahalanobis distance** from the mean $D_i = (X_i - \overline{X})' S^{-1} (X_i - \overline{X})$. The traditional multivariate outlier statistic, Wilk's lambda, is a monotonic function of D_i. Sequential deletion successively trims the case with the largest D_i from the current sample mean vector using the current sample covariance matrix.

The likelihood outlier model can handle **generalized linear models**. If the deviance of any fitted model is S_0 and the deviance obtained by deleting some suspect case and refitting is S_1, then the deviance explained by deleting the case is $S_0 - S_1$, and this can be referred to its asymptotic chi-squared distribution to get an outlier test. This framework covers **Poisson** and **logistic regression** and **loglinear modeling**, among others.

The generalized linear model framework is also useful for outliers in **contingency tables** – for example individual cells whose frequencies violate independence, which holds in the rest of the table. Deleting a particular cell, refitting the model, and computing the change in deviance between the two fits gives an outlier test statistic for that cell.

Time series can have two types of outlier – an "additive outlier" displaces a single reading from where it should have been, but does not affect the subsequent observations. "Innovative outliers" displace the whole time series from their point of occurrence onward, and, apart from their occurrence at an unexpected time, can be modeled by the intervention analysis likelihood.

Example

Rousseeuw and Leroy [7] discuss a data set relating the body weight and brain weight of 25 animals alive today, along with three dinosaurs. Least-squares regression of $Y = \log_e$ (brain weight) on $X = \log_e$ (body weight) gives (standard errors in parentheses)

$$\begin{aligned} Y = 2.555 \; &+ \; 0.496 \quad X \\ &(0.413) \quad (0.078). \end{aligned} \tag{2}$$

Species	Body weight	Brain weight	Outlier t after deletion number				
			0	1	2	3	4
Diplodocus	11 700	50.0	−2.507	−2.507	−3.646	−6.649	
Brachiosaurus	87 000	154.5	−2.505	−3.644	−3.644	−6.804	
Triceratops	9400	70.0	−2.094	−2.835	−6.045	−6.045	
Human	62	1320.0	1.789	1.861	2.098	3.232	
Residual SS			60.988	48.733	31.372	12.117	8.217

With 28 data points, a maximum of four deletions (15% of the data) seems reasonable. Starting with the full data set, and sequentially deleting the case with the largest absolute externally studentized residual for four iterations gives the following set of externally studentized residual of each of the four suspect cases and residual sum of squares of the fitted regression.

The pseudo-F ratios for the successive deletions are 6.29, 13.28, 36.55, and 10.44 with 1 numerator degree of freedom and denominator degrees of freedom 25, 24, 23, and 22. Start with the last of these, 10.44, whose right tail area is 0.004. Multiplying this figure by the remaining sample size, 25, gives a Bonferroni ***P* value** of 0.1, which argues against making the fourth deletion. Going to the next F ratio of 36.55 gives a P value of 3.6×10^{-6}, indicating that the deletion of the third dinosaur, and by implication, its two even more extreme companions, is clearly called for.

With an initial sample size of 28, the Bonferroni 5% and 1% points for the outlier t statistic would be the two-sided $5/28 = 0.179$ and $1/28 = 0.036\%$ points of a t distribution with 25 degrees of freedom, which are 3.50 and 4.13, respectively. None of these four cases is close to significance, illustrating the masking effect. Successively deleting the three dinosaurs makes humans the most outlying species. At this point, humans' t of 3.232 corresponds to a right tail area of 0.0038, which after Bonferroni adjustment, makes us unremarkable. The regression found after deleting the dinosaurs is

$$\begin{array}{cccc} Y = 2.150 & + & 0.752 & X \\ & & (0.201) \quad (0.046). & \end{array} \tag{3}$$

Evidence of the damaging effect of the dinosaurs is that the slope fitted after their removal is 3.3 standard errors away from the full-sample estimate.

The high breakdown regression fit using the least **trimmed** squares criterion gives the model $X = 1.88 + 0.776W$, close to what we get with ordinary regression after deleting the dinosaurs.

Further Reading

The text by Barnett and Lewis [2] provides an exhaustive coverage of the standard outlier situations and models. Additional useful theoretical material on the robust estimation aspects of outliers may be found in Hampel et al. [3]. Rousseeuw and Leroy [7] is a valuable exposition of the high breakdown approach, though readers should be aware that many of the specifics (notably computational procedures and outlier flagging rules) are now obsolete. Better **algorithms** for high breakdown estimation in the difficult multivariate location/scatter case are given in [6, 8], and for the regression case, in [4].

Atkinson and Riani [1] provide discussion centered on sequential identification starting from an outlier-free subset of cases.

Hawkins and Olive [5] provide theoretical and empirical support for routine use of a variety of multiple regression methods, including sequential outlier identification, in analysis of real data. They also argue that in games against nature, in which a malicious opponent tries to place outliers where you cannot find them in a tolerable amount of time, the opponent will always win, given large enough data sets. In other words, it is impossible to guarantee finding even huge outliers in a large data set if an opponent is allowed to hide them. This argument generalizes to other outlier settings – for example, multivariate location/scatter.

Overdispersion

The phenomenon which has come to be termed *overdispersion* arises when the empirical variance in the data exceeds the nominal variance under some presumed model. Overdispersion is often observed in the analysis of discrete data, for example count data analyzed under a Poisson assumption, or data in the form of proportions analyzed under a binomial assumption. Support for overdispersion is most likely first obtained when the "full" model is fitted (*see* **Generalized Linear Model**), and the Pearson or deviance **residuals** are predominantly too large [4]; the corresponding Pearson and deviance **goodness-of-fit** statistics indicate a poor fit (*see* **Chi-square Tests**).

The **Poisson** and **binomial** distributions are derived from simple, but fairly strict assumptions, and it is not surprising that these do not apply generally in practice. Fitting either of these distributions assumes a special mean–variance relationship, since both distributions are fully characterized by a single parameter. This can be contrasted with the analysis of continuous data using a normal assumption. Consider a simple example where a set of univariate observations is modeled by a common $N(\mu, \sigma^2)$ distribution. In estimating the fitted distribution, the sample average of the data points defines the location of the normal distribution on the number line (μ), while the sample variance determines the spread of the fitted bell-curve (σ^2). The normal distribution is characterized by two parameters, while the Poisson and binomial distributions are completely specified when only the mean, or the probability of success, respectively, is determined; the variance is fixed by the mean.

The existence of overdispersion is not a recent observation. Student [27] comments upon this problem, and Fisher [13] discusses a goodness-of-fit statistic for testing the adequacy of the Poisson distribution in the single sample problem, i.e. when the counts $Y_i, i = 1, \ldots, n$, are assumed to be independent variates from a Poisson distribution with common mean. The statistic is $\sum_{i=1}^{n}[(Y_i - \overline{Y})^2/\overline{Y}]$, where $\overline{Y} = \sum_{i=1}^{n} Y_i/n$, and is called the sample index of dispersion (*see* **Poisson Distribution**).

An important question to ask when a model is suspect is: Will the lack-of-fit affect inference and lead to incorrect conclusions? If the effect is negligible, and if the efforts involved in fitting a more "exact" model are substantial, then the approximate inference obtained under the simpler model may well suffice. In what follows the effect of overdispersion is shown to be nonignorable, and can be quite drastic, so inference under a Poisson or binomial model when overdispersion is present may be very misleading. We focus on the analysis of count and categorical responses, because these are the two areas where overdispersion most commonly arises, with binary responses being an important special case of the latter.

Effect of Overdispersion on Standard Poisson or Binomial Analyses

The effect of overdispersion is determined primarily by how it arises and its degree of incidence. One common way that overdispersion arises in the analysis of proportions is through a failure of the binomial independence assumption. In animal litter studies, for example, responses of animals in a litter are often positively correlated; so, too, in dental studies for responses on individual teeth for a single individual. Let Y denote a binomial response, $Y = \sum_{j=1}^{m} Y_j$, where Y_j are independent binary variates taking values 0 or 1 with probabilities $(1 - p)$ and p, respectively. Then, $E(Y) = mp$, and $\text{var}(Y) = mp(1 - p)$. If the independence assumption does not hold, and the correlation $(Y_j, Y_k) = \tau > 0$, then $E(Y) = mp$, and $\text{var}(Y) = \text{var}(\sum_{j=1}^{m} Y_j) = mp(1 - p)[1 + \tau(m - 1)]$, leading to overdispersion with respect to the binomial model. Note that $\tau < 0$ leads to underdispersion, which is rare in practice, but might correspond to competition among the binary variates for a positive response.

Another way overdispersion may arise is through a failure of the binomial assumption of constant probability of success from trial to trial. This might occur if the population can be subdivided into naturally occurring subunits, for example colonies, where the probability of a positive response varies over these subunits.

Similarly, for count data, failure of the assumptions underlying the use of the Poisson distribution generally leads to overdispersion. In particular, the probability of an event may vary over individuals or over time. For a simple example, suppose the

response is the number of days absent due to illness over a period of time, in a situation where the number of episodes of illness, Y, are Poisson (μ) distributed but will likely lead to consecutive days of absence. The distribution of the number of days of absence due to illness will then be overdispersed with respect to the Poisson model. If A represents the number of days absence during a single episode, A and Y being independent, then the total number of days of absence is $\sum_{i=1}^{Y} A_i$, which has mean and variance, $\mathrm{E}(\sum_{i=1}^{Y} A_i) = \mu\mathrm{E}(A)$, and $\mathrm{var}(\sum_{i=1}^{Y} A_i) = \mu\mathrm{E}(A)\{\mathrm{E}(A)+[\mathrm{var}(A)/\mathrm{E}(A)]\} > \mu\mathrm{E}(A), \text{if} \mathrm{E}(A) > 1$.

In some contexts the Poisson or binomial variation is only a minute part of the overall variability. This is typical, for example, in cancer **mapping** studies, where the distribution of rates over a region is to be determined (*see* **Clustering**). In many cases it is the spatial variation of the cancer mortality rates which is the main component of the dispersion.

Overdispersion cannot be ignored. In fact, many statistical packages routinely incorporate overdispersion (*see* **Software, Biostatistical**). The magnitudes and signs of the estimated covariate effects in a loglinear or logistic analysis can be quite similar whether or not overdispersion is properly accounted for, so a researcher may gain no hint of an inappropriate analysis by there being strikingly strange estimated effects. However, the standard errors of the estimated regression parameters will be underestimated; these will reflect only the Poisson or binomial variation. The precision of the resulting estimates will be too high and P values for testing the significance of the included covariates will be correspondingly too low. This will very likely lead to incorrect inference, unless the overdispersion is almost negligible.

Testing for Overdispersion

In many situations the presence of overdispersion is clearly indicated by the presence of overly large values of the Pearson or deviance goodness-of-fit statistics, even when the full model is fitted. Formal tests for overdispersion have also been discussed in the literature. Score tests (*see* **Likelihood**) for overdispersion [3, 9, 10] compare the sample variance with what is expected under the model. For the testing of extra-Poisson variation, the adjusted score test statistic, for testing the null hypothesis H_1: $\tau = 0$ in the model with overdispersed variance function $\mu_i + \tau\mu_i^2$, is

$$T_{P1} = \frac{\sum_{i=1}^{n}\{(y_i - \hat{\mu}_i)^2 - (1 - \hat{h}_i)\hat{\mu}_i\}}{\left(2\sum_{i=1}^{n}\hat{\mu}_i^2\right)^{1/2}}. \qquad (1)$$

In (1) h_i is the ith diagonal element of the hat matrix, $\mathbf{H}$, for **Poisson regression**; $\mathbf{H} = \mathbf{W}^{1/2}\mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}^{1/2}$, where $\mathbf{W} = \mathrm{diag}(\mu_1, \ldots, \mu_n)$, and $\mathbf{X}$ is $n \times p$ with ijth entry $\mu_i^{-1}(\partial\mu_i/\partial\beta_j)$, $\mu_i = \mu_i(\mathbf{x}_i; \boldsymbol{\beta})$. For loglinear regression, $\log\mu_i = \mathbf{x}_i'\boldsymbol{\beta}$, and $\mathbf{X}$ is the usual matrix of covariates. Estimates $\hat{\mu}_i$ and $\hat{h}_i$ are obtained by replacing $\boldsymbol{\beta}$ by $\hat{\boldsymbol{\beta}}$, its maximum likelihood estimate under the Poisson assumption. The statistic T_{P1} converges in distribution, as $n \to \infty$, to a standard normal under H_1. For testing the null hypothesis H_2: $\tau = 0$, in the model with variance function $(1 + \tau)\mu_i$, the score test statistic is

$$T_{P2} = \frac{1}{\sqrt{(2n)}}\sum_{i=1}^{n}\left\{\frac{(y_i - \hat{\mu}_i)^2 - (1 - \hat{h}_i)\hat{\mu}_i}{\hat{\mu}_i}\right\}, \qquad (2)$$

which is also asymptotically ($n \to \infty$) distributed as standard normal, under H_2.

It is interesting to note that the test statistic for testing H_2 when considering $\mu_i \to \infty$ asymptotics, for fixed n, is equivalently

$$T'_{P2} = \sum_{i=1}^{n}\frac{(y_i - \hat{\mu}_i)^2}{\hat{\mu}_i}, \qquad (3)$$

which has a limiting distribution of $\chi^2(n - p)$. This is just the Pearson statistic, which is traditionally used to assess correct specification of the mean. The derivation of the tests for extra-Poisson variation assumes that the regression specification is correct. Hence, the Pearson statistic arises as a test of either of two alternative hypotheses: namely, $\mu_i = \mu_i(\mathbf{x}_i, \boldsymbol{\beta})$ is incorrectly specified, or the distribution of the counts has variance form $\phi\mu_i$. We would not, however, interpret a significantly large Pearson statistic as indicating overdispersion in a **generalized linear model**, unless the mean had been reasonably well modeled. Otherwise, the apparent overdispersion could reflect missing covariates, e.g. interaction terms, implying systematic lack of fit, or, the functional form of the mean may be inappropriate. Pregibon [22] develops

a test for checking the form of the mean in generalized linear models; for multinomial models, O'Hara Hines et al. [21] develop diagnostic tools for this purpose.

Smith & Heitjan [25] develop a test for overdispersion which results when the vector of coefficients in the mean is considered to be random. The score tests T_{P1} and T_{P2} arise from a random intercept model, and can therefore be considered a special case of Smith & Heitjan's test. Dean [8] discusses testing for overdispersion with **longitudinal** count data.

A score test for the adequacy of the binomial model against an alternative with variance form $m_i p_i(1-p_i)[1+\tau(m_i-1)]$ is

$$T_B = \frac{\left(\sum_{i=1}^{n} (\hat{p}_i(1-\hat{p}_i))^{-1}[(y_i - m_i\hat{p}_i)^2 + \hat{p}_i(y_i - m_i\hat{p}_i) - y_i(1-\hat{p}_i)] \right)}{\left[2\sum_{i=1}^{n} m_i(m_i-1) \right]^{1/2}}, \quad (4)$$

which has a standard normal distribution as $n \to \infty$. This variance form is obtained from the correlated binomial model, discussed in the previous section. Prentice [23] derives this statistic as a score test statistic against **beta-binomial** model alternatives; Tarone [28] derives it by considering correlated binomial alternatives.

As an example in the application of the tests, consider the data, given in [29], from a clinical trial of 59 patients with epilepsy, 31 of whom were randomized to receive the anti-epilepsy drug Progabide and 28 of whom received a placebo. The total seizure count over four follow-up periods is taken here as the response variable. Table 1 shows the results of a Poisson regression analysis of the effect of Progabide on seizure rate which includes two covariates and their interactions, plus terms for a main and interaction treatment effect. The data and this fitted model have been discussed at length in Breslow [4] and his results are given here. The Pearson and deviance goodness-of-fit statistics clearly indicate lack-of-fit of the Poisson model. The score test statistics T_{P1} and T_{P2} have observed values 36.51 and 37.56, respectively. The overdispersion here is very substantial.

Table 1 Loglinear Poisson regression fit to the epilepsy data; case no. 207, with high leverage, omitted. Reproduced from *Statistica Applicata*, Vol. 8, pp. 23–41, by permission of Rocco Curto Editore

Coefficient	Value	Std. error	t Statistic
Intercept	3.079	0.451	6.833
ln(base count/4)	−0.074	0.201	−0.366
Age/10	−0.511	0.153	−3.332
ln(base count/4): age/10	0.351	0.068	5.164
Progabide	−0.610	0.191	−3.197
Progabide: ln(base count/4)	0.204	0.088	2.325

Deviance = 408.4; Pearson $\chi^2 = 456.52$; df = 52.

Accounting for Overdispersion

With overdispersion present, the use of the Poisson or binomial **maximum likelihood** equations for estimating the regression parameters in the mean is still valid. These are the usual generalized linear model (GLM) or **quasi-likelihood** (QL) estimating equations, and they are unbiased estimating equations regardless of any misspecification of the variance structure. However, the estimated variances of the parameter estimates will be in error, and possibly severely so.

If there are alternative "overdispersed" models which are postulated, then certainly one could proceed by maximum likelihood estimation. This will be discussed further below. There are, however, some robust, simple methods for adjusting standard errors to account for overdispersion and these will be considered first.

McCullagh & Nelder [20] suggest a simple adjustment, which is to multiply $\text{var}(\hat{\boldsymbol{\beta}})$, obtained from the Poisson or binomial model, by an estimate of the GLM scale factor, ϕ. This estimate is usually the Pearson or deviance statistic divided by its degrees of freedom. This is appropriate if the overdispersion gives rise to a variance model which is a constant times the nominal variance, e.g. $\phi\mu$ for counts and $\phi mp(1-p)$ for proportions. This variance form may also well approximate other, possibly more complicated, variance structures in certain situations; for example, for count data, when $\text{var}(y_i) = \mu_i + \tau\mu_i^2$ and $\tau\mu_i$ do not vary greatly with i.

If the sample is large, then an empirical variance estimate can be computed. This is called the "sandwich" variance estimate, cf. Liang & Zeger [17].

For loglinear models, for example, the sandwich estimator is

$$\text{var}(\hat{\beta}) = \left[\sum_{i=1}^{n} \hat{\mu}_i \mathbf{x}_i \mathbf{x}_i'\right]^{-1} \left[\sum_{i=1}^{n} \left(\frac{y_i - \hat{\mu}_i}{\hat{\mu}_i}\right)^2 \mathbf{x}_i \mathbf{x}_i'\right] \times \left[\sum_{i=1}^{n} \hat{\mu}_i \mathbf{x}_i \mathbf{x}_i'\right]^{-1}. \quad (5)$$

Unless very large samples are available, the sandwich estimator tends to underestimate the true variance.

Resampling techniques, although typically **computer-intensive**, have become popular for providing estimates of the variance of regression parameters. **Bootstrap** and **jackknife** estimates are discussed in [12], and there are methods of approximating these which require less computing effort, e.g. the one-step jackknife estimate. The bootstrap estimates are considered to be quite accurate. Table 2, from [4], compares these estimators in the analysis of the data from [29], mentioned earlier. Notice how much larger these estimates of the standard errors are compared with those obtained from the Poisson model. The treatment effect is no longer significant when overdispersion is taken into account.

Model-based methods for incorporating overdispersion lead to mixture models or **random effects models**. A simple Poisson random effects model can be derived by considering a model with individual-specific random effects $\nu_i > 0$ where, conditional on $(\nu_i, \mathbf{x}_i)$, the distribution of Y_i is Poisson with a mean of $\nu_i \mu_i(\mathbf{x}_i; \boldsymbol{\beta})$, and the ν_i are continuous, independent variates with probability density function $p(\nu; \tau)$ depending on a parameter τ. If $\mu_i(\mathbf{x}_i; \boldsymbol{\beta})$ takes the common form $\exp(\mathbf{x}_i' \boldsymbol{\beta})$, then the fixed and random effects are added on the logarithmic scale and the random effects can be construed as representing covariates which are unavailable. The probability function of Y in the mixed model is

$$\int_0^\infty \frac{(\mu\nu)^y \exp(-\mu\nu)}{y!} p(\nu)\, \mathrm{d}\nu \quad (6)$$

and the score function for estimating the regression parameters has the intuitively appealing form

$$\sum_{i=1}^{n} [y_i - \mu_i \mathrm{E}(\nu_i | y_i)] \frac{1}{\mu_i} \left(\frac{\partial \mu_i}{\partial \beta_r}\right) = 0. \quad (7)$$

This equation, with $\mathrm{E}(\nu_i | y_i)$ omitted, is the maximum likelihood equation for Poisson regression [Eq. (8), with $\sigma_i^2 = \mu_i$]. If the distribution of ν is specified, then full maximum likelihood estimation can be performed; if ν is assumed to be **gamma**, then this leads to a **negative binomial distribution** for the counts. However, it is more common to adopt the more robust approach of specifying only the first two moments for Y, i.e. μ_i and σ_i^2, respectively; the parameters in the mean are then estimated using the quasi-likelihood estimating equation,

$$\sum_{i=1}^{n} \frac{(y_i - \mu_i)}{\sigma_i^2} \left(\frac{\partial \mu_i}{\partial \beta_r}\right) = 0, \quad (8)$$

for count data, together with another estimating equation for the additional parameter τ in σ_i^2.

There are many important reasons for the widespread use of the quasi-likelihood approach. For generalized linear models with a full likelihood, these are the maximum likelihood equations. From the viewpoint of estimating equations (*see* **Estimating Functions**), Godambe & Thompson [14] (see also Nelder's discussion of that paper) derive important optimality properties of the estimators. When $\sigma^2 = \mu\tau$, estimation of the regression coefficients is not affected by the value of τ. Estimation is easy with standard software. An important point is that

Table 2 Overdispersion adjusted standard errors for Table 1 coefficients. Reproduced from *Statistica Applicata*, Vol. 8, pp. 23–41, by permission of Rocco Curto Editore

Coefficient	Scale method	Sandwich	One-step jackknife	True jackknife	Bootstrap (nb = 5000)
Intercept	1.263	0.711	0.792	0.792	0.870
ln(base count/4)	0.564	0.326	0.368	0.369	0.424
Age/10	0.430	0.237	0.264	0.263	0.291
ln(base count/4): age/10	0.190	0.104	0.117	0.117	0.137
Progabide	0.535	0.403	0.440	0.448	0.466
Progabide: ln(base count/4)	0.246	0.188	0.210	0.214	0.226

the asymptotic variance of $\tilde{\boldsymbol{\beta}}$, the estimate of $\boldsymbol{\beta}$, is independent of the choice of the estimating function for τ, and depends only on the first two moments of the distribution. This is also, asymptotically, a very **efficient estimator** for a wide range of models. Simulation studies have been conducted to investigate the performance of $\tilde{\boldsymbol{\beta}}$ in small samples; they support the **unbiasedness** and efficiency of this estimator.

A popular method for estimating τ is **pseudo-likelihood**. Davidian & Carroll [7] derived the pseudo-likelihood estimating equation as the maximum likelihood equation when residuals are normally distributed. An alternative simple choice is equating the Pearson statistic to its degrees of freedom.

Nonparametric methods of modeling random effects for handling overdispersion have been shown to be useful. Lindsay [18] is a comprehensive source on the topic. He discusses the geometry and theory of mixture models and describes a plethora of applications where mixture models are used, including overdispersion, measurement errors, and latent variable models for **cluster analysis**. Practical issues for estimation of nonparametric mixing distributions, such as algorithms and computational problems, are discussed at length in [2] and [16].

The preceding overdispersion models incorporated a single random effect which was independent over subjects. More general models might include multiplicative random effects [25]; large numbers of random effects are common in animal breeding experiments, where it is the prediction of the random effects, representing sire effects, which is the main focus of the study. In studies of the **geographic** distribution of cancer mortality rates, or disease incidence, the random effects may represent area-specific effects and there may be good reason to suspect that such area effects are not independent, and in some circumstances may be quite similar within small neighborhoods.

A general body of theory which synthesizes the incorporation of several random effects, which are not necessarily independent, falls under the heading of generalized linear mixed models. It permits a simple incorporation of overdispersion, as discussed previously, and can also model dependences in outcome variables or random effects, as are typical in repeated measures design (*see* **Nonlinear Mixed Effects Models for Longitudinal Data**). A generalized linear mixed logistic model specifies that

$$\log\left(\frac{p_i}{1-p_i}\right) = \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}, \tag{9}$$

where p_i and $\mathbf{x}_i$ are the probability of a positive response and the vector of covariates, corresponding to the ith proportion, respectively, $\mathbf{z}_i$ is a vector of covariates, and $\boldsymbol{\gamma}$ is distributed with a mean of zero, and finite variance matrix. Conditional on $\boldsymbol{\gamma}$, the responses are supposed binomially distributed. As an aside, note that the representation above elucidates that apparent overdispersion can be induced by missing covariates, or by **outliers**. Residual **diagnostics** are important for identifying the latter.

In generalized linear mixed models the random effects are usually assumed to be Gaussian, and maximum likelihood estimation involves q-dimensional integration; here q is the dimension of $\boldsymbol{\gamma}$. Alternative simpler approaches for inference have been proposed, using generalizations of moment methods or penalized quasi-likelihood [5]. The penalized quasi-likelihood is a Laplace approximation to the integrated likelihood, with some seemingly harmless other approximations added. Breslow & Clayton [5] provide simple algorithms for estimation using an iterative fitting procedure which updates both the parameter values and a modified response variable at each step. They also evaluate the performance of their estimators. It seems that bias corrections are required for small samples, and these are given in [6].

Lee & Nelder [15] discuss hierarchical generalized linear models, where the distribution of the random components is not restricted to be normal, and where, like penalized quasi-likelihood, estimation avoids numerical integration. Maximizing what they call the h-likelihood, a posterior density, gives fixed effects estimators which are asymptotically equivalent to those obtained using the corresponding **marginal likelihood**. Here, "asymptotically" refers to cluster sizes tending to infinity, and the random effects are cluster-specific. This is important to note because many applications with random effects involve several small-sized clusters. In general, their asymptotic arguments require that the total number of random effects remains fixed, as the overall sample size becomes large. However, they also derive properties of their estimators on a model-by-model basis, and some models require less strict assumptions. When there are many random effects to be estimated, none of the procedures described here will be simple,

as can be expected when dealing with complicated mechanisms for incorporating overdispersion.

Technical Reference Texts and Software Notes

The general topic of overdispersion is discussed in McCullagh & Nelder [20, Sections 4.5, 5.5, 6.2]. Chapters 9 and 10 of that text are also relevant and discuss quasi-likelihood and joint modeling of mean and dispersion. Diggle et al. [11] discuss random effects models for longitudinal data, and Chapter 5 of Lindsey [19] is devoted to the topic of overdispersion in models for categorical data.

Software for incorporating overdispersion includes S-PLUS [26], function glm, SAS ([24], procedures LOGISTIC, MIXED GENMOD, and CATMOD), and GLIM [1].

Overmatching

Overmatching refers to the unnecessary or inappropriate use of **matching** in a **cohort** or **case–control study**. Matching on intermediate factors on the causal pathway (*see* **Causation**) can inappropriately attenuate estimates of exposure effect, and matching on factors that are not **confounders** can needlessly reduce the **power** of the study [1, pp. 104–106]. Overmatching is also sometimes used to describe elaborate matching schemes that make it difficult to find suitable **controls** satisfying all matching criteria (*see* **Matched Analysis**).

P Value

The *P* value is probably the most ubiquitous statistical index found in the applied sciences literature and is particularly widely used in biomedical research. It is also fair to state that the misunderstanding and misuse of this index is equally widespread. A complete discussion of all issues relevant to the *P* value could touch on many of the subtlest and most difficult areas in statistical **inference**. In this article we will focus on those aspects most relevant to the interpretation of results arising from biomedical research.

The *P* value, as it is used and defined today, was first proposed as part of a quasi-formal method of inference by **R.A. Fisher**, and popularized in his highly influential 1925 book, *Statistical Methods for Research Workers* [13]. It is defined as the probability, under a given simple hypothesis H_0 (the **null hypothesis**), of a statistic of the observed data, plus the probability of more extreme values of the statistic (*see* **Hypothesis Testing**). Other names that have been used for the *P* value include "tail-area probability," "associated probability," and "significance probability" [16]. It can be written as

$$P \text{ value} = \Pr(\mathrm{t}(\mathbf{X}) \geq \mathrm{t}(\mathbf{x})|\mathrm{H}_0),$$

where $\mathbf{X}$ is a random vector, $\mathbf{x}$ is a vector of observed results, and $\mathrm{t}(\mathbf{X})$ is a function of the data, known as a *test statistic* (e.g. the sample average).

This seemingly simple mathematical definition belies the complexity of its interpretation, and even the occasional difficulty of its calculation in real-world settings. The seeds of this difficulty are embodied in its definition, which is partly conditional (depending on observed data for calculation), and partly unconditional (calculated over a set of unobserved outcomes defined by the study design) [26]. It is therefore an index that seems to measure simultaneously an "error rate" (pre-experiment, unconditional perspective) and the strength of inferential evidence (post-experiment, conditional perspective). Fisher's original purpose for the *P* value was in the latter category, as an index that denoted the statistical compatibility between observed results and a hypothetical distribution. He meant it to be used informally as a measure of statistical evidence. The larger the statistical distance (and the smaller the *P* value), the greater was the evidence against the null hypothesis.

While the basic idea had undeniable appeal, this definition posed several problems, some logical, some practical, which Fisher never fully resolved. They included the following:

1. How a measure of distance from a single hypothesis could be interpreted as a measure of evidence without consideration of other hypotheses [6].
2. How the probability of unobserved "more extreme" results were relevant to the evidential meaning of the observed result [19, 21].
3. How to calculate a *P* value when the experimental design (e.g. **sequential**) or execution (unanticipated events) rendered the sample space uncertain [8, 11].
4. How to choose an appropriate test statistic [9, 10, 20].
5. How the numerical magnitude of the *P* value should be interpreted operationally [2, 3, 12].

These questions were difficult to address because the *P* value was not part of any formal system of inference. This contrasted with the **likelihood ratio**, which was a part of **Bayes' theorem**. But while Fisher also developed the idea of mathematical **likelihood**, he eschewed Bayes' theorem as a useful tool in scientific inference. In its stead, he developed a panoply of methods which were meant to be tools in what he regarded as the fluid and nonquantifiable process of scientific reasoning. He offered various "rules of thumb" for the use of these tools. Among such rules were the suggestion that if the *P* value were less than 0.05, one might start doubting the null hypothesis. He was clear that the response to such a finding would generally be to conduct another experiment, or gather more data.

Had this been the full extent of the *P* value's theoretical foundation, it is doubtful that it would occupy as central a role as it does today. It is ironic that it became popularized, and indeed reified, because of the development of another method that did not include it, and which explicitly denied that conditional inference could be part of a "scientific" method [18].

The *P* Value as an "Observed Error Rate"

In 1933, **J. Neyman** and **E.S. Pearson** (N–P) proposed the "hypothesis test", which involved

"rejecting" or "accepting" null or **alternative hypotheses** with predetermined frequencies when they were true [24]. The probabilities of making the wrong decision were called error rates, and designated into two classes: α, (or type I) error (the probability of rejecting the null hypothesis when it was true) and β (type II) error (the probability of accepting the null hypothesis when the alternative was true) (*see* **Level of a Test**). A critical value for a test statistic is determined (via a likelihood ratio), and the null hypothesis is rejected if the statistic exceeds that critical value, and is accepted if not (*see* **Critical Region**). This methodology borrowed several of Fisher's ideas, most notably that of mathematical likelihood, and, with its introduction of the concept of an alternative hypothesis and associated **power**, appeared to address some of the logical problems posed by Fisher's less formal system. But N–P explicitly rejected P values, because for the "error rates" to have meaning (and for a method to be "scientific"), an hypothesis had to be rejected or accepted; a result could not reflect back on underlying hypotheses in a graded way, which use of the P value implied.

The N–P method provided the formal framework of statistical inference (or at least decision-making) that the P value lacked, but it was a framework that encouraged the misinterpretation of P values. The juxtaposition of the two approaches has been the source of considerable confusion ever since. Since both P values and type I error rates were tail-area probabilities under the null hypothesis, the P value came to be interpreted as an "observed type I error", and defined in most applied textbooks that way. While it is mathematically true that the P value is smallest alpha level at which one could still justify the rejection of the null hypothesis, this fact does make not make the P value an error rate. (It should be stressed that the confusion we are discussing here is not the more common lay misperception that P value represents the probability of the null hypothesis.) The outcome cannot fall within the region over which the P value is calculated; by definition, the observed outcome is always on the border of that region, and is usually the most probable. In an applied setting, this confusion is manifested in the inability to quantitatively distinguish between the very different inferential implications of a result reported as "$P \leq 0.05$" vs. "$P = 0.05$". It is fascinating how few users of P values recognize the profound difference in inferential weight introduced by that subtle change in inequality sign, whereas many agonize over the far smaller difference between $P = 0.04$ and $P = 0.07$.

The identification of the P value as a form of *post hoc* type I error rate, or as an "improved" estimate of that error, created a powerful illusion that is undoubtedly the source of its appeal; that a deductively derived error rate and inductive measure of inferential strength were identical, and that the "objective" qualities of the first could be bestowed upon the latter.

Fisher and Neyman fought vigorously in print over which approach was preferable, and Fisher in particular expressed profound dismay at seeing his "significance probability" absorbed into hypothesis testing ("acceptance procedures", in his words) [14, 23]. But textbook and **software** writers, either not wanting to confuse readers, or perhaps themselves not being clear about the issues, obscured the distinction, and technology triumphed over philosophy [17].

The *P* Value as a Measure of Evidence

We have seen above how the conditionality of the P value makes it inappropriate to view as a post-test α level. We will see that its unconditional characteristics render it problematic as an evidential measure as well. Fisher's proposal that the P value be used as a measure of evidence appeared based on the intuitively appealing idea that the more unlikely an event was under the null hypothesis, the more "evidence" that event provided against the hypothesis. The tail area appeared to be a convenient way in which to index the statistical distance between the null hypothesis and the data. Fisher himself did not seem wedded to that measure, simultaneously endorsing the use of the mathematical likelihood as an alternative.

If the P value were used informally as Fisher originally intended, it could be viewed as equivalent to any other functional transformations of the distance between the observed statistic and its null value, like a Z-score, or standardized likelihood. But its use in any formal way poses several difficulties. Because the P value is calculated only with respect to one hypothesis, and has no information, by itself, of the magnitude of the observed effect (or equivalently, of power), it implicitly excludes the magnitude of effect from the definition of "evidence". Small deviations from the null hypothesis in large experiments can have the same P value as large deviations in small experiments. The likelihood functions for these two

results are quite different, as are any data-independent summaries of the likelihoods. This difference is also reflected in the perspective of most scientists, who would typically draw different conclusions from such a pair of results.

The corrective in the biomedical literature has been to urge the reporting of P values together with estimates of effect size, and of the precision of the measured effect, usually reported as a **confidence interval** [1, 15, 25]. This does not completely solve the problem of representing the evidence with the same number when the data appear quite different, but it at least gives scientists additional information upon which to base conclusions.

The dependence on only one hypothesis means that data with different inferential meaning can have the same P value [4]. A converse problem occurs when the same data can be represented by two different P values. This problem is created by the inclusion of "unobserved" outcomes in the tail area calculation of the P value. Experiments of different design can have different "unobserved" outcomes even if the observed data are identical. The classic example involves the contrast between a fixed sample size experiment and one in which a data-dependent stopping-rule is used. Suppose that two treatments, A and B, are applied to each subject in a clinical trial, and the preferred treatment for that subject recorded. The sequence of preferred treatments are five A s followed by one B. If this was planned as an experiment with $n = 6$, then the one-sided P value based on the **binomial distribution** is

$$\binom{6}{1}\left(\frac{1}{2}\right)^5\left(\frac{1}{2}\right)^1 + \frac{1}{2}^6 = 0.11.$$

If the experiment had been designed to stop when the first B success was observed, then the more extreme results would consist of longer sequences of As, and the P value based on the **negative binomial** would be

$$\frac{1}{2}\left(\frac{1}{2}\right)^5 + \frac{1}{2}\left(\frac{1}{2}\right)^6 + \cdots = 0.031.$$

While this is an idealized situation, this issue is manifest in the real-world applications by the discussions of how to measure appropriately the evidence provided by biomedical experiments that have stopped unexpectedly or because of large observed differences. In one trial of medical therapy known by its acronym of "ECMO", a variety of P values could be derived from the data presented [22].

Perhaps the most illuminating examinations of the inferential meaning of P values have used **Bayesian** or likelihood approaches. Bayesian analyses show that the P value is approximately the Bayesian posterior probability, under a diffuse **prior**, of an effect being in the direction opposite to the one observed, relative to the null hypothesis. More generally, the one-sided P value is the lower bound on that probability for all unimodal symmetric priors centered on the null [7].

Both likelihood and Bayesian arguments show that the P value substantially overstates the evidence against a simple, "sharp" null hypothesis, particularly for P values above 0.01. In the **normal** (Gaussian) case, the minimum likelihood ratio for the null, which is the minimum Bayes factor as well, is substantially higher than the associated P value, as shown in Table 1 [5, 12].

Since the P value is usually calculated relative to a sharp null hypothesis, most users interpret its magnitude as reflecting on the null hypothesis. The standardized likelihood $[\exp(-Z^2/2)]$ is the smallest Bayes factor that can multiply the prior odds of the null hypothesis to calculate the posterior odds. We see that the odds are not changed nearly as much as the P value's magnitude would suggest; nor is the probability. In the range of very small P values ($P < 0.001$) the quantitative differences are not likely to be important in practice. But in the range which includes many P values reported in biomedical research – that is, $0.01 < P < 0.10$ – the differences between most users' impression of the P value's meaning and its

Table 1 The relationship between the observed Z-score, (**standard normal deviate**), the fixed-sample size two-sided P value, the Gaussian standardized likelihood $\exp(-Z^2/2)$, and the smallest possible Bayesian posterior probability when the prior probability on the simple null hypothesis is 0.5. The latter is calculated using Bayes' theorem, and equals stand.lik./(1 + stand.lik.)

Z-score	P value (two-sided)	Gaussian standardized likelihood	Min. $\Pr(H_0\|Z)$ when $\Pr(H_0) = 0.5$
1.64	0.10	0.26	0.21
1.96	0.05	0.15	0.13
2.17	0.03	0.09	0.08
2.58	0.01	0.036	0.035
3.29	0.001	0.0045	0.0045

maximum inferential weight is striking. When one-sided P values are used, the contrast is even more marked.

One-sided vs. Two-sided *P* Values

Much has been written about how one could choose whether to cite a one- or two-sided P value. This is somewhat academic, since the *de facto* standard in the biomedical literature is for two-sided tests. Some writers have stressed that this is little more than a semantic distinction – that is, about what label should be attached to a $Z = 1.96$ – and that if the result is completely reported, a reader could make the appropriate adjustment if they judge it appropriate. It is interesting to note that this distinction becomes more than academic if one dichotomizes results into "significant" and "not significant". Then, whether the test was one- or two-sided is an important factor in assessing the meaning of the verdict. However, this assumes that not even the direction of the result is reported, which is unlikely.

This issue is similar to that confronting the experimenter who stops a trial before its planned end. In both situations, an experimenter's intentions or thoughts are taken as relevant to the strength of evidence, such that two persons with the same data could quote different P values. There is no clear resolution to this, since those who focus on the unconditional aspects of the P value will see such considerations as important, and those who regard it primarily as a conditional evidential measure will insist that such considerations should be irrelevant. In general, the custom that most or all P values be reported as two-sided seems a good one, with the condition that if one-sided P values are used, this be indicated clearly enough so their value could be doubled by a reader. If the P values are in a range in which doubling makes a substantive difference, the evidence is equivocal enough so there will be controversy regardless of how the P value is reported.

Conclusions

The P value represented an attempt by R.A. Fisher to provide a measure of evidence against the null hypothesis. Its peculiar combination of conditionality and unconditionality, combined with its absorption into the hypothesis testing procedure of Neyman and Pearson, have led to its misinterpretation, widespread use, and seeming imperviousness to numerous criticisms. Since P values are not likely to soon disappear from the pages of medical journals or from the toolbox of statisticians, the challenge remains how to use them and still properly convey the strength of evidence provided by research data, and how to decide whether issues of design or analysis should be incorporated into their calculation.

STEVEN N. GOODMAN

Pain

There are many situations in clinical medicine when it is necessary to assess how much pain a patient is feeling. This may be either to ascertain how painful a clinical procedure is, or to compare the pain relief, or pain inflicted, by two or more modes of treatment. In the medical literature, there is a fairly clear distinction between acute pain and chronic pain.

Types of Pain

Chronic Pain

There are many ailments where patients suffering from long-term illnesses are assessed for how much pain they are experiencing. In particular, patients with rheumatoid arthritis, back pain, and cancer often fall into this category. Owing to the wide range of illnesses, such studies appear in many specialist areas of the medical literature. A typical example is a study of chronic low back pain by Marchand et al. [10].

Acute Pain

There are many examples where patients undergoing a medical procedure are asked postoperatively about the level of pain they are suffering. Such studies include patients having hip or knee replacements, hysterectomies, and wisdom tooth removal. While they cover many different types of operation, these studies are particularly common in the anesthesia literature. A typical example is a study by Hommeril et al. [6] exploring pain relief after hip and knee arthroplasty.

Experimental Pain

A further category is that of experimental pain. An example is where volunteers immerse their hands in ice or are subjected to small electric shocks. These experiments usually yield straightforward data that can be analyzed using conventional statistical methods. A good example of such studies is that by Bjorkman & Elam [1].

Historical Development

To study pain it is first necessary to measure it reliably. Unfortunately, it is not possible (yet) to attach an instrument to a patient to obtain a direct objective measure of how much their pain hurts. There are two common methods of getting round this problem.

The 10 cm Visual Analog Scale (VAS)

This is the most common method for measuring pain in the medical literature. It is used in all three types of pain study described earlier. A standard 10 cm scale is illustrated in Figure 1. The patient is asked to mark on the line how much his or her pain hurts. This is a very important component of the literature and is addressed in detail in later sections.

Questionnaires

There are several pain questionnaires. The one which seems to be the most used and respected is the McGill Pain Questionnaire published by Melzack [12] in 1975. However, more recently, Thomas [16] published the Glasgow Pain Questionnaire. Neither of these is disease specific. This is an important point because there is an expanding literature of pain scores developed to assess the pain and disability associated with particular conditions. Two good examples are the Aberdeen Back Pain [14] score and Psoriasis Disability Index [5].

Measurement of **quality of life** is an expanding area of the medical literature. The most commonly used questionnaires are the Nottingham Health Profile [7] and the SF-36 [3]. Both have particular domains dedicated to pain. Methodology for calculating sample sizes for the SF-36 was described by Julious [8]. In order to study a particular disease it is important to note that if either of these is to be used, then a disease-specific score such as those mentioned above should also be used. This is because they are both general health questionnaires.

Two other approaches are worth mentioning. Rather than a VAS score, the patient is asked to fill in a four- or five-point categorical scale ranging from no/little pain to very bad/unbearable.

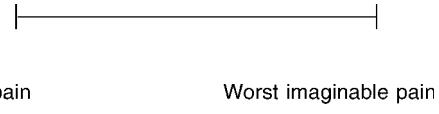

Figure 1 Standard 10 cm scale

This is most useful when the aim is to obtain a single pain assessment and the subsequent analysis is straightforward. The other method is to use the amount of analgesia consumed by a patient as a surrogate for pain. An example of this sort is discussed later.

Different Types of Study

Chronic Pain

The usual aims for studying chronic pain are (i) to ascertain the "average" amount of a pain a patient suffers in daily life and (ii) to intervene with a treatment that will hopefully reduce the suffering. Any of the pain measures discussed above can be used, although the questionnaires are particularly popular. Usually, data are collected at baseline and at a fixed point in time after treatment. These studies do not present with any particular statistical problems and can be analyzed using conventional techniques.

Acute Pain

The questionnaire-based measures of pain that are appropriate to chronic pain are clearly not appropriate for measuring acute pain. There are two reasons for this. First, in acute pain studies the patients are often in great distress. Secondly, some of the questionnaires take several minutes to complete, which is too onerous for the patient and not suitable if the experimenter wishes to assess pain levels at regular intervals. The most common form of measurement of acute pain is the 10 cm VAS. The properties of the VAS have been explored by many authors. A good source of references can be found in [13].

A common study design is to allocate randomly patients recovering from an operation under general anesthetic to receive pain relief from different analgesic agents (*see* **Randomization**). Patients are then asked to fill in a VAS at regular intervals. These intervals are not always of equal length, and such studies vary from 2 h to 48 h in duration. The most common form of analysis in the medical literature is to use either *t* tests (*see* **Student's *t* Statistics**) or **Wilcoxon–Mann–Whitney tests** to compare **mean** pain levels at each time point between groups.

A typical example by Doyle et al. [4] is worth describing. Forty children undergoing appendicectomy were allocated randomly to receive one of two bolus doses of morphine upon waking from the operation. Each group then used the same patient-controlled analgesia (PCA) regime to control their own pain. An observer filled in a VAS every 4 h for 48 h for each child at rest and during movement. The data were then analyzed using a Wilcoxon–Mann–Whitney test at each time point. The slight difference with this study is that the patients did not fill in the VAS but an observer did.

A study by Hommeril et al. [6] is also worth illustrating. In a double-blind (*see* **Blinding or Masking**) randomized study 32 subjects were allocated to receive either ketoprofen or morphine after undergoing hip and knee arthroplasty. The ketoprofen regime was a continuous infusion over 13 h, whereas the morphine regime was a single large bolus dose. The patients filled in a VAS upon recovery and 1, 3, 5, 7, 9, and 13 h after recovery. Patients suffering from extreme pain were allowed extra help in the form of an intravenous paracetamol injection. In total, nine of these injections were administered. The data were analyzed using a Mann–Whitney test at each time point. No attention was given to the fact that the study had in effect changed due to the extra "treatment" received by some of the patients.

Experimental Pain

In these studies the pain is usually very short lived and can be reproduced by an identical stimulus. Hence **crossover designs** are quite popular. The use of crossover designs in acute pain studies is not possible. There are examples of crossover designs for chronic pain studies in the medical literature, although the washout period must be such that the effect of the drug administered in the first experimental period has time to wear off.

Landmark Studies

Anybody wishing to learn about pain should consult the volumes edited by Melzack & Ward [13] which cover the entire subject from a medical viewpoint. One paper well worth a mention is that by Matthews et al. [11]. Here, they demonstrate in a major medical journal the flaws of repeated significance testing at successive time points (*see* **Sequential Analysis**). Kelly reviewed 12 journals from the anesthesia literature from 1991 and found that 59 out of 71 papers used this flawed method as the basis of

their analysis. The logic of comparing bolus dosages of analgesia is criticized in a *British Journal of Anaesthesia* editorial [9]. However, despite this, the practice is still very common.

Particular Statistical Concepts, Problems, and Techniques

The flaws in making significant tests at repeated time points are described by Matthews et al. [11] as:

1. A single curve joining the mean values at each point may hide important variation between patients within the same group.
2. The analysis does not take account of the fact that measurements at different time points are from the same patients.
3. Successive observations on a given patient are likely to be **correlated**. Note that this is particularly true for pain data.
4. Dividing the results into "significant" or "non-significant" introduces an artificial dichotomy into serial data (*see* **Hypothesis Testing**).

Statistically valid alternatives used in the medical literature are either to use repeated measures **analysis of variance** or to use summary measures as suggested by Matthews et al. [11]. The latter route is certainly the easier to interpret and in my view is more appropriate for most medical applications. Problems with both approaches include **missing data**. A patient may be in a deep sleep or decide to drop out of the study at any point. In most pain studies it is necessary for ethical reasons to allow the patient to take additional analgesia if they request it. This use of so-called escape analgesia is often ignored when it comes to data analysis. However, such data clearly **confound** the intended comparison.

Solutions

The key to using a summary measure approach is to ensure that the chosen measure is clinically meaningful. For this reason, summaries such as time to taking first escape analgesia, rate of pain reduction over a fixed time period, minimum pain, or the number of unacceptable pain observations in a fixed time period are all appealing in various circumstances. Here are three examples that illustrate the use of summary measures.

Bray et al. [2] compared the efficacy of morphine infusion against patient-controlled analgesia in a double-blind randomized study on 30 children undergoing major abdominal surgery. The time period of interest was the first 4 h after the child recovered from the general anesthesia from the operation. Prior to commencing the study, the authors decided to ask the children to fill in a 10 cm VAS every half hour for 4 h once awake after the operation. The outcome of interest to the clinician was how long each child's pain is at an unacceptable level. Hence, a VAS score of 50 mm or more was defined as unacceptable. The authors simply counted how many of the pain scores were unacceptable and compared them between groups using a Mann–Whitney test. This simple summary encapsulated precisely the aim of the clinicians in performing the study and provided very clear and easily interpretable results which they readily accepted.

Seymour et al. [15] explored the efficacy of ketoprofen and paracetamol for pain relief in patients recovering from the extraction under general anesthesia of their third wisdom tooth. A total of 206 patients entered the study into one of five groups, a placebo and two dosages of each drug. Patients filled in a 10 cm VAS at 15, 30, 45, 60, 90, 120, 180, 240, 300, and 360 min after administration of the analgesia. The investigators were interested in: (i) How quickly does each treatment act? (ii) For how long does the treatment have an effect? (iii) What is the maximum pain relief provided from the treatment? For each of these a summary measure was used. The speed with which the drug acted was measured by simply looking at the change in pain score over the first hour. The effective length of the treatment was assessed by observing the times at which patients made requests for escape analgesia, and the resulting information was analyzed using the **logrank test**. The maximum pain relief was calculated for each patient as the difference between their baseline pain and their lowest VAS score. A global summary in the form of the area under the curve (*see* **Bioequivalence**) of the pain profile of each patient was also calculated. The interpretation of such a quantity is not clear and is complicated by patients taking escape analgesia. This is a popular measure with pharmaceutical companies but is not in my view as useful as carefully thought out summaries such as those illustrated which clearly provide useful information for the researchers' questions.

The use of the cumulative amount of analgesia consumed by a patient as a measure of pain was mentioned earlier. This is appealing; however, a warning to be wary of such studies is necessary. Welchew & Breen [17] compared the pain relief received between patient-controlled on-demand fentanyl delivered epidurally or intravenously. Here, it is the method of delivery that is being tested rather than the analgesia. The subjects were 20 patients undergoing upper abdominal surgery. They used two methods of analysis. Each patient filled in a 10 cm VAS every hour for 24 hours after recovering from the operation. The Mann–Whitney test was used to compare the means at each time point. They also plotted the mean cumulative doses of drug consumed by patients in each group and compared these at each time point with an unpaired t test. Apart from the obvious statistical error, they forgot that, because of the safety lockouts on the patient-controlled analgesia equipment, patients in each group would automatically receive differing amounts of drug.

Anticipated Developments and Unresolved Problems

There is great potential for statistics to make a major and direct impact upon research into pain and pain relief. The use of summary measures should be explained and illustrated with the appropriate medical literature. There seems to be a characteristic shape to a pain curve which could be modeled. The parameters of such a curve could then be compared between different treatment groups, giving a comparison of the pain profiles rather than many individual time points. Methods for dealing with missing data and for patients taking additional analgesia should be developed.

Increasingly, chronic pain is been assessed by qualitative methods. While these do not readily lend themselves to statistical analysis, and indeed are sometimes directly opposed to classical statistical concepts of randomization and **outcome variables**, there is some merit in their aim to provide better quality information on pain.

PETER J. KELLY

Paired Comparisons

The term *paired comparisons* is used in two rather different senses. This article is not concerned with the comparison of two treatments by the use of **matched pairs** (*see* **Paired *t* Test**), but focuses on the *method of paired comparisons*. In this method, t "treatments" are compared pairwise in situations in which full measurement of the responses is not feasible or is inappropriate [7].

A good example is provided by preference testing where, on the basis of the $\frac{1}{2}t(t-1)$ preferences expressed by each of n respondents, one wishes to test whether there are significant differences among the treatments (*see* **Hypothesis Testing**), and, if so, to rank the treatments or, better still, place them on some preference scale. In each paired comparison involved, the preferred treatment receives a score of 1 and the other a score of 0. Subsequent analysis is based on the (total) *scores*, $a_1, \ldots, a_t$, attained by the treatments at the end of the experiment. This requires in all $N = \frac{1}{2}nt(t-1)$ paired comparisons, which are assumed to be stochastically independent.

It will be seen that the method is not confined to preference testing, the essential feature being the allocation of 1s and 0s for each paired comparison. "Treatments" is a covering term that can also denote "objects", "individuals", and so on.

An interesting application is given by Jin et al. [5] in their study of whether there is segregation distortion in the human leukocyte antigen complex. For a parent of genotype ij, $i \neq j$, at a particular locus ($i = 1, \ldots, t$; $j = 1, \ldots, t$), a score of 1 is given to whichever allele, i or j, is transmitted to an offspring. Here, block size two (pairing) is forced on the experimenter, as it is for matching body parts or in round robin tournaments.

Sometimes it is possible for a respondent to rank all t treatments directly. If this is easily done, it may be an appropriate procedure. However, the method of paired comparisons allows inconsistencies to show up. Thus, if $A_1 \rightarrow A_2$ signifies that treatment A_1 scores 1, it may happen that $A_1 \rightarrow A_2$ and $A_2 \rightarrow A_3$ but $A_3 \rightarrow A_1$. Such *circular triads* [6] are an indication that the respondent finds it difficult to be consistent. This may be due to small perceived differences among treatments, or to the fact that the *merit* or *worth* of the treatments cannot be represented on a linear scale. If such a representation is possible, we say that a *linear* (paired comparison) *model* holds.

It can be shown [4, 6] that small values of the total number of circular triads are equivalent to large values of the sum of squares of the scores. Clearly, either of these would lead us to suspect the null hypothesis H_0 of no treatment differences. A simple approximate test may be made by rejecting H_0 if

$$\frac{4}{nt}\sum_{i=1}^{t}(a_i - \overline{a})^2 > \chi^2_{1-\alpha}(t-1), \qquad (1)$$

where $\overline{a} = \frac{1}{2}n(t-1)$ and $\chi^2_{1-\alpha}(t-1)$ is the upper α significance point of the **chi-square distribution** with $t-1$ **degrees of freedom**. The approximation is good except when N is small, in which case exact tables of upper 5% and 1% points are available in [4]. **Multiple comparison** methods, based on the a_i, may be used to rank the treatments (see [4]).

Of course, it is not always possible to make all pairings equally often. The analysis of such unbalanced experiments, where A_i and A_j are compared n_{ij} times ($i = 1, \ldots, t$; $j = 1, \ldots, t$; $n_{ij} \geq 0$) is treated in [1].

The foregoing procedures are applicable generally, but the interpretation of the results is simpler when a linear model can be assumed. An important example is the **Bradley–Terry model** [3], for which

$$\Pr(A_i \rightarrow A_j) = \frac{\pi_i}{(\pi_i + \pi_j)}, \qquad i = 1, \ldots, t, \quad j = 1, \ldots, t, \qquad (2)$$

where $\pi_i (> 0)$ represents the merit of $A_i (i = 1, \ldots, t)$. To fix the scale of the π_i, it is usual to impose the constraint $\sum \pi_i = 1$. General theory may be used to test H_0: $\pi_i = 1/t (i = 1, \ldots, t)$ and to estimate the π_i. It can be shown that the resulting estimates are ranked exactly as the a_i. Moreover, the method of **maximum likelihood** also allows the immediate estimation of the π_i for unbalanced experiments.

Ties in individual paired comparisons produce a complication. The simplest way of handling them is to allot a score of $\frac{1}{2}$ to each of the two tied treatments, especially when the number of ties is relatively small. For a full discussion, see [4].

A review of the subject, with emphasis on the Bradley–Terry model, is given in [2]. The general account [4] also deals with issues such as (i) designs

for paired comparison experiments when not all possible pairings can be made, (ii) multivariate paired comparisons, and (iii) selection and ranking of treatments.

Paired *t* Test

A basic concept in study design is that extraneous sources of variation should be controlled, so that the comparison is made among groups which are alike except for the intervention (*see* **Experimental Design**). Techniques which may be used include **stratification** and **analysis of covariance**. Data which are naturally paired form useful strata and often facilitate a more precise comparison than one in a set of unrelated subjects. This leads to the paired t test. The cost of pairing lies in the effort needed to determine the values of the **matching** variables (which is low when there are natural pairs such as litter mates or pre- and post-intervention measures), and the reduction of **degrees of freedom** (df) from $2(n-1)$ to $n-1$ (*see* **Student's *t* Statistics**). The loss of degrees of freedom is almost never a problem when n is greater than 15. The statistic is based on the difference of the members of the pair, so the variance of the difference is $2\sigma^2(1-\rho)$, where ρ is the **correlation** coefficient, and σ^2 is the variance of a single observation. If $\rho = 0$, then the variance is the same as that of the difference between unpaired observations ($2\sigma^2$). In this case, the loss is that of half of the degrees of freedom. When the pairing is effective, $\rho > 0$, and the difference will have a smaller variance than if the observations were unpaired. The tradeoff is almost always in favor of pairing.

The paired t test is used to compare mean differences when the observations have been obtained in pairs, and are thus dependent. Examples include observations made on weight before and after an intervention in a subject, serum cholesterol of two members of a family, and blood concentration of a toxin in litter mates. Subjects are often matched on characteristics such as age, gender, race, and study site (in multicenter studies). In each of these examples, the two observations are made on the same response and will be correlated. Accounting for this is necessary to analyze the study properly. For paired data, it is natural to form the differences, and perform the analysis on the differences. An interesting recent account is by Senn & Richardson [5] who discuss the study which **W.S. Gosset** (Student) used in his paper. Moses [3] gives a summary of the theoretical aspects of this test.

We assume that there are n pairs of observations, and that each pair is independent of the other pairs. Denote the paired observations as x_i and y_i, and their difference as d_i for $i = 1, \ldots, n$. The analysis assumes that the observations are normally distributed with means μ_x and μ_y. The random variable $D = X - Y$ is then normally distributed with mean $\mu_d = \mu_x - \mu_y$ and variance σ_d^2. The **null hypothesis** is $\mathrm{H}_0 : \mu_d = 0$. A Student t statistic can be computed as

$$t = \frac{\overline{d}}{(s_d/\sqrt{n})}.$$

This statistic is then compared to **Student's *t* distribution** with $n-1$ df. This analysis is equivalent to a **randomized blocks** analysis of variance in which the pairs correspond to blocks.

If the variances in X and Y are equal, the variance of D is $2\sigma^2(1-\rho)$, as noted above. If $\rho < 0$, the variance is increased. This would not usually be the case when the matching process is effective. If the variances are unequal, the variance of D is $\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2$. The relative efficacy of a paired t-test is $1/(1-\rho)$ as compared with a two-independent-sample t test in a parallel comparison. For example, if $\rho = 1/3$, the relative efficacy is 1.5. This means that 100 paired observations would have the same power to detect differences as an unpaired study of 150 observations per group.

Example

We give here, in Table 1, data used by Student (Gosset) as cited in Senn & Richardson [5]. The data were on the amount of sleep gained under two soporic drugs.

The means given here agree with those of Senn & Richardson, but the standard deviations are slightly larger. The values they report were those given by Student, who used the divisor n in computing the variance. Using the unpaired t-test we obtain a $t = 1.86$ with 18 df and a ***P* value** of 0.0792. By pairing the observations, as we should, the result is $t = 1.58/(0.39/\sqrt{10}) = 4.06$ with 9 df and a P value of 0.0028. It is better to report the mean of the differences and its standard deviation rather than showing only the t statistic or the P value (or worse, NS for "not significant", or some number of asterisks!).

Table 1

Patient	Dextro	Laevo
1	0.7	1.9
2	−1.6	0.8
3	−0.2	1.1
4	−1.2	0.1
5	−0.1	−0.1
6	3.4	4.4
7	3.7	5.5
8	0.8	1.6
9	0.0	4.6
10	2.0	3.4
Mean	0.75	2.33
Standard deviation	1.79	2.00

Robustness

The **robustness** properties correspond to those of the one-sample t test. The effect of nonnormality is fairly small if n is at least 30, since the distribution of d will be close to normal in that case. If one difference (or a few) appear to be quite large (i.e. **outliers**) the results can be affected. Outliers can be considered a form of nonnormality. They affect the variance of the observations, and can also affect the **skewness** of the distributions. The P values reported from an analysis are often given as $P < 0.05$ or $P < 0.01$. Since the P value depends on the behavior of the distribution in its tails, nonnormality generally means that statements such as $P < 0.001$ are rarely accurate (the quoted P value for the example thus should be regarded as $P < 0.01$). Lack of independence among the pairs (which might arise if multiple members of a litter or a family were included in a study, i.e. clustering) can seriously affect the level of the test. If the correlation between any pair of differences is γ, the variance of the differences is $\sigma^2(1 + 2\gamma)$. Thus, the estimated variance is biased. If $\gamma > 0$, the denominator of the t statistic is too small, and the significance levels are incorrect. If the correlation holds only among certain pairs (e.g. independent clusters would lead to a block diagonal **covariance matrix**), the analysis is more complex, but the estimated variance is still biased. Lack of common variance in X and Y does not formally affect the analysis. However, unless the primary interest is in the difference between the observations, the lack of common variance indicates that X and Y do not have the same distribution, although they might have the same mean. If the variance differs over the pairs, heteroscedasticity concerns arise (*see* **Scedasticity**). Rosner [4] has suggested a **random effects** model which accounts for this. Missing values can create problems. Usually, only one member of the pair is missing. If the missing value is related to the mean value within the pair, the missingness is not random, and the t test is affected (*see* **Missing Data**). For further discussion of these points, see Miller [2] or Madansky [1].

Several alternatives exist to the paired t test. These are useful if the distribution is not normal and there is concern that this may affect the performance of the test. The **sign test** uses the number of positive (or negative) signs as a **binomial** variable with probability parameter 1/2 under H_0, and, for large samples, computes the **standard normal deviate**, z, to test H_0. The **asymptotic relative efficiency** (ARE) of this test is 0.637 when the differences are normal. The **signed-rank** test ranks the absolute values of the differences and sums the ranks corresponding to the positive (or negative) signs. The ARE of this test is 0.955. The **normal scores** test replaces the ranks of the differences by their expected values under normality and computes a t test on these. Its ARE is 1.0. For observations from nonnormal distributions, the efficiencies of the **nonparametric** procedures may be higher than indicated here and the t test can be very inefficient.

Pairwise Independence

Suppose that two variables are considered as potentially **explanatory** for a further variable, called the **response**, and that the dependence of the response on each of the variables taken alone and on both acting jointly is of main interest. For an appropriately chosen scale and measure of dependence, suppose furthermore that the effects of both variables turn out to be (essentially) additive (*see* **Additive Model**). This means that the effect of one of them on the response is (nearly) the same no matter at which level the other explanatory variable is fixed. Often, this is described as the absence of an **interaction** but the presence of two main effects.

An important role of pairwise **independence** of explanatory variables is then as follows: it is certain that no dependence reversal can occur for the (nearly) additive effect of one of the explanatory variables in comparison with the effect of this variable taken alone. To put it differently, if the explanatory variables are nearly independent, and have essentially additive effects on the response, then the overall effect of just one of them coincides at least qualitatively with the corresponding effects considered conditional given the other variable. A strong reversal of treatment success as related to variable B occurs instead in the 2^3 contingency table displayed in Table 1, since the explanatory variable pair B, C is highly dependent.

For both discrete and for continuous responses, further discussions of dependence reversal in spite of essentially additive main effects are to be found, for instance, in Snedecor & Cochran [5, p. 472], Good & Mittal [1], Wermuth [6,7], and Guo & Geng [2]. In a **contingency table** context early insights are due to Yule [8] and Simpson [4], (*see* **Simpson's Paradox**).

Mutual Dependence in Spite of Pairwise Independences

In general, no mutual independence results even if several variables are all pairwise independent. Instead, more complicated types of dependencies may still exist, which are often called higher-order interactions. An important implication is that methods of analysis relying completely on pairwise associations, **correlation**-based techniques or **correspondence analysis**, will overlook the existing dependencies in such situations and are therefore likely to lead to misleading interpretations.

An empirical example with four **binary** variables is due to Lienert [3]. He reported on symptoms after LSD intake. The 2^3 contingency table shown in Table 2 is an adaptation of his results. The three transient symptoms, recorded to be present (level 1) or absent (level 2), are distortions in affective behavior (A), distortions in thinking (B), and dimming of consciousness (C). There is a strong three-way interaction, as reflected for instance in the quite distinct **odds ratios** at the two levels of C; at the same time, the frequencies in the three marginal tables show all three symptom pairs as being close to independence.

With completely randomized designs (*see* **Randomization**) it will typically occur that – at the time a study starts – not only observed variables but also unobserved variables will essentially be both pairwise, and mutually, independent. Note, however, that even with this technique it is not possible to avoid dependencies with unobserved intermediate variables,

Table 1 Dependence reversal because of strongly associated explanatory variables

	C, site				Overall; that is, summed over sites	
	$k = 1$		$k = 2$			
A,	B, treatment		B, treatment		B, treatment	
outcome	$j = 1$	$j = 2$	$j = 1$	$j = 2$	$j = 1$	$j = 2$
$i = 1$ (success)	96 (96%)	600 (60%)	400 (40%)	4 (4%)	496 (45%)	604 (55%)
$i = 2$	4	400	600	96	604	496
Sum	100	1000	1000	100	1100	1100
Odds ratio	16		16		0.67	

Table 2 Symptoms after LSD intake: mutual dependence and pairwise independence

	C, dimming of consciousness			
	$k = 1$ (yes)		$k = 2$	
A, distorted affective behavior	B, distorted thinking		B, distorted thinking	
	$j = 1$, (yes)	$j = 2$	$j = 1$, (yes)	$j = 2$
$i = 1$ (yes)	21	5	4	16
$i = 2$	2	13	11	1
Odds ratio	27.30		0.023	

i.e. with unrecorded variables related to both treatment and outcome, but occurring unnoticed before observing outcome. Typical examples are noncompliance of some patients (*see* **Compliance Assessment in Clinical Trials**) or, more generally, unrecorded treatment effects or changes in measurement devices before treatment outcome is established.

NANNY WERMUTH

Panel Study

In a panel study a number of individuals are followed for a given period of time. At each of a predetermined set of time points several measurements on each individual are taken. Data obtained from a panel study are called *panel data*. A panel study designed to have observations at k time points is called a k-wave panel design. Under this definition the term *panel study* could be used to refer to a large range of studies in biostatistics, particularly in epidemiology and **clinical trials**, although in many cases the term panel study is not used. The main advantage of a panel study is that individual changes over time can be modeled and the unobserved heterogeneity across individuals and over time can be taken into account.

In many panel studies, especially those lasting for a long period, attrition or loss to follow-up is an important issue. To keep the study population at a proper size during the study, two variations of the simple panel study can be used [3]. One is the *rotating panel study*, which replaces a part of the previous panel by a new panel at some time points and each individual only stays in the study for a certain period. Another is the *split panel design*, which recruits a new panel at some time points and keeps following all the panels until the end of the study.

Two important design issues are the calculation of sample size and the choice of time points to take the observations. For studies with continuous or categorical outcomes, standard sample size calculation procedures for repeated measurement models can be used. For panel studies that measure time to event (*see* **Survival Analysis, Overview**) the exact time of an event may not be obtained. In these cases the panel data are interval **censored**. With a predetermined number of waves, optimal time points can be obtained by using **optimal design** procedures [2]. These choose designs according to a criterion based on the Fisher **information matrix**, e.g. the D-optimality criterion. Similar procedures can be used for estimating duration of diseases or other recurrent events [1] (*see* **Repeated Events**). For the variable k there is a tradeoff between increasing costs and the gains in efficiency.

Several models can be used for the analysis of panel data. A simple model for continuous outcomes is a linear model with normally distributed variance components. Suppose a panel consists of n individuals and k observations are taken on each individual. Letting y_{ij} be observation j from subject i, this model can be written as [7]

$$y_{ij} = u_{ij} + \mathbf{x}_{ij}\boldsymbol{\beta}, \tag{1}$$

where $\mathbf{x}_{ij}$ is a vector of covariates and $\boldsymbol{\beta}$ is a vector of coefficients. Here u_{ij} is a term which can be either random or fixed, representing the variation among individuals and over time. For random u_{ij}, y_{ij}, $j = 1, \ldots, k$, may be correlated and several correlation patterns can be modeled by imposing properties on the u_{ij}. A simple model assumes that $u_{ij} = u_i + e_{ij}$, where u_i and e_{ij} are independent random errors. This model results in compound symmetry correlation in the linear models. Another commonly used model for u_{ij} in panel studies is the **time series** model or **serial correlation** model. An example is the AR(1) model (*see* **ARMA and ARIMA Models**) in which $u_{ij} = au_{ij-1} + e_{ij}$, for some constant a. A more complicated model may be a combination of these two. In (1) $\boldsymbol{\beta}$ (or a part of $\boldsymbol{\beta}$) can also be random. Models with random β are called **random coefficient** models [11]. For example, in a linear growth model, the growth rate for each subject may be different and may be considered as a random variable. Other kinds of models for panel studies include **lagged dependent variables** and lagged independent variables as **covariates**. These models are also known as the *dynamic* models.

To include discrete outcomes we may use (1) as a model for a latent variable, then discretize y_{ij} [6] or, more generally, assume that conditional on u_{ij}, y_{ij} belongs to the **exponential family**. This model is known as the generalized linear mixed model and can be used to model several types of data such as nonnormal continuous data and **binary**/count data (*see* **Generalized Linear Models for Longitudinal Data**). However, there are other models which are not included in this family [5], such as the **loglinear** models that are widely used in panel studies. A large amount of work has been done in the context of modeling repeated measurement data.

The main problem in analyzing panel data is the correlation between repeated measures. Several procedures have been developed for this purpose. For linear models with normally distributed errors, **marginal models** can easily be found and either **least squares** or generalized least squares can be used to estimate $\boldsymbol{\beta}$. The parameters for the variance components can be estimated using either the **maximum likelihood** estimator (MLE) or the

residual (or **restricted**) **maximum likelihood** estimator (REML), or by the **method of moments**.

The analysis of discrete data is much more difficult. For generalized linear mixed models the marginal likelihood function normally does not have a closed form and **numerical integration** has to be used to obtain the MLE. An alternative is to use approximations either when the **variance components** are small or the number of observations from each subject is large.

When $u_{ij} = u_i$ and u_i is fixed, the number of parameters for the subject effects increases with increasing total sample size so that the asymptotic properties of the MLE do not apply here. One approach to deal with this problem is to use conditioning (*see* **Conditionality Principle**). For example, for binary data the total responses are **sufficient statistics** for the subject effects. Conditioning on them can eliminate the subject effects and yield a consistent estimate of β. Conditioning is easy to perform when k is small but complicated even for moderate k. Conditioning can also be used for models with random u_{ij}.

In the last 10 years the **generalized estimating equation** (GEE) procedure [9] has been widely used. To use GEE only a marginal model and a **covariance matrix** for the outcomes are needed. This procedure gives consistent estimates as long as the model for the mean is correct, and in many cases it is effective compared with the MLE if the "working covariance matrix" is close to the true one.

Some special issues in panel data analysis are worth consideration. Often, in panel data u_{ij} contains both random subject effects and serial correlation. For the analysis of continuous outcome models, the Prais–Winston transformation can be used and the correlation coefficient can be tested by the generalized **Durbin–Watson test** [8]. For generalized linear mixed models the MLE is difficult to obtain and some approximation methods may be used.

Attrition also causes problem in the analysis of panel data, especially when loss to follow-up is outcome related. In panel studies loss to follow-up often depends on the previous observations. This is classified in missing data analysis as missing at random (MAR) [10]. In MAR data the missing mechanism depends on the observed data (here the previous observations) but not the missing data (here the outcome after the loss to follow-up). Several procedures have been proposed for analyzing MAR data and even more complicated missing mechanisms [4] (*see* **Nonignorable Dropout in Longitudinal Studies**).

Parallel-line Assay

Parallel-line assays are the most common type of indirect analytical dilution assays (*see* **Biological Assay, Overview**). The response, which is measured on subjects at each of several fixed dose levels of the standard and test preparations, may be either quantitative or an "all-or-none" (quantal) variable, such as "dead" or "surviving" for each subject. In the parallel-line assay the measured response or an appropriate transformation of response, referred to as the response metameter, is a linear function of the logarithm of the dose administered. The condition of similarity, which is a prerequisite of all analytical dilution assays, specifies that the test preparation behaves like a dilution of the standard preparation. Furthermore, the expected response (y_S) of the standard is generally assumed to be linear in some known power of dose; that is,

$$\mathrm{E}[y_S|d_S] = \alpha_S + \beta x_S,$$

where

$$x_S = d_S^{\lambda}.$$

When $\lambda \to 0$, then $x_S = \log d_S$. If we next also assume that a dose of the standard (d_S) is equivalent to the product of the relative potency parameter ρ, times the dose of the test, d_T for all dose levels, then

$$\mathrm{E}[y_T|\log d_T] = \mathrm{E}[y_S|\log(\rho d_T)]$$

and

$$x_S = \log d_S = \log(\rho d_T) = \log\rho + x_T.$$

Therefore (see Figure 1),

$$\mathrm{E}[y_T|x_T] = \alpha_S + \beta\log\rho + \beta x_T = \alpha_T + \beta x_T.$$

When the responses are equivalent for the standard and test, i.e.

$$\alpha_S + \beta x_S = \alpha_S + \log\rho + \beta x_T.$$

Then

$$\log\rho = \frac{\alpha_T - \alpha_S}{\beta}.$$

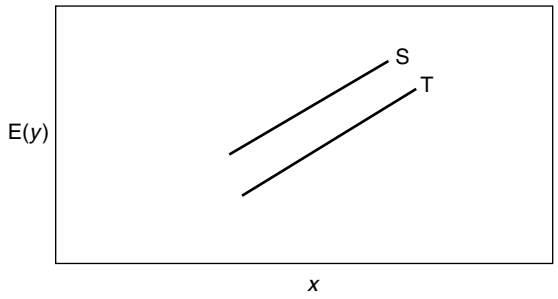

Figure 1 Expected response (E(y)) vs. dose metameter (x) for standard (S) and test (T) preparations in a parallel-line assay

Relative Potency Estimation and Validity Tests

Quantitative Responses

Estimates of the parameters are readily calculated from standard **least squares** regression programs. The common slope and intercepts for test and standard preparations are estimated as follows (see Table 1 for notation):

$$\hat{\beta} = \frac{\sum_{S,T} S_{xy}}{\sum_{S,T} S_{xx}},$$

$$\hat{\alpha}_T = \overline{y}_T - \hat{\beta}\overline{x}_T,$$

and

$$\hat{\alpha}_S = \overline{y}_S - \hat{\beta}\overline{x}_S.$$

Accordingly, the log relative potency estimate is

$$\log\hat{\rho} = \frac{\hat{\alpha}_T - \hat{\alpha}_S}{\hat{\beta}} = (\overline{x}_S - \overline{x}_T) - \frac{(\overline{y}_S - \overline{y}_T)}{\hat{\beta}}.$$

Before proceeding to calculate the **confidence intervals** for ρ, it is useful to verify that the assumptions of the model are not seriously violated. Table 1 summarizes in general form the **analysis of variance** (ANOVA) used to validate the assumptions. The method of least squares used to estimate the regression parameters, and to determine the confidence interval for ρ, further assumes that the y_i are

independent normally distributed variables and that

Table 1 Analysis of variance in quantitative parallel-line assay

Source	df	Sums of squares	Mean squares	F
Total	$N-1$	$\mathrm{SS}_y = \sum_{\mathrm{S,T}} \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} \left(y_{pij} - \overline{y}\right)^2$	$\mathrm{MS}_y = \dfrac{\mathrm{SS}_y}{N-1}$	
Among doses	$K-1$	$\mathrm{SS}_{\mathrm{D}} = \sum_{\mathrm{S,T}} \sum_{i=1}^{K_p} n_{pi} \left(\overline{y}_{pi} - \overline{y}\right)^2$	$\mathrm{MS}_{\mathrm{D}} = \dfrac{\mathrm{SS}_{\mathrm{D}}}{K-1}$	$\dfrac{\mathrm{MS}_{\mathrm{D}}}{\mathrm{MS}_{\mathrm{E}}}$
Preparations	1	$\mathrm{SS}_{\mathrm{P}} = \sum_{\mathrm{S,T}} N_p \left(\overline{y}_p - \overline{y}\right)^2$	$\mathrm{MS}_{\mathrm{P}} = \mathrm{SS}_{\mathrm{P}}$	$\dfrac{\mathrm{MS}_{\mathrm{P}}}{\mathrm{MS}_{\mathrm{E}}}$
Common slope	1	$\mathrm{SS}_{\mathrm{R}} = \dfrac{\left(\sum_{\mathrm{S,T}} S_{xy}\right)^2}{\sum_{\mathrm{S,T}} S_{xx}}$	$\mathrm{MS}_{\mathrm{R}} = \mathrm{SS}_{\mathrm{R}}$	$\dfrac{\mathrm{MS}_{\mathrm{R}}}{\mathrm{MS}_{\mathrm{E}}}$
Parallelism	1	$\mathrm{SS}_{\mathrm{PL}} = \sum_{\mathrm{S,T}} \left(\dfrac{S_{xy}^2}{S_{xx}}\right) - \mathrm{SS}_{\mathrm{R}}$	$\mathrm{MS}_{\mathrm{PL}} = \mathrm{SS}_{\mathrm{PL}}$	$\dfrac{\mathrm{MS}_{\mathrm{PL}}}{\mathrm{MS}_{\mathrm{E}}}$
Nonlinearity	$K-4$	$\mathrm{SS}_{\mathrm{NL}} = \mathrm{SS}_{\mathrm{D}} - \mathrm{SS}_{\mathrm{P}} - \mathrm{SS}_{\mathrm{R}} - \mathrm{SS}_{\mathrm{PL}}$	$\mathrm{MS}_{\mathrm{NL}} = \mathrm{SS}_{\mathrm{NL}}/(K-4)$	$\dfrac{\mathrm{MS}_{\mathrm{NL}}}{\mathrm{MS}_{\mathrm{E}}}$
Within doses (error)	$N-K$	$\mathrm{SS}_{\mathrm{E}} = \mathrm{SS}_y - \mathrm{SS}_{\mathrm{D}}$	$\mathrm{MS}_{\mathrm{E}} = \dfrac{\mathrm{SS}_{\mathrm{E}}}{N-K} = \hat{\sigma}^2$	

Notation (adapted from [8]):

$$n_{pi} = \text{number of observations at dose } i \text{ of preparation } p,$$

$$y_{pij} = \text{response for subject } j \text{ to dose } i \text{ of preparation } p,$$

$$x_{pij} = \text{dose metameter for subject } j \text{ to dose } i \text{ of preparation } p,$$

where

$$i = 1, 2, \ldots, K_p, \qquad p = \text{S(Standard) or T(Test);}$$

and

$$K_p = \text{number of dose levels of preparation } p,$$

$$N_p = \sum_{i=1}^{K_p} n_{pi},\ N = \sum_{\mathrm{S,T}} N_p,\ K = \sum_{\mathrm{S,T}} K_p,$$

$$S_{yy} = \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (Y_{pij} - \overline{y}_p)^2,$$

where

$$\overline{y}_p = \frac{\sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} y_{pij}}{N_p}, \qquad S_{xx} = \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (x_{pij} - \overline{x}_p)^2,$$

in which

$$\overline{x}_p = \frac{\sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} x_{pij}}{N_p},$$

and

$$S_{xy} = \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (y_{pij} - \overline{y}_p)(x_{pij} - \overline{x}_p).$$

$\text{var}(y_i) = \sigma^2$ for all dose levels d_i. Absence of heteroscedasticity should be verified, whenever possible, by an appropriate statistical test.

The five **hypothesis tests** of interest for parallel-line assays, as shown in Table 1, are:

1. $H_1 : \alpha_T = \alpha_S$ and $\beta_S = \beta_T = 0$. Reject if

$$F = \frac{MS_D}{MS_E} > F_{(K-1,N-K)},$$

the critical level of the ***F* distribution** on $(K - 1, N - K)$ **degrees of freedom** (df). Failure to reject indicates the likelihood of poor selection of dose levels, e.g. that they were outside a dose range for observing changes in response for either of the two preparations. (Calculated variance ratios, F, in the analysis of variance are often conventionally compared to tabulated $F_{(df_1,df_2)}$ values corresponding to a 5% significance level (*see* **Level of a Test**).)

2. H_2: Reject linearity if

$$F = \frac{MS_{NL}}{MS_E} > F_{(K-4,N-K)}.$$

If this hypothesis is rejected, indicating statistical invalidity in the linearity assumption, then a nonlinear regression function, such as a quadratic, may be applicable. More usually, a different part of the dose range might be used, or, alternatively, a **transformation** of the response variable might achieve linearity.

3. $H_3 : \beta_S = \beta_T = \beta$. If

$$F = \frac{MS_{PL}}{MS_E} > F_{(1,N-K)},$$

then there is evidence of fundamental invalidity of the assay and the assumption of a constant relative potency is suspect.

4. H_4: Reject equivalence of mean responses for the test and standard preparations if

$$F = \frac{MS_P}{MS_E} > F_{(1,N-K)}.$$

If the dose-ranges for the two preparations are not equivalent, then the parallel lines may be far apart even when the mean responses are the same. Although in bioassay the differences between treatment means are not of primary interest, a significant mean square for H_4 indicates a design problem associated with the doses chosen for the experiment. On the other hand, a nonsignificant test cannot necessarily be interpreted as assurance that the dose ranges were appropriate [8].

5. $H_5 : \beta = 0$; reject if

$$F = \frac{MS_R}{MS_E} > F_{(1,N-K)}.$$

It is expected that a well-designed assay will have a highly significant common regression coefficient.

If the analysis of variance does not indicate any validity concerns and there was no evidence of heteroscedasticity, **Fieller's theorem** [6] for ratio estimators can be applied to obtain the confidence interval for ρ. In a parallel-line assay the 95% confidence intervals for $\log \rho$ are calculated as

$$\log \hat{\rho}_L, \log \hat{\rho}_U = (\bar{x}_S - \bar{x}_T) + \left[(\log \hat{\rho} - \bar{x}_S + \bar{x}_T) \pm \frac{\hat{\sigma} t}{\hat{\beta}} \left\{ (1 - g) \left(\frac{1}{N_S} + \frac{1}{N_T} \right) + \frac{(\log \hat{\rho} - \bar{x}_S + \bar{x}_T)^2}{\sum S_{xx}} \right\}^{1/2} \right] \Big/ (1 - g),$$

where

$$g = \frac{t^2 \hat{\sigma}^2}{\hat{\beta}^2 \sum_{S,T} S_{xx}}$$

and t has $N - K$ degrees of freedom.

Quantal Responses

Toxicological assays frequently involve **quantal responses**. In quantal assays the response is the proportion of subjects responding at a fixed dose level, d_i. If the proportion responding is plotted against $\log d_i$, the curve is generally sigmoid in shape. This leads to consideration of various probability density functions for the tolerance distribution (*see* **Quantal**

Response Models). The normal and the **logistic** are the two most frequently used tolerance distributions, but others such as the **Cauchy** or the angular have been proposed for some applications. To illustrate, when the normal probability density is specified, the expected proportion responding at dose, d_i is

$$P_i = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{y_i=(x_i-\mu)/\sigma} \exp\left(-\frac{1}{2}u^2\right) \mathrm{d}u.$$

Hence the linearizing transformation is the normal equivalent deviate (ned)

$$y_i = -\frac{\mu}{\sigma} + \frac{1}{\sigma}x_i = \alpha + \beta x_i,$$

where y_i is usually referred to as the probit of P_i [2, 3]. (In order to avoid negative values, most references add 5 to each ned. [8].)

When the logistic transformation is used

$$P_i = \frac{1}{1 + \exp[-(\alpha + \beta x_i)]}$$

and

$$y_i = \text{logit}\left(\frac{P_i}{1 - P_i}\right) = \alpha + \beta x_i.$$

Often, the estimates of ρ will be quite similar regardless of which linearizing transformation is employed, since the curves will overlap over a wide range of responses, with only the extremes differing. There are varying viewpoints about how to select an appropriate theoretical unknown tolerance distribution. Furthermore, validity tests seldom discriminate between the normal and logistic functions in practice, so that for estimation purposes there is limited basis for preferring one over the other.

If the probability of responding at a particular dose is a **binomial**, such that

$$\Pr(r_i \text{ responding}) = \binom{n_i}{r_i} P_i^{r_i} Q_i^{n_i - r_i}$$

and P is defined by the ned above, then the parameters α and β can be estimated iteratively by usual **maximum likelihood** procedures (*see* **Optimization and Nonlinear Equations**). Estimation involves weighting the observed proportions at specified doses since the binomial responses will have unequal variances. (Weights are symmetric about the middle of the tolerance distribution, with lesser weights at the extremes.) For the probit transformation, the weight at each fixed log dose d_i is $n_i w_i$, where n_i is the number of subjects at $\log d_i$ and

$$w_i = \frac{\Phi_i}{P_i Q_i}.$$

Φ_i is the ordinate of the standard normal density curve corresponding to y_i, the expected probit of P_i. While the calculations are somewhat laborious, they are readily programmed and available in standard packages such as SAS [11] or GLIM [9] (*see* **Software, Biostatistical**). Following the notation adopted above for quantitative response curves, the weighted sums of squares and cross products obtained by maximum likelihood estimation are used to calculate the estimated log relative potency,

$$\log \hat{\rho} = \frac{\hat{\alpha}_\mathrm{T} - \alpha_\mathrm{S}}{\hat{\beta}} = \overline{x}_\mathrm{S} - \overline{x}_\mathrm{T} - \frac{\overline{y}_\mathrm{S} - \overline{y}_\mathrm{T}}{\hat{\beta}}$$

and

$$\hat{\beta} = \frac{\sum_{\mathrm{S,T}} S_{xy}}{\sum_{\mathrm{S,T}} S_{xx}} = \frac{\sum_{\mathrm{S,T}} Snw(x - \overline{x})(y - \overline{y})}{\sum_{\mathrm{S,T}} Snw(x - \overline{x})^2},$$

where $\overline{x}_\mathrm{S}$, $\overline{x}_\mathrm{T}$, $\overline{y}_\mathrm{S}$, and $\overline{y}_\mathrm{T}$ are weighted means, e.g. $\overline{x}_\mathrm{S} = Snwx/Snw$, etc.

As before, the confidence interval for $\log \rho$ is calculated by application of Fieller's theorem. Since the standard normal density is assumed for the tolerance distribution, the within-subject error (σ^2) is assumed to be 1 and normal distribution values are used for specifying confidence intervals. The 95% confidence intervals are, therefore,

$$\log \hat{\rho}_\mathrm{L}, \log \hat{\rho}_\mathrm{U}$$

$$= (\overline{x}_\mathrm{S} - \overline{x}_\mathrm{T}) + \Bigg[(\log \hat{\rho} - \overline{x}_\mathrm{S} + \overline{x}_\mathrm{T})$$

$$\pm \frac{1.96}{\hat{\beta}} \Bigg\{ (1 - g) \sum_{\mathrm{S,T}} \left(\frac{1}{Snw}\right)$$

$$+ \frac{(\log \hat{\rho} - \overline{x}_\mathrm{S} + \overline{x}_\mathrm{T})^2}{\sum_{\mathrm{S,T}} S_{xx}} \Bigg\}^{1/2} \Bigg] \Big/ (1 - g),$$

where

$$g = \frac{1.96^2}{\hat{\beta}^2 \sum_{\mathrm{S,T}} S_{xx}}.$$

Validation of the model assumed for quantal assays is analogous to the ANOVA performed for quantitative parallel line assays. In quantal assays the statistical significance for hypothesis tests is compared to the **chi-square distribution** with appropriate degrees of freedom. Hypothesis tests of interest are:

1. H_1: reject if

$$X^2 = \sum_{\mathrm{S,T}} S_{yy} - \sum_{\mathrm{S,T}} \left\{ \frac{S_{xy}^2}{S_{xx}} \right\} > \chi^2_{K_\mathrm{S}+K_\mathrm{T}-4}.$$

   H_1 is a test for nonlinearity of regression. When the calculated X^2 is not significant, the observed data are not inconsistent with the assumption of a normal log tolerance distribution. Where H_1 is rejected, consideration should be given as to whether there is a systematic deviation from normality in the dose–response relationship or whether there is nonsystematic heterogeneity. In the latter case, it is customary to employ a heterogeneity factor for the variance in calculating the confidence intervals; the variances are multiplied by the X^2 calculated for nonlinearity divided by its degrees of freedom (*see* **Overdispersion**). The estimated variance is, therefore,

$$\hat{\sigma}^2 = \frac{X^2}{K_\mathrm{S} + K_\mathrm{T} - 4}.$$

   All variances will thus have only $K_\mathrm{S} + K_\mathrm{T} - 4$ degrees of freedom when this adjustment is made.
2. H_2: reject if

$$X^2 = \sum_{\mathrm{S,T}} \left\{ \frac{S_{xy}^2}{S_{xx}} \right\} - \frac{\left(\sum_{\mathrm{S,T}} S_{xy} \right)^2}{\sum_{\mathrm{S,T}} S_{xx}} > \chi_1^2.$$

   H_2 is a test for parallelism of the transformed regression lines, and therefore a nonsignificant X^2 verifies the fundamental validity of the assay.

A common extension employed in quantal assays introduces an additional parameter, C, in the estimation to incorporate a proportion responding (dying) at zero dose level, which provides for a natural event (death) rate in the absence of exposure. This leads to an adjusted proportion responding at each dose level:

$$P_i' = C + (1 - C) P_i.$$

Therefore,

$$P_i = \frac{P_i' - C}{1 - C}.$$

Estimation of parameters, including C, can proceed as previously using standard iterative approaches to obtain the maximum likelihood estimates. The expression for P_i above is generally referred to as Abbot's formula [1].

Detailed illustrations of the design and analysis of quantal assays are provided in [7, 8], and [10].

Additional Remarks

The formulas presented in Table 1 are general in form and do not depend on having a symmetrical, balanced design for the assay or equal spacing between doses. For both design and efficiency reasons, a symmetric design with equal numbers of subjects at each dose level is preferable. Modern statistical analysis software such as GLIM [9] or SAS [11] can readily accommodate either unsymmetric or symmetric designs. At least three dose levels of the test and standard preparations are required to test all validity assumptions in the ANOVA. With regard to quantal assays, analyses using normal or logistic tolerance distributions can also be done in most general statistical software packages, such as SAS, GLIM, or **S-PLUS** (for examples, see references to statistical software at the end of this section or [12]).

The methodology is easily extended to designs in which multiple test preparations are simultaneously compared to the same standard. In parallel-line assays with more than one test preparation, optimal allocation among r test preparations given a total number of subjects would be

$$N_\mathrm{s} = r^{1/2} N_\mathrm{T}$$

assuming that the variance of ρ is approximately proportional to $N_\mathrm{s}^{-1} + N_\mathrm{T}^{-1}$.

Finney [8] demonstrates that the analyses described above may provide very similar estimates of the relative potency and its confidence intervals even when the normality assumption is not fulfilled, but other model assumptions are not seriously violated. Information derived from evaluating validity across a related class of independent assays is preferred to justify an appropriate choice for the response metameter.

A useful indicator of the optimality of assay design is the value of g from Fieller's theorem. In quantitative parallel-line assays, g can be rewritten as

$$g = \frac{F_{\text{tabulated}}}{F_{\text{calculated}}},$$

where the numerator is the variance ratio for regression. Well-designed and well-executed assays will generally have values of $0 < g < 0.05$, whereas high values of g indicate some lack of efficient design. A comparative measure proposed by Bliss & Cattrell [4] to evaluate the sensitivity among assays is $\hat{\sigma}/\hat{\beta}$. Smaller values of $\hat{\sigma}/\hat{\beta}$ are indicative of "better sensitivity", whereas larger values indicate lesser precision, less steep slopes or a combination of both.

Finney [7, 8] and Brown [5] give detailed discussions of considerations important for optimizing design of quantitative or quantal parallel-line assays.

CAROL K. REDMOND

Parametric Models in Survival Analysis

Survival analysis in biostatistical applications involves the analysis of times to events (*see* **Survival Analysis, Overview**); for conciseness we refer to these times as lifetimes. Sometimes the objective is to model or describe the distribution of lifetimes in a single homogeneous population of individuals. More generally, we wish to compare distributions or to assess the relationship of **explanatory variables** to lifetimes. In some instances different types of events may occur to an individual, and the joint distribution of several lifetimes may be of interest.

Parametric survival models are ones in which the distribution of lifetimes is specified up to a parameter $\boldsymbol{\theta}$ that is of finite, and usually rather small, dimension. A major advantage of parametric models is the availability of straightforward methods of **estimation** and **inference** based on the **likelihood** function. In addition, parametric representations facilitate the accumulation of scientific evidence across different but similar studies. However, fully parametric models involve stronger assumptions than semi- or nonparametric models. The choice of a parametric model is more often based on a combination of tractability and ability to fit the data than on any deep physical motivation, and it is therefore important to check the adequacy of models and to consider the sensitivity of inferences and conclusions to plausible variations in them. The next two sections describe the main families of models used for parametric survival analysis, and how such analysis is carried out.

Parametric Models

Following standard terminology, let $T \geq 0$ be a **random variable** representing lifetime and assume that T has a continuous distribution with cumulative distribution function (cdf) $F(t) = \Pr(T \leq t)$, probability density function (pdf) $f(t) = F'(t)$, survivor function $S(t) = \Pr(T \geq t)$, **hazard** function $h(t) = f(t)/S(t)$, and cumulative hazard function $H(t) = \int_0^t h(u)\,\mathrm{d}u$. Any one of these five functions specifies the distribution of T (*see* **Survival Distributions and Their Characteristics**). It is useful to note that $S(t) = \exp[-H(t)]$.

Parametric models are specified in terms of a parameter $\boldsymbol{\theta}$, and in this case we write $F(t;\boldsymbol{\theta}), f(t;\boldsymbol{\theta})$, and so on. A wide variety of models has been used for univariate lifetime distributions. The merits of specific families of distributions are often discussed both in terms of their ability to fit existing data and the shapes of their hazard functions, which specify the instantaneous probability of death or failure at time t, given survival up to t. In the following subsection we describe some important parametric families. Two additional subsections discuss models involving covariates and models that are multivariate or involve random effects.

Some Important Parametric Families

Below we summarize the most widely used parametric lifetime distribution models. Unless specified otherwise, the range of the lifetime variable t is $t \geq 0$.

Exponential distribution. The **exponential distribution** has survivor, density, and hazard functions of the form

$$S(t) = \exp(-\lambda t), \quad f(t) = \lambda \exp(-\lambda t) \quad h(t) = \lambda,$$

where $\lambda > 0$ is a parameter; it is easily seen that $\mathrm{E}(T) = \lambda^{-1}$. The exponential family has constant hazard functions and the associated "lack of memory" property: $\Pr(T \geq t + x | T \geq t) = \Pr(T \geq x)$. These characteristics are obviously restrictive, and limit the applicability of the model. Approximate sample-size calculations for clinical trials (*see* **Sample Size Determination in Survival Analysis**) are sometimes based on it, but require careful application [22]. It is a useful fact that if T is an arbitrary random variable with cumulative hazard function $H(t)$, then the transformed variable $H(T)$ has a standard ($\lambda = 1$) exponential distribution.

Weibull distribution. The **Weibull distribution** with inverse scale parameter $\lambda > 0$ and shape parameter $\delta > 0$ has survivor, density, and hazard functions

$$S(t) = \exp[-(\lambda t)^{\delta}],$$

$$f(t) = \delta\lambda(\lambda t)^{\delta-1} \exp[-(\lambda t)^{\delta}], \quad h(t) = \delta\lambda(\lambda t)^{\delta-1}.$$

The two parameters allow the Weibull density to take a variety of shapes, and the hazard function is either monotone increasing, decreasing, or constant according to whether $\delta > 1$, $\delta < 1$, or $\delta = 1$. The case $\delta = 1$ gives the exponential distribution, and, more generally, T^δ has an exponential distribution with hazard function λ^δ. The Weibull distribution often fits biostatistical survival data well, and in some applications there is physical justification for a Weibull model through weakest link or multistage waiting time arguments (e.g. Armitage & Doll [3]) (*see* **Multistage Carcinogenesis Models**).

Lognormal distribution. The **lognormal** distribution has the property that log lifetime, $Y = \log T$, is normally distributed with mean μ and variance σ^2. This gives a two-parameter family with survivor and density functions

$$S(t) = 1 - \Phi\left(\frac{\log t - \mu}{\sigma}\right),$$

$$f(t) = \frac{1}{(2\pi)^{1/2}\sigma t}\exp\left[-\frac{1}{2}\left(\frac{\log t - \mu}{\sigma}\right)^2\right],$$

where $\Phi(x)$ is the standard normal cdf. The hazard functions are nonmonotonic: they rise from 0 at $t = 0$ to a maximum, and then decrease to 0 as $t \to \infty$. This shape is implausible for some, but by no means all, survival analysis applications. Moreover, the proportion of the population with lifetimes greater than the hazard function mode can vary widely according to the values of (μ, σ). The lognormal model has the advantage that when there is no **censoring** of lifetimes we can apply simple normal distribution inference methods to the log lifetimes (see the section "Model Fitting and Inference" below). However, censoring is more the rule than the exception in survival data, and so this is a relatively minor advantage.

Log-logistic distribution. The log-logistic family has survivor, density, and hazard functions of the form

$$S(t) = \frac{1}{1 + (\lambda t)^\delta}, \quad f(t) = \frac{\delta\lambda(\lambda t)^{\delta-1}}{[1 + (\lambda t)^\delta]^2},$$

$$h(t) = \frac{\delta\lambda(\lambda t)^{\delta-1}}{1 + (\lambda t)^\delta},$$

where $\lambda > 0$ and $\delta > 0$ are inverse scale and shape parameters. It derives its name from the fact that $Y = \log T$ has a **logistic distribution**. This family is similar to the lognormal family, and its hazard functions also increase from 0 at $t = 0$ to a maximum, and then decrease to 0 as t becomes large. It is slightly more convenient than the lognormal family for survival analysis, since its survivor and hazard functions have simple closed-form expressions.

Location-scale models for $Y = \log T$. The Weibull, lognormal, and log-logistic distributions share a property: log lifetime Y has a **location-scale** distribution with survivor and density functions of the form

$$S_Y(y) = G\left(\frac{y - \mu}{\sigma}\right), \qquad f_Y(y) = \frac{1}{\sigma}g\left(\frac{y - \mu}{\sigma}\right), \tag{1}$$

where $\mu(-\infty < \mu < \infty)$ is a location parameter, $\sigma > 0$ is a scale parameter, and $G(z)$ and $g(z) = -G'(z)$ are the survivor function and pdf for the standardized variable $Z = (Y - \mu)/\sigma$. When T is Weibull the distribution of $Y = \log T$ is called the **extreme-value** distribution. When T is lognormal, Y is normal, and when T is log-logistic, Y is logistic. The three respective survivor functions for Z are:

1. extreme-value $\quad G(z) = \exp(-e^z)$,
2. normal $\quad G(z) = 1 - \Phi(z)$,
3. logistic $\quad G(z) = (1 + e^z)^{-1}$,

where $-\infty < z < \infty$ in each case.

Other lifetime models can be formed by choosing other distributions for Z or Y. Sometimes the distribution of Z is allowed to depend upon one or two additional parameters, thus giving very flexible three- or four-parameter lifetime distributions. Two such families are the generalized log **gamma** [16; 23, Section 5.3] and the Burr–**Pareto** [6, 25]. The latter, for example, gives a three-parameter distribution with survivor function for T of the form

$$S(t) = [1 + \alpha^{-1}(\lambda t)^\delta]^{-\alpha}, \tag{2}$$

where $\alpha > 0, \lambda > 0$, and $\delta > 0$. This is obtained from (1) by taking $G(z) = (1 + \alpha^{-1}e^z)^{-\alpha}$ and defining $\lambda = e^{-\mu}$ and $\delta = \sigma^{-1}$. It may also be obtained from a Weibull **frailty** model with gamma-distributed

random effects (e.g. [12]). The special case $\alpha = 1$ gives the log-logistic distribution, and as $\alpha \to \infty$ the Weibull distribution is obtained, so the Burr–Pareto model may be used to discriminate between these two models.

The generalized log gamma model is similar, and includes the Weibull and lognormal distributions as special cases. An even more comprehensive four-parameter family is obtained by choosing Z to have a standardized log ***F* distribution** [20, pp. 28, 63; 7]. This includes as special cases all of the distributions considered thus far.

Some other models. A number of other parametric models are occasionally used as lifetime distributions; two of the more common models are the gamma and the **inverse Gaussian**. In some circumstances it is convenient to formulate a model so as to give certain shapes for the hazard function. For example, the Gompertz distribution has loglinear hazard, $\log h(t) = \alpha_1 + \alpha_2 t$. Another example arises in contexts where the hazard function is thought to exhibit the so-called "bathtub" shape, in which it decreases from a local maximum at $t = 0$ to a local minimum, and then increases thereafter. None of the models discussed so far allows hazard functions of this shape. Models that do have been proposed by various authors; Hjorth [18], for example, considers a three-parameter family with $h(t) = \lambda t + \alpha/(1 + \beta t)$, where $\lambda > 0, \alpha > 0$, and $\beta > 0$. If $\lambda \leq \alpha\beta$, then the hazard function has the bathtub shape.

Finally, lifetimes are by convention usually taken to be nonnegative, and the models discussed so far all assume $T \geq 0$. In some applications it is argued that there exists an unknown minimum or "threshold" time $\gamma > 0$ before which the event in question cannot occur. In that case we can model the lifetime distribution by replacing t by $t - \gamma$ in previous expressions for survivor functions, hazard functions, and so on. For example, in the case of the exponential distribution this yields a two-parameter model with pdf $f(t) = \lambda \exp[-\lambda(t - \gamma)], t \geq \gamma$. A practical difficulty when γ is unknown is that threshold parameters are difficult to estimate precisely unless there is a considerable amount of data.

Regression Models

In most survival analysis applications there are groups of individuals to be compared, or explanatory variables, such as individual characteristics or environmental conditions, whose relationship to lifetime is to be examined. A small number of homogeneous groups may be compared by fitting separate lifetime distributions for each group, but more generally, regression models that employ covariates to model the effects of explanatory variables are used. For example, in studying the survival time from diagnosis of patients with multiple myeloma, Krall et al. [21] considered 16 covariates representing factors such as the white blood-cell count at diagnosis, the presence or absence of infection at diagnosis, and the sex and age of the subject.

Survival analysis may also involve covariates that vary over time. **Time-varying covariates** are usually handled through hazard-based **semiparametric** models, especially Cox's proportional or multiplicative hazards model [1, Chapter VI; 20, Chapters 4 and 5] (*see* **Cox Regression Model**). This is to a large extent because **"partial" likelihood** methods of analysis for such models [9] tend to be simpler than methods based on fully parametric models. Most of the discussion below deals with cases where the covariates are fixed, i.e. constant over time, since that is the main domain of application of parametric models. We return to time-varying covariates later in the article.

Let T denote a lifetime and $\mathbf{x}$ a $p \times 1$ vector of covariates associated with each individual. Fully parametric regression models are in principle obtained by taking any parametric lifetime distribution and allowing its parameters to depend upon $\mathbf{x}$ in some specified way. For example, Weibull regression models are obtained by taking

$$S(t|\mathbf{x}) = \exp\{-[\lambda(\mathbf{x})t]^{\delta(\mathbf{x})}\}, \tag{3}$$

where we write $S(t|\mathbf{x})$ to denote the survivor function of T given $\mathbf{x}$. To complete the model we must specify how $\lambda(\mathbf{x})$ and $\delta(\mathbf{x})$ depend on $\mathbf{x}$. In many applications it happens that $\delta(\mathbf{x})$ does not vary much with $\mathbf{x}$, and so $\delta(\mathbf{x}) = \delta$ is assumed fixed. Models with $\lambda(\mathbf{x}) = \exp(\mathbf{x}'\boldsymbol{\beta})$, where $\boldsymbol{\beta}$ is a $p \times 1$ vector of regression coefficients, are often used; this form is flexible and automatically constrains $\lambda(\mathbf{x})$ to be nonnegative.

Although a very wide range of parametric regression models is possible, two types of models dominate. These are termed **accelerated failure time** (AFT) and **proportional hazards** (PH) models; each

has both fully parametric and semiparametric versions. They are described in turn.

Accelerated failure time models. It was noted previously that for several common parametric survival models the distribution of log lifetime Y is of location-scale form (1). An important class of regression models is obtained by allowing the location parameter μ in (1) to depend on $\mathbf{x}$, so that the survivor function of Y, given $\mathbf{x}$, is

$$S_Y(y|\mathbf{x}) = G\left[\frac{y-\mu(\mathbf{x})}{\sigma}\right], \tag{4}$$

where $G(z)$ is a specified survivor function on $-\infty < z < \infty$. We may also write (4) as

$$Y = \mu(\mathbf{x}) + \sigma\varepsilon, \tag{5}$$

where the "error" ε has a distribution with survivor function $G(z)$. In the case where $\mu(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$, we have a linear model, although the errors are not necessarily normal. The name "accelerated failure time" derives from the corresponding model for T given $\mathbf{x}$, which has survivor function

$$S(t|\mathbf{x}) = G\left[\frac{\log t - \mu(\mathbf{x})}{\sigma}\right] = S_0\left[\frac{t}{\alpha(\mathbf{x})};\delta\right], \tag{6}$$

where $\alpha(\mathbf{x}) = \exp[\mu(\mathbf{x})]$, $\delta = \sigma^{-1}$, and $S_0(t;\delta) = G(\delta \log t)$. The effect of the covariates is to alter the time scale for t multiplicatively, i.e. either to accelerate or decelerate time. Other models that alter the time scale are also possible; in particular, nonlinear **transformations** of t may be used. In this sense, (6) is actually a special type of "accelerated failure time" model.

The most widely used parametric AFT models are those for which ε in (5) has either a standard extreme value, logistic, or normal distribution, corresponding to T being Weibull, log-logistic and lognormal, respectively. However, other distributions may be used, as described in the preceding subsection. It may be noted that the Weibull model, (3), is an AFT model only if $\delta(\mathbf{x}) = \delta$. Semiparametric versions of the AFT family are also based on (4), but do not assume any specific form for $G(z)$ (*see* **Semiparametric Regression**).

Proportional hazards models. A proportional hazards (PH) family of regression models is one for which the hazard function of T given $\mathbf{x}$ is of the form

$$h(t|\mathbf{x}) = h_0(t)r(\mathbf{x}), \tag{7}$$

where $r(\mathbf{x})$ is a positive-valued function and $h_0(t)$ is a "baseline" hazard function. The hazard function for any individual is proportional to $h_0(t)$, hence the name of the family. Fully parametric PH models specify parametric forms $h_0(t;\boldsymbol{\alpha})$ and $r(\mathbf{x};\boldsymbol{\beta})$ for the two components of (7); in its semiparametric version [9], $h_0(t)$ is left unspecified. The specification $r(\mathbf{x};\boldsymbol{\beta}) = \exp(\mathbf{x}'\boldsymbol{\beta})$ is often used.

From (7) and the relationship $S(t) = \exp[-H(t)]$ it follows that the survivor function of T given $\mathbf{x}$ is of the form

$$S(t|\mathbf{x}) = S_0(t)^{r(\mathbf{x})}, \tag{8}$$

where $S_0(t) = \exp[-H_0(t)]$ is the baseline survivor function. A feature of PH models is that if $S_0(t;\boldsymbol{\alpha})$ is in a family of parametric models, then $S(t|\mathbf{x})$ is not always in the same family. It is, however, if $h_0(t)$ is of the form $\alpha_1 h_1(t;\alpha_2)$; this includes the Weibull family, (3), with $\delta(\mathbf{x}) = \delta$. It is also easily checked that the family of Weibull regression models, (3), with $\delta(\mathbf{x}) = \delta$, is both a PH and an AFT model, and that it is the only set of distributions with this property. In other words, the class of PH and the class of AFT models are distinct aside from models (3) with $\delta(\mathbf{x}) = \delta$.

The AFT and PH models make fairly strong assumptions about the relationship between T and $\mathbf{x}$. Among other things, they imply that the survivor functions for individuals with different covariate vectors never cross. Two extensions that relax these assumptions are often useful. The first retains a location-scale model, (4), for $\log T$, but allows the scale parameter σ to depend on $\mathbf{x}$; the parametric form $\sigma(\mathbf{x}) = \exp(\boldsymbol{\gamma}'\mathbf{x})$ is convenient (e.g. [28]). The second is a relaxation of the PH assumption that allows the regression coefficients in $r(\mathbf{x})$ of (7) to change over time, giving

$$h(t|\mathbf{x}) = h_0(t)r[\mathbf{x};\boldsymbol{\beta}(t)].$$

A simple example is the two-step model in which there is a specified value τ such that $\boldsymbol{\beta}(t) = \boldsymbol{\beta}_1$ for $0 \le t \le \tau$ and $\boldsymbol{\beta}(t) = \boldsymbol{\beta}_2$ for $t > \tau$.

Covariates may be linked to lifetimes in a variety of other ways. For example, **additive hazards models** with

$$h(t|\mathbf{x}) = h_0(t;\alpha) + r(\mathbf{x};\boldsymbol{\beta}) \tag{9}$$

are in some circumstances more plausible than PH models. In another direction, so-called **proportional-odds regression** models [5, 25], in which

$$\log\left[\frac{S(t|\mathbf{x})}{1-S(t|\mathbf{x})}\right] = \log\left[\frac{S_0(t;\alpha)}{1-S_0(t;\alpha)}\right] + \alpha(\mathbf{x};\boldsymbol{\beta}),$$

are sometimes useful; there is an obvious connection with **logistic regression** models for binary responses, and such models are especially useful in situations where T is a discrete variable.

Let us now consider briefly time-varying covariates, in which case we write $\mathbf{x}(t)$ instead of $\mathbf{x}$. Situations in which time-varying covariates can arise include (i) clinical studies where the treatment assigned to an individual may change during the course of the study, (ii) observational studies in which time-dependent environmental variables or exposures affect individuals, and (iii) studies where covariates internal to an individual are prognostic with respect to survival; for example, CD4 lymphocyte counts for subjects infected with the human immunodeficiency virus (HIV) are prognostic for time to death (*see* **AIDS and HIV**). In addition, synthetic time-dependent covariates may be used to test a PH assumption [9].

A general treatment of time-varying covariates is delicate if we allow "internal" covariates; see [20, Chapter 5] or [1, Section III.5]. We restrict the discussion here to "external" covariates whose values are determined independently of individuals who are under study, and assume that an individual's hazard function at time t depends only on covariates $\mathbf{x}(t)$ whose value can be determined at time t.

Such covariates are readily incorporated into models via the hazard function. For PH models, (7), or additive hazards models, (8), for example, we merely replace $\mathbf{x}$ with $\mathbf{x}(t)$. The same thing can be done for AFT models by writing down the hazard function $h(t|\mathbf{x})$ that corresponds to (4), but the resulting models are less appealing than in the case of multiplicative or additive hazards.

Even when the hazard function depends in a simple way on time-varying covariates, calculation of survival probabilities is more involved than for fixed covariates, as is the comparison of survival distributions for individuals with different covariate values. In particular, if we condition on the external covariate history $\mathbf{x}^* = [\mathbf{x}(s), s \geq 0]$, then

$$\Pr(T \geq t|\mathbf{x}^*) = \exp\left\{-\int_0^t h[s|\mathbf{x}(s)]\,\mathrm{d}s\right\}. \quad (10)$$

This requires knowledge of all covariate values over $(0, t)$.

Other Models

Survival models that involve more elaborate structure are sometimes needed. For example, there may be several modes of death or failure, such as in carcinogenicity studies in which animals are determined at autopsy to have died from one of several causes (*see* **Tumor Incidence Experiments**). This is often referred to as a competing modes of death or **competing risks** problem; the observable data consist of a lifetime $T \geq 0$ and mode of death C, which is in some set $(1, \ldots, k)$. Models with covariates are conveniently expressed in terms of mode-specific hazard functions [23, Chapter 9].

$$h_j(t|\mathbf{x}) = \lim_{\Delta t \to 0} \frac{\Pr(T < t + \Delta t, C = j | T \geq t, \mathbf{x})}{\Delta t}, \quad j = 1, \ldots, k.$$

Parametric representations $h_j(t|\mathbf{x};\boldsymbol{\theta})$ similar to those used for the hazard functions of parametric lifetime distributions, discussed above, can be employed here.

Multivariate lifetime models in which m lifetimes $(T_{i1}, \ldots, T_{im})$ are associated with an individual i are sometimes needed; for example, T_{i1} and T_{i2} might represent the ages at death of identical twins [19]. It is also occasionally useful to associate individual latent failure times $T_{i1}, \ldots, T_{ik}$ with multiple modes of failure, as described in the preceding paragraph (*see* **Competing Risks**). Various parametric families have been proposed for **multivariate survival analysis**.

Discrete or continuous mixture models are also employed frequently. For example, discrete mixtures have been used in situations where a fraction $1 - p$ of individuals have an effectively infinite lifetime whereas the remaining fraction p have lifetimes that follow a distribution with survivor function $S_1(t;\boldsymbol{\theta})$. A main area of application is in connection with the survival times of cancer patients, when a fraction $1 - p$ of patients are cured (*see* **Cure Models**). The long-term survivors cannot be distinguished a

priori, so a randomly selected individual has survivor function

$$S(t;\boldsymbol{\theta}, p) = 1 - p + pS_1(t;\boldsymbol{\theta}).$$

Models in which both p and $S_1(t)$ depend upon covariates may be considered (e.g. [15]).

More general mixture models are obtained when individuals or groups ("clusters") of individuals have unobservable random effects associated with them. "Frailty" models, for example, assume that there is a positive-valued random effect α associated with an individual and that, conditional on α, the individual's lifetime distribution has cumulative hazard function $\alpha H(t)$. The random effect is assumed to have a cdf G, in which case the unconditional survivor function for T is

$$S(t) = \int_0^\infty \exp[-\alpha H(t)]\, \mathrm{d}G(\alpha), \qquad (11)$$

which is a Laplace transform. Multivariate lifetime models may similarly be obtained by assuming that there is a common random effect α associated with a group of lifetimes $T_1, \ldots, T_m$, which, given α, are independent (e.g. [11]). Different parametric choices for $H(t)$ and $G(\alpha)$ in (11) provide a wide variety of models.

Model Fitting and Inference

Model fitting involves estimation of the unknown parameters in the models on the basis of observed data. More generally, we may wish to estimate, or test hypotheses about, certain features of the model. Maximum likelihood methods are favored for most applications, and software is widely available for the most common lifetime models. Standard procedures are described below, followed by a discussion of model checking and an example.

Likelihood-based Estimation and Inference

Suppose that individuals $i = 1, \ldots, n$ have independent lifetimes T_i with density and survivor functions $f_i(t;\boldsymbol{\theta})$, and $S_i(t;\boldsymbol{\theta})$, respectively. The index i is used with f and S to indicate that they may depend upon covariates associated with individual i. Data on lifetimes are frequently right-censored, so we will assume that for some individuals ($i \in D$) the exact lifetime t_i is known, and for others ($i \in C$) only the fact that t_i exceeds the observed censoring time c_i is known. The likelihood function for $\boldsymbol{\theta}$ is based on the joint pdf of the observed data. Under the assumption that the censoring of an individual at a point in time cannot be related to future events, the likelihood function is proportional to

$$L(\boldsymbol{\theta}) = \prod_{i\in D} f_i(t_i;\boldsymbol{\theta}) \prod_{i\in C} S_i(c_i;\boldsymbol{\theta}). \qquad (12)$$

The maximum likelihood estimate $\hat{\boldsymbol{\theta}}$ is obtained by maximizing $L(\boldsymbol{\theta})$ with respect to $\boldsymbol{\theta}$, or equivalently, the log likelihood function

$$\ell(\boldsymbol{\theta}) = \sum_{i\in D} \log f_i(t_i;\boldsymbol{\theta}) + \sum_{i\in C} \log S_i(c_i;\boldsymbol{\theta}). \qquad (13)$$

With the models considered here, $\ell(\boldsymbol{\theta})$ can typically be maximized by solving the maximum likelihood or "score" equations $\partial\ell(\boldsymbol{\theta})/\partial\boldsymbol{\theta} = \mathbf{0}$.

Maximum likelihood **large-sample theory** provides several ways of constructing tests or confidence intervals for model parameters [23, Appendix C]. The two which are most readily available in software are termed the Wald and **likelihood ratio test** procedures, and are described briefly.

Suppose the $p \times 1$ parameter vector $\boldsymbol{\theta}$ is partitioned as $\boldsymbol{\theta}' = (\boldsymbol{\phi}', \boldsymbol{\lambda}')$, where the $r \times 1 (r \le p)$ parameter $\boldsymbol{\phi}$ is the parameter of interest and $\boldsymbol{\lambda}$ is a **nuisance parameter**. The $p \times p$ observed **information matrix** $\mathbf{I}(\boldsymbol{\theta})$ and its inverse,

$$\mathbf{I}(\boldsymbol{\theta}) = -\frac{\partial^2\ell}{\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}'} = \begin{pmatrix} \mathbf{I}_{\phi\phi} & \mathbf{I}_{\phi\lambda} \\ \mathbf{I}_{\lambda\phi} & \mathbf{I}_{\lambda\lambda} \end{pmatrix},$$

$$\mathbf{V}(\boldsymbol{\theta}) = \mathbf{I}(\boldsymbol{\theta})^{-1} = \begin{pmatrix} \mathbf{V}_{\phi\phi} & \mathbf{V}_{\phi\lambda} \\ \mathbf{V}_{\lambda\phi} & \mathbf{V}_{\lambda\lambda} \end{pmatrix},$$

play a key role in the Wald method. Under the hypothesis that $\boldsymbol{\phi} = \boldsymbol{\phi}_0$, the quantity $\hat{\mathbf{V}}_{\phi\phi}^{-1/2}(\hat{\boldsymbol{\phi}} - \boldsymbol{\phi}_0)$ is approximately standard r-variate normal in large samples, where $\hat{\mathbf{V}}$ stands for $\mathbf{V}(\hat{\boldsymbol{\theta}})$. Equivalently, the Wald statistic (*see* **Likelihood**),

$$W_1(\boldsymbol{\phi}_0) = (\hat{\boldsymbol{\phi}} - \boldsymbol{\phi}_0)^{\mathrm{T}} \hat{\mathbf{V}}_{\boldsymbol{\phi}\boldsymbol{\phi}}^{-1} (\hat{\boldsymbol{\phi}} - \boldsymbol{\phi}_0), \qquad (14)$$

is approximately distributed as the **chi-square distribution** with r **degrees of freedom**, $\chi^2(r)$. The statistic (14) can be used to test H: $\boldsymbol{\phi} = \boldsymbol{\phi}_0$; large values of $W_1(\boldsymbol{\phi}_0)$ provide evidence against the hypothesis. **Confidence** regions with approximate confidence

coefficient q are obtained as the set of parameter values $\boldsymbol{\phi}$ that satisfy $W_1(\boldsymbol{\phi}) \leq \chi_q^2(r)$, where $\chi_q^2(r)$ is the qth **quantile** of $\chi^2(r)$.

The likelihood ratio method utilizes the statistic

$$W_2(\boldsymbol{\phi}_0) = 2\ell(\hat{\boldsymbol{\phi}}, \hat{\boldsymbol{\lambda}}) - 2\ell[\boldsymbol{\phi}_0, \hat{\boldsymbol{\lambda}}(\boldsymbol{\phi}_0)], \qquad (15)$$

where $\hat{\boldsymbol{\theta}} = (\hat{\boldsymbol{\phi}}', \hat{\boldsymbol{\lambda}}')'$; and $\hat{\boldsymbol{\lambda}}(\boldsymbol{\phi}_0)$ is the value of $\boldsymbol{\lambda}$ that maximizes $\ell(\boldsymbol{\phi}_0, \boldsymbol{\lambda})$. Under H: $\boldsymbol{\phi} = \boldsymbol{\phi}_0$, $W_2(\boldsymbol{\phi}_0)$ is approximately $\chi^2(r)$ in large samples, and tests and confidence regions are obtained in the same way as with the Wald statistic.

The methods based on (14) and (15) produce two-sided confidence regions consisting in the case $r = 1$ of parameter values on either side of $\hat{\phi}$. If one-sided intervals are wanted, they may be based on sign $(\hat{\phi} - \phi_0)W_1(\phi_0)^{1/2}$ or sign $(\hat{\phi} - \phi_0)W_2(\phi_0)^{1/2}$, assumed to be approximately standard normal.

The asymptotic theory upon which these methods rely requires that the models satisfy some mild regularity conditions. Of the models described earlier, the only cases which are problematic concern threshold parameters. For censored data a "large" sample is essentially one for which n is large and not too high a proportion of lifetimes is censored. For practical purposes what we desire is that significance levels (*see* ***P*** **Value**) or confidence coefficients calculated from the asymptotic χ^2 or normal distributions for W_1 or W_2 are sufficiently close to their true values. If there is doubt about the adequacy of the approximations, they may be checked by **simulation**. A warning about accuracy is signaled by any large differences in confidence intervals or significance levels based on $W_1(\boldsymbol{\phi}_0)$ and $W_2(\boldsymbol{\phi}_0)$; in such cases intervals based on $W_2(\boldsymbol{\phi}_0)$ are likely to be more accurate. Analytic adjustments to improve accuracy have been developed (e.g. [4]), but are not yet widely available in software. Parametric **bootstrap** procedures [13] provide another possibility for improving accuracy.

Most survival analysis software relies solely on Wald or likelihood ratio procedures. Major packages with parametric survival analysis capabilities include SAS (see PROC LIFEREG and PROC RELIABILITY), SAS JMP, **S-PLUS** (see especially the function Censor Reg), SYSTAT (see the Survival module), and LIMDEP. All handle estimation for accelerated failure time regression models based on the Weibull, lognormal, and log-logistic distributions. In addition to right censoring, they handle interval censoring: in this case the ith lifetime t_i is known to lie in an interval (a_i, b_i), yielding the likelihood function

$$L(\boldsymbol{\theta}) = \prod_{i=1}^{n} [S_i(a_i; \boldsymbol{\theta}) - S_i(b_i; \boldsymbol{\theta})].$$

The likelihood (12) is a special case of this.

More complicated parametric models involving multivariate lifetimes, competing failure modes, or random effects may also be handled by maximum likelihood. Although software is not widely available for specific models, general purpose **optimization** software allows one to deal quite easily with most situations. Problems that cause difficulty tend to be ones in which the observed data are uninformative about certain aspects of the model, thus leading to flat regions in the likelihood function (see, for example, [15]).

Model Checking

Parametric survival models assume a specific form for lifetime distributions and, in addition, the dependence upon any covariates must be specified. At preliminary stages of analysis it is useful to group individuals so that within groups they have similar values of important covariates. Nonparametric (**Kaplan–Meier**) estimates $\hat{S}(t)$ of the survivor function for each group may be compared graphically to detect prominent features of the data, to assess the shape of the lifetime distributions, and to see whether a fairly simple regression model will suffice. A particularly useful procedure is to plot $\log[-\log \hat{S}(t)]$ (vertical axis) vs. $\log t$ (horizontal axis) for each group. If a PH model is reasonable, then the curves should be roughly parallel in the vertical direction [see (8)]; if the curves are roughly parallel in the horizontal direction, an AFT model is suggested. If Weibull distributions are reasonable, then the curves should be roughly linear [see (3)]; differences in slope indicate a shape parameter that depends upon x. This is often termed a Weibull probability plot and is an example of probability or hazard plotting, which can also be used to explore other models.

Graphical tools such as scatter plots or box plots are also valuable (*see* **Graphical Displays**), but must be modified to deal with censored observations. For box plots the empirical quantiles for a group of individuals may be determined from the Kaplan–Meier estimate, provided they are not beyond the largest observation. For plots that involve the lifetimes

directly it is important to plot lifetimes and censoring times with different symbols.

Probability plots of empirical survivor functions can provide checks on parametric models, as suggested above. We may also compare fitted parametric models $S_0(t;\hat{\boldsymbol{\theta}})$ for baseline distributions, or models without covariates, with nonparametric estimates. Formal **goodness-of-fit** tests based on this idea exist for certain parametric models when there are strict limitations on censoring and the presence of covariates (e.g. [23, Chapter 10]), and in some cases for more complex situations [1, Sections VI.3 and VII.6]. However, most regression model checking is based on model expansion or on graphical assessment of **residuals**.

Model expansion involves fitting models with additional parameters that represent specific types of departures from the current model; the need for the extra parameters may be assessed via likelihood ratio or Wald tests. Score tests for which only the current model has to be fitted are also useful on occasion (e.g. [23, Section 10.2.2]). Some examples of model expansion are: (i) adding covariates representing **interactions** or other effects, as a check on a specified regression model; (ii) allowing σ in a location-scale model (4) to depend on $\mathbf{x}$, as a check on the AFT assumption; and (iii) using the Burr–Pareto distribution (2) in order to test the assumption of a baseline Weibull distribution ($\alpha = \infty$).

Location-scale models (4) are the most widely used parametric regression models, and for them residuals are naturally defined as

$$\hat{z}_i = \frac{y_i^* - \mu(\mathbf{x}_i;\hat{\boldsymbol{\beta}})}{\hat{\sigma}}, \tag{16}$$

where $y_i^* = \min(y_i, \log c_i)$ is either a log lifetime or log censoring time, depending on what was observed. If the model is appropriate, the $\hat{z}_i$s should look roughly like a censored random sample from the distribution with survivor function G. Probability or hazard plots of the $\hat{z}_i$s may be used to assess the baseline distribution G, and plots of the $\hat{z}_i$s vs. covariates or other factors can be used to check on the constancy of σ or to look for systematic departures from the assumed specification $\mu(\mathbf{x};\boldsymbol{\beta})$. Departures from the location-scale form itself are harder to detect and are best examined by model expansion or the graphical methods mentioned at the beginning of this subsection. Plots should designate censored and uncensored residuals with different symbols. Sometimes it may be useful to adjust censored $\hat{z}_i$s upwards to give imputed uncensored residuals; a way of doing this is described below.

In general, residuals for an arbitrary parametric survival model may be defined as

$$\hat{r}_i = H(t_i^*|\mathbf{x}_i;\hat{\boldsymbol{\theta}}), \tag{17}$$

where $t_i^* = \min(t_i, c_i)$ and $H(t|\mathbf{x}) = -\log S(t|\mathbf{x})$ is the cumulative hazard function. The motivation for (17) is that the variables $H(T_i|\mathbf{x}_i;\boldsymbol{\theta}_0)$ have a standard exponential distribution if the model is correct and $\boldsymbol{\theta} = \boldsymbol{\theta}_0$. If the model is appropriate, the $\hat{r}_i s, i = 1, \ldots, n$, should look roughly like a censored sample of exponential variates. These residuals can be plotted in ways described above to check on the model. It will be noted that the AFT residuals, (16), are related to the residuals (17) by $\hat{r}_i = -\log G(\hat{z}_i)$. Residuals based on score or log likelihood contributions by each individual are also used.

Sometimes censored residuals $\hat{r}_i$ are adjusted upwards to give imputed values for corresponding uncensored residuals. This is usually done by adding either 1 or log 2 to r_is for $i \in C$. The motivation for doing this is that if r_i is a standard exponential random variable then $\mathrm{E}(r_i|r_i > r) = r + 1$ and $\Pr(r_i > r + \log 2|r_i > r) = 0.5$. If such imputed values are shown on plots, then it is also advisable to show the censored residuals from which these were calculated.

Conclusions about explanatory variables are generally not affected much by mild misspecification of the baseline distribution in an AFT or PH model, or by mild departures from the AFT or PH frameworks themselves. Moreover, unless there is a considerable amount of data it is difficult to discriminate among parametric distributions with rather similar shapes, such as the Weibull, log-logistic, and log-normal. One should, however, check carefully for significant departures from assumed models. Observations that are unusual or highly influential should also be scrutinized; in some cases it is a good idea to refit models with certain observations omitted. The fitting of expanded models is encouraged both as a **model checking** device and as a way to assess the sensitivity of inferences to variations in the model that are plausible on the basis of the observed data.

An Example

As a brief example we consider data on survival times for leukemia patients given by Feigl & Zelen [17] in an early paper on regression analysis of lifetime data. Survival times are in weeks from diagnosis, and there are two covariates: white blood-cell count (WBC) at diagnosis and a binary covariate AG that indicates a positive or negative (positive $= 1$, negative $= 0$) test related to white blood-cell characteristics. The data are given in Table 1, where *wbc* denotes white blood-cell count divided by 1000. The original data had no censored lifetimes, but for illustrative purposes three of the lifetimes have here been replaced with censoring times.

Exploratory analysis suggests an AFT regression model in which covariates $x_1 = AG$ and $x_2 = \log(wbc)$ are included. Figure 1 shows a plot of log (survival time) vs. log (wbc), with AG positive- and negative-valued observations denoted by P and N, respectively. Small letter ps denote the three censoring times. There are 17 AG-positive and 16 AG-negative subjects; two of the AG-positive subjects have $wbc = 100$ and $t = 1$, and their symbols are overlaid in the figure. The plot suggests that lifetimes tend to be shorter for subjects with higher WBC and longer for AG-positive subjects.

Accelerated failure time models (5) with extreme value and logistic error distributions were fitted, corresponding to Weibull and log-logistic lifetime distributions. Figure 1 suggests possibly different effects of WBC for subjects with $AG = 1$ and $AG = 0$, so models with and without a log $(wbc) - AG$ interaction term were fitted in each case. The two distributions gave very similar results and in neither case was the interaction term significant. The maximum log-likelihood values $\ell(\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2, \hat{\sigma})$ for the models without the interaction terms (i.e. with $\mu(x)$ in (5) given by $\beta_0 + \beta_1 x_1 + \beta_2 x_2$) were -52.9 (Weibull) and -53.0 (log-logistic), and so provide no evidence to favor one distribution over the other. Model checks described below also showed the two models to be comparable. For convenience we consider only the Weibull model in the remainder of the discussion.

Table 1 Leukemia survival data

Time	*AG*	*wbc*	Time	*AG*	*wbc*
65	1	2.3	56	0	4.4
140[a]	1	0.75	65	0	3.0
100	1	4.3	17	0	4.0
134	1	2.6	7	0	1.5
16	1	6.0	16	0	9.0
106[a]	1	10.5	22	0	5.3
121	1	10.0	3	0	10.0
4	1	17.0	4	0	19.0
39	1	5.4	2	0	27.0
121[a]	1	7.0	3	0	28.0
56	1	9.4	8	0	31.0
26	1	32.0	4	0	26.0
22	1	35.0	3	0	21.0
1	1	100.0	30	0	79.0
1	1	100.0	4	0	100.0
5	1	52.0	43	0	100.0
65	1	100.0			

[a] Denotes a censoring time; *wbc* = WBC ÷ 1000.

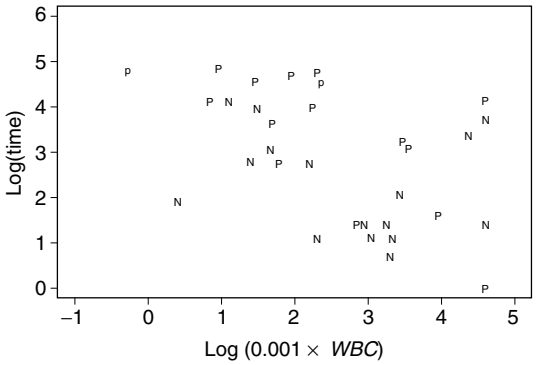

Figure 1 Leukemia data: log lifetime vs. log *wbc*

For the Weibull model the estimates (with standard errors obtained from the observed information matrix given in parentheses) are

$$\hat{\beta}_0 = 3.841(0.534), \qquad \hat{\beta}_1 = 1.177(0.427),$$

$$\hat{\beta}_2 = -0.366(0.150), \quad \hat{\sigma} = 1.119(0.164).$$

There is clearly no evidence against the hypothesis that $\sigma = 1$, suggesting that the exponential model could be used. The effects of WBC and AG are both significant, and are in the directions suggested by Figure 1.

Model checks may be based on residuals $\hat{z}_i$ of the form (16). We use the extreme value residuals with $\hat{\sigma} = 1.119$, but residuals based on the exponential model give essentially the same picture. Plots of the $\hat{z}_i$s against x_{1i}, x_{2i}, or fitted values $\mu(\mathbf{x}_i; \hat{\boldsymbol{\beta}})$ do not suggest any major problems with the model. Figure 2 shows a **diagnostic** probability plot designed to check on the assumed baseline extreme

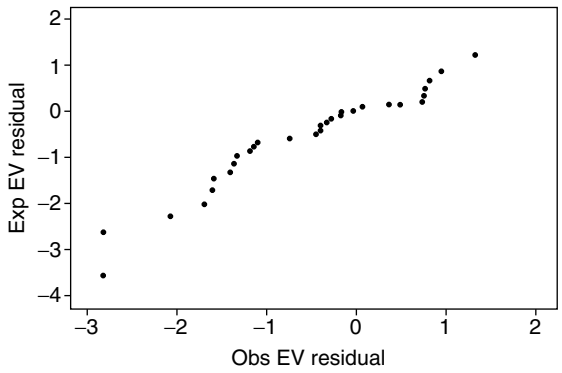

Figure 2 Leukemia data: probability plot of residuals

value distribution. This is obtained by treating the $\hat{z}_i$s as a censored sample of 33 log lifetimes, and computing the Kaplan–Meier estimate $\hat{S}(z)$ of the survivor function of Z based on them. Figure 2 is an extreme value probability plot of the points $\hat{z}_i$, $w_i = 0.5\hat{S}(\hat{z}_i - 0) + 0.5\hat{S}(\hat{z}_i + 0)$, based on plotting $\hat{z}_i$ vs. $\log(-\log w_i)$ for the uncensored residuals. The plot is roughly linear, and provides no evidence against the extreme value assumption.

One feature of the data is worth noting: for the AG-positive group there is an individual with a high WBC along with a reasonably large lifetime. For the AG-negative group there are two such individuals. It is clear from Figure 1 that these observations are very influential. If they were omitted, then the effects of WBC and AG would be increased substantially. We have no reason to isolate these observations and so they are retained, but their influence is noted.

Bibliographic Notes

Parametric models for lifetime data have been in existence for a long time, but received increasing attention from about 1950. The books by Lawless [23] and Cox & Oakes [10] reference many models. Early work on parametric methods for the regression analysis of survival data emphasized exponential, Weibull, and lognormal models, and may especially be found in the biostatistics and reliability literature. Papers with biostatistics applications include those by Sampford & Taylor [27], Feigl & Zelen [17], Pike [26], and Zippin & Armitage [29]. The focus for parametric analysis quickly became the accelerated failure time and location-scale models. The books by Kalbfleisch & Prentice [20, Chapter 3] and Lawless [23, Chapter 6] provide detailed treatments. Other good sources include Cox & Oakes [10], Andersen et al. [1], and Collett [8]. Some papers that study specific families of models include Farewell & Prentice [16], Bennett [5], Ciampi et al. [7], and Anderson [2]. Escobar & Meeker [14] consider diagnostics and influence analysis. Lawless [24] discusses general classes of lifetime regression models.

The proportional or multiplicative hazards model gained popularity quickly following the landmark paper by Cox [9]. The emphasis has been very much on semiparametric methods, however, and relatively little fully parametric inference for these models is found in the literature.

Parental Effects

A parental effect refers to a situation where, conditional on the individual's own genotype, the phenotype of an individual depends upon the mother's or father's phenotype or **genotype**. For example, a factor complicating **gene** discovery in asthma is the possibility, based on epidemiologic studies, that maternal phenotype influences the inheritance of asthma and atopy [10, 12]. The presence of asthma and associated phenotypes such as atopy in children has been consistently associated with an increased prevalence of asthma or atopy in mothers [10]. The differential risk of transmission between parents may be fourfold. The mechanism, or mechanisms, for these parental effects are unknown, but possibilities include genomic imprinting (see below) or maternal modification of the developing infant's immune system by transmission of immune factors across the placenta or through breast milk. The latter is likely to be affected by a complex **interaction** between maternal and fetal genetic and environmental factors. Similar parental effects have been noted in other immunologic disorders, most notably type I diabetes [21], rheumatoid arthritis [9], inflammatory bowel disease [1], and selective IgA deficiency [20], suggesting that parental effects on the developing infant's immune system may be an important common process modifying genetic diseases that are immunologic in origin. The remainder of this article describes the phenomena of genomic imprinting and maternal effects and their implications for genetic analysis. While there are clear theoretic differences between these two mechanisms, in practice they may be difficult to distinguish in **complex diseases**.

Genomic Imprinting

Imprinting refers to the situation where the relationship between a genotype and a phenotype (or disease-status) in an offspring depends upon which parent passed on the disease susceptibility or phenotype-modifying gene. When imprinting exists, the **penetrance** of the disease susceptibility allele will be different for maternally derived vs. paternally derived alleles. The observation that certain genes are expressed differently depending on whether they are inherited from the father or mother implies that genetic alteration of a gene or its expression has taken place. For example, a chromosomal deletion of a certain part of human chromosome 15 in a father results in an offspring with Prader–Willi syndrome. However, when the same part of chromosome 15 is missing in a mother, the offspring has Angelman syndrome [2] (*see* **Genetic Counseling**).

Concrete examples of genomic imprinting derive largely from studies of transgenic mice [16, 17]. However, imprinting has been suggested to play a role in several complex human diseases in addition to asthma, including bipolar affective disorder [4] and type 2 diabetes mellitus [8]. The mechanisms causing imprinting are poorly understood, but are thought to involve DNA methylation. The effect of imprinting can range from total inactivation of a gene and its expression (*see* **Gene Expression Analysis**) to the reduced expression in specific tissues. Interestingly, the imprinting effect can appear to be **heritable** only in a single generation. That is, the effect is unmasked if it passes through the nonimprinting sex. For instance, a gene inactivated by maternal imprinting that is inherited by a son will be reactivated in the next generation, i.e. the offspring of the son inheriting the gene. (Note, however, that should the son then have a daughter, her children will not express the phenotype.) Conversely, the same gene inherited by a daughter will remain inactivated in the next generation.

For a quantitative phenotype assessed in a nuclear family, the possible existence of imprinting upon offspring phenotype may be crudely assessed by estimating a basic variance component model (*see* **Variance Component Analysis**, Equation (2)) or its extensions. The basic variance component model is

$$Y_i = \mu_i + G_i + C_i + E_i, \qquad (1)$$

where Y_i is a continuous trait measured on individual i, μ is the conditional trait mean, and G_i, C_i and E_i are independent random variables with zero means and represent genetic factors, factors common to relatives (i.e. familial environmental factors), and factors specific to an individual (including measurement error, assumed to arise from nongenetic environmental factors), respectively (*see* **Familial Correlations**).

The result of imprinting at a locus on the expression of a quantitative phenotype will be to reduce the expected phenotypic covariance between parents and offspring relative to that between sibs (*see* **Genetic**

Correlations and Covariances). Gametic imprinting would be suggested if the difference between the parent–offspring covariance and twice the covariance between paternal half sibs derived from (1) were significantly less than zero. Imprinting can be explicitly assessed by extending (1):

$$Y_i = \mu_i + G_{if} + G_{im} + C_i + E_i, \qquad (2)$$

where the subscript f denotes components of genetic variance derived from the father, and the subscript m denotes components of genetic variance derived from the mother. Note that in an imprinting model, covariances between pairs of relatives are also estimated separately for male–male, female–female, and male–female relationships [3].

The phenomenon of imprinting has potentially important implications for genetic analysis. The reduction of the expected phenotypic covariance between parents and offspring relative to that between sibs caused by imprinting can lead to greatly reduced power to detect **linkage** for both quantitative and qualitative traits when such imprinting effects are not considered in the analysis. Similarly, **association** analyses are compromised when the differential risk for outcome among individuals with the same genotype (but alleles derived from different parent genders) is not considered. In an imprinting situation, genotypes of high risk are considered in the same "exposure" category as genotypes conferring no increased risk due to imprinting, biasing the **association** towards the null. For these reasons, inclusion of terms reflecting imprinting effects in models of quantitative and qualitative traits is important for **segregation analysis**, linkage analysis (*see* **Linkage Analysis, Model-free**; **Software for Genetic Epidemiology**) and association analysis (*see* **Disease-marker Association**; **Family-based Case–Control Studies**).

Maternal Effects

Maternal effects arise when, for reasons that may be environmental (e.g. *in utero* environmental effects or the effects of breast feeding), genetic, or a combination of the two, the phenotype of an offspring depends more upon maternal phenotype than on paternal phenotype. Such an observed effect may arise due to maternal genotype (any genetic effects on the mother's *in utero* environment or other nontransmitted maternal genotype effect) or maternal phenotype (any characteristic in the mother – possibly nongenetic – that influences the child's phenotype). For example, children of mothers with the genetic disorder phenylketonuria may develop mental retardation and small head size regardless of the child's genotype unless dietary intervention during pregnancy is pursued [5]. This disorder in the child is due to the maternal genotype rather than transmitted genes carried by the child.

The basic variance component model given in (1) (*see* **Genetic Correlations and Covariances**; **Variance Component Analysis**) can be extended to allow for maternal effects [25] by splitting each of the original components of variance into two components, representing the direct expression of each individual's genotype and environmental components as well as indirect maternal components of variance:

$$Y_i = \mu_i + (G_{oi} + C_{oi} + E_{oi}) + (G_{mi} + C_{mi} + E_{mi}), \qquad (3)$$

where the subscript o denotes components of variance reflecting a direct effect of an individual's genotype and environmental exposures, and the subscript m denotes components of variance reflecting an indirect effect of the maternal phenotype. Note that this formulation explicitly ignores epistatic sources of maternal genetic variation.

As with imprinting effects, inclusion of terms reflecting maternal effects in variance components models of quantitative traits can be readily extended to segregation analysis and variance-component-based linkage analysis.

Failure to account for maternal effects (when present) in variance component and segregation analysis can result in misleading inferences regarding mode of phenotypic inheritance. This is also true for linkage and association analysis of qualitative traits, where failure to account for potential maternal or paternal effects can **bias** tests of the **null hypothesis** regarding linkage or association to a particular genetic variant possessed by affected individuals [22]. For example, in the **transmission-disequilibrium test** (TDT) setting, maternal effects that increase risk for a disease among children (regardless of the child's genotype) will result in an excess of affected child–mother pairs, compared with

affected child–father pairs. This may lead to a false conclusion of a maternal imprinting genetic effect, when no such genetic effect (in the children) exists.

Paternal effects, while far less common than maternal effects, can be dealt with analytically in the same way as maternal effects.

Linkage Analysis

Methods to test and account for imprinting when evaluating linkage have been proposed for model-based linkage analysis, model-free allele-sharing methods and variance component methods. Model-based linkage analysis can be performed by specifying male and female recombination fractions separately [15], or by fixing the recombination fraction of the assumed imprinting gender at 0.5 and then estimating the recombination fraction of the other gender [7]. Alternatively, a four-penetrance model can be created in which the disease locus **heterozygotes** have different penetrances depending on the parental origin of the particular alleles [18]. Because imprinting can occur for dominant and recessive modes of inheritance, maximized lod score (mod score) analysis can also be pursued under this four-penetrance model [14, 18]. Tests of linkage can be carried out via **likelihood ratio testing** of the four-penetrance model under linkage vs. the same model under no linkage. Explicit tests of imprinting can be carried out by comparing the four-penetrance model under linkage with a standard three-penetrance model, which assumes the two types of heterozygotes have equal penetrance. The GENEHUNTER-IMPRINTING software can perform parametric lod score linkage analysis under the four-penetrance model (*see* **Software for Genetic Epidemiology**).

Imprinting can be detected in model-free linkage as differential results when stratifying family sets according to paternal and maternal meioses [13]. For quantitative traits, **marker** allele sharing can be estimated for maternally derived and paternally derived alleles separately, and variance components or Haseman–Elston regression used to assess linkage as departure from the expected 25% sharing of a particular parental allele [6]. A similar method for qualitative traits has also been described [11]. Under the variance component framework, linkage in the presence of imprinting can be assessed by comparing the likelihood of the data using the **maximum likelihood** estimators (MLEs) of the parent-specific major-gene variance components with the likelihood obtained when constraining these to 0. Imprinting can be tested in a manner similar to that described for the model-based methods described above by comparing a likelihood where both parent-specific major gene variance components are estimated with a model where they are constrained to be equal (but not necessarily 0). A similar strategy can be employed for Haseman–Elston regression by estimating regression coefficients for paternal allele sharing and maternal allele sharing separately, and testing whether they are equal to 0 (test of linkage) or whether they are equal to each other (test of imprinting). These analyses can be carried out using available identity-by-descent (*see* **Identity Coefficients**) estimation software and standard statistical packages for variance components and linear regression. Testing for maternal or paternal effects not due to imprinting can be allowed for in linkage analyses by the inclusion of parental phenotype through conditioning, covariate adjustment or, in the case of a quantitative phenotype, inclusion of random effects representing the indirect parental components of individual phenotypic variance (as in (3) above).

Association Analysis

Association analyses that incorporate parental effects must include parental information. For parental genotype effects and imprinting effects, family-based association methods are needed. The most commonly used method of family-based association, the TDT, has been extended to allow for parent-of-origin effects [19, 22–24]. As mentioned above, failure to account for imprinting or parental effects can bias TDT results because decreased expression of phenotypes among children of the imprinting gender may dilute transmission effects. Simple comparisons of transmission estimates for father–child pairs vs. mother–child pairs can also lead to erroneous conclusions about imprinting and genetic effects, when nontransmitted parental effects influence the phenotype [22]. For these reasons, recent methods have proposed the use of conditional logistic [22] (*see* **Logistic Regression, Conditional**) or log-linear models [23], expressed in terms of direct genetic effects, imprinting effects, and additional (nontransmitted) parental effects. For

both approaches, trios can be characterized by the joint mother, father, and child genotypes, resulting in 15 distinct trio-types whose expected frequencies can be calculated theoretically according to the (child) genotype [genetic association], imprinting, and parental genotype (or environment) effect sizes. Logistic regression conditional on trio-type or log-linear regression of expected trio-type cell counts can be used to estimate these effect parameters and test for association using **likelihood ratio** methods. Such methods can be carried out in standard statistical software packages for conditional logistic regression and Poisson regression.

Conclusion

While the theory is well developed for parental effects, little empirical work in human genetics has focused on these issues. The identification of imprinted genes, methodologic development to assess and incorporate parental effects into genetic analysis, and further understanding of the imprinting mechanism all represent important challenges for **genetic epidemiology**.

DANI FALLIN & LYLE J. PALMER

Pareto Distribution

The Pareto distribution comes in several different forms. Its original form, with cumulative distribution function

$$F_X(x) = 1 - \left(\frac{x}{\sigma}\right)^{-\nu}, \quad \sigma, \nu > 0,\ x \geq \sigma, \tag{1}$$

was introduced by Vilfredo Pareto in [8] as a model for the distribution of income, and now commonly goes by the name of the classical Pareto distribution or *Pareto distribution of the first kind*. The parameter σ is the scale parameter, and ν is related to the expected value of X by the equation $\mu = \nu\sigma/(\nu - 1)$. Two other forms of this distribution were also proposed by Pareto. One of them, which is now known as the *Pareto distribution of the second kind*, takes the following form,

$$F_X(x) = 1 - \left(1 + \frac{x - \mu}{\sigma}\right)^{-\nu}, \quad x > \mu,\ \sigma, \nu > 0, \tag{2}$$

and is obtained from the classical Pareto distribution by a shift in location, as well as the addition of the location parameter μ. The other one, the *Pareto distribution of the third kind*, is given by

$$F_X(x) = 1 - \frac{C\exp(-bx)}{(x + C)^{\nu}}, \quad x > 0,\ C, \nu, b > 0. \tag{3}$$

The fourth form of the Pareto distribution

$$F_X(x) = 1 - \left[1 + \left(\frac{x - \mu}{\sigma}\right)^{1/\gamma}\right]^{-\nu}, \quad x > \mu,\ \alpha, \gamma, \sigma > 0, \tag{4}$$

is a direct generalization of (2), with the parameter γ providing additional flexibility, and has been defined in Arnold [1], which is a general reference book for this distribution; see also Arnold [2], and Johnson et al. [6].

For the classical Pareto distribution, the **maximum likelihood** estimators (MLEs) of σ and ν are given by

$$\hat{\sigma} = X_{1:n}, \qquad \hat{\nu} = n\left[\sum_{j=1}^{n} \ln\left(\frac{X_j}{\hat{\sigma}}\right)\right], \tag{5}$$

where $X_{1:n}$ is the smallest **order statistic**, from which one may obtain the following **unbiased** estimators of σ and ν,

$$\sigma^* = \left[1 - \frac{1}{(n-1)\hat{\nu}}\right]\hat{\sigma}, \qquad \nu^* = \left(1 - \frac{2}{n}\right)\hat{\nu}. \tag{6}$$

If ν is known, then the MLE of σ is $\hat{\sigma} = X_{1:n}$, while the best linear unbiased estimator (BLUE) is given by

$$\sigma^* = \frac{\nu n - 1}{\nu n\sigma}\hat{\sigma}. \tag{7}$$

If σ is known then the MLE of ν is given by $\hat{\nu}$ above with $\hat{\sigma}$ replaced by σ.

Parameter **estimation** for the Pareto distribution in (2) is discussed in [7], where exact explicit expressions for the BLUEs of μ and σ are given for the case in which ν is known.

For the situation in which a location parameter μ (*see* **Location–Scale Family**) is added to the classical Pareto distribution, exact explicit expressions for the BLUEs of μ and σ have recently been derived in [3], for complete as well as right-**censored** samples. The **robustness** of these BLUEs is also examined in [3], where recommendations are made as to how to protect against the situation in which the strict distributional assumptions are not completely satisfied.

Many of the applications of the distribution in (2) (with $\mu = 0$) stem from the fact that it is the mixture (or compound) of **exponential** distributions, $f_{X|\Theta}(x|\theta) = \theta\exp(-\theta x)$, where Θ has a **gamma** distribution, $f_{\Theta}(\theta) = [\sigma/\Sigma(\nu)](\sigma\theta)^{\nu-1}\exp(-\sigma\theta)$. This is used, for example, in the analysis of heart transplant data in [9], where X represents the survival time of a patient entering the study if no heart transplant were received, and the hazard rate θ varies from patient to patient and is assumed to follow a gamma distribution. It is also used in the study of remission rates of psychiatric patients in [4], where X represents the time to rehospitalization for psychiatric reasons, and the differing hazard rates among patients are reflected by different values of θ, which are assumed to follow a gamma distribution.

The multivariate form of (2), with survival function (*see* **Survival Distributions and Their Characteristics**),

$$S_X(\mathbf{x}) = \Pr\left[\bigcap_{i=1}^{k}(X_i \geq x_i)\right] = \left[1 + \sum_{i=1}^{k}\left(\frac{x_i - \mu_i}{\sigma_i}\right)\right]^{-\nu}, \qquad (8)$$

has been used (with $k = 2$) in [5] to model the injuries to two drivers in a road accident, where X_i is a measure of the severity of the injuries to driver $i, i = 1, 2$. In the same paper, (8) has been used to model the severity of a lesion in a patient as assessed by two physicians, and is discussed as a model for the liability of two people who are related to each other of acquiring a certain disease (*see* **Frailty**). In the former situation, X_i is a measure of the severity of the lesion as assessed by doctor $i, i = 1, 2$, and in the latter case, X_i is a measure of how likely each person is to acquire the disease.

Parsimony

In the development of statistical models, parsimony is often viewed as desirable or, even, as embodying a logical principle. In application, this requires that models be based on as few assumptions as possible and include as few parameters as possible. For example, Box & Jenkins [1] advocated the choice of **time series** models with the smallest number of parameters which gives adequate representation, and **Mallow's C_p** statistic [2], which is used to choose between alternative regression models, incorporates a penalty for additional parameters.

Such thinking is linked to the more general philosophical principle of Occam's Razor, "A plurality (of reasons) should not be posited without necessity", which was named after William of Occam (1280–1349).

VERN T. FAREWELL

Partial Likelihood

Somewhat surprisingly, the **robustness** of the **likelihood** function extends to various approximate likelihoods used in models where likelihoods may be difficult to calculate, or that may not be characterized by a complete parametric specification. The partial likelihood is one such approximate likelihood.

Partial likelihoods seem to have been used formally for the first time in D.R. Cox's introduction of the semiparametric **proportional hazards** model (*see* **Cox Regression Model**) [1], and were discussed as a separate topic in a later paper [2]. The partial likelihood is based on a simple **conditional probability** argument. Suppose that $(A_1, B_1), (A_2, B_2), \ldots, (A_K, B_K)$ is a collection of pairs of observations. If the probability of these outcomes depends on a parameter θ, then the likelihood for θ based on the $2K$ observations can be written:

$$\begin{aligned}
&\Pr(A_K B_K A_{K-1} B_{K-1} \ldots, A_1 B_1) \\
&\quad = \left[\prod_{k=2}^{K} \Pr(A_k B_k | A_{k-1} B_{k-1} \ldots A_1 B_1)\right] \Pr(A_1 B_1) \\
&\quad = \left[\prod_{k=2}^{K} \Pr(A_k | B_k A_{k-1} B_{k-1} \ldots A_1 B_1)\right] \Pr(A_1 | B_1) \\
&\qquad \times \left[\prod_{k=2}^{K} \Pr(B_k | A_{k-1} B_{k-1} \ldots A_1 B_1)\right] \Pr(B_1).
\end{aligned}$$

In general, all four terms in this product may depend on θ; the first two terms comprise the partial likelihood for θ based on the As in the sequence (A_k, B_k).

The loss of information about θ caused from dropping the last two terms will depend on how strongly the conditional distribution of B_ks, given the previous events in the sequence, depends on θ. Balanced against the loss of **efficiency** is the possibility that the partial likelihood may be simpler to compute or may not depend on highly dimensional **nuisance parameters**. The partial likelihood for the proportional hazards regression model does not include an infinite dimensional nuisance parameter that is part of the full likelihood.

Consider a regression problem with right-**censored data** with no tied values in the set of observation times. Set $X_j = \min(T_j, U_j)$, $\delta_j = I_{X_j = T_j}$, and denote the observed data by (X_j, δ_j, Z_j), $j = 1, \ldots, n$, where $\mathbf{Z}_j$ denotes a vector of covariates for the jth case. Let $T_1^{\mathrm{o}} < \cdots < T_L^{\mathrm{o}}$ denote the L ordered times of observed failures, and set $T_0^{\mathrm{o}} \equiv 0$ and $T_{L+1}^{\mathrm{o}} \equiv \infty$. Let (k) be the case label for the patient failing at T_k^{o}. Let B_k be the event describing the observed times of censoring in the interval $[T_{k-1}^{\mathrm{o}}, T_k^{\mathrm{o}}]$, the case labels associated with the censored times, and the fact that a failure has been observed at T_k^{o}. Finally, let A_k specify the label, (k), of the case failing at T_k^{o}. The likelihood of the observed data is $\Pr(B_1 A_1 \ldots B_L A_L B_{L+1})$.

In the proportional hazards regression model the conditional **hazard** for T_j given $\mathbf{Z}_j$ is $\lambda_0(t) \exp(\boldsymbol{\beta}' \mathbf{Z}_j)$. If the conditional distributions B_k contain little information about the regression parameter $\boldsymbol{\beta}$, then a reasonable partial likelihood for $\boldsymbol{\beta}$ would be

$$\left[\prod_{k=2}^{L} \Pr(A_k | B_k A_{k-1} B_{k-1} \ldots A_1 B_1)\right] \Pr(A_1 | B_1).$$

For fixed k, since there are no ties in the observation times, it can be established that

$$\begin{aligned}
\Pr(A_k | B_k A_{k-1} B_{k-1} \ldots A_1 B_1) &= \frac{\lambda(T_k^{\mathrm{o}} | \mathbf{Z}_{(k)})}{\sum_{j \in R_k} \lambda(T_k^{\mathrm{o}} | \mathbf{Z}_j)} \\
&= \frac{\exp(\boldsymbol{\beta}' \mathbf{Z}_{(k)})}{\sum_{j \in R_k} \exp(\boldsymbol{\beta}' \mathbf{Z}_j)},
\end{aligned}$$

where R_k is the set of cases at risk at time T_k^{o}, i.e. $\{j : X_j \geq T_k^{\mathrm{o}}\}$ (*see* **Risk Set**). The partial likelihood for $\boldsymbol{\beta}$ will thus be

$$L(\boldsymbol{\beta}) = \prod_{k=1}^{L} \frac{\exp(\boldsymbol{\beta}' \mathbf{Z}_{(k)})}{\sum_{j \in R_k} \exp(\boldsymbol{\beta}' \mathbf{Z}_j)}.$$

The infinite dimensional nuisance parameter λ_0 does not appear in the partial likelihood.

The derivation of the partial likelihood for the proportional hazards model requires more care when there are **tied survival times** and **time-dependent covariates**; the details for these cases can be found in [1] and [4].

The general construction of a partial likelihood is very similar. Suppose a data vector $\mathbf{X}$ has

density $f_{\mathbf{X}}(\mathbf{x}, \boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a vector parameter $(\boldsymbol{\phi}, \boldsymbol{\beta})$, and that the primary inference question is about $\boldsymbol{\beta}$ in the presence of the nuisance parameter $\boldsymbol{\phi}$. If $\mathbf{X}$ can be transformed into a sequence $(V_1, W_1, V_2, W_2, \ldots, V_N, W_N)$, then the likelihood for $\boldsymbol{\theta}$ can be written as

$$\begin{aligned} f_{\mathbf{X}}(\mathbf{x};\boldsymbol{\theta}) &= f_{V_1,W_1,\ldots,V_N,W_N}(v_1, w_1, \ldots, v_N, w_N;\boldsymbol{\theta}) \\ &= \prod_{n=1}^{N} f_{W_n|V_1,W_1,\ldots,V_n}(w_n|v_1, w_1, \ldots, \\ &\quad v_{n-1}, w_{n-1}, v_n;\boldsymbol{\theta}) f_{V_n|V_1,W_1,\ldots,V_{n-1},W_{n-1}}(v_n|v_1,w_1,\ldots, \\ &\quad v_{n-1}, w_{n-1};\boldsymbol{\theta}) \\ &= \left[\prod_{n=1}^{N} f_{W_n|Q_n}(w_n|q_n;\boldsymbol{\theta})\right] \\ &\quad \times \left[\prod_{n=1}^{N} f_{V_n|P_n}(v_n|p_n;\boldsymbol{\theta})\right], \end{aligned} \tag{1}$$

where $P_1 = \{\emptyset\}$, $Q_1 = V_1$, and, for $n = 2, \ldots, N$,

$$P_n = (V_1, W_1, \ldots, V_{n-1}, W_{n-1})$$

and

$$Q_n = (V_1, W_1, \ldots, W_{n-1}, V_n).$$

When the first product on the right-hand side of (1) depends only on $\boldsymbol{\beta}$, Cox called this term the partial likelihood for $\boldsymbol{\beta}$ based on W in the sequence $(V_1, W_1, \ldots, V_N, W_N)$. Because of the way the conditioning events are used in the construction, a partial likelihood is not the likelihood of either the observable or derived data, so the usual properties of likelihood-based estimates do not hold automatically.

There are a number of results that are true for partial likelihoods generally. Cox [2] shows that asymptotic sampling distributions for maximum partial likelihood estimates follow from standard arguments about score statistics (*see* **Likelihood**) applied to the partial likelihood score. Wong [6] gives a more formal account, and shows how to calculate the **asymptotic relative efficiency** of a maximum partial likelihood estimate compared to an estimate from the full likelihood. Oakes [5] and Efron [3] illustrate asymptotic efficiency calculations for maximum partial likelihood estimators in the proportional hazards model, finding conditions under which the partial likelihood estimators are fully efficient.

Cox [2] cites a number of difficulties that the concept of partial likelihood presents, including the possibility that since the conditioning argument used to construct the partial likelihood is not necessarily unique, different partial likelihood estimates may be obtained from the same observations. The principal difficulty from the practitioner's perspective may be that there is no direct, routine method for constructing a partial likelihood in the presence of difficult likelihoods or highly dimensional nuisance parameters.

DAVID HARRINGTON

Partially Balanced Incomplete Block Design

Partially balanced incomplete block designs (PBIBDs) are used in the testing of drugs [2] and in the design of **factorial experiments**.

As with other **incomplete block designs**, PBIBDs are defined on a set of v treatments. The set of v treatments is structured: for each treatment the set of the remaining $v-1$ treatments is partitioned into a set of subsets called *associate classes*. This partitioning is usually based on inherent attributes of the treatments. For example, consider a combination drug study (see [4]). Treatments having the same level of factor 1 are first associates, treatments having the same level of factor 2 are second associates and treatments which have neither factor 1 nor factor 2 at the same level are third associates.

We will define the concept of an association scheme and of a PBIBD and then describe some association schemes that have been used in the biosciences.

If a set of v treatments has an *association scheme with m associate classes* defined on it, then:

1. any two distinct treatments are ith associates for exactly one value of i, $1 \leq i \leq m$;
2. each treatment has exactly n_i ith associates, $1 \leq i \leq m$;
3. for any pair of ith associates, x and y, say, there are a fixed number of treatments which are both ith associates of x and hth associates of y, and this number is independent of the particular pair of ith associates chosen.

The *parameters of the association scheme* are v and $n_i, 1 \leq i \leq m$. Since each treatment is an associate of every other, $\sum_i n_i = v - 1$.

A design based on a set of v treatments with an m-associate class association scheme defined on them is a *partially balanced incomplete block design with m associate classes* (PBIBD(m)). There are b blocks of size k and each treatment is replicated r times. If treatments x and y are ith associates then there are λ_i blocks containing both x and y. The PBIBD determines the association scheme, but not conversely (see [8]).

The parameters of a PBIBD(m) are not independent of each other. Counting plots, we see that there are v treatments each replicated r times and there are b blocks each with k plots. Thus $vr = bk$. Counting pairs, we have that $\sum_i n_i \lambda_i = r(k-1)$.

For example, let the treatments be 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 and let the pairs of first associates be $\{1, 6\}$, $\{2, 7\}$, $\{3, 8\}$, $\{4, 9\}$ and $\{5, 10\}$. Any other pair of treatments is a pair of second associates. So $v = 10$, $n_1 = 1$, $n_2 = 8$. If the blocks of the designs are $\{1, 2, 3, 4, 5\}$, $\{1, 2, 3, 9, 10\}$, $\{1, 7, 8, 4, 5\}$, $\{1, 7, 8, 9, 10\}$, $\{6, 2, 8, 4, 10\}$, $\{6, 2, 8, 9, 5\}$, $\{6, 7, 3, 4, 10\}$, and $\{6, 7, 3, 9, 5\}$, then $b = 8$, $k = 5$, $r = 4$, $\lambda_1 = 0$, $\lambda_2 = 2$.

The most commonly used association schemes are the *factorial association schemes*. These include the group-divisible, with two classes, and the rectangular, with three. Both of these schemes have been generalized to have more classes.

For the *group-divisible association scheme* there is a set of $v = mn$ treatments which may be viewed as being divided into m subsets, (or *groups*, in the nonalgebraic sense) each of n treatments. Treatments in the same group are first associates; treatments in different groups are second associates. We see that $n_1 = n - 1$ and $n_2 = n(m-1)$. This association scheme arises naturally when there are two factors, the first with m levels and the second with n levels, and the second factor is nested in the first. For example, the first factor might be one of three types of support provided to new mothers and the second factor hospitals. Each hospital treats all new mothers in the same way and so hospitals are nested within type of support. The hospitals can be compared within type of support and the types of support can be compared across hospitals.

If instead the two factors are not nested but crossed, then the corresponding association scheme is the *rectangular association scheme*. This scheme has three associate classes and is most easily visualized by writing the treatments in an $m \times n$ array. Treatments in the same row are first associates (having the same level of factor 1), treatments in the same column are second associates (having the same level of factor 2) and treatments which have neither factor 1 nor factor 2 at the same level are third associates. Combination drug studies provide one example of this structure (see [4]).

Other schemes can be built up by repeated nesting and crossing or a mix of these.

For complete diallel cross experiments the *Latin-square-type (L_i-type) association scheme* is

appropriate. In this scheme there are n^2 treatments which are laid out in an $n \times n$ array. In an L_2-type scheme, a pair of treatments in the same row or the same column are first associates and a pair of treatments not in the same row or column are second associates. In an L_i-type scheme, we also need $i-2$ mutually **orthogonal Latin squares** of order n. Then a pair of treatments are first associates if they occur in the same row, or in the same column, or in a cell with the same symbol when any of the Latin squares is superimposed on the square array. We see that $n_1 = i(n-1)$ and $n_2 = (n-1)(n-i+1)$ for $i \leq n-1$. If $i = n$, then the scheme is a group-divisible one with n subsets and with the names of the first and second associate classes reversed. If $i = n+1$, then all treatments are first associates of each other and the PBIBD will be a **balanced incomplete block design**.

Lattice designs with $n-1$ replicates are examples of L_2-type designs. Lattice designs were introduced by Yates [9] for crop cultivar trials and have been extended by various authors, most recently Patterson & Williams [6] to α-designs. These designs have been shown to give slightly more precision than **randomized complete block designs** for immunosorbent assays [1].

For complete half-diallel cross experiments the triangular association scheme is appropriate. In the *triangular association scheme* there are $v = n(n-1)/2, n \geq 5$, treatments. Arrange these treatments in a symmetrical $n \times n$ array with the diagonal cells empty. First associates are those in the same row or column. Treatments not in the same row or column are second associates.

For a partial diallel cross the scheme proposed by Kempthorne & Curnow [5], and attributed to G.W. Brown, is equivalent to a cyclic association scheme. In the *cyclic association scheme* use the integers modulo v, usually written as $Z_v = \{0, 1, 2, \ldots, v-1\}$, as the treatment names. Partition the $v-1$ nonzero entries in Z_v by $\{1, 2, \ldots, v-1\} = D \cup E$, where $D = \{d_1, d_2, \ldots, d_{n_1}\}$. For each $d_i \in D$ we must have that $v - d_i \in D$. There are $n_1(n_1-1)$ differences of distinct elements of D. These differences must contain each element of D equally often and each element of E equally often. The first associates of treatment i are the treatments in $i + D = \{i + d_1, i + d_2, \ldots, i + d_{n_1}\}$, where the sum (modulo v) always lies between 0 and $v-1$.

Further details about PBIBDs may be found in [7] and [8]. Clatworthy [3] provides an extensive tabulation of the two-associate-class PBIBDs mentioned here.

Partner Study

Partner studies are epidemiologic investigations of transmission of infectious diseases in susceptible partners of known infected individuals. Widely used for studying transmission of sexually transmitted diseases (STD) such as Human Immunodeficiency Virus (HIV) (*see* **AIDS and HIV**), these studies are applicable in situations in which "partnerships" that link known susceptible and infectious individuals can be identified. Eligibility typically requires that exposure to infection in susceptible individuals is limited to a previously infected partner. This allows potential bias associated with uncertainty about the source of infection to be reduced or eliminated. Partner studies focus primarily on the influence of measured **covariates** on the probability of transmission, but can also be used to gain knowledge of key parameters such as the *infectivity* (transmission risk per unit of exposure). Statistical analyses of data from these studies provide a number of unique challenges, most of which arise from the incomplete nature of data describing exposure and infection (*see* **Infectious Disease Models**).

Study Designs and Data

Study designs for investigations of infectious disease transmission depend on linking infection outcomes in susceptible individuals to exposure to infectious individuals. Thus, factors that characterize exposure as well as those related to the nature of infectiousness and susceptibility are important considerations in design and analysis. Because of the difficulty in directly observing such factors, most studies are carried out in restricted settings where exposure, susceptibility, and infectiousness can be more clearly identified. Classical examples include observation of disease outbreaks in households and island communities, where exposure can be assumed to be limited to a group. The primary focus of statistical analyses for such studies has been on describing epidemic spread at the group level [2]. For sexually transmitted diseases (STD), transmission must occur via sexual contacts within partnerships. This suggests that sexual partnerships are an ideal experimental unit on which to study transmission, and motivates the notion of a partner study. Partner studies have recently become a popular tool for investigating HIV transmission, although similar designs have undoubtedly been used to study other STDs. Most studies focus on a particular mode of sexual contact in a select type of partnership (e.g. heterosexual transmission in monogamous couples), but other modes of contact (e.g. needle sharing among intravenous drug users) can be investigated as well. Because the majority of statistical work has focused on monogamous couples, most of the development here will be restricted to this setting.

A partner study consists of a sample of partnerships, each composed of an infected individual called the *index case*, and a susceptible individual referred to here as the *partner*. For a single such couple, complete data on transmission include the total number of contacts and time of occurrence of each, information about the degree of susceptibility of the partner and infectiousness of the index case at the time each contact is made, and indicators of whether or not each contact induced infection in the susceptible partner. In actual studies, the timing and outcome of individual contacts is unknown, and exposure histories and infection indicators can only be measured following an interval of contact. As a result, direct biological measures of susceptibility and infectiousness at the time transmission occurred are almost always unavailable. The vast majority of studies can be described as either **cohort**, with a sample of partnerships consisting of a known infected and susceptible individual followed over time and infections observed and exposure measured at intervals; **case–control**, in which infected and uninfected susceptible individuals and their index case partners are recruited and exposure histories and covariates are ascertained retrospectively; or **cross-sectional**, where only infection status and risk behaviours are collected, but no direct measures of exposure are available. Kim & Lagakos [8] and Jewell & Shiboski [4] provide more details about study designs.

The remainder of this entry will focus primarily on retrospective studies of sexually transmitted diseases which exhibit minimal latency periods (i.e. infected individuals become infectious almost immediately after getting infected) (*see* **Latent Period**) and for which no immunity or recovery is possible. HIV provides a good example [1]. This simplifies the presentation and best reflects the existing statistical work in this area. Such studies are generally characterized by incomplete observations of relevant exposure and infection data. In Figures 1 and 2 are

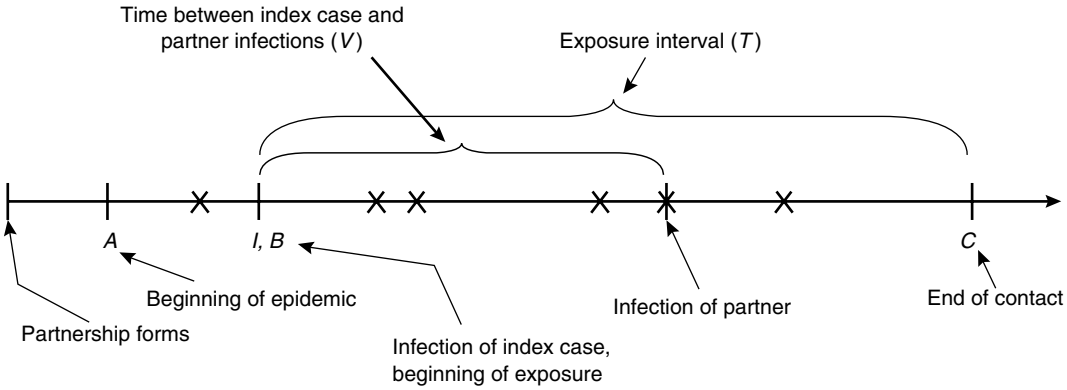

Figure 1 Exposure history from a long-term monogamous partnership formed prior to the earliest possible time of infection of the index case, A. The index case is infected at chronological time I, which also marks the beginning of exposure B. Exposure ends at C, where the infection status Y of the partner is first determined. The duration of exposure T and the time between the infections of the two partners V are also indicated. Contacts are indicated by the symbol "**X**"

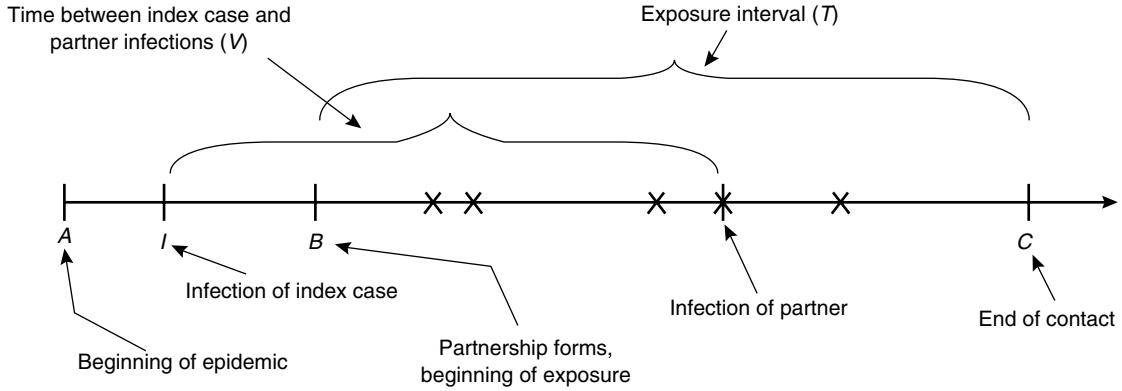

Figure 2 Exposure history from a short-term monogamous partnership, where I, the time of infection of the index case, is bounded below by A (see Figure 1), and contact (and hence exposure) begins at a subsequent time B. Contact ends at C, where the infection status Y of the partner is first determined. Contacts are indicated by the symbol "**X**"

provided schematic representations of exposure data commonly observed in retrospective studies. Both represent exposure histories for single partnerships. Let A denote a chronological time which provides a lower bound on the infection time of the index case, denoted I. This could represent the beginning of an epidemic, date of sexual debut, or other relevant information, and is useful in cases when the actual data of infection is unknown. Let B denote the chronological time when actual exposure to infection in the partner begins, C the time exposure ends or the partnership is recruited, and T the duration of exposure, $C - B$. In "long-term" partnerships which are formed prior to I (Figure 1), $B \equiv I$; for "short-term" partnerships which commence after the infection of the index case (Figure 2), $B > I$. In both situations, the time V between index case infection and partner infection along with the actual degree of exposure during the period $[B, C]$ are the quantities of primary interest, but neither can be observed directly. Rather, the infection status of the partner, denoted by the **binary** random variable Y, is ascertained at the time the partnership is recruited along with retrospective information on exposure.

In some cases (e.g. couples where the index case is infected with HIV via blood transfusion), the time

of infection of the index case I and the exposure interval $[B, C]$ can be identified along with an estimate of the number or rate of contacts during this period. Here, observations of V are **censored** on the left for infected partners ($Y = 1$) and on the right for uninfected partners ($Y = 0$). This form of interval censoring is also known as *current status data* on V. In cases in which the time of index case infection is unknown, it is impossible to identify correctly the beginning of the exposure interval. In this case, observations are limited to the knowledge that infections for both partners occurred in the interval $[A, C]$, and that the infection of the index case preceded the partner's. For a long-term partnership (Figure 1), only A, C, Y, and contact information are observed. For a short-term partnership (Figure 2), the initiation of contact B is observed as well. Both of these types of observations are examples of *doubly censored current status data* on the time to partner infection V. In practice, retrospective studies may contain a mixture of observations of both types, in addition to more complex exposure patterns.

Statistical Models

Statistical interpretation of partner study data is usually based on simplified models for the *transmission probability* of infection in the susceptible partner, defined as the probability of infection occurring, conditional on a specified exposure history. Consider the case of a single couple from a retrospective study in the case that the time of the infection of the index case is known. Let $K(x)$ represent a **counting process** with intensity $\mu(x)$ which measures contacts in the interval beginning at the initiation of contact B. Let $\lambda(x)$ represent the probability that infection is transmitted via a contact occurring at time x following the index case's infection at I. This represents the transmission risk associated with a single contact and is often referred to as the *infectivity* of the disease. Necessarily, $\lambda(x)$ depends on both susceptibility of the partner and infectiousness of the index case, and the relative influence of these cannot be investigated in the absence of additional data. If complete data in the sense described above are available, the conditional probability of the partner being infected following an exposure of length $T = C - B$, given the observed sample path of $K(x)$ can be written:

$$P_{t,k} = \Pr[Y = 1 | K(x) : B - I \le x \le C - I; \; K(C - I) = k] = 1 - \prod_{j=1}^{k} [1 - \lambda(x_j)], \quad (1)$$

where $(x_1, \ldots, x_k)$ are the times of contacts. This probability affords two interpretations in a survival analysis context: (i) the probability that the partner's true infection time V does not exceed $C - I$; and (ii) the probability that the number of contacts $K(V)$ required for infection to occur does not exceed $K(C - I) = k$. If $\lambda(x)$ is assumed to be a constant, then this reduces to the *constant infectivity model* $P_k = 1 - (1 - \lambda)^k$, which is frequently used as a null model against which more complex models are compared. Since the times $(x_1, \ldots, x_k)$ of contacts are unlikely to be available in any of the study designs mentioned above, most analyses are based on the marginal transmission probability based on the time V between infections of the two partners, or on the discrete scale provided by the number of contacts $K(V)$ required for infection to occur. The marginal probability for becoming infected following an exposure of duration t beginning at B is computed from (1) by taking the expectation with respect to the sample paths of the contact process $K(x)$ [16]. When $K(x)$ is a nonhomogeneous **Poisson process** with intensity $\mu(x)$,

$$P_t = 1 - \exp\left[- \int_{B-I}^{C-I} \lambda(x)\mu(x) \, \mathrm{d}x \right] = \frac{G(C - I) - G(B - I)}{1 - G(B - I)}, \quad (2)$$

where G denotes the distribution function for the infection time V, with **hazard** function $\lambda(x)\mu(x)$. For long-term partnerships $B \equiv I$, and the right hand side equals $G(C - I)$. When $\lambda(x)$ and $\mu(x)$ are both constant this is the **exponential** model, the time-based analog of the constant infectivity model mentioned above. The infectivity $\lambda(x)$ is clearly not estimable without external information on $\mu(x)$. If this is available, the model affords a **proportional hazards** interpretation, with $\lambda(x)$ representing the "baseline" hazard of infection associated with a unit contact rate. The effects of a vector Z of covariates can also be considered, as discussed below. Because

of these close ties with conventional **survival analysis** methods, models based on P_t are in general preferred to those based on the marginal transmission probability P_k for becoming infected following an exposure of k contacts. In the constant infectivity case, these models are almost indistinguishable.

When the time of infection of the index case is unknown, the exposure interval is also impossible to specify. If, as discussed above, a lower bound A on the time I of index case infection is known, and if additional information on the distribution F of this time in the interval $[A, C]$ is available, the transmission probability P can be computed as follows [6]:

$$P = \frac{1}{F(C)}\left[\int_A^B \frac{G(C-s)-G(B-s)}{1-G(B-s)}\,\mathrm{d}F(s) + \int_B^C G(C-s)\,\mathrm{d}F(s)\right] \tag{3}$$

The first integral on the right-hand side of (3) is necessary for short-term partnerships, where it is unknown whether or not the index case infection preceded the initiation of contact B (Figure 2). In long-term partnerships formed prior to A this term vanishes, consistent with the assumption that the index case was infected subsequent to this time (Figure 1).

Estimation and Inference

Estimation and **inference** for parameters in transmission models are most commonly based on **maximum likelihood** methods. For a sample of n partnerships from a retrospective or cross-sectional study, the log **likelihood** function (conditional on the observed exposure information) is

$$\sum_{i=1}^{n} y_i \log P_i + (1-y_i)\log(1-P_i), \tag{4}$$

where P_i represents the transmission probability as described above. In the case in which index case infection times are known (i.e. current status information is available on partners' infection times), **nonparametric maximum likelihood** estimates of the distributions of V and $K(V)$ can be obtained using **isotonic regression** [3, 7]. If index case infection times are unknown (i.e. doubly censored current status information is available on partners' infection times), nonparametric estimation of G from (3) is also possible in the case of long-term partnerships if the distribution F of index case infection times is assumed to be uniform [6].

In many cases it is desirable to estimate the infectivity $\lambda(x)$ directly, and to investigate covariate effects in a regression setting. Using the proportional hazards structure of (2), which is appropriate for current status information on partner infection in a retrospective design, the complementary log–log transformation (*see* **Binary Data**) yields the following regression model:

$$\log[-\log(1-P_i)] = \log\left[\int_{B_i-I_i}^{C_i-I_i} \lambda(x)\,\mathrm{d}x\right] + \log\mu_i + \beta z_i. \tag{5}$$

Here, the contact rate μ_i for the ith partnership has been assumed to be constant and $\log\mu_i$ represents an offset term. For parametric choices of $\lambda(x)$ the techniques of **generalized linear models** can be used to estimate parameters in this model. For example, when this parameter is assumed to be constant in (2) (or (1)), (4) is a standard generalized linear model for the binary outcome Y and can be treated using standard techniques and **software** [3]. When no parametric assumptions are made about $\lambda(x)$ the resulting models are **semiparametric**. For (5), the constraint that the integrated infectivity is nondecreasing in the duration of exposure must also be taken into account in estimation. Estimation techniques include estimating $\lambda(x)$ and β jointly using **penalized maximum likelihood** and the **EM algorithm** [16]; **profile likelihood** [12]; or modified **generalized additive models** [15, 16, 18]. The regression coefficients β can also be estimated separately, treating the infectivity as a **nuisance parameter** using an approximate **partial likelihood** approach [13]. Estimation methods for doubly censored current status observations are poorly developed in the semiparametric setting. Recent results indicate that such data generally provide inconsistent estimates (*see* **Consistent Estimator**) of the distribution G unless additional assumptions (e.g. smoothness) are imposed [5], and that, for estimation of β, methods for current status data can be applied with little loss of **efficiency** [10]. Fully parametric models for such data can be also handled using standard maximum likelihood techniques.

Inference about the parameters introduced in the models above is typically focused on two areas: (i) the effects of covariates on the probability of disease transmission; and (ii) investigation of the properties of the infectivity $\lambda(x)$. Techniques for parameters in fully parametric transmission models are straightforward, and in many cases follow standard practice for generalized linear models. By contrast, asymptotic theory for parameter estimates in semiparametric models is not well developed. In addition, there are a number of complicating issues in inference which arise from the lack of information most studies provide about exposure and the infection process. These include the possibilities of measurement error in exposure data related to retrospective **ascertainment**, and the potential for uncontrolled heterogeneity of infectivity between partnerships reflecting unmeasured factors influencing infectiousness and susceptibility. Ignoring these factors may lead to biased estimates of λ and β [3, 14, 16]. Unfortunately, data from partner studies is usually extremely limited, making it very difficult or impossible to correct for these problems using existing methods. For example, data are rarely sufficient to allow mixture models incorporating heterogeneity into λ to be fit, except in cases in which the latter is assumed to be constant [20]. Similarly, **validation** data for use in modeling measurement error are rarely if ever available. Finally, even in well conducted studies with valid exposure information it is rare that data are extensive enough to yield much detailed information about the form of the infectivity. Despite these limitations, partner studies remain valuable tools in understanding infectious disease transmission, and are worthy of further statistical research.

Many of the above techniques can be generalized to apply in other settings, including studies in which identification of the index case is uncertain [9], and in which multiple potential index cases may be associated with each partner [11, 17, 19]. Obtaining reliable estimates of the per-contact infectivity is extremely difficult in these situations, but the effects of covariates on the probability of transmission can still be investigated.

Pascal, Blaise

Born: June 19, 1623, in Clermont, France.
Died: August 19, 1662, in Paris, France.

Blaise Pascal was one of the most influential figures in French life and literature. Here, only his contributions to mathematics are considered.

In 1631, Pascal's father Etienne moved from Clermont to Paris in order to secure his son a better education, and in 1635 he was one of the founders of Marin Mersenne's "Academy", to which he introduced his son at the age of 14. The younger Pascal immediately put this new source of knowledge to good use, producing (at the age of 16) his famous *Essay pour les coniques*.

In the succeeding years, Pascal *fils* designed and had built the first mechanical adding machine (there is now a computer language called "Pascal") and conducted experiments into the nature of a vacuum (the "Pascal" is the SI unit of pressure), but his chief mathematical contribution was to lay the foundations of the **theory of probability**.

Before his time, probability calculations amounted to no more than the enumeration of equally probable outcomes in games of chance, but Pascal introduced the important idea of **expectation** and used recursively the fact that if expectations of gain X and Y are equally probable, the expectation is $\frac{1}{2}(X+Y)$. He also introduced the **binomial distribution** for equal chances and, with its help, and that of mathematical induction applied to expectations, solved the Problem of Points for two players.

This problem was the topic of correspondence between Pascal and Pierre de Fermat in 1654 which, together with Pascal's contemporary *Traité du triangle arithmétique*, includes three methods of solution. Two players stake equal money on being the first to win n points in a game in which the winner of each point is determined by the toss of a coin. If such a game is interrupted when one player still lacks a points and the other b, how should the stakes be divided between them?

Fermat and Pascal independently concluded that the problem could be solved by noting that at most $a+b-1$ more tosses will settle the game, and that if this number of tosses is imagined to have been made, the resulting 2^{a+b-1} possible games (each equally probable) may be classified according to the winner in each case, the stakes then being divided accordingly. Thus, the real game, of indeterminate length, is embedded in an imaginary game of fixed length. Apart from this novel idea, however, such a solution by enumeration was straightforward, but Pascal offered both an independent method based on expectations which is valid for any number of players, and, in the *Traité du triangle arithmétique*, the solution for two players in terms of the binomial distribution, proved by induction. He did not give the binomial distribution algebraically, but by reference to the "arithmetical triangle" of binomial coefficients, the properties of which he elaborated in his *Traité* (whence the name "Pascal's Triangle").

Pascal's seminal work laid the foundations of probability theory, influencing Christian Huygens (*De Ratiociniis in Ludo Aleae*, 1657) and thence James **Bernoulli** (*Ars Conjectandi*, 1713). Already in 1710, we find the binomial distribution being applied to a biological problem (John Arbuthnot, *An Argument for Divine Providence, taken from the constant regularity observ'd in the births of both sexes*) and giving rise to the first test of significance (*see* **Hypothesis Testing**).

Paternity Testing

Paternity testing on the basis of **blood group** typing has been known since 1920, but at that time was only used to prove nonpaternity by way of exclusion. For example, in the case of a child with blood group AB, and mother with blood group B, a man with blood group O could be excluded from paternity, because the true father must have the component A in his phenotype. In 1938, Essen-Möller [2] was the first author to propose a statistical approach in nonexclusion situations to quantify the available genetic information. For the standard trio case (child, mother, putative father) he defined the two alternative hypotheses "paternity" vs. "unrelated" and, on the basis of estimated population frequencies, evaluated the likelihoods:

$$X = L(\text{observed phenotypes}|\text{"paternity"})$$

and

$$Y = L(\text{observed phenotypes}|\text{"unrelated"}).$$

Essen-Möller then used X and Y in a **Bayesian methods** approach with equal prior probabilities to calculate the probability of paternity as

$$W = \frac{X}{X+Y},$$

thus starting a never-ending discussion regarding the appropriateness of introducing prior probabilities into the statistical argument. It has to be pointed out, though, that already at this stage it was evident that the likelihood ratio X/Y (now known as the paternity index ([1] and [5]) contained the complete genetic evidence for a given case. Because of differing legal situations in different countries, development since the 1950s has not always been parallel, but by now has led to more or less general scientific agreement and standardization regarding the following aspects:

1. Use of high-quality **genetic marker** systems with adequately estimated gametic population frequencies.
2. Exact formulation of hypotheses for standard trio cases, as well as complex relationships in deficiency cases.
3. Standard **likelihood** calculation on the basis of well-defined hypotheses and adequate parameter estimates.
4. **Likelihood ratio** as the basis of decision making.
5. Additional statistics for the general and case-specific probability of exclusion.

Marker Systems

The basis for all statements are the genetic marker systems used for typing and the knowledge of the genetic parameters governing these systems. In the case of fully **penetrant** marker systems, these parameters are the mutation rates, the recombination fractions and the gametic population frequencies of the respective allelic expressions (*see* **Gene Frequency Estimation**). Quality aspects regarding the selection of markers make it preferable to have systems with a negligible amount of mutation, free recombination between marker loci and no **linkage disequilibrium**, which is equivalent to intragametic independence, thus allowing easy calculation of overall likelihoods by multiplication of marginal frequencies [4]. In addition, the quality of such a marker system is measured by its power to exclude paternity for an unrelated man (general power of exclusion, *GPE*), which is a direct function of the number of alleles and their population frequencies. The historical development has led from blood groups, protein systems, enzyme systems (*see* **Polymorphism**) to the highly polymorphic **HLA system** with all its complexity of closely linked loci and linkage disequilibrium, to the now available (over)abundance of **DNA sequence** marker systems. Within the group of DNA markers the multilocus probes (MLPs) are being used less and less due to the impossibility of determining the **genotypes** corresponding to a given set of phenotypic signals. The standard systems now being used almost worldwide are the two groups of single locus probes (SLPs) with a continuous distribution of allelic "fragment length" and the short tandem repeat (STR) systems with discrete alleles [3]. Although SLP systems have extreme discrimination powers (high **heterozygosity**, high *GPE*), the problem of measurement error for the continuous fragment lengths in these systems leads to complications in their statistical evaluation. It can be expected that STRs, with their simplicity of allele and genotype definition, their ever-increasing number, their good discrimination power and their increasing ease of typing, will become the standard in all kinds of relationship testing.

Hypotheses

The basis of all statistical argument in cases of nonexclusion is well-defined hypotheses. In the standard trio case, the following are usually the two alternatives:

H_1: The putative father is the true biological father of the child.

H_2: The putative father is not the biological father of the child: he is an unrelated random male from a given population.

It must be pointed out that the second hypothesis is not simply the negation of the first hypothesis and has to be clearly distinguished from the situation where the putative father could be related to the true father (for example, he is his brother). Furthermore, the ethnic background(s) of the putative father, the implicitly postulated true father and, to a lesser extent, that of the mother, are part of the hypotheses. For more complex situations in deficiency cases (such as when the putative father is not available for testing, but information on blood relatives is available) two (or more) hypotheses must be well defined and can be represented by the corresponding pedigree(s) that include all individuals necessary to represent the postulated relationships, irrespective of the availability for marker typing. Figure 1 represents the situation of a case with a deceased putative father whose parents are both available for typing.

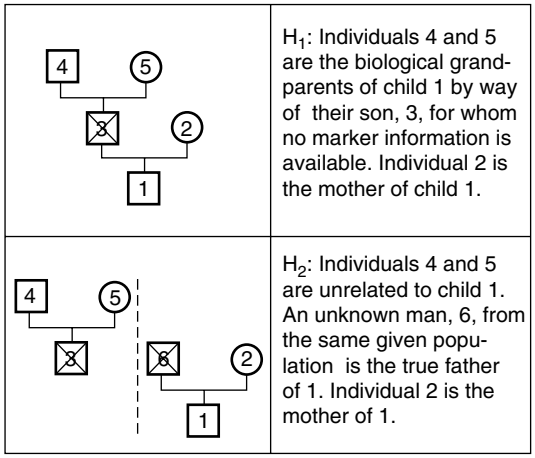

Figure 1 Hypothesis formulation and representation by way of corresponding pedigrees

Likelihood Calculation

Every conceivable well-defined hypothesis can be represented as a pedigree. Consequently, the calculation of the likelihood of the given hypothesis for the observed phenotypes is identical to the probability of the observed phenotypes given the corresponding pedigree. Let $g_{i,j}$ be the ith possible genotype for the jth person, with population frequency $f_{i,j}$, ph_j be the genotype of the jth person, and $\Pr(g_{i,j}|g_{i,p}, g_{i,m})$ be the probability of $g_{i,j}$ conditional on the genotypes of j's parents. Then the general formulation of such a likelihood is

$$L(\text{phenotypes}|\text{pedigree}) = \sum_{g_{i,1}} \sum_{g_{i,2}} \cdots \sum_{g_{i,k}} \prod_{k} P(ph_k|g_{i,k}) \times \prod_{\text{founders}} f_{i,k} \prod_{\text{descendants}} P(g_{i,k}|g_{i,p}, g_{i,m})$$

(*see* **Elston–Stewart Algorithm**).

For the case of high-quality marker systems, this general formulation is considerably simplified:

1. The nested summation for all individuals reduces to a single term for one-to-one correspondence of genotype and phenotype, which is the case for single locus DNA markers with no silent alleles.
2. Marker systems having complete penetrance reduce the number of terms.
3. In the case of intragametic independence, population frequencies are given by the product of the allele frequencies for each marker.
4. Transmission probabilities are 1 for a homozygous parent and 1/2 for a **heterozygous** parent.

For example, consider the simple case of a trio with the following typing results:

child (a/c), mother (c/d), putative father (a/b).

Letting f_i be the population frequency of allele i, the likelihoods of the hypotheses evaluate to

$$X = L(\text{genotypes}|H_1) = f_a f_b f_c f_d,$$
$$Y = L(\text{genotypes}|H_2) = 2 f_a f_b f_a f_c f_d.$$

The general likelihood formulation can handle dominance or untyped individuals by summation over

all compatible genotypes, closely linked loci with linkage disequilibrium by using **haplotype** frequencies on the population level and recombination fractions in the transmission probabilities, and even possible mutations can be modeled into this component (if reliable estimates are available). Ihm & Hummel [6] were the first to present an algorithm to evaluate the likelihood for a complex hypothesis in relationship testing and today many software packages for pedigree analysis (*see* **Software for Genetic Epidemiology**) can perform this calculation, given the parameter estimates.

Likelihood Ratio, *PI*, and Posterior Probability, *W*

In the case of two well-defined hypotheses with corresponding likelihoods X and Y, the likelihood ratio statistic X/Y has been termed the *paternity index*, *PI*. The *PI* contains the complete genetic information and has the general property that with increasing *PI* the probability of H_1 in comparison with H_2 also increases. Consequently, the decision process for the acceptation or rejection of H_1 ("Paternity") is the process of setting a decision threshold for the *PI* statistic. In most countries, a likelihood ratio of $PI = 1000 : 1$ has been chosen for the verbal conclusion "Paternity practically proven". Some countries are asking for $PI = 10\,000 : 1$. The power of the marker systems now available for typing is strong enough to exceed this threshold in almost all situations when there is paternity, and, in nonpaternity situations, one or several exclusions will most likely be detected. The evaluation of type I and type II errors (*see* **Hypothesis Testing**) would be theoretically possible on the basis of the two distributions of all possible genotype constellations conditional on the two hypotheses. Because of the fact that new marker systems are constantly being developed and introduced into paternity testing, these conditional distributions would have to be re-evaluated for any new set of marker systems.

The alternative approach, which dates back to the original paper of Essen-Möller [2] is the calculation of posterior probabilities using **Bayes' theorem**. Given the conditional likelihoods, X_j, for two or more mutually exclusive hypotheses H_j with prior probabilities p_j, the posterior probability of H_i is given by

$$\Pr(H_i|\text{phenotypes}) = \frac{p_i X_i}{\sum_j p_j X_j}.$$

This expression can only be evaluated if, in addition to the conditional likelihoods, X_j, the prior probabilities of the hypotheses H_j are given. For the simple situation of two alternative hypotheses, the above expression reduces to

$$W = \Pr(\text{paternity}|\text{phenotypes}) = \frac{pX}{pX + (1-p)Y},$$

and, if one is willing to set both prior probabilities to $p = 1/2$,

$$W = \frac{X}{X+Y},$$

the formula given by Essen-Möller [2]. It has to be pointed out that the **information** contained in W (with equal priors) is identical to that of *PI* since

$$W = \frac{PI}{PI+1}.$$

A threshold of $PI = 1000$ is equivalent to $W = 0.9990$.

The argument about the use of the paternity index only, the use of the probability of paternity with equal priors, or the estimation of prior probabilities from "similar" previous cases and thereby the introduction of nongenetic evidence, has governed the scientific debate for decades. However, it has recently ended because the strength of the genetic evidence is so extreme that, no matter what decision procedure is used, the amount of error in standard cases is negligible. In complex deficiency cases with two alternative hypotheses, the likelihood ratio is again the statistic presenting the complete genetic information for the postulated relationship. Since, in many situations, direct exclusions are structurally not possible – for example, child, mother and one putative grandparent – the likelihood ratio symmetrically provides information against the postulated relationship. The complex situation with more than two mutually exclusive hypotheses is not directly accessible. Pairwise comparisons with likelihood ratios is feasible but the comparison of one conditional likelihood, X_i, simultaneously with all others is only possible by way of the general Bayesian formulation using

assigned priors. The approach using equal priors for all hypotheses allows easy calculation, but provides nothing more than a representation of the conditional likelihoods, X_i, normed. Nevertheless, in this way, preponderance of one of the hypotheses becomes easily visible.

General and Case-specific Probability of Exclusion

In addition to the above defined likelihood statements, there are two further statistics used in paternity testing, one characterizing the general power of a marker system to detect an exclusion (*GPE*), the other characterizing its power to exclude an unrelated man in the case of a specific mother–child phenotype (*SPE*).

Let M be a marker system with $i = 1, \ldots, n$ different phenotypes, ph_i. For a given mother–child constellation $(ph_\mathrm{m} : ph_\mathrm{c})$ the set of all phenotypes $\{ph_i\}$ contains a uniquely defined subset of phenotypes genetically compatible for a father of the child. The sum of the frequencies of these phenotypes is the probability that a random man is not excluded (*RMNE*):

$$RMNE(ph_\mathrm{m} : ph_\mathrm{c}) = \sum_{\text{compatible}} f(ph_i),$$

and the specific probability of exclusion consequently is defined as

$$\begin{aligned} SPE(ph_\mathrm{m} : ph_\mathrm{c}) &= 1 - RMNE(ph_\mathrm{m} : ph_\mathrm{c}) \\ &= 1 - \sum_{\text{compatible}} f(ph_i). \end{aligned}$$

Obviously, *SPE* depends on the phenotypes of the given mother–child constellation. For any marker system M the general power to exclude a random man, *GPE*, is given as follows. Let $i = 1, \ldots, l$ be the number of all possible mother–child constellations $(ph_\mathrm{m} : ph_\mathrm{c})_i$. Let f_i be the corresponding frequencies of these constellations (easily calculated from the general likelihood formulation for pedigrees; see above) and SPE_i the corresponding specific probability of exclusion defined above. Then, the general exclusion probability of this system M is given by

$$GPE_M = \sum_{i=1}^{l} f_i SPE_i.$$

For a set S of k independent marker systems M_i, the overall exclusion probability is simply

$$GPE_S = 1 - \prod_{i=1}^{k} (1 - GPE_{M_i}).$$

Given the new DNA polymorphisms available for testing, it is no problem to reach overall exclusion probabilities $\geq$99.9% with sets of 8–10 independent single locus systems. Cost–benefit analysis has shown that for a given level of GPE_S the overall cost, C_S, is minimized if markers, M_i, with corresponding costs, C_i, are selected according to the magnitude of the benefit–cost relationship, R_i, defined by

$$R_i = \frac{-\log_{10}(1 - GPE_i)}{C_i}.$$

Note that in deficiency cases the evaluation of *SPE* may be very complex, or for certain hypotheses structurally equal to zero and thus meaningless.

Conclusion

Paternity testing on the basis of marker typing has become a highly efficient and standardized procedure due to the large amount of information now available. Marker systems with high discrimination power are available, statistical procedures have been developed to describe the general quality of the marker system (*GPE*) as well as statistics for the given case (*PI*, *W*, *SPE*) – see, for example, [7]. Complex relationship testing as an extension of paternity testing can be performed on the basis of exact formulation of hypotheses and corresponding likelihood statements. Quality assessment requires continuous quality control of the laboratory work and a good data base to determine relevant population parameters of the marker systems used. The selection of marker systems with a high benefit–cost ratio leads to improved discrimination power at reduced cost.

Path Analysis in Genetics

The method of **path analysis**, introduced by the pioneer population geneticist Sewall Wright [40, 41] over 70 years ago, is a form of structural linear regression analysis of standardized variables whose purpose is two-fold: to explain the interrelationships among a given set of variables, and to evaluate the relative importance of varying causes influencing a variable of interest. Algebraic equations that specify the structural interrelationships among the variables are known as **structural equations**. Although path analysis can be pursued strictly through structural equations, path diagrams that specify the proposed structural relationships schematically are often more helpful for conceptualizing a complex path model quickly, and for determining the internal consistency and limitations of a given model. Algebraic manipulation of structural equations or analysis of path diagrams using a standard set of tracing rules [19] both yield identical results.

Path analysis was originally developed by Sewall Wright for a systematic study of **inbreeding** and systems of mating. Despite its application in a variety of contexts and despite its inherent appeal, it remained a secluded method for a long time. In later years this method has been used extensively in sociological and econometric modeling in the guise of structural equation models (e.g. [9]). The method was largely neglected by the statistical community perhaps because, around the same time that path analysis was being developed, statisticians were overwhelmed by the beauty and logic of the formal statistical methods that were being rapidly developed. A relative lack of mathematical formalization appears to have rendered path analysis less attractive [15]. Starting in the mid 1970s, however, path analysis was widely applied in human genetics and **genetic epidemiology**, perhaps partly aided by the development of formal tests of hypotheses [33].

Path analysis is especially useful for studying the genetic epidemiology of complex phenotypes. In terms of specifying the interrelationships among variables in a path model, there is a theoretical basis at least for some of the relationships in families. For example, **genes** cause phenotypes (*see* **Genotype**) and not the other way around, and the genes of children are determined (caused) by those of their parents. When the direction of "causation" is less clear, ambiguous correlational and other associative relationships, such as *copaths* [3] and *delta paths* [38], are used. Formal tests of hypotheses are now routine in such situations, and path analysis enables testing whether the theoretical model is consistent with the observed interrelationships among variables (i.e. assessment of **goodness of fit**). A rich battery of path models have been developed over the years for dealing with a variety of situations in genetic epidemiology and behavioral genetics; see, for example, [25].

For the purposes of evaluating familial resemblance, path models are based on *multifactorial inheritance*, which means that multiple genetic and/or familial environmental effects contribute to the resemblance within families where none of the individual effects is large. In turn, the genetic effects are assumed to be polygenic (*see* **Polygenic Inheritance**) (i.e. many genes each with a small and equal effect). While some models accommodate interactions at the polygenic level, polygenic effects are often assumed to be additive, and this is the case in the path analysis models used in genetic epidemiology.

Under a given path model, correlations among the variables (or, more specifically, among phenotypes of family members) can be derived either by taking the mathematical expectations of products of (standardized) variables, or directly from the path diagram following a simple set of tracing rules (see [19]). The gist of the method of path analysis consists of a comparison of these model-based correlations, which are functions of unknown parameters, with the actual data. Fitting path models to family data needs appropriate statistical methods for obtaining consistent and efficient estimates of the parameters of the model, as well as for testing specific null hypotheses. Path analysis usually considers a series of hypotheses and rejects some as being inconsistent with the data, thus leading to what appears to be a plausible model for the observed data. For recent reviews of path analysis in genetic epidemiology see [25] and [16].

The basic path model for familial resemblance described in what follows can be extended to suit other needs. For example, it is easily expanded to include temporal and developmental variations across time, to assess heterogeneity among multiple studies, and to assess multiple correlated traits simultaneously (i.e. **multivariate analysis**). The complexity of the models depends on the particular need as well as

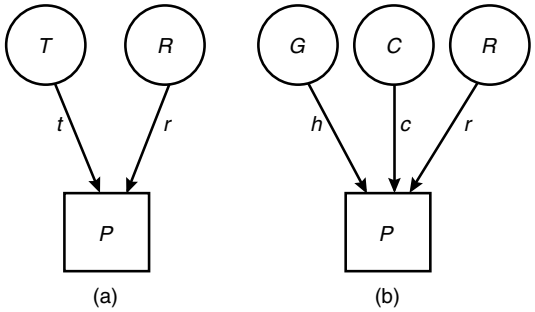

Figure 1 Path diagram for the basic model. Part (a) depicts the generic model involving a combined familial component (T) and a residual (R). Part (b) depicts the specific model with latent genetic (G), familial environmental (C), and residual (R) sources of phenotypic (P) variation in an individual. Path coefficients are defined in the text

the type of data collected and the type of family structures represented in the families.

The Basic Model

At an individual level, one may distinguish between two variations of the basic model (Figure 1). A *generic* model (Figure 1(a)) postulates that the measured variable (the phenotype P) is derived from the additive effects of two sources: the total familial effect, where both genetic and familial environmental effects are lumped together (T), and a residual that is not familial (R). A *specific* model (Figure 1(b)) further splits the total familial effect (T) into a separate genetic effect (G) which is assumed here to be polygenic with additive gene action, and a familial environmental effect (C). The observed (measured) variables are shown in squares and latent (unobserved) variables are shown in circles.

The Generic Model

In terms of the corresponding unstandardized variables (P^*, T^*, and R^*, each with zero mean), the generic basic model may be expressed as

$$P^* = T^* + R^*, \tag{1}$$

where the familial and residual effects are assumed to be uncorrelated. The total phenotypic variance is given by

$$\sigma_p^2 = \sigma_t^2 + \sigma_r^2, \tag{2}$$

where σ_x^2 denotes the variance of X. The components (σ_t^2 and σ_r^2) are called variance components. The basic structural equation underlying this model is obtained by dividing both sides of (1) by σ_p:

$$P = tT + rR, \tag{3}$$

where P, T, and R denote standardized variables, and the standardized partial regression coefficients t and r, called path coefficients, are given by

$$t = \frac{\sigma_t}{\sigma_p} \quad \text{and} \quad r = \frac{\sigma_r}{\sigma_p}. \tag{4}$$

The variance of P in (3) defines what is called the equation for complete determination:

$$t^2 + r^2 = 1, \tag{5}$$

the components of which provide the variance components relative to the total phenotypic variance. Therefore, the components of (2) may be referred to as absolute variance components, while those of (5) may be called relative variance components.

The Specific Model

Likewise, the specific model may be expressed as

$$P^* = G^* + C^* + R^*. \tag{6}$$

Although exceptions exist in the literature (e.g. see [25]), here all three causes are assumed to be uncorrelated with each other and to act additively to produce the phenotype. The corresponding structural equations, absolute and relative variance components, and path coefficients are given by

$$\begin{gathered} P = hG + cC + rR, \\ \sigma_p^2 = \sigma_g^2 + \sigma_c^2 + \sigma_r^2, \\ h^2 + c^2 + r^2 = 1, \\ h = \frac{\sigma_g}{\sigma_p}, c = \frac{\sigma_c}{\sigma_p}, r = \frac{\sigma_r}{\sigma_p}. \end{gathered} \tag{7}$$

Historically, the classic quantitative genetic model postulated that the phenotype was merely derived from the additive effects of genes and (residual) environments, where the environment was totally nonfamilial. This is equivalent to the specific model

without the familial environment (C). The equation for complete determination would reduce to $h^2 + r^2 = 1$. Because all familial effects are then only due to genes, h^2, the proportion of phenotypic variance explained by the genetic component (G), was simply called **heritability**. With the introduction of familial nongenetic effects, vis-à-vis the familial environment (C), some prefer to call h^2 the genetic heritability. Likewise, one may define cultural heritability (c^2) as the proportion of the phenotypic variance explained by the familial environment. In the specific basic model, h^2 and c^2 are the two unknown parameters, since r^2 is readily obtained from (7). If it were possible to measure the underlying genes and environments (G and C), then this model would be identified and we could estimate the heritabilities directly from individual data. However, lacking such measures, we have to resort to indirect methods of estimating them and testing hypotheses about them from particular types of family data.

Path Models for Familial Resemblance

Extending the basic model for an individual (Figure 1) to groups of related individuals (families) involves additional assumptions. These concern specification of marital resemblance and **assortative mating**, transmission from parents to offspring and other effects that are unique to subjects and their relatives. One of the simplest extensions is to nuclear families consisting of parents and offspring, which demonstrate most of the concepts.

Nuclear families are the most frequently used study design for assessing family resemblance, and have the advantage of providing the most representative sample of the population to which the results are to be generalized. However, phenotypic data alone from nuclear families do not provide enough information to differentiate between genetic and family environmental (cultural) sources of family resemblance. Therefore, such data can be used only to assess the combined effect of both genetic and cultural effects. To resolve the genetic and cultural sources of variance, several strategies have been developed which use either additional types of family members such as twins, adoptees, and extended families, or use measured variables to index the latent familial environment.

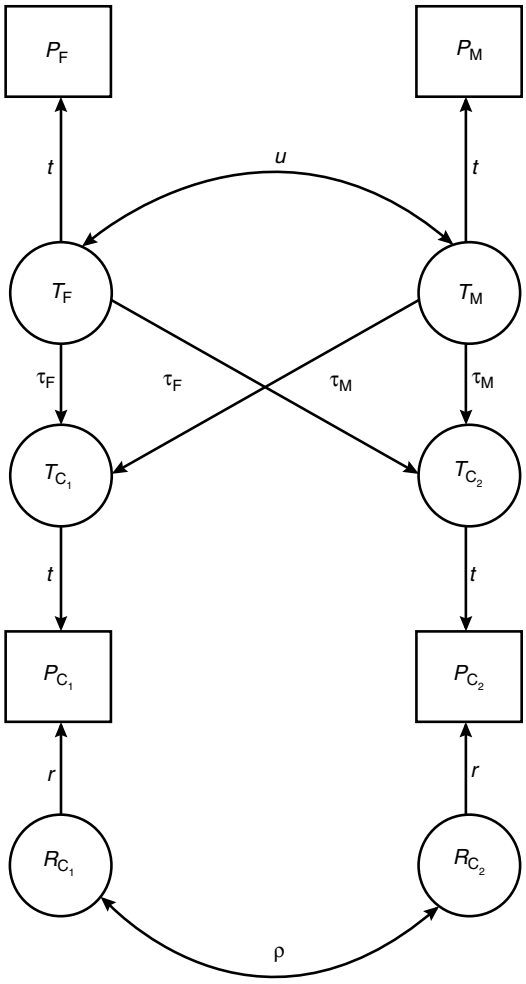

Figure 2 TAU path model of resemblance among relatives in nuclear families. P denotes a phenotype, T indicates transmissible influences, and the subscripts F, M, C_1, and C_2 denote father, mother, and two children, respectively. R denotes nontransmitted residual environment. Path coefficients are defined in the text

Simple Familial Model for Nuclear Families (TAU Model)

In the absence of additional information, the familial components h^2 and c^2 are not resolvable in nuclear families. However, the basic generic model (Figure 1(a)) is useful in this context. This model of familial resemblance, shown in Figure 2, has been termed the TAU model by Rice et al. [37]. The TAU model for nuclear families in Figure 2 depicts a father

Table 1 Expected correlations for nuclear families predicted under the TAU (Figure 2) and BETA (Figure 3) models

Correlation between	TAU model Expected correlations	BETA model Expected correlations
(P_F, P_M)	t^2u	uc^2
(P_F, P_C)	$t^2(\tau_F + u\tau_M)$	$(1/2)h^2 + c^2(f_F + uf_M)$
(P_M, P_C)	$t^2(\tau_M + u\tau_F)$	$(1/2)h^2 + c^2(f_M + uf_F)$
(P_{C_1}, P_{C_2})	$t^2(\tau_M^2 + \tau_F^2 + 2u\tau_M\tau_F) + r^2\rho$	$(1/2)h^2 + c^2\psi$

Note: $\psi = b^2 + f_F^2 + f_M^2 + 2uf_Ff_M$.

(F), mother (M), and two children (C_1 and C_2) yielding four correlations (r_{FM}, r_{FC}, r_{MC}, and $r_{C_1C_2}$). An additional latent residual variable (R) reflecting additional environments shared only by sibs is included in order to account for the possibility that sibling correlations can be higher than parent–offspring correlations. The parameters of the model include: t (the square root of the proportion of phenotypic variance explained by familial factors); u (the correlation between spousal transmissible effects); ρ (the residual sibling correlation); and τ_F and τ_M (the effects of the transmissible factor of fathers and mothers, respectively, on that of a child). Using structural equations or path analysis tracing rules [19], the four correlations can be expressed in terms of the path coefficients, as shown in Table 1. **Maximum likelihood** techniques are then used to estimate the path coefficients and test hypotheses about the model, as discussed later. However, because there is insufficient information in nuclear family data to estimate all five path coefficients, we need to make some additional assumptions. In one case, τ_F may be fixed at the value of 1/2 (expected under polygenic inheritance), and τ_M can differ from 1/2 to allow for maternal influences. Alternatively, if the sibling phenotypic correlation is less than both parent–child correlations, then ρ may be fixed at 0 and both τ_M and τ_F estimated in addition to t and u. Another alternative is the pseudo-polygenic model, where both τ_F and τ_M are fixed to 1/2 and only t, u, and ρ are estimated. It is called pseudo-polygenic because the τs may equal 1/2 due to nongenetic causes as well. Extensions of the TAU model include sex differences in the parameters and alternative sources of spouse resemblance (i.e. social vs. phenotypic homogamy).

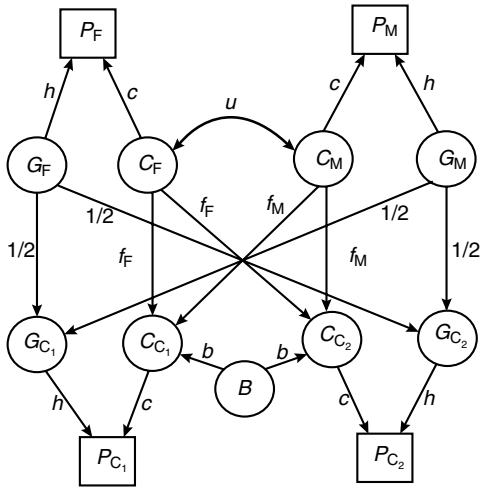

Figure 3 BETA path model of resemblance among relatives in nuclear families. P, G, and C denote phenotype, genotype, and familial environment, respectively. Subscripts F, M, C_1, and C_2 denote father, mother, and two children, respectively. B is the nontransmitted common sibship environment. Path coefficients are defined in the text

Genetic and Familial Environmental Effects (BETA Model)

A more informative model which permits differentiation between the genetic and cultural heritabilities as noted in (7) above is depicted in Figure 3 for nuclear families. This model was termed the BETA model by Rice et al. [37]. As in the specific basic model, each phenotype is assumed to be caused by genes (G), family environments (C), and a residual (R). Also, there is another latent variable (B) reflecting additional shared sibling resemblance. The parameters in the BETA model include: h (square

root of genetic heritability); c (square root of cultural heritability); u (correlation between familial environments of mates); b (additional correlation between sibling familial environments); and f_F and f_M (paternal and maternal, respectively, cultural transmission). Genetic transmission is fixed at 1/2 since each parent transmits half his/her genes to his/her offspring. The correlations expressed in terms of the path coefficients under the BETA model are also given in Table 1 (last column). A more detailed discussion of the BETA model and its theoretical development can be found elsewhere [3, 4, 31–33, 41]. Extensions of the BETA model include intergenerational differences in the genetic and environmental heritabilities (e.g. h^2 in children vs. h^2z^2 in adults), and alternative sources of spouse resemblance.

When nuclear families consisting of fathers, mothers, and children are used, the BETA model is not identified, since there are more unknown parameters (six) than observed correlations (r_{FM}, r_{FC}, r_{MC}, and $r_{C_1C_2}$). There are two basic approaches which have been taken to resolve the BETA model. The first method stays within the basic nuclear family approach and involves introducing additional imputed variables into the model, which generates additional equations and affords resolution of the model. For example, one approach was taken by incorporating the concept of an environmental index measured for each individual in the family, which was assumed to be an imperfect estimate of C [33], thus generating two "observed" variables on each member (the phenotype P and an index I). This provides enormous power for resolution of genetic and familial environmental effects. Unfortunately, unless the indices are based on extensive information, they are known to underestimate the familial environmental effect (c^2) and overestimate the genetic heritability (h^2) [35].

Alternately, extended families or pedigrees provide additional information on other relationships such as uncle–niece, half sibs, and first cousins. While this information helps to fit contemporary path models (such as the BETA model) to analyze the data, it also poses two challenges. First, it is difficult to model cultural transmission adequately for more remote relatives. Secondly, as the degree of relatedness decreases, the information about genetic heritability relies on increasingly larger multiples of small differences in correlations. For these reasons, arbitrarily large pedigrees are not ideal for path analysis. Therefore, when extending nuclear family designs, the benefits associated with increased identifiability should be weighed against the potential error associated with the design. However, nuclear families with twin offspring provide a more appealing design. Several investigators have taken advantage of an even more complex study design involving twins and their spouses and offspring [6, 25].

Simple Twin Model of Family Resemblance

One of the simplest designs capable of resolving genetic and cultural heritabilities is the twin study (*see* **Twin Analysis**). Monozygotic (MZ) twins share all of their genetic material, while dizygotic (DZ) twins are genetically only as similar as full siblings and share half of the **genotype** (*see* **Zygosity Determination**). Assuming that the correlation due to familial environmental effects is identical for both types of twins, the most commonly used estimates of genetic (h^2) and cultural (c^2) heritabilities are: $h^2 = 2(r_{MZ} - r_{DZ})$, and $c^2 = 2r_{DZ} - r_{MZ}$, where r_{MZ} and r_{DZ} are the observed twin correlations estimated from the data. A path diagram of the basic twin model is shown in Figure 4. Each member of the twin pair has his/her their own phenotype (P), genotype (G), and unique or residual environment (R), but the pair shares a common familial environment (C). The additive genetic correlation (path between G_1 and G_2) is 1.0 for MZ and 1/2 for DZ twins. The standardized path coefficients h and c are the square roots of the genetic and cultural heritabilities, and r [derived such that $r^2 = 1 - (h^2 + c^2)$] represents the effect of the unique environment on the phenotype. A powerful (yet rare) design for directly estimating genetic heritability involves the study of MZ twins reared apart (e.g. [22]). Since these twin pairs are assumed to share exactly the same genes and no common environments, the simple MZ twin correlation reflects the genetic heritability.

Adoption Model of Family Resemblance

Adoption studies permit a direct assessment of genetic and cultural heritabilities because, under ideal

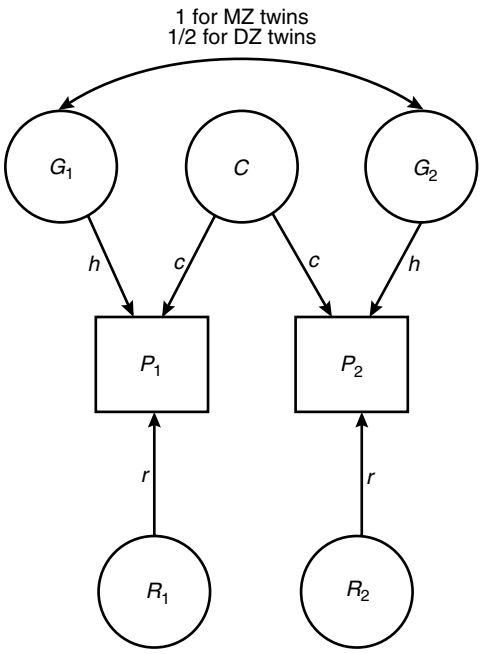

Figure 4 Path model of twin resemblance. P_1 and P_2 are the observed quantitative phenotypes for two members of a twin pair; G_1 and G_2 denote latent additive genetic effects which are correlated (1 for MZ twins and 1/2 for DZ twins); C is the latent familial environment shared by both members of a twin pair; R_1 and R_2 are latent residual environmental influences not shared by the twins. Path coefficients are defined in the text

circumstances, any resemblance between an adopted child and his/her biological parents will be due strictly to genetic effects, and resemblance between an adopted child and adoptive parents (and between adopted siblings) should be attributable strictly to familial environmental effects. In principal, adoption studies are one of the most powerful designs for separating genetic and cultural effects, but in practice full adoption studies are rare, especially those with measurements on the biological father. A noteworthy exception is the Colorado Adoption Project (e.g. [8]). The more common partial adoption studies include those where measures are available only on the adoptee and one set of relatives, usually the adoptive family. While this design allows direct estimation of the cultural effect, critical assumptions regarding selective placement are not testable. An additional crucial assumption is that adoptions take place at (or shortly after) birth so as to preclude any shared environmental resemblance with the biological parents.

Other Developments

Combining multiple family designs into a single approach by using the most informative relationships (e.g. [12]) is one way to overcome the weaknesses of individual approaches. One of the most appealing designs combines nuclear family data with the basic twin design which permits: explicit modeling of complex effects (i.e. separation of genetic and cultural heritabilities); testing critical assumptions (e.g. parent–offspring, sibling, and marital resemblance); and some cross-checks for consistency of the model fit to the data (e.g. see [25]). In one of the more powerful twin-family designs, twins (as well as nontwins) are included as offspring in the nuclear family (e.g. [12]). Another combined approach incorporates data on spouses and offspring of adult twins [5]. Here, the cousins (offspring of MZ twins) are biological half siblings. While these combined designs provide a wealth of information regarding marital resemblance, maternal vs. paternal effects, and sex-linkage, they present difficulties in modeling cultural transmission across the resulting nonnuclear relationships.

Spouse resemblance is a critical aspect in path models (*see* **Assortative Mating**), and if not accounted for can lead to bias in the genetic and cultural heritabilities [24]. Alternate models of spouse resemblance include correlations between the transmissible factors and/or genotypes of mates (called social homogamy; [33]), or between the phenotypes of mates (called phenotypic homogamy), usually modeled as a copath [3]. Models for phenotypic homogamy in the presence of cultural inheritance were developed and studied extensively by Wright [41], Cloninger et al. [4], and Jencks [14]. A path model for generalized assortative mating, called mixed homogamy, was presented by Rao et al. [32], in which both phenotypic homogamy and social homogamy were incorporated. However, distinguishing between these sources of marital resemblance is difficult using only nuclear family data, and additional information such as twins [6] or multiple measurements in the spouses are needed in order to identify the model. Heath & Eaves [11] presented a model involving MZ and DZ twin pairs, their spouses, and offspring which allows one to

estimate all possible sources of resemblance between mates and to test alternative hypotheses.

Temporal and developmental trends have also been explored (e.g. [13, 27, 28, 7], and [30]). Models with temporal changes in genetic and cultural heritability that give rise to changes in family resemblance have been developed for family data (e.g. [13, 27], and [28]) twin data (e.g. [7]) and adoption data (e.g. [26]), and some of these will be discussed later.

It must be clear from the preceding discussion of familial models that we cannot fit any given model to any type of data set. A given model requires certain type(s) of data. For example, even the simple TAU model cannot be fitted to nuclear family data without making additional assumptions. On the other hand, data on MZ and DZ twins alone can resolve genetic (h^2) and familial environmental (c^2) components under certain assumptions. The type of data at hand determines what kinds of questions can be answered by a study.

Statistical Analysis

When dealing with family data of one type or another, the method of choice is maximum likelihood under the assumption that all the observed variables within a family jointly follow a **multivariate normal distribution**. To illustrate the method, let us consider a random sample of nuclear families with variable sibship sizes. Let $\mathbf{X}' = (X_{11}, X_{21}, X_{31}, X_{32}, \ldots, X_{3s})$ denote the row vector of phenotypes for the father (X_{11}), mother (X_{21}), and s children (X_{3k}, $k = 1, \ldots, s$). Assuming that the means and variances are equal for all children, the vector of means ($\boldsymbol{\mu}'$) of $\mathbf{X}'$ is given by (μ_1, μ_2, μ_3) for the father, mother, and offspring, and the corresponding variances are σ_1^2, σ_2^2, and σ_3^2. A correlation matrix ($\mathbf{R}$) is defined as the one that consists of the intercorrelations among all variables in $\mathbf{X}'$. Depending on the model, many of the elements of the correlation matrix can be further equated. For example, in the nuclear family TAU model, there are four independent correlations:

$$\begin{array}{lll} \text{spouse} & \rho(X_{11}, X_{21}), & \\ \text{father–child} & \rho(X_{11}, X_{3k}), & k = 1, \ldots, s, \\ \text{mother–child} & \rho(X_{21}, X_{3k}), & k = 1, \ldots, s, \\ \text{sibling} & \rho(X_{3k}, X_{3l}), & k \neq l = 1, \ldots, s. \end{array} \tag{8}$$

In path analysis, these correlations are expressed as functions of the path coefficients of the model (see Table 1). The covariance matrix ($\boldsymbol{\Sigma}$) is defined in terms of the correlations (or path coefficients) and variances ($\boldsymbol{\Sigma} = \boldsymbol{\sigma}'\mathbf{R}\boldsymbol{\sigma}$, where $\boldsymbol{\sigma}$ is a diagonal matrix of standard deviations).

Assuming that the data vector $\mathbf{X}$ for a given family follows a multivariate normal distribution, the log-likelihood function for the family is given by

$$\ln L = -\left(\frac{1}{2}\right)[\ln|\boldsymbol{\Sigma}| + (\mathbf{X} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu})] + \text{constant}, \tag{9}$$

where $|\boldsymbol{\Sigma}|$ is the determinant and $\boldsymbol{\Sigma}^{-1}$ is the inverse of the covariance matrix $\boldsymbol{\Sigma}$. The total log-likelihood function for a sample is derived by summing across the families. Because the likelihood function is computed separately for each family and the model is fitted directly to the data, a fixed family structure is not required. Therefore, missing data are allowed, as are variable sibship sizes. Parameters of the model (path coefficients, means, and variances) are estimated simultaneously by maximizing $\ln L$. Maximization routines commonly used in genetic epidemiology include GEMINI and ALMINI [17]. Tests of hypotheses are conducted by comparing the log likelihoods across different models. The **likelihood ratio test**, which is the difference between $-2\ln L$ with $k + w$ parameters estimated and $-2\ln L$ when only k of the parameters are estimated, is asymptotically distributed as a $\boldsymbol{\chi}^{\mathbf{2}}$ with w degrees of freedom. The only requirements for this asymptotic distribution are that the reduced model (with only k parameters) must be nested within the more general model (with $k + w$ parameters) and the reduced model must not be on the boundary of the more general model (*see* **Generalized Linear Model**).

The familial sources of variation may also be estimated as variance components (*see* **Genetic Correlations and Covariances**). The maximum likelihood methods described here are formally equivalent for both variance components analysis and path analysis. The advantage of path analysis is that the model is schematically represented, and all assumptions are obvious from examining the diagram. Several computer programs for estimating familial effects using family data are currently available (*see* **Software for Genetic Epidemiology**).

Modeling Assumptions

Implicit in the path models are several assumptions. Linearity and additivity (*see* **Additive Model**) of effects represent two fundamental assumptions. Choice of scale is important for these assumptions to hold, and such a scale may not exist for some variables. Secondary assumptions include the absence of gene–gene interactions (dominance and epistasis (*see* **Genotype**), and **gene–environment interactions**). It is also assumed that the genes and familial environment (partly) determine the phenotype, and not vice versa, and that parental genes and environments determine those of the offspring. While these assumptions may be reasonable for many phenotypes, in some situations they may not be. For example, the phenotype may temporally influence the environment, such as when high blood pressure may modify a person's subsequent lifestyle. Additional assumptions concern the resemblance between parents (*see* **Assortative Mating**). We generally assume that spouses resemble each another only due to their correlated environment (u). However, if spouse selection is based in part on the phenotype of interest, and if there is a partial genetic determination for that trait, then the correlations between parents may also include a genetic component (mixed homogamy). Violations of any of these modeling assumptions can give rise to errors in inference [24].

Maximum likelihood methods require certain distributional assumptions. For example, the assumption of multivariate normality is critical, especially for hypothesis testing which is sensitive to moderate departures from normality [23]. Deviations from normality can be controlled using suitable data **transformations**. Although transformations do not guarantee multivariate normality, they tend to minimize the impact [31].

Nonrandom Samples

The maximum likelihood techniques described for random samples can be used to analyze data that have been collected under an **ascertainment** scheme that provides a selected sample, if adjustment for ascertainment is incorporated into the likelihood function. One method of adjusting for single ascertainment through a proband is by conditioning the likelihood function for a particular family on the phenotypic value of the proband [1]. The conditional likelihood for a family given the proband's phenotype value is then:

$$L(\mathbf{X}|X_{\mathrm{p}}) = \frac{f_k(\mathbf{X})}{f_1(X_{\mathrm{p}})}, \tag{10}$$

where $\mathbf{X}$ is the $(k+1)$-dimensional vector of data for a family, X_{p} is the proband's phenotypic value, and f_k is the k-variate normal density function. This conditional likelihood approach is generally used for any sample of families each of which is ascertained through a single proband, and for that reason is termed the *generic* method [36]. If a particular variable (such as the father's phenotype) is the variable on which selection occurs in every family, then there is no information for estimating the mean and variance of that variable and these parameters must be estimated from other sources.

Additional information regarding ascertainment can be used to increase the efficiency of **estimation** and **power** of hypothesis tests [36]. For example, there are different methods to correct for ascertainment when probands are selected by truncation on the distribution of a phenotype or a correlated trait, such that families of probands whose selection variable lies above a defined threshold are included in the sample (otherwise they are excluded). Provided the region of truncation is known and adherence to the sampling scheme is maintained, then *specific* methods to correct for ascertainment are available and provide more efficient parameter estimates and more powerful hypothesis tests. If the region of truncation is not known and must be estimated, then the generic method and the specific method are approximately equal in efficiency and power. The generic method is computationally simpler and easier to implement and is relatively robust (*see* **Robustness**) to departures from adherence to the truncation sampling scheme.

Another method for adjusting for nonrandom ascertainment was developed by Hanis & Chakraborty [10]. This method yields accurate estimates of parameters for most types of nonrandom sampling, and is robust against departures from multivariate normality. However, it is computationally intensive and provides only approximate tests of hypotheses, and while it can be theoretically applied to multiple ascertainment schemes, the sample sizes required for implementation become impracticably large [34].

Temporal/Developmental Trends

Three kinds of temporal trends may be distinguished for quantitative traits. First, the mean of the population can change systematically over time. These mean effects are relatively easy to detect, and the clinical relevance of such trends quantify how the average individual in the population will change over time.

The second kind of temporal trend occurs when the variance changes over time/age. Such heteroscedasticity with time, a second-order effect, is more difficult to diagnose and is often viewed as a nuisance that must be dealt with rather than an effect of primary interest. Temporal changes in the mean and variance can be dealt with outside of familial models simply by analyzing the residual phenotype after adjusting for age in both the mean and variance.

The third kind of temporal trend manifests in the correlations (or covariances) between related individuals. These trends are more complex because two ages are involved (one for each individual), and are both interesting and important to investigate from a genetic epidemiological point of view. It is natural to ask whether the familial components within the path model framework also vary as a function of time. The presence of secular trends (e.g. increased obesity in the population over time) could be manifesting as intergenerational differences in genetic or cultural heritabilities. Developmental trends, as for example growth spurts characteristic in adolescence before attaining more stable adult values, also may be a function of intergenerational differences in the genetic or cultural heritabilities.

Several models take the approach of assuming a particular temporal structure of the genotype (and environment) that gives rise to the temporal changes in family resemblance [2, 7, 13, 18]. For example, Eaves et al. [7] presented a developmental model that includes one constant pool of genes acting with constant effect throughout all time, and at each time point a specific set of genes that is active at that time and no other. Such a model predicts exponential trends in overall heritability. Boomsma & Molenaar [2] model the genotype (and environment) as a first-order autoregressive process (*see* **ARMA and ARIMA Models**), with each pool of genes depending only on the previous time's pool. This model gives rise to a simplex temporal structure. Each of these models make assumptions about the underlying genetic mechanisms and therefore anticipate a particular kind of temporal change. Other models [27, 28, 30] make no assumptions about the gene action. There is a myriad of alternative genetic mechanisms that can cause temporal variability. For example, there can be a variable lag time between gene action and observed product, or more than one common set of genes acting independently over time, or pools of genes acting with one magnitude of effect at one time and a different magnitude at another time, or environmental triggers of gene action, etc.

A simple extension of path models that incorporates time-dependent effects using cross-sectional family data may be considered for analyzing phenotypes that warrant temporal effects. For example, the basic structural equation in (7) may be extended so that each parameter is made a function of the individual's age (A):

$$P(A) = h(A)G + c(A)C + r(A)R. \qquad (11)$$

It is possible to describe the temporal variability in $h(A)$ and $c(A)$ as continuous functions of age and the two basic parameters at birth (h and c). An important feature of this extension is that it enables testing null hypotheses of alternate forms of temporal trends as well as no temporal variation at all. The simple TAU model has been expanded to incorporate temporal trends in the familial correlations using cross-sectional data [27]. The path coefficients are functions of an individual's age [i.e. $t(A)$ and $r(A)$], and the residual sibling correlation is a function of the absolute age difference between the sibs. The effects of parental transmissible factors on those of their children (τ_F, τ_M) are the same for each child, regardless of age, and the spouse correlation is also assumed to be a constant. The functional forms available for modeling the age trends are chosen such that virtually any shape of trend can be modeled. For example, it is possible to choose a function that permits the **heritability** to increase or decrease monotonically, or to increase (decrease) up to a certain age and then decrease (increase) again to a different value. A detailed discussion of the available functional forms and the justification for their parameterization can be found elsewhere [27].

A restriction in this model based on cross-sectional family data is that the genes, habits, etc. that parents give to their children are constant in their effects over time, although all individuals express these factors in the phenotype to varying degrees as a function of their age at the time [$t(A)$]. However, temporal

models based on longitudinal or repeated measures family data (e.g. [30]) allow for temporal changes in several components, including the mean and variance functions, the transmissibility, the marital residual correlation (which is a function of the cohabitation time), and the sibling residual correlation. In the repeated measures temporal model, the familial and nonfamilial components are modeled as a correlation between the residuals of a pair of repeated measures on the same individual. The later component exists even if the phenotype is nonfamilial. Another feature is that with repeated measures the model is completely resolvable in nuclear families, whereas the classic TAU model and the cross-sectional trend extension are not fully identified.

Multivariate Models

A simple approach for addressing multivariate questions using only univariate path models involves preadjusting one variable for the effects of a second variable using **multiple linear regression**. The residual score from the regression represents the independent effects of the first variable after those from the second have been removed. Comparison of the univariate results prior to and after the adjustment suggests whether the same or different familial factors underlie each of the traits. While this approach is relatively simple to perform, a more informative approach is to analyze correlated variables simultaneously with multivariate methods. Although increased computation is associated with **multivariate analysis**, there are several advantages, including greater power to detect effects, and the ability to resolve bivariate correlations into genetic and familial environmental effects.

Formal multivariate path analysis decomposes the phenotypic covariance of two or more traits into additive genetic and familial environmental correlations. Figure 5 illustrates the path diagram for two correlated traits P_1 and P_2 for the simple case of uncorrelated G and C in an individual. The expected correlation between P_1 and P_2 is

$$r_{P_1P_2} = h_1 r_G h_2 + c_1 r_C c_2, \tag{12}$$

where $h_1 r_G h_2$ is the standardized genetic covariance and $c_1 r_C c_2$ is the standardized environmental covariance. This expression reduces to $h^2 + c^2$ when $P_1 = P_2$.

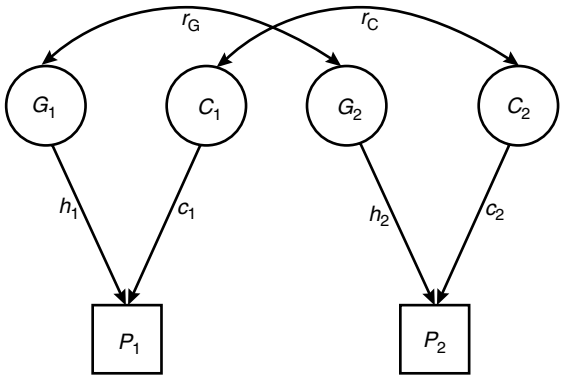

Figure 5 Path model of genetic (G) and familial environmental (C) influences on two correlated phenotypes (P_1 and P_2) measured on the same individual

In the context of path analysis of multivariate family data, the basic structural model is invoked repeatedly for each phenotype, so that the system of linear structural equations defining a multivariate system is given by ($P_i = h_i G_i + c_i C_i, i = 1, \ldots, k$) which can be represented in general matrix formulation simply as

$$\mathbf{P} = \mathbf{hG} + \mathbf{cC}, \tag{13}$$

where $\mathbf{P}$, $\mathbf{G}$, and $\mathbf{C}$ represent ($k \times 1$) column vectors of phenotypic, genetic, and environmental standardized deviations from the mean, respectively; $\boldsymbol{h}$ represents a ($k \times k$) diagonal matrix containing the square roots of the genetic heritabilities of the k traits; and $\mathbf{c}$ is a ($k \times k$) diagonal matrix containing the square roots of the proportions of phenotypic variance that are attributable to the environment.

The structural equation is used to derive the matrix of expected covariances within individuals, or the phenotypic correlation matrix $\mathbf{R}_P$:

$$\mathrm{E}(\mathbf{R}_P) = \mathbf{hR}_G\mathbf{h}' + \mathbf{cR}_C\mathbf{c}' + \mathbf{hsc}' + \mathbf{cs}'\mathbf{h}', \tag{14}$$

where $\mathbf{R}_G$ is the matrix of correlations among the genotypes for each variable within an individual, $\mathbf{R}_C$ is the environmental correlation matrix, and $\mathbf{s}$ is a full, nonsymmetric matrix consisting of the genotype–environment correlations among all measures.

In the context of a family design, the algebraic derivations for expected correlations among relatives are essentially obtained by using the univariate

model. However, each variable in the diagram represents not a single measure, but a $(k \times 1)$ column vector of measures, and path coefficients represent $(k \times k)$ diagonal matrices of path coefficients. Tracing rules for multivariate diagrams is straightforward, consisting of the conventional path analysis rules [19] with extensions developed by Vogler [39].

There is little difference between the analysis of multiple phenotypes measured simultaneously and the analysis of the same character in an individual at different points in time. When multiple measures are obtained at discrete points that are identical for all individuals, the multivariate methods presented here can be applied directly to developmental or longitudinal data.

Combined Path Analysis

Many traits are multifactorial and complex in the sense that there are a number of genetic and/or nongenetic determinants. For each of these traits it is highly unlikely that anything close to "the gene" will ever be discovered that explains most of the variation for that phenotype and solves the whole puzzle. Instead, the genetic component of many of these traits is expected to be in the oligogenic (few genes) to polygenic (many genes) range. What we know so far leads us to expect an elaborate interplay between many factors in the development of the phenotypes, including gene–gene and gene–environment interactions. While much analytic progress can be made using the standard genetic tools of path analysis, **segregation analysis**, and **linkage analysis**, a combined approach is potentially more powerful and holds great promise for these traits. Indeed, a combined approach may be the only way to disentangle the interplay of the multiple underlying processes. The utility of this approach has been demonstrated through combined segregation and path analysis.

The general model [29] includes both a segregation component (g) and a multifactorial path model component (m), as well as fixed effects (f), so that the phenotype (P), univariate or multivariate, is determined by

$$P = g + m + f + r, \qquad (15)$$

where r is the residual. In this formulation g can denote any number of major genes, with whatever pleiotropic effects they may have on the (multivariate) phenotype(s), and m denotes an arbitrary path model so that m may be a linear expression with many terms containing multiple heritable components. Likewise, f represents any number of fixed covariate effects (e.g. sex, age, measured genotypes). Eq. (15) defines a set of regression equations for each person in a pedigree that are then linked via both m and g. **Interactions** among effects (e.g. $g \times f$) can be included in the model. No distributional assumptions need be made about observable fixed effects such as sex. The segregation portion of the model is an independent additive term in the regression equations, above and beyond any specified by the path analysis part of the combined model. For models with a segregation component, the log likelihood of each pedigree is partitioned as a sum of conditional probabilities over every possible latent genotypic vector. With large numbers of subjects per pedigree, however, an exact likelihood formulation can be impracticable to compute. Finally, considerable progress has been made in combining path and regressive models by extending the regressive models to incorporate the simple TAU model [21] as well as the BETA [20] model.

Conclusion

Going from genes and their products to the expression of normal variation involves a leap of faith, and complex statistical procedures are often necessary to demonstrate a relationship between the two. Here we have discussed one such procedure (path analysis) that attempts to relate the observations to the underlying determinants.

Important considerations include alternate family designs (e.g. families, twins, adoptions) as well as alternate models of family resemblance (e.g. univariate, multivariate, TAU or BETA, marital resemblance, temporal trends). The increasing availability of computer programs that empower the genetic epidemiologist to create appropriate models to fit their data, instead of forcing their data to fit existing models, is particularly helpful in testing alternate modes of genetic and cultural transmission. The relatively new approach of combining models (e.g. path and segregation analysis) should yield new insights into determining how the multiplicity of causes underlying a phenotype are interrelated. Figure 6 illustrates a possible scenario for complex phenotypes

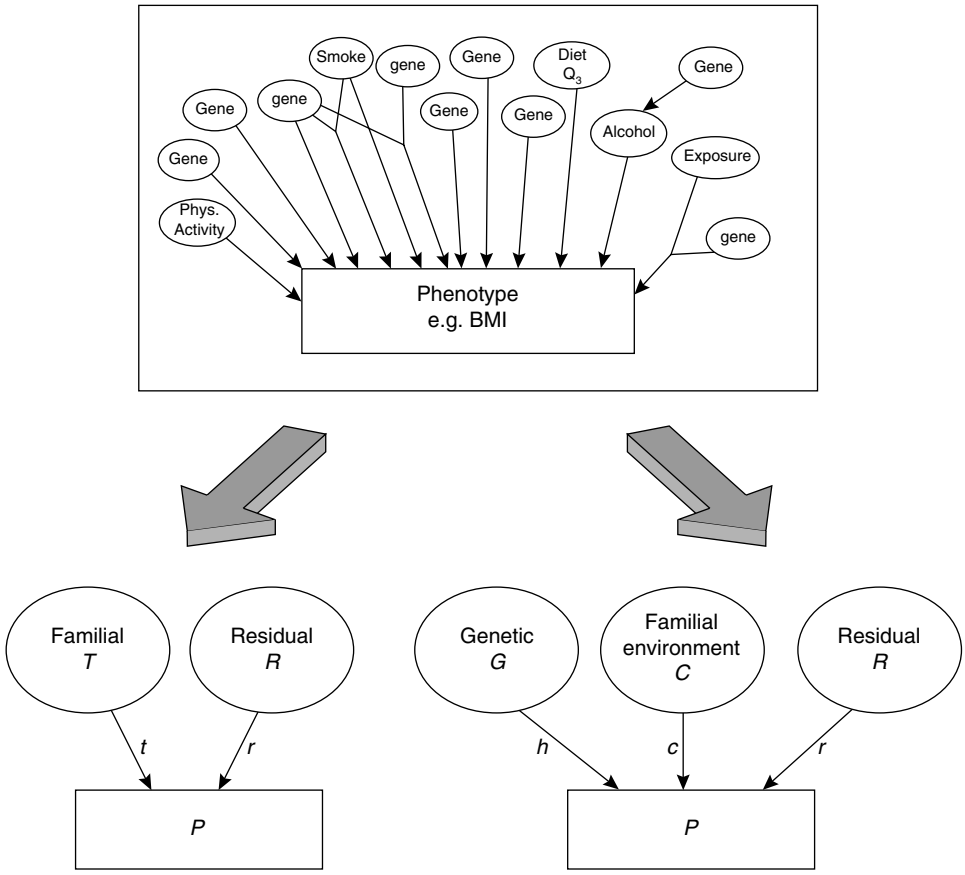

Figure 6 Hypothetical model of the underlying genetic and environmental factors giving rise to a complex phenotype. Modeling approximations are shown at the bottom

using body mass index (BMI) as an example. The figure illustrates how complex phenotypes are determined by multiple genes, multiple environments, and interactions among them. The complicated reality is often approximated by simple and feasible models, as shown at the bottom of Figure 6. Path analysis offers a promising method for disentangling these underlying causes by formulating simple refutable hypotheses.

Path Analysis

Path analysis is a statistical methodology that begins with a model. Each model consists of a system of equations and assumptions about the relationships between a set of variables. The variables can be *observed, latent* (unobserved), or *disturbances* (errors). In some applications the observed variables are nonstochastic, but in nearly all models the latent and disturbance variables are **random variables**. The hypothesized model originates with the researcher. Path analysis provides an **algorithm** for understanding the direct, indirect, and total effect of one variable on another in this hypothesized structure. It also allows a test of whether the hypothesized model is consistent with the covariances **(correlations)** of observed variables. A lack of fit (*see* **Goodness of Fit**) is an indicator of an error in model specification (*see* **Misspecification**). A "good" fit lends plausibility to the model, but it does not rule out the possibility of other models with as good, or superior, fits.

Path analysis was invented by Sewall Wright in graduate school. His first publication using the method was in 1918 [12]. One of the most common misunderstandings about path analysis is the belief that it is a tool to "discover" causal relationships (*see* **Causation**). This critique accompanied the introduction of path analysis and periodically appears in the contemporary literature. Wright explicitly denies this in several places: ". . . the method of path coefficients is not intended to accomplish the impossible task of deducing causal relations from the values of the correlation coefficients" [15, p. 193]. Instead, Wright describes path analysis as a method that

> depends on the combination of knowledge of the degrees of correlation among the variables in a system with such knowledge as may be possessed of the causal relations. In cases in which the causal relations are uncertain the method can be used to find the logical consequences of any particular hypothesis in regard to them [13, p. 557].

Thus, path analysis is best seen as a method to test the implications of a given model structure.

The primary components of path analysis are: (i) the path diagram, (ii) the estimation of path coefficients, and (iii) the decomposition of effects. The next sections provide details on each.

Path Diagrams

Path diagrams are *pictorial or graphical representations of a system of equations and assumptions* (*see* **Graphical Displays**). The diagrams are most useful for the analysis of two or more equations that link observed or latent variables and disturbances or errors to each other in a system. The path diagram is easy to interpret and it readily reveals relationships that might be missed if viewing only the equations of a model. Furthermore, the tracing of effects across variables also is made easier with the diagrams.

Figure 1 contains standard and some nonstandard notational conventions in path analysis. A basic distinction between the variables is whether they are latent (unobserved), observed, or disturbance (error) variables. Each observed variable is enclosed in a box. Latent variables appear in ellipses or ovals. Disturbances are not enclosed in either, although some researchers place disturbances in ovals to signify that they are latent.

Other symbols are best illustrated by way of examples. Figure 2(a) is the path diagram for a multiple **regression** equation with four **explanatory variables** and one dependent **response variable**. The straight line with multiple arrow heads coming down from it and pointing to the X_1 to X_4 variables indicates that each pair of variables is associated. The reason for their association is not explained by the model. In the language of econometrics, these are correlated exogenous variables.

Each straight single headed arrow signifies the influence of an X on Y_1. The coefficients corresponding to these paths are the *path coefficients*. Originally, Wright used path coefficients that were equivalent to what are commonly called standardized regression coefficients. The standardized coefficient is the product of the unstandardized coefficient times the ratio of the standard deviation of the explanatory variable to the standard deviation of the "dependent" variable. Now it also is common to use unstandardized regression coefficients in path diagrams. The final symbol in Figure 2(a) is the disturbance, ζ_1, that summarizes the other influences on Y_1 besides those of the Xs. Exogenous variables or disturbances (errors) that are not connected by two-headed arrows are treated as having no linear association. Thus, the lack of two-headed arrows linking ζ_1 and the Xs represents the usual multiple regression assumption that the disturbance is uncorrelated with the explanatory variables.

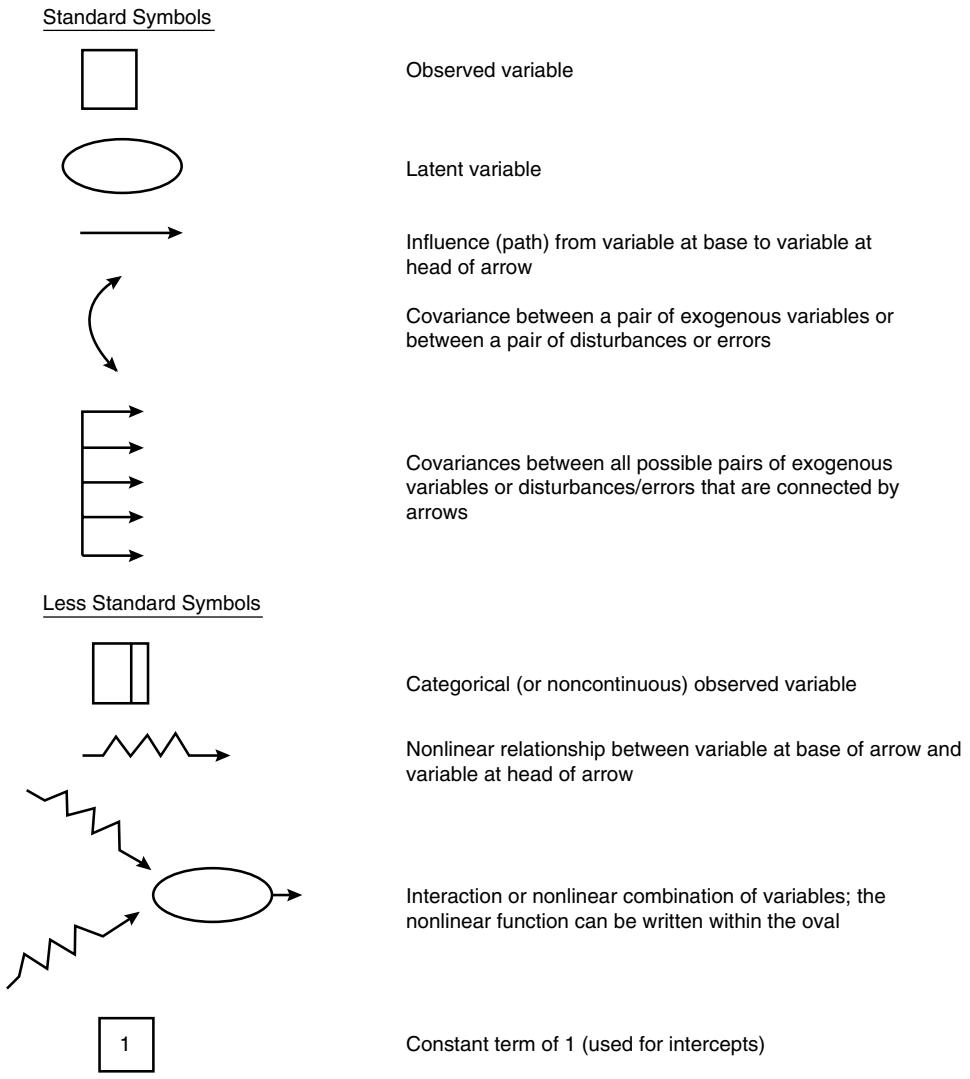

Figure 1 Symbols for path analysis

Figure 2(b) contains an example of a simultaneous equations model. The equations that correspond to this path diagram are:

$$Y_1 = \alpha_1 + \gamma_{11} X_1 + \zeta_1,$$
$$Y_2 = \alpha_2 + \beta_{21} Y_1 + \gamma_{22} X_2 + \zeta_2,$$
$$Y_3 = \alpha_3 + \beta_{31} Y_1 + \beta_{32} Y_2 + \zeta_3,$$
$$\text{cov}(x_k, \zeta_i), \qquad \text{cov}(\zeta_i, \zeta_j) \neq 0,$$
$$\text{E}(\zeta_i) = 0, \qquad i, j = 1, 2, 3 \text{ for } i \neq j, k = 1, 2.$$

The β and γ coefficients correspond to the straight, single-headed arrows. Sometimes these coefficients are placed on the arrows in the diagram. The αs are equation intercepts. They often do not appear in a path diagram to avoid cluttering the figure. The curved arrows indicate correlations among the exogenous variables. These are not explained in the model. Although econometricians rarely use path diagrams, they have considerable experience with simultaneous equation models such as this.

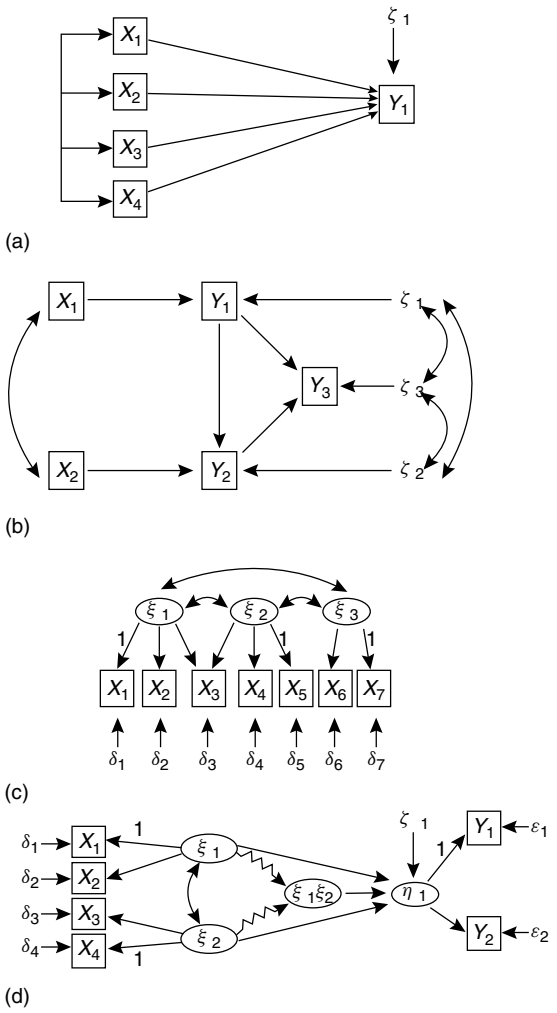

Figure 2 Examples of path diagrams. (a) Multiple regression; (b) simultaneous equation model; (c) confirmatory factor analysis; (d) general model with product interaction of latent variables

A factor analysis example is given in Figure 2(c). The three latent variables (the ξs) are in ovals. The indicators of the latent variables are the X variables that are in boxes. Errors of measurement (δs) are unenclosed. The lack of two-headed arrows connecting them to each other or to the latent variables signifies the assumption that these variables are uncorrelated.

The final illustration of a path diagram is a more complicated general model [Figure 2(d)]. This model has both a latent variable structure that allows the latent variables to influence each other and it has a measurement model linking the measures to the latent variables that influence them. In addition, this model includes a product interaction of latent variables. The nonlinear function of the latent variables that forms the interaction term is inside the middle oval in the diagram. The nonlinear linkage of variables is diagrammed with a saw-toothed, single-headed arrow from its components to the product latent variable.

Researchers can construct a wide variety of other path diagrams from the basic symbols given in Figure 1. In all cases the diagram is just an alternative to a system of equations and assumptions that show the relationship between variables in a model.

Estimation of Model Parameters

Wright originally used the path diagrams as an aid to writing the variances and covariances of the observed variables in terms of the parameters of the model. The parameters included the coefficients in the equations as well as the variances and covariances of the exogenous variables and disturbances (errors). He then would solve for the model parameters in terms of the variances and covariances of the observed variables. Contemporary estimation procedures are more sophisticated and use **maximum likelihood** and **least squares** methods (*see* **Structural Equation Models** for more details).

Decomposition of Effects

Path analysis makes a distinction between the direct, indirect, and total effects of one variable on another. The direct effect is the influence of one variable on another that is not mediated by any other variable that is part of the model. It corresponds to the coefficient of a variable in the original structural form of an equation. The indirect effect is the effect of one variable on another that is mediated by, or passes through, at least one other variable in the system. The total effect is the sum of the direct and indirect effects. In the special case of simultaneous equation models, the total effect equals the reduced-form coefficients that econometricians use.

Figure 2(b) is useful for illustrating these definitions. The variable X_1 has a direct effect on Y_1 of γ_{12} and X_1 has zero direct effect on Y_2 and Y_3. The indirect effect of X_1 on Y_2 is $\gamma_{11}\beta_{21}$, the product of the

paths that connect these variables. The X_1 variable has two indirect paths to Y_3: $\gamma_{11}\beta_{21}\beta_{32}$ and $\gamma_{11}\beta_{31}$. The total effect is simply the sum of the direct effect and all the indirect effects. Since the X_1 variable has zero direct effect on Y_3, its total effect on Y_3 is the sum of its indirect effects, i.e. $\gamma_{11}\beta_{21}\beta_{32} + \gamma_{11}\beta_{31}$.

The decompositions of effects in the multiple regression in Figure 2(a) or the confirmatory **factor analysis** of Figure 2(c) are less interesting since all the effects are direct effects. Figure 2(d) with the interaction of latent variables complicates the decomposition since in such models the influences of the component variables in the interaction depend on the value that the other components of the interaction take. See Stolzenberg [11] for guidance on interpreting the decomposition of effects in models with interaction terms.

Several issues surround the discussion of the decomposition of effects. First, general formulas exist for the decomposition of effects [7] (*see* **Structural Equation Models**) or for finding the effects that operate only through specific variables in the system [3]. Secondly, the decomposition of effects is always with respect to a specific path model. If a researcher adds intervening variables between two variables that previously had a direct relation, then in the new model this new link would be indirect. Thirdly, definitions of the decomposition of effects differ among authors when unanalyzed associations between exogenous variables or disturbances are in the model (e.g. [5]). Two-headed arrows connecting variables signify that the association between these variables is not explained by the model structure. This creates ambiguity in understanding the effects that might occur with a change in an exogenous variable. For instance, in Figure 2(b) the X_1 and X_2 exogenous variables have a linear association, but we do not show the reason for that association in the path diagram. If, in reality, X_1 affects X_2, a shift in X_1 will lead to real influences beyond those estimated with the decomposition of effects given above. In the decomposition of the covariance (correlation) between two variables into its structural components (see the section "Implied Covariance Matrix" in **Structural Equation Models**), terms that involve the covariance (correlation) of exogenous variables or disturbances are sometimes called *spurious effects*. A final issue to consider is that there is some work that has redefined the decomposition of effects to conform to specific definitions of causality that involve the manipulation of variables in the model. These definitions can lead to different decomposition formulations than those described here [9].

Sewall Wright's Contributions with Path Analysis

Wright's applications of path analysis led to many innovations. His first application in 1918 modeled size as a latent variable that underlied the dimensions of rabbit bones [12]. His latent variable analysis was developed without knowledge of Spearman's [10] article that independently proposed factor analysis. In 1925, Wright [14] employed path analysis to estimate a longitudinal **panel** analysis with latent variables in a study of corn and hog associations. This was decades before similar models would become more commonplace in the social sciences. Goldberger [6] suggests Wright's use of path analysis in supply and demand models was a forerunner of the simultaneous equation approach later developed by econometricians. The influence of Wright's path analysis on sociometrics is clearly seen in the many sociological publications on the technique that began to appear in the 1960s and 1970s (e.g. [1, 2], and [4]). Provine's [8] biography documents Wright's many contributions to evolutionary biology.

Since Wright's early work, the path analysis technique has evolved in many directions. Its current form is best represented in **structural equation models**. These models and path analysis arc widely known in the social sciences and are receiving renewed interest in the biological sciences.

Pattern Recognition

The term *pattern recognition* refers to a technology that recognizes and analyzes patterns automatically by machine. Human beings are of course subjective experts in both the discernment and imposition of patterns in nature; pattern recognition by machines commonly excludes gestalt theory, although figure/ground phenomena and other aspects of sensory perception are common to both. The present brief treatment of various topics in pattern recognition favors breadth over depth, application over theory. Pattern recognition has been employed successfully in many areas of application including optical character recognition, speech recognition, face recognition, remote sensing (sonar, radar, and satellite), mining, and medical image processing (*see* **Image Analysis and Tomography**). Specific examples include automatic reading of addresses and postal codes, both machine- and handwritten; training a programmable computer chip to recognize its owner's voice in executing a limited command vocabulary; employee identification through video camera security systems; classification of picture elements (pixels) as containing water, land, or ice in a satellite image of the earth's surface; tracking cracks and fissures in geological core samples; breast cancer detection in digital mammography (*see* **Screening, Overview**); karyotyping for identification of chromosomal abnormalities; detection of ventricular fibrillation; and semiautomatic classification of volume elements (voxels) in human brain images as representing white matter, gray, matter or cerebrospinal fluid. Data in all of these cases are multivariate objects consisting of one-dimensional temporal waveforms, two- or three-dimensional images in space, and four-dimensional **time series** of image volumes. Pattern recognition involving automatic scene analysis is also known as image understanding and computer vision [7]. Relevant temporal/spatial patterns (signals) are often obscured by irrelevant detail (noise). In addition to analyzing differences in signal intensity and contrast, pattern recognition also employs color, shape, and texture gradients, as in counting and categorizing different types of white blood cells for instance. Statistical models for pattern recognition problems help to decide what is and is not relevant and take advantage of some form of averaging and aggregation across replications when possible and advisable to reduce extraneous sources of variance and thus increase signal-to-noise ratio. While pattern recognition techniques are widely used, many are patented and only available commercially. There do not yet exist definitive solutions to any one of the aforementioned general problems.

Relatives of Pattern Recognition in Other Fields

In biostatistics, pattern recognition is not as well established as in engineering and industrial applications, yet its status is changing as biostatisticians participate in continued cross-fertilization with these and other disciplines. The reasons for the relative paucity of pattern recognition applications in biostatistics to date may involve preferences in engineering and industry for certainty over uncertainty, determinism over randomness, in applications that do not seem to warrant formal statistical **inference**. While the availability of massive amounts of data may indeed favor deterministic **algorithms** and reduce the need for classical distributional assumptions in some cases, statistical models of uncertainty and inference continue to play a central role in pattern recognition. Some authors use the term *statistical pattern recognition* to describe the line of research that probes structure and pattern in very large data sets without recourse to classical assumptions that may be too inflexible for practical use. Yet there do not appear to be major differences between statistical pattern recognition and pattern recognition *per se*. What differences, then, exist between pattern recognition and its relatives: **artificial intelligence**, expert systems, artificial **neural networks**, and machine learning?

Artificial intelligence is "the science of making machines do the sorts of things done by human minds" [3]. Expert systems "attempt to organize the knowledge of human experts in [a] particular field. . . [and] contain domain specific knowledge" [6]. An artificial neural network is "a massively parallel distributed processor that has a natural propensity for storing experiential knowledge and making it available for use" [1]. Machine learning is "generally taken to encompass automatic learning procedures based on logical or binary operations that learn a task from a series of examples" [15]. A distinguishing characteristic of pattern recognition is perhaps that no direct analogy is made in its methodology to underlying biological processes, animal or human brains and

minds, real or imagined. Pattern recognition appears most closely related to machine learning, **decision theory**, and **information** theory, all of which rely heavily on statistical theory and methods. In fact, the related fields cited here have their origins in multidisciplinary interactions between engineers building pattern recognition machines, biologists, mathematicians, psychologists, and statisticians. Statistics is one of the oldest fields to study pattern recognition problems and has perhaps seen the greatest duplication of its approaches in other fields [6].

Classification

"Recognition" often means **"classification"**. In optical character recognition, for instance, automatic algorithms are used to classify intensity patterns in a scanned digital image of a printed page as members of an alphabet of allowable characters. Figure 1 is a portion of text, from [21], that has been scanned, blurred, and degraded with different types of noise. A commercial optical character recognition algorithm, set at default values of tuning constants, recognized italics as italics and correctly classified 98.7% (221/224) of the characters in the original, sharper image. Instances of errors were "machrnes" and "recogmtion". The process took 2 seconds (112 characters per second) on an IBM-compatible PC with a Pentium® 133 MHz chip. While a 1.3% error rate may be unacceptable in certain cases, as in automatic processing of lottery tickets for example, it is perhaps surprising that an off-the-shelf computer program could do so well with no tuning or training whatsoever. An automatic spell-checker, another pattern-recognizer, could have made good guesses in replacing these nonwords to achieve a perfect match.

There is a subject known as machi
from the artificial intelligence and comp

Figure 1 Optical character recognition is one example of pattern recognition; text source, [21]

Adding a small amount of Gaussian **noise** to the original image and repeating the optical character recognition task, without retaining any information on this particular set of characters from the previous run, resulted in slight degradation of results (adding "superrised" and "mtelligence" as errors). Blurring the image slightly yielded similar results; adding simulated dust and scratches doubled the processing time and decreased accuracy to 90.6% (203/224). With such good performance, it may also be surprising that none of the characters in the degraded image in Figure 1, which includes Gaussian noise, blur, dust, and scratches, was able to be classified correctly by the machine. A human reader can easily obtain a perfect, meaningful classification. Although a more finely tuned test could surely have done better, this small experiment demonstrates that, in pattern recognition, subjective (prior) knowledge plays an important role and that adding noise to a signal is not necessarily an invertible process. Another example of the current necessity of subjective human judgments is in the classification of pixels in human brain images as white matter, gray matter, or cerebrospinal fluid, the application mentioned in the introduction. While sophisticated and highly successful pattern recognition algorithms exist to get the job done, this task remains at best semiautomatic, requiring a technician to clean up and make sense of automatic results that are not realistic despite all efforts to the contrary by neuroscientists building the tools. Nonetheless, a job that would take hours if done manually takes minutes if done semiautomatically. A major attractive feature of pattern recognition is its ability to yield objective, automatic, and rapid results. Tedium and human error in repetitive, routine tasks can often be removed automatically by designing and implementing clever algorithms. Errors can be further reduced through screening of results by human operators in a multistage process of quality control.

Feature Detection, Extraction, and Classification

Classical pattern recognition proceeds in two stages, feature detection and extraction followed by classification. Pattern features, such as the number of closed loops in hand-written characters, are detected and extracted at a first stage. **Principal component analysis** and singular value decomposition (*see* **Matrix**

Computations) are examples of dimension reduction techniques that are often used in pattern recognition as preprocessing strategies for feature extraction (*see* **Reduced Rank Regression**). At a second stage, vectors of features, the dimensions of which are usually much lower than those of the original multivariate objects, are classified and a decision is made (e.g. "This is a valid alphanumeric string"). Modern pattern recognition involves bi-directional feedback and iteration between these two stages. The classifier adapts itself to subtleties of detected features, creating new features to be extracted, classified, refined, and so forth. Instead of detecting a fixed list of features according to fixed rules, new classes are spawned and eliminated as dynamic algorithms adapt to local data characteristics. These dynamic algorithms may be either entirely deterministic or include a random component. Features and their classifications can also be arranged in dynamic hierarchies and dependency relationships, such as characters, words, sentences, paragraphs, etc. These hierarchies are traversed and altered, either bottom-up or top-down or both, according to some **goodness-of-fit** criterion, to converge at some final pattern classification and ultimate decision.

Invariants and Deformable Templates

One important property of feature detectors and classifiers for pattern recognition is their invariance with respect to minor pattern distortions or deformations. In the optical character recognition example, placements of characters on the page should not matter much, for an "r" is generally an "r" regardless of its orientation. Identification of invariants constitutes important prior knowledge of the problem at hand. Such invariance (in this case, translation, rotation, and scale), as well as other forms of invariance (such as reflection), suggest a class of deformable template models. In deformable template approaches to pattern recognition individual instances of a particular class of objects of interest are represented as deformations of an archetypal, template shape, or form, or texture, etc. from which they all derive according to some specified mechanism, usually a random one. All machine-written or hand-written instances of "r" are seen as distorted instances of some common template for "r", all triangles share common properties that qualify them as members of the geometric class "triangle", all normal electrocardiograms are modeled as perturbations of the same basic waveform of a normal template electrocardiogram, and so forth (*see* **Clinical Signals**). Identification of invariants to be preserved from one instance to the next is a key component in the design of modern pattern recognition systems. Such identification suggests how multivariate objects are best represented as input to the algorithm for the first-stage feature detection and extraction mentioned previously. Until the late 1980s, for instance, most text recognition consisted of matrix matching methods in which a data matrix of 0s (for white) and 1s (for black) containing a particular character was matched with the best fitting matrix from a fixed library of font-specific character shapes. One approach to optical character recognition in the 1990s consists of passing the data matrix containing a character (getting to this point is a major problem in itself) through a series of machine "experts", one for each possible character, that seek to detect the presence of features that are invariant to irrelevant transformations, such as font changes, minor pixel shifts, etc. within the group defining their character class. As another example, in the analysis of human growth, triangles of landmarks for developing structures can be located on two-dimensional images collected over time for each subject and the changing patterns of shapes recognized and analyzed statistically. Shape changes may in some cases be invariant with respect to changes in size. A pattern recognition algorithm for classification could then represent these triangles, with size removed, by two of their interior angles. In general, the best results from pattern recognition systems appear to be those built by human subject-matter experts who have worked out important features and their invariants in painstaking detail and have embodied this knowledge in clever algorithms. Yet this is should come as no surprise, since in biostatistical science detailed substantive models, when available, generally outperform rote, empirical ones.

Learning from Examples: Supervised and Unsupervised Learning

Pattern recognition is an exercise in learning from examples. Under supervised learning, the machine is given a labeled collection of examples. In optical character recognition, for instance, examples of scanned alphanumeric data along their correct character assignments are used to train the algorithm to

recognize pattern features in data that are indicative of particular characters and hence to assign character labels to new test data correctly. This training usually involves some form of **cross-validation**. Unsupervised learning, which occurs less frequently in practice, refers to a pattern recognition exercise that does not involve preassigned labels in either training or test phases of algorithm development. The emphasis in unsupervised learning is on the discovery of new groupings and common characteristics amongst previously unclassified ensembles of examples.

Linear Discriminant and Nearest Neighbor Rules: The Curse of Dimensionality

Pattern recognition systems built according to well-established criteria from statistical decision and information theory are known to outperform systems built using *ad hoc* methods. A **loss function** is defined through consideration of losses incurred by making different sorts of classification errors, such as the **false positives** and **false negatives** of medical diagnoses. A classification rule is then chosen which minimizes total risk, i.e. total expected loss, when assigning class labels. When classification probabilities are assumed to be known, the best that a pattern recognition system can do is determined by Bayes' rule, minimizing Bayes' risk (*see* **Bayesian Methods**). Criteria for label assignment can be parametric or nonparametric. When feature vectors have been generated by **multivariate normal** (Gaussian) **distributions**, with different means yet a common variance–**covariance matrix**, then the optimal classification (Bayes) rule that minimizes total **Mahalanobis distance** is the well-known linear discriminant function (*see* **Discriminant Analysis, Linear**). (Note the distinction between this pattern recognizer and Fisher's linear discriminant, which instead maximizes the ratio of between-class to within-class variance.) Many other parametric, **likelihood**-based classifiers exist. Nonparametric, nearest-neighbor pattern recognition assigns labels to new examples by measuring distances to their nearest neighbors under some particular metric. Metrics for determining nearness may be either fixed or adaptive, Euclidean or non-Euclidean. Class labels are determined by assigning a new example to that class that minimizes the combined distance from the example to a fixed number k (much lower than the total number of examples) of previous examples of that same class over all possible class assignments. When $k = 1$, and for feature vectors of dimension $p \geq 2$, nearest-neighbor pattern recognition is equivalent to Dirichlet tessellation or tiling of the feature space. When $k = 1$ and $p = 2$, nearest-neighbor rules produce a feature space tiling by what are also known as Voronoi or Theissen polygons [21]. Linear discriminant, nearest-neighbor, and other pattern recognition rules, whether parametric or nonparametric, can be extended to allow for reject options or doubt probabilities for uncertain classifications. When p is large, pattern recognition is subject to the so-called curse of dimensionality, i.e. the inability in high-dimensional spaces to obtain enough examples to pack the feature space densely. All examples are close to an edge rather than uniformly spread throughout that space, and thus geometric intuition gained from low-dimensional problems is often inapplicable [8]. The curse of dimensionality is particularly vexing because it may be the extremely high dimension of a multivariate problem that recommends it for treatment by pattern recognition techniques to begin with. There appears to be no substitute in the applied pattern recognition problems of biostatistics for careful selection and representation of the most important features of interest, for incorporation of prior knowledge whenever possible, and for careful checking of results from automatic algorithms by end users.

Prediction and Generalization: Bias/Variance Tradeoff

The construction of pattern recognition systems and the evaluation of their performance usually involves some form of prediction. One way to assess the predictive performance of a pattern recognizer is to estimate its generalization ability, that is, how well it performs on an entirely new set of examples (test set) after having recognized patterns in previous, similar examples (training set). Some form of bias/variance tradeoff in algorithm design is required to avoid too much variance, or overfitting, on the one hand, and too much **bias**, or underfitting, on the other. This is a type of model selection. For a fixed number of examples, bias/variance tradeoffs within nested families of models (*see* **Hierarchical Models**) relate to algorithmic complexity: if a pattern recognizer is too simple, then it is biased and makes systematic prediction

errors, whereas if it is too complex, then it will make unreliable predictions. An additional and somewhat complementary way of assessing predictive performance is to fix algorithmic complexity and to graph generalization error as a function of training set size. This produces a learning curve which, in general, is a monotonically decreasing function. Repeating this exercise for a pattern recognizer of different complexity enables a comparison: when learning curves for two algorithms cross, one outperforms the other for small vs. large numbers of examples.

Layered Feed-forward Networks and Their Equivalent Statistical Models

Artificial neural networks embody many key pattern recognition ideas and principles. The artificial neural network school gained a large following in the 1960s and 1970s, dwindled somewhat in the late 1970s and early 1980s, and is experiencing a resurgence in the 1990s. Many of the ideas and principles of artificial neural networks are common to biostatistical sciences, although sometimes under different names. Figure 2 depicts perhaps the simplest artificial neural network, the McCullough–Pitts neuron, or single-unit perceptron [5, 13], whose algebraic formula is $y = \text{sign}\left(w_0 + \sum_{i=1}^{p} w_i x_i\right)$, where sign$(\cdot)$ equals $+1$ if its argument is nonnegative and -1 otherwise. This artificial neural network is a type of multiple linear regression of y on $x_1, \ldots, x_p$ with unknown weights (parameters) to be estimated and without any formal error term (although many can of course be specified at this point). This pattern recognizer is not ordinary **least squares** regression but rather some form of discriminant analysis with an indicator variable,

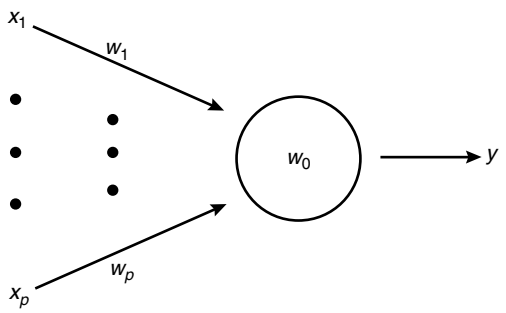

Figure 2 This pattern recognizer is a simple form of artificial neural net [5]

y, as the output of the "neuron" modeled as a linear function of its inputs, the xs, which are themselves indicator variables. The neuron "fires" or does not fire depending on whether or not the summation is positive. Networks of artificial neurons such as these are constructed by forming interconnected banks of such elements with xs feeding into every such node, such as the circle in Figure 2, and the outputs of these nodes feeding into similar nodes at another level, and so forth. Such an arrangement is a layered feed-forward neural network or, equivalently, a multilayer perceptron [10]. This toy example shows that, in one sense, artificial neural networks "can be regarded as a graphical notation for specific regression and classification techniques" [18]. Layers in between input and output are called *hidden layers* since they are not observable directly. Nodes at the same level are not connected to one another directly in a feed-forward net; otherwise, the construction is a recurrent net, Hopfield net, Boltzmann machine, or associative memory the stable patterns of which can be recognized using **Markov chain Monte Carlo** ("Gibbs sampler") methodology [5, 21].

The layered feed-forward neural network is an important pattern recognizer and a powerful tool for general problems of classification and function approximation [8]. Many forms of biostatistical models can be represented as artificial neural nets, and vice versa [20]. For instance, when output y is an indicator variable and is modeled as a function of inputs x that is loglinear in its parameters, we have a form of multiple **logistic regression** or logistic discrimination (*see* **Discriminant Analysis, Linear**) that classifies new examples according to maximum posterior probability. This is equivalent to the "softmax" approach of artificial neural networks, and indeed predated it by decades. Extensions to more than two classes lead to **canonical correlation** analysis [12] and flexible discriminant analysis by optimal scoring [4, 9]. When regression functions are not necessarily linear and are allowed to be members of a general feature space spanned by smooth functions of x, artificial neural networks have been shown to be equivalent to various forms of **generalized additive models**, **projection pursuit** regression, and multivariate adaptive regression **splines**. Expansions by Fourier and **wavelets** bases are also possible. For more detail on the relationships between layered feed-forward nets and these models, and well as radial basis functions, **nonparametric**

regression, and high dimensional **density estimation**, see [5], [8], and [20] and discussions and references therein. Demonstrations of close connections between statistical methods and artificial neural networks such as these provide some idea of the depth and breadth of pattern recognition – a truly multidisciplinary field.

Optical Character Recognition of Handwritten Zip Codes

One prized accomplishment of the neural network school is in automatic recognition of handwritten zip codes, which are US postal codes [5, 11]. This artificial neural network received multivariate input of dimension $p = 256$ consisting of a 16×16 matrix of 0s and 1s representing a single numeric character. Each input was processed by three hidden layers consisting of a total of 1256 nodes connected by a total of 63 660 links and 9760 parameters, to yield an output classification as one of the digits 0 through 9. The network was trained to recognize patterns in a training set of 7291 handwritten zip code digits, adapting to data features by back-propagation, which is a form of gradient descent. The resulting discrimination rule misclassified about 1% of the training set cases, rejecting 12% of them as undecidable, and misclassified 5.1% (102/2007) new test cases. The network was subsequently refined by pruning to reduce problems of overfitting through reductions in the number of free parameters, to retain a 1% misclassification rate with only a 9% case rejection rate.

Some Benchmark Data Sets for Biostatistical Pattern Recognition Research

The zip code data set has become a benchmark for research in artificial neural networks and in other approaches to statistical pattern recognition. There does not yet appear to be a well-defined collection of benchmark data sets for strictly biostatistical pattern recognition problems. However, some biostatistical pattern recognition applications are mentioned in [20] and [21] with accompanying data sets available through Statlib. These include data on R.A. Fisher's irises, hemophilia, Cushing's syndrome, diabetes (in North American Indians, and for analysis of an oral glucose tolerance test), renal disease and hypertension, and differential diagnosis of liver disease, tobacco viruses, and rock crabs.

The pattern recognition literature is enormous, spanning many disciplines. In addition to the works cited herein, the articles that appear after the Reference list are useful sources for further study.

NICHOLAS LANGE

Pearl, Raymond

Born: June 3, 1879, in Farmington, New Hampshire.
Died: November 17, 1940, in Hershey, Pennsylvania.

Photograph supplied by The Alan Mason Chesney Medical Archives of the Johns Hopkins Medical Institutions

Raymond Pearl was a member of the original faculty of the Johns Hopkins University School of Hygiene and Public Health. In a very real sense he established biostatistics as a central discipline for the schools of public health that were to follow.

Pearl's primary training was in biology, with A.B. and Ph.D. degrees in that subject from Dartmouth College in 1899 and the University of Michigan in 1902, respectively. He remained at Michigan as an instructor in zoology until 1905. By then, Pearl recognized a need for sound statistical methods for application in biology, because in the study of human biology it would not be enough to know the individual organism in as much detail as possible; one needed to know the characteristics of the group or groups to which the individual belonged. The most informative characteristics were usually quantitative, and mathematical models and statistical methods were required to study them.

Accordingly, he arranged to spend a year studying biometrics with **Karl Pearson** at University College, London. The impression Pearl made on Pearson was apparently favorable, as he served as a ***Biometrika*** associate editor from 1906 to 1910.

After a year as a junior faculty member in biology at the University of Pennsylvania, Pearl joined the Department of Biology of the Maine Agricultural Experiment Station in 1907, where he rose to department chairman and remained until 1918.

By 1917, Pearl was nationally known and respected, particularly for his application of statistical methods to population studies. In that year, he accepted an appointment as wartime chief of the statistical division of the US Food Administration (later the **Food and Drug Administration (FDA)**).

Coincidentally, the Rockefeller Foundation had decided to make funds available to establish an institute of hygiene, a new type of institution for increasing scientific knowledge, not only about how to interrupt the spread of contagious disease, but also about how to promote health and prevent disease generally. William Henry Welch, a Johns Hopkins University School of Medicine pathology professor, had been selected to organize the new institution as a component of Johns Hopkins. Welch saw in Pearl just the individual to "provide a general theoretical and philosophical approach to quantitative methods as applied to human health and disease" [1, p. 63].

Pearl thus became the first professor and chairman of the Department of Biometry and Vital Statistics of the Johns Hopkins University School of Hygiene and Public Health, the first institution of its kind anywhere. His series of appointments at Johns Hopkins were Professor of Biometry and Vital Statistics in the School of Hygiene and Public Health, 1918–1925; Professor of Biology in the School of Medicine, 1923–1940, and in the School of Hygiene and Public Health, 1930–1940; and Research Professor and Director of the Institute of Biological Research, 1925–1930.

Pearl published more than 700 books, articles, and reviews. In his own listing they fell into the categories: animal behavior; biology – general; biometric theory; biometry – general; duration of life (*see* **Life Expectancy**) and biology of death; effects of physical agents on organisms; **eugenics**; evolution; food and economics; general physiology; genetic technique (*see* **Genetic Epidemiology**); heredity and breeding (*see* **Human Genetics, Overview**); pathology; physiology of **reproduction**; population; poultry husbandry; **public health** and hygiene; sex;

teratology; tuberculosis; variation and **correlation**; **vital statistics**; zoological and physiological technique; and miscellaneous.

One major line of research involved the mathematical modeling of population sizes (*see* **Population Growth Models**), especially using the **logistic** function. With his Johns Hopkins colleague Lowell Reed, Pearl showed that US total population sizes as reported from decennial **census** data from 1790 to 1910 matched very closely a certain logistic curve [2]. The significance of this, to Pearl, was that the parameters of the model were easy to explain in terms of such concepts as the natural limit of the population size, which, in turn, lent strong credibility to **predictions** from the fitted curve. The publication appeared in 1920; the predicted 1940 population size differed by only 3.7% from that reported from the actual 1940 census count.

Naturally, predictions of national population size attracted the attention of the general public, as did quite a few of Pearl's other research endeavors. He concluded from the analysis of data from a large group of his fellow Baltimore citizens that those using alcohol in moderation lived longer on the average than those abstaining and than those using it to excess. He also produced analyses indicating the negative impact of cigarette use on life span (*see* **Smoking and Health**).

Pearl was elected to the US National Academy of Sciences at the relatively early age of 37, the American Philosophical Society, and the American Academy of Arts and Sciences. He served as **American Statistical Association** president in 1939. The University of Maine, Dartmouth College, and St John's College (Annapolis) conferred honorary doctorates. He founded, and was first editor of, two journals, *Quarterly Review of Biology* in 1926 and *Human Biology* in 1929.

When Pearl died suddenly in 1940 at age 61, his obituary appeared in many publications, including the *American Journal of Public Health, Science, The Scientific Monthly, The New York Times*, and *Newsweek*. The obituary in Baltimore's *Evening Sun* was written by his close friend H.L. Mencken.

DENNIS O. DIXON

Pearson Distributions

This system of **probability** distributions (often known as *Pearson curves*) was developed by **Karl Pearson** in 1894 and 1895 to provide flexible descriptions of the nonnormal distributions encountered in his biometric research. The original papers are reproduced in [5].

Apart from the fitting of models for observed frequency distributions, the Pearson distributions have also been used to provide approximations to other theoretical distributions, and to study the effect of nonnormality on **sampling distributions**. An early book by W.P. Elderton, now available under joint authorship [1], provided a popular guide to the Pearson curves. For a fuller description, see [3].

Pearson noticed a difference equation satisfied by adjacent probabilities in the **hypergeometric distribution**, and produced an analogous differential equation for continuous distributions with probability density function (pdf) $f(x)$:

$$f'(x) = \frac{(x-a)f(x)}{b_0 + b_1 x + b_2 x^2}. \qquad (1)$$

Variations in the four parameters of (1) produce a wide range of unimodal distributions, including **U-** and **J-shaped distributions**. Pearson identified 12 types, the **normal distribution** being a limiting case of several types. The types can conveniently be distinguished by the indices of **skewness** and **kurtosis**, $\beta_1 = \mu_3^2/\mu_2^3$ and $\beta_2 = \mu_4/\mu_2^2$, respectively (see Figure 1).

Several well-known distributions are special cases: the **beta distribution** (I), the **chi-square** or **gamma** (III), the ***F* distribution** (VI), **Student's *t*** (VII), the **exponential** (X), and the **Pareto** (XI). Pearson advocated the fitting of the distributions by the **method of moments**, equating the observed and theoretical values of the first four **moments**. **Efficient** methods such as **maximum likelihood** are now regarded as preferable.

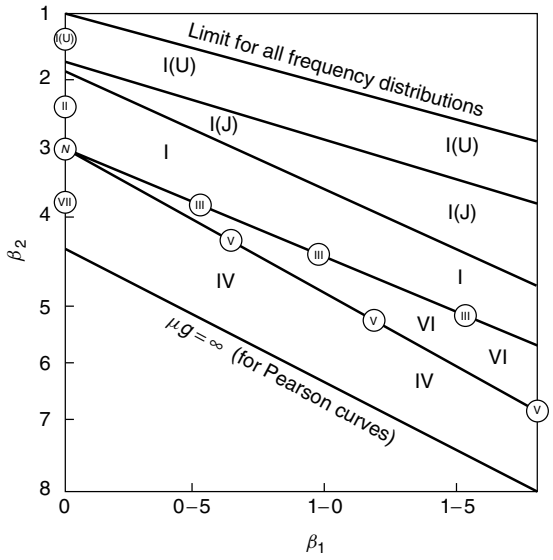

Figure 1 A chart relating types of Pearson distributions to measures of skewness and kurtosis (based, with permission, on Table 43 in [4])

Another general system of continuous distributions, by Johnson [2], is based on **transformations** of a normally distributed variable.

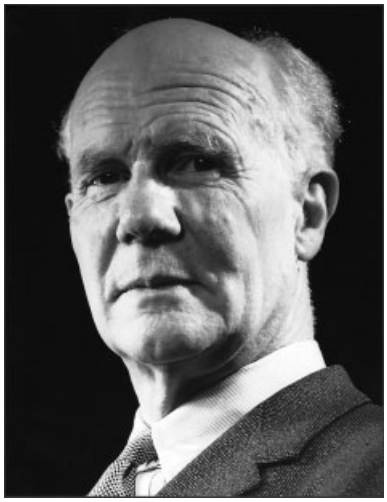
PETER ARMITAGE

Pearson, Egon Sharpe

Born: August 11, 1895, in Hampstead, UK.
Died: June 12, 1980, in Midhurst, UK.



Reproduced by permission of the Royal Statistical Society

Egon Pearson was the only son among the three children of **Karl Pearson**. After education in Oxford and Winchester, in 1914 he went to Trinity College, Cambridge, to read mathematics. War service at the Admiralty and Ministry of Shipping delayed his graduation until 1920.

After leaving Cambridge, Pearson became a statistics lecturer in his father's department at University College, London. Here he helped his father to edit ***Biometrika***. In 1924 he was appointed assistant editor, and after his father's death in 1936 he became managing editor, a position he held until 1965. After Karl Pearson had retired in 1933 his department was split into two, with Egon Pearson becoming head of the new statistics department and **R.A. Fisher** becoming head of the **eugenics** department. In 1935 Pearson was made professor.

From the 1920s Pearson began to develop his personal philosophy of statistics, with two main strands. Most famously, he embarked on an important collaboration with **Jerzy Neyman** which led to the philosophy of statistical **inference**, now known as "**Neyman–Pearson** theory". In this work, Neyman and Pearson introduced ideas of the **alternative hypothesis** and the **power** of a test [2]. Later papers included ideas of suspended judgment in addition to formal acceptance or rejection of a hypothesis [3, 4] (*see* **Hypothesis Testing**).

Pearson's other main field of activity was the promotion of use of statistical methods in industry, with an emphasis on model building. His interest in this area arose from meeting W.H. Shewhart of Bell Telephone Laboratories when Pearson was visiting North America. An influential paper [6] led to the formation of the Industrial and Agricultural Section of the **Royal Statistical Society** (RSS) in 1933 and the appearance of the *Supplement* to the ***Journal of the Royal Statistical Society***, starting in 1934. In 1936 Pearson broke new ground with the publication of a handbook (BS600) on statistical methods in standardization.

During World War II Pearson worked for the Ordnance Board, after which he returned to University College, where he remained until, and indeed after, his retirement in 1960. Among his other publications, the two volumes of statistical tables (with H.O. Hartley) [8] were especially valuable, their title disguising their rich content.

Pearson was made CBE in 1946. He received the Guy medal in gold from the RSS in 1955, and was president in 1955–1956. He was elected FRS in 1966.

Further details of Pearson's life are given by Moore [1] in an eightieth birthday tribute. Many of his important papers are republished in [5] and [7].

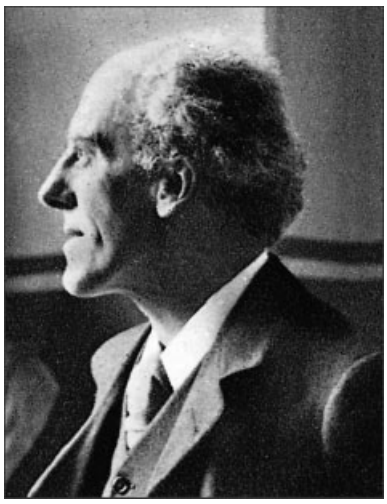
Pearson, Karl

Born: March 27, 1857, in London, UK.
Died: April 27, 1936, Coldharbour under Dorking, Surrey, UK.



Reproduced by permission of the Royal Statistical Society

The founder of biometrics, Karl Pearson was one of the principal architects of the modern theory of mathematical statistics. He was a polymath whose interests ranged from astronomy, mechanics, meteorology, and physics to the biological sciences in particular (including anthropology, **eugenics**, evolutionary biology, heredity, and medicine). In addition to these scientific pursuits, he undertook the study of German folklore and literature, and of the history of the Reformation and German humanists (especially Martin Luther). He also contributed hymns to the *Socialist Song Book*. Pearson's writings were prodigious: he published more than 650 papers in his lifetime, of which 400 are statistical. Over a period of 28 years, he founded and edited six journals and was a cofounder of the journal ***Biometrika***. University College London (UCL) houses the main collection of Pearson's papers, consisting of 235 boxes containing family papers, scientific manuscripts, and 16 000 letters.

Largely because of his interests in evolutionary biology, Pearson created, almost single-handedly, the modern theory of statistics in his Biometric School at UCL from 1892 to 1903 (which was practiced in the Drapers' Biometric Laboratory from 1903 to 1933). These developments were underpinned by Charles Darwin's ideas of biological variation and "statistical" populations of species – arising from the impetus of statistical and experimental work of his colleague and closest friend, the Darwinian zoologist, W.F.R. Weldon (1860–1906). Additional developments emerged from **Francis Galton's** law of ancestral heredity. Pearson also devised a separate methodology for problems of eugenics in the Galton Eugenics Laboratory from 1907 to 1933.

In his creation of biometrics, out of which the discipline of mathematical statistics had developed by the end of the nineteenth century, Pearson introduced a new vernacular for statistics (including such terms, for example, as the **standard deviation, mode**, homoscedasticity, heteroscedasticity (*see* **Scedasticity**), **kurtosis**, and the product-moment **correlation** coefficient). Like a number of scientists at the end of the nineteenth century, Pearson was interested in the developing etymology in various disciplines, especially biology. Though he attempted to coin a number of biological words, the only word that survived him is "siblings", which he used "to cover a group of brothers and sisters regardless of sex".

Family and Education

Karl was the second of three children born to William Pearson and Fanny Smith. His mother came from a family of seamen and mariners, and his father was a barrister. The Pearsons were a Yorkshire family of dissenters and of Quaker stock. By the time he was in his twenties, Pearson had rejected Christianity and had become a Freethinker, which involved the "rejection of all myths as explanation and the frank acceptance of all ascertained truths to the relation of the finite to the infinite". Though he did not regard himself as an atheist, "he vigorously denied the possibility of a god ... because the idea of one and all of them by contradicting some law of thought involves an absurdity". To Pearson "religion was the relation of the finite to the infinite". Politically, he was a socialist whose outlook was similar to the Fabians, but he never joined the Fabian Society (despite requests from Sidney and Beatrice Webb). Socialism was a form of morality for Pearson; the

moral was social and the immoral was antisocial in conduct.

There were a number of lawyers in the Pearson family, including William's brother Robert and Robert's son, Hugh, as well as William's eldest child, Arthur, all of whom read law at the Inner Temple in London. William was a very hard-working and taciturn man who was never home before 7 p.m. he continued to work until about midnight and was usually up at 4 a.m. reviewing his briefs. To both of his sons, William regularly emphasized the importance of hard work, especially so once they were at Cambridge University. The children only really spent any time with their father during vacations. In a letter to Karl, his elder brother Arthur described the experience of being home with their father as "simply purgatory ... the governor never spoke a word". In this desolate atmosphere, with her husband working incessantly and never talking to anyone when he was home, Fanny was deeply unhappy in her marriage. Thus she transferred her love to her two sons, and she was deeply affectionate to Karl, who was, without doubt, her favorite child.

For a short time in 1866, both boys received tuition from a Mr William Penn, who had started a small school at Harrow, near London. As a child, Karl was rather frail, delicate, often ill, and prone to depression. On a number of occasions he received tuition at home because he was too unwell to go to school. After the Pearsons moved to 40 Mecklenburgh Square, in Holborn, London, in June 1866 (where they stayed until 1875), Karl and Arthur began attending University College London School.

When they went up to Cambridge, at least one of the Pearson boys was expected to read mathematics. The Cambridge Mathematics Tripos was, at that time, the most prestigious degree in any British university. Although his father urged him to read mathematics, Arthur settled on Classics. Thus when Karl was 15 years old, his father was already looking for someone to prepare him for the Mathematics Tripos. Karl first received tuition from the Reverend Louis Hensley at Hitchin (50 miles from Cambridge). Subsequently he was tutored in mathematics at Merton Hall in Cambridge, by John Edward Rendall Harris, John P. Taylor, and Edward John Routh.

By the spring of 1875, Pearson was ready to take the entrance examinations at various Cambridge colleges. His first choice was Trinity College, where he failed the entrance exam; his second choice was King's College, from which he received an Open Scholarship on April 15, 1875. Pearson found that the highly competitive and demanding system leading up to the Mathematical Tripos was the tonic he needed. Though he had been a rather delicate and sickly child with a nervous disposition, he came to life in this environment and his health improved. In addition to the highly competitive and intellectually demanding system, students of the Mathematics Tripos were expected to take regular exercise as a means of preserving a robust constitution and regulating the working day. Pearson carefully balanced hard mathematical study against such physical activities as walking, skating, ice-hockey, and lawn tennis.

As a diversion from studying mathematics, Pearson read works from such Romantics as Goethe and Shelley in his second year. He also read Rousseau and Dante, and wrote a couple of articles on Spinoza for the *Cambridge Review*. Pearson's time at King's College left its legacy through his revolt over the compulsory divinity examination. Near the beginning of his third year in 1877, he decided that he no longer wished to be compelled to attend church services. Pearson also refused to retake one of his divinity papers, as it would have interfered with his study for the Mathematics Tripos. The events that transpired led eventually to King's College abolishing the whole system of compulsory divinity examinations in March 1878.

Pearson spent the rest of 1878 in preparation for the Mathematics Tripos examination, which he took in January 1879. He graduated with honors; subsequently, he received a Fellowship from King's College which he held for seven years. He was made an Honorary Fellow of King's in 1903.

A couple of weeks after Pearson had taken his degree, he began to work in Professor James Stuart's engineering workshop and read philosophy during the Lent Term in preparation for his trip to Germany. After making arrangements with Kuno Fischer, Pearson left for Heidelberg in April 1879. Philosophically and professionally, his time in Germany was a period of self-discovery. The romanticist and idealist discovered positivism: Pearson thus adopted and coalesced two different philosophical traditions to fulfill two different needs. Around this time, he began to write the *New Werther*, a literary work on idealism and materialism, written in the form of letters to his fiancée from a young man wandering in Germany. For Pearson the book was "about conflict

between the ideal and the real, spirit and matter". The book was published in 1880 under the pseudonym of Loki (a mischievous Norse god).

Germany and University College London

During his time in Heidelberg Pearson read Berkeley, Fichte, Locke, Kant, and Spinoza, but he subsequently abandoned philosophy because "it made him miserable". He studied physics under Quincke and metaphysics under Kuno Fischer. He then considered becoming a mathematical physicist, but decided not to pursue this since he "was not a born genius". In November 1879, he went to Berlin to hear Kirchhoff and Helmholtz and began to study Roman law under Bruns, Baron, and Dernburg. A year later, he took rooms back in London at the Inner Temple and read law at Lincoln's Inn. He became a barrister at the end of 1881 and practiced law for a very short time only. Still searching for some direction when he returned to London, Pearson lectured on socialism, Marx and Lassalle at the working men's clubs and on Martin Luther at Hampstead, near London, from 1880 to 1881.

By 1882 Pearson had decided that he did not want to pursue the law because it depressed him, and he decided instead to "devote his time to the religious producing of German literature before 1300". Later that year his work on *The Trinity, A Nineteenth Century Passion-Play, The Son; or Victory of Love* was published. From 1882 to 1884, he lectured on German society from the medieval period up to the sixteenth century. He became so competent in German that by the late spring of 1884 he was offered a post in German at Cambridge. In his pursuit of German history, Pearson consulted his friend, the Cambridge University librarian, Henry Bradshaw, who taught him the meaning of thoroughness and patience in research. With Bradshaw's help, Pearson finished in 1887 *Die Fronica: Ein Beitrag zur Geschichte des Christusbildes im Mittelalter* (which involved a collection of the so-called Veronica portraits of Christ).

Nevertheless, Pearson found all these pursuits deeply dissatisfying, and he "longed to be working with symbols rather than words". He then began to write some papers on the theory of elastic solids and fluids as well as some mathematical physics papers on optics and ether squirts. He deputized mathematics at King's College, London and for Professor Rowe at UCL in 1883. Between 1879 and 1884 he applied for more than six mathematical posts and he received the Chair of "Mechanism and Applied Mathematics" at UCL in June 1884.

During Pearson's first six years at UCL, he taught mathematical physics, hydrodynamics, magnetism, electricity, and his specialty, elasticity, to engineering students. Nearly all of his teaching on dynamics, general mechanics, and statics was based on geometrical methods. He finished editing the incomplete manuscript of William Kingdom Clifford's *The Common Sense of Exact Science* in 1885 and a year later he finished Todhunter's *History of the Theory of Elasticity*.

The Gresham Lectures on Geometry and Curve Fitting

Pearson was a founding member of the Men's and Women's Club established in London in 1885 "for the free and unreserved discussion of all matters in any way connected with the mutual position and relation of men and women". Among the various members was Marie Sharpe, whom he married in June 1890. They had three children, Sigrid, Helga, and Egon. Six months after his marriage, he took up another teaching post as Gresham Professor of Geometry, which he held for three years concurrently with his post at UCL. As Gresham Professor, he was responsible for giving 12 lectures a year, delivered on four consecutive days, from Tuesdays to Fridays, during the Michaelmas, Easter, and Hilary terms. The hour-long lectures, which were free to the public, were held at Gresham Collage, in London, and began at 6 p.m. Between February 1891 and November 1893, Pearson delivered 38 lectures. His first eight lectures formed the basis of his book, *The Grammar of Science*, which was published in several languages.

Pearson's earliest teaching of statistics can, in fact, be found in his lecture of November 18, 1891 when he discussed **graphical** statistics and the mathematical **theory of probability**, with a particular interest in **actuarial methods**. Two days later he introduced the histogram – a term he coined to designate a "time-diagram" to be used for historical purposes. He introduced the standard deviation in his Gresham lecture of January 31, 1893. Pearson's early Gresham lectures on statistics were influenced by the work of **Edgeworth**, Jevons, and Venn. Until November 1893, these lectures covered fairly conventional statistical and probability methods. While the material in

these lectures was not original in content, Pearson's approach to teaching was highly innovative. In one of his lectures, he scattered 10 000 pennies over the lecture room floor and asked his students to count the number of heads or tails: "the result was very nearly half heads and half tails, thus proving the law of average and probability".

Pearson's last 12 Gresham lectures signified a turning-point in his career owing, in particular, to his relationship with Weldon – who was the first biologist Pearson met who was interested in using a statistical approach for problems of Darwinian evolution. Their emphasis on Darwinian population of species not only implied the necessity of systematically measuring variation, but also prompted the reconceptualization of statistical populations. Moreover, it was this mathematization of Darwin which led to a paradigmatic shift for Pearson from the Aristotelian essentialism underpinning the earlier use and development of social and **vital statistics**. Weldon's questions not only provided the impetus for Pearson's seminal statistical work, but also led eventually to the creation of the Biometric School at UCL.

In Pearson's first published statistical paper of October 26, 1893, he introduced the **method of moments** as a means of curve-fitting asymmetrical distributions. One of his aims in developing the method of moments was to provide a general method for determining the values of the parameters of a **frequency distribution** (i.e. central tendency, variation, **skewness**, and kurtosis). In 1895 Pearson developed a general formula to use for subsets of various types of frequency curve and defined the following curves: type I (asymmetric **beta** density curve), type II (symmetric beta curve), type III (**gamma** curve), type IV (family of asymmetric curves), and type V (**normal** curve). In his first supplement to this family of curves in 1901 he defined types VI and VII (type VII is now known as **"Student's" distribution**), and then in his second supplement in 1916 types VIII and IX. Many of his curves were J-shaped, U-shaped, and skewed. Pearson derived all of his curves from a differential equation whose parameters were found from the moments of the distribution. As Churchill Eisenhart remarked in 1974, "Pearson's family of curves did much to dispel the almost religious acceptance of the normal distribution as the mathematical model of variation of biological, physical and social phenomena" (*see* **Pearson Distributions**). Though the method of moments is not widely used by biostatisticians today, it still remains a very powerful tool in econometrics.

The Biometric School

Following the success of his Gresham lectures, Pearson began to teach statistics to students at UCL in October 1894. By 1895, four years after Pearson first started to teach statistics, he had worked out the mathematical properties of the product-moment correlation coefficient (which measures the relationship between two continuous variables) and **simple regression** (used for the linear prediction between two continuous variables). By then, Francis Galton had determined graphically the idea of correlation and regression for the normal distribution only. Because Galton's procedure for measuring correlation involved measuring the slope of the regression line (which was a measure of regression instead), Pearson kept Galton's r to symbolize correlation. Pearson later used the letter b (from the equation for a straight line) to symbolize regression. After Weldon had seen a copy of Pearson's paper on correlation, he suggested to Pearson that he should extend the range for correlation from 0 to $+1$ (as used by Galton) so that it would include all values from -1 to $+1$.

In this seminal paper on "Regression, heredity and panmixia" in 1896, Pearson introduced **matrix algebra** into statistical theory (Arthur Cayley, who taught at Cambridge when Pearson was a student, created matrix algebra by his discovery of the theory of invariants during the middle of the nineteenth century). In the same paper, Pearson also introduced the following statistical methods: η as a measure for a curvilinear relationship, the **standard error** of an estimate, **multiple regression**, and multiple, part and partial correlation, and he also devised the coefficient of variation as a measure of the ratio of a standard deviation to the corresponding mean, expressed as a percentage.

From 1896 to 1911, Pearson devised more than 18 methods of correlation. By the end of the nineteenth century he began to consider the relationship between two discrete variables. In 1900, he devised the tetrachoric correlation and the phi-coefficient for dichotomous variables (*see* **Categorical Data Analysis**). The tetrachoric correlation requires that both X and Y represent continuous, normally distributed and linearly related variables, whereas the phi-coefficient

was designed for so-called point distributions, which implies that the two classes have two point values or merely represent some qualitative attribute. Nine years later, he devised the **biserial correlation** when one variable is continuous and the other is discontinuous. With his son Egon, he devised the polychoric correlation in 1922 (which is very similar to **canonical correlation** today). Though not all of Pearson's correlational methods have survived him, a number of these methods are still the principal tools used by psychometricians for test construction (*see* **Psychometrics, Overview**). Following the publication of his first three statistical papers in *Philosophical Transactions of the Royal Society*, Pearson was elected a Fellow of the Royal Society in 1896. He was awarded the Darwin Medal from the Royal Society in 1898.

Pearson's Chi-square Tests

At the turn of the century, Pearson reached a fundamental breakthrough in his development of a modern theory of statistics when he found the exact **chi-square distribution** from the family of Gamma distributions and devised the chi-square **goodness-of-fit** test. The test was constructed to compare observed frequencies in an empirical distribution with expected frequencies in a theoretical distribution to determine "whether a reasonable graduation had been achieved" (i.e. one with an acceptable probability). This landmark achievement was the outcome of the previous eight years of curve fitting for asymmetrical distributions and, in particular, of Pearson's attempts to find an empirical measure of a goodness-of-fit test for asymmetric curves.

Four years later, he extended this to the analysis of manifold **contingency tables** and introduced the "mean square contingency coefficient" which he also termed the **chi-square test** of independence (which **R.A. Fisher** termed the chi-square statistic in 1923). While Pearson used $n - 1$ for his **degrees of freedom** for the chi-square goodness-of-fit test, R.A. Fisher claimed in 1924 that Pearson also used the same degrees of freedom for his chi-square test of independence. However, in 1913, Pearson introduced what he termed a "correction" (rather than degrees of freedom) for his chi-square test of independence of 1904. Thus, he wrote, if x is the number of rows and λ the number of columns, then on average the correction for the number of cells is $(x - 1)(\lambda - 1)/N$. (As may be seen, Fisher's degrees of freedom for the chi-square statistic as $(r - 1)(c - 1)$ is very similar to that used by Pearson in 1913.)

Pearson's conception of contingency led at once to the generalization of the notion of the association of two attributes developed by his former student, **G. Udny Yule**. Individuals could now be classed into more than two alternate groups or into many groups with exclusive attributes. The contingency coefficient and the chi-square test of independence could then be used to determine the extent to which two such systems were contingent or noncontingent. This was accomplished by using a generalized theory of association along with the mathematical theory of independent probability.

Pearson's Four Laboratories

Pearson established and ran four laboratories. He set up the Drapers' Biometric Laboratory in 1903 following a grant from the Worshipful Drapers' Company (which continued to fund Pearson's work in this laboratory until his retirement in 1933). The methodology incorporated in the Drapers' Biometric Laboratory was twofold: the first was mathematical, and included the use of Pearson's statistical methods, matrix algebra, and analytical solid geometry. The second involved the use of such instruments as integrators, analyzers, curve plotters, the cranial coordinatograph, silhouettes, and cameras. The problems investigated by the biometricians included natural selection, Mendelian genetics (*see* **Mendel's Laws**) and Galton's law of ancestral inheritance, craniometry, physical anthropology, and theoretical aspects of mathematical statistics. By 1915, Pearson established the first degree course in mathematical statistics in Britain.

Though Pearson did not accept the generality of Mendelism, he did not reject it completely, as is commonly believed. When William Bateson published his fiercely polemical attack on Weldon in 1902, Bateson saw Mendelism as a tool for discontinuous variation only. As a biometrician, most of the variables that Pearson and his co-workers analyzed were continuous, and only occasionally did they examine discontinuous variables. While Pearson and Weldon used Galton's law of ancestral inheritance for continuous variables, they used Mendelism for discontinuous variables. Indeed, Pearson argued that his

chi-square test of independence was the most appropriate statistical tool for the analysis of Mendel's discrete data for dominant and recessive alleles (such as color of eyes where brown is dominant and blue is recessive). Even today, Pearson's chi-square tests remain the most widely used technique for analyzing Mendelian data.

A year after Pearson had established the Biometric Laboratory, the Worshipful Drapers' Company gave him a grant so that he could establish an Astronomical Laboratory equipped with a transit circle and a 4-inch (10 cm) equatorial refractor. Hence, he also referred to his two observatories as the Transit House and the Equatorial House. Pearson was interested in determining the correlations of stellar rotations and the variability in stellar parallax. He was also instrumental in setting up a degree course in astronomy in 1914 at UCL.

In 1907, Francis Galton (who was then 85 years old) wanted to step down as director from the Eugenics Record Office which he had set up three years earlier, and he asked Pearson if he would take it on. Though Pearson had "great hesitation in taking any initiative at all ... because he did not want Galton to think that [he] was carrying all things into the biometric vortex!", he took on the directorship reluctantly and renamed the office the Galton Eugenics Laboratory. Pearson made very little use of his biometric methods in this laboratory; instead he developed a completely different methodology for problems relating to eugenics. This methodology was underpinned by the use of actuarial death rates (*see* **Actuarial Methods**) and by a very highly specialized use of family pedigrees assembled in an attempt to discover the inheritance of various diseases (which included, for example, such conditions as alcoholism, cancer, diabetes, epilepsy, paralysis, and pulmonary tuberculosis; *see* **Population Genetics**).

These family pedigrees became the vehicle through which Pearson could communicate statistical ideas to the medical community by stressing the importance of using quantitative methods for medical research. This tool enabled doctors to move away from concentrating on individual pathological cases or "types" and to see, instead, a wide range of pathological variation of the disease (or condition) of the doctors' specialty. Such work attracted the interest of **Major Greenwood**, who was the first medically qualified person to take an interest in Pearson's statistics in 1902, and who subsequently became Reader of Medical Statistics in the University of London in 1922 (the first position to be held at a university in Britain). The statistical work of Pearson and Greenwood was further promulgated by their student, **Austin Bradford Hill**, who had the greatest impact on the successful adoption of mathematical statistics in the medical community. In 1924, Pearson set up the Anthropometric Laboratory, this was made possible by a gift from one of his students, Ethel Elderton. The laboratory was open to the public and used to collect and display statistics related to problems of heredity.

In the spring of 1909, Galton was discussing the future of the Eugenics Laboratory with Pearson. While Galton thought that Pearson would have been "the most suitable man for the first Galton Professor", Pearson let Galton know that he was "wholly unwilling to give up superintendence of the Biometric Laboratory [he] had founded and confine [his] work to Eugenics Research". A month later, Galton added a codicil to his will stating that he desired that the first professor of the post should be offered to Pearson on such condition that Pearson could continue to run his Biometric Laboratory. Six months after Galton's death in January 1911, Pearson first learned about Galton's codicil to his will. He then relinquished the Goldsmid Chair of Applied Mathematics after 27 years of tenure to take up the Galton Chair. The Drapers' Biometric and the Galton Eugenics laboratories, which continued to receive separate funding, then became incorporated into the Department of Applied Statistics. The essential aim in combining both laboratories was to enable Pearson to give up his undergraduate teaching of applied mathematics and to devote himself "solely to what had been for many years the main element of [his] research: the advancement of the modern theory of statistics".

Statistical Charts and Gunnery Computations

Pearson then proceeded to raise funding for a new building for his Department of Applied Statistics. Adequate funding had been raised by 1914 and contracts for the fittings had been made. In the early summer of 1914, the new laboratory was complete and preparations were under way for the occupation and fitting up of the public museum and the Anthropometric Laboratory. It was hoped that the building

would be occupied by October 1915. These developments and further biometric work were shattered by the onset of World War I. The new laboratory building was taken over by the government to be used as a military hospital. Pearson and his co-workers took on special war duties. They produced statistical charts for the Board of Trade's Labor Department as well as for its Census production. Pearson was also involved in elaborate calculations concerned with antiaircraft guns and bomb trajectories "both through air and air and water". By June 1919, Pearson was in possession of his building and plans were under way for the opening in October 1920. It was not until December 4, 1922, when the work had been completed, that the building was occupied.

His wife, Marie Sharpe, died in 1928, and in 1929 he married Margaret Victoria Child, a co-worker in the Biometric Laboratory. Pearson was made Emeritus Professor in 1933, and was given a room in the Zoology Department at UCL which he used as the office of *Biometrika*. From his retirement until his death in 1936, he published 34 articles and notes, and continued to edit *Biometrika*. Pearson was twice offered honors by King George V, but declined on both occasions. He also declined the **Royal Statistical Society** Guy Medal in the society's centenary year in 1934. Pearson believed that "all medals and honours should be given to young men, they encourage them when they begin to doubt whether their work was of value". Pearson accepted an honorary Doctorate of Science (D.Sc.) from the University of London in 1934 because if he had refused he "would have hurt the executive of the university where he had worked" for nearly half a century.

Pearson's statistical achievement not only provided continuity from the mathematical and statistical work that preceded him (including that of Francis Ysidro Edgeworth, Francis Galton, **Adolphe Quetelet**, and John Venn), but also engendered the modern theory of mathematical statistics in the twentieth century which, in turn, provided the foundation for such statisticians as R.A. Fisher who went on to make further advancements for a modern theory of statistics.

Pedigrees, Sequential Sampling

The great majority of genetic epidemiologic study designs involve data not just on individuals, but rather on *families*. Generally speaking, we can envision collection of such data as involving two separate operations: first, *individuals* are selected from the target population, or ascertained (*see* **Ascertainment**); secondly, *intrafamilial sampling* among the relatives of these ascertained individuals is conducted. The resulting pedigrees are thus composed of ascertained individuals and (subsets of) their relatives. (In many applications, only affected individuals are eligible for the initial ascertainment, which results in ascertainment bias.)

One technique sometimes used for obtaining families is sequential sampling, in which intrafamilial sampling proceeds in stages, with the decision to continue (or stop) the sampling process made subsequent to completion of each stage. For example, a sequential sampling protocol might require observation of all first-degree relatives of any previously observed affected individual. In this case, all first-degree relatives of initially ascertained individuals would be evaluated, and, if any of them were affected, then all of their (previously unobserved) first-degree relatives would be sampled, and so forth, with sampling continuing or stopping at each stage, depending on whether any newly observed individuals were affected. Such schemes can obviously result in highly variable observed pedigree structures, depending on the ascertainment scheme, the underlying genetic etiology of the disease under study, and the particular intrafamilial sampling rule employed.

Cannings & Thompson [2] defined a broad class of sequential sampling procedures, by allowing for any intrafamilial sampling scheme meeting the following restrictions: (i) the decision as to which individuals to sample next depends only on the phenotypes of individuals who have already been observed, and possibly on other, auxiliary considerations (see below); and (ii) all observed relatives are included in the final sample. These restrictions preclude, for instance, sampling schemes in which the investigator "looks ahead" for affected individuals and then preferentially includes them in the sample, or in which individuals are dropped from the sample after determining that they are unaffected. (When these restrictions are violated, unbiased parameter estimation can become impossible.) It is interesting to note that these criteria permit sampling (and stopping) decisions to be based on auxiliary factors such as cost-effectiveness, or the current **likelihood ratio**, which introduces a sequential element in the classical statistical sense [7]. Also, many other sampling schemes that do not entail sequential decision-making *per se*, nevertheless belong to the class of schemes defined by these restrictions. For instance, sampling of all and only full-siblings of any ascertained individual(s) satisfies (i) and (ii) above.

Sampling family members in a sequential manner can, in some circumstances, greatly increase the amount of genetic information in the sample [4]. For example, Boehnke et al. [1] simulated a quantitative trait under the mixed model (*see* **Segregation Analysis, Mixed Models**), and compared the efficiency of nonsequential and sequential sampling schemes. They found that sampling sequentially could increase **power** to detect segregation at a dominant major locus by over 60%. (However, the amount of increased efficiency actually achieved depends upon the underlying genetic etiology of the disease under study.) Thus, sequential schemes for intrafamilial sampling constitute an extremely flexible and efficient class of procedures for sampling of pedigrees in human genetics.

It is worth noting, however, that sequential sampling introduces certain technical complications into the calculation of **likelihood**, particularly when conducted in conjunction with ascertainment through affected individuals. Strictly speaking, observed pedigree structure is a random variable, which may depend upon genetic parameters as well as the sampling procedures, and should then be included in the formal (likelihood) model. Cannings & Thompson [2] showed that, when intrafamilial sampling is sequential, conditioning the likelihood on the observed pedigree structure does not produce bias in genetic parameter estimates, provided that ascertainment is random, i.e. not a function of phenotype (see also [5]), or single (see also [3] and [5]), and provided that the Cannings & Thompson criteria given above are not violated. However, when ascertainment is neither random nor single, conditioning likelihoods on the observed pedigree structure will introduce (asymptotic) bias into parameter estimation when families are sequentially sampled [5]. In

fact, this result extends to nonsequentially sampled families whenever the observed pedigree structure depends on which among a set of relatives happen to have been the initially ascertained individuals [5]. This result applies not only to segregation analysis, but to linkage analysis as well [6]. It is also important to note that while **maximum likelihood** parameter estimates may not be (asymptotically) affected by the use of sequential sampling procedures, standard errors of estimators cannot be calculated in the usual way when intrafamilial sampling is sequential. As a result, it may be inappropriate to assume that test statistics (e.g. $-2 \times$ the natural logarithm of the likelihood ratio) follow their canonical distributions (e.g. a **chi-square distribution**) (*see* **Likelihood Ratio Tests**).

VERONICA VIELAND

Peirce, Charles Sanders

Born: September 10, 1839, in Cambridge, Massachusetts.
Died: April 19, 1914, in Milford, Pennsylvania.

C.S. Peirce is regarded by many as the greatest philosopher the US has ever produced and is considered to be the creator of pragmatism. He wrote and published articles upon a wide range of subjects including logic, mathematics, metaphysics, psychology, optics, astronomy, chemistry, religion, and other subjects. Many of his ideas are of significance to statisticians. These ideas include his thoughts about statistical **inference**, **random samples**, **randomization** of treatments, the definition of probability, formulation of hypotheses (*see* **Hypothesis Testing**), and errors of measurement (*see* **Measurement Error in Epidemiologic Studies**).

Charles Sanders Peirce (pronounced Purse) was the second of five children born to Benjamin Peirce, the leading American mathematician of that time, and Sarah Hunt (Mills) Peirce.

Charles entered Harvard in 1855, graduated in 1859, and ranked seventy-first in a class of 91 graduates. In July of 1861, he joined the US Coast Survey as a computing aide to his father, who had been employed with the Survey since 1852 and who served as superintendent of the Survey, from 1867 to 1874. Charles married Harriet Melusina (Zina) Fay on October 16, 1861. He received an M.A. degree from Harvard in 1862 and an S.B. degree in chemistry, summa cum laude, from the Lawrence Scientific School at Harvard in 1863.

He prepared 11 lectures on the logic of science to be given at Harvard in the spring of 1865. It appears that the lectures were not given at Harvard but were given in revised form at Lowell Institute in 1866. In 1867, he was elected to membership as resident fellow in the American Academy of Arts and Sciences. He worked as an assistant at Harvard Observatory from 1869 to 1872 and lectured on philosophy in 1869–1870. In 1870, he was sent by his father to find suitable observation sites in Europe along the path of totality to observe the solar eclipse of December 22, 1870. He was a member of an observation party near Catania, Sicily.

In 1871, he was in charge temporarily of the Coast Survey. He included astronomical observations made at Harvard Observatory from 1872 to 1875 in *Photometric Researches* (1878). In 1872, he became assistant at the Coast Survey and held this position until 1884. In 1877, he was elected as a fellow of the National Academy of Sciences. He was appointed lecturer in logic at Johns Hopkins University in 1879 and in 1880 he was elected as a member of the London Mathematical Society.

In 1876, he was separated from his wife, Melusina. His father died in 1880. Charles divorced Melusina in 1883 and married Juliette Froissy. He lost his position at Johns Hopkins University in 1884 for unspecified reasons and never held another academic position. In 1887, he and Juliette moved to a country home, Arisbe, near Milford, Pennsylvania. Possibly because of incompleted work, he was forcibly retired from the Coast Survey in 1891.

He continued to write articles for periodicals, *The Monist* and *Nation*, for example [1]. He became an editor and contributor for *Century Dictionary*. He continued to give lectures, which included lectures on the history of science at the Lowell Institute in 1892, a lecture on number at Bryn Mawr College in 1896, lectures on logic at the Lowell Institute in 1903, and lectures on the scientific method before the Philosophy Club at Harvard in 1907. Because of the strong friendship and support of William James, he informally added Santiago (Saint James) to his name.

In Peirce's study of inductive science, the need for random samples is explicitly stated. Peirce ("Lessons from the history of science", *c*. 1896 [2]) says, "A sample is a *random* one, provided it is drawn by such machinery, artificial or physiological, that in the long run any one individual of the whole lot would get taken as often as any other."

Peirce thought of the need for experimental randomization much before **R.A. Fisher**. Gustav Fechner had performed a multifactor experiment in 1860 to study sensory perception. In 1885, Peirce and Joseph Jastrow (see [4]) designed a similar experiment that used randomization of treatments. They presented slightly different weights in random order to subjects who were asked to state which of the two orders they had received. Two well-shuffled decks of cards were used to make the randomization.

Peirce was interested in the meaning and interpretation of probability and tried to give an operational definition of probability. In a letter to William James in 1909, he gave a long-range definition of probability

and he continued to work on a definition of probability in terms of endlessly diminishing oscillations.

On the subject of data analysis, Peirce [2] emphasized the importance of formulating hypotheses before examining the sample. He said, "We must first decide for what character we propose to examine the sample and only after that decision examine the sample." Peirce gave as an example the examination of a random sample of names from a biographical reference. If one allowed the data to suggest hypotheses, one might reach some very unlikely conclusions. For example, he listed several eminent men whose death dates met the following criterion "... All eminent men die in years whose date doubled and increased by one gives a number whose last figure is the same as that in the ten's place of the date itself."

Peirce [3] wrote a paper in 1870 entitled, "On the theory of errors of observation". The paper included a lengthy theoretical development that resulted in the normal law of errors (*see* **Normal Distribution**) and the analysis of a large data set. He studied the reaction times of an untrained 18-year-old boy to signals received. He recorded 500 measurements for each of 24 days and fit normal curves to the data sets.

He died at Milford, Pennsylvania, on April 19, 1914, at the age of 74. His unpublished papers and his library were left to the Harvard department of philosophy.

J. LEROY FOLKS

Penalized Maximum Likelihood

The standard approach to analyzing a set of observations $x_i, i = 1, \ldots, n$, thought to be a random sample from some population with density $f(\cdot)$ is to assume a parametric form for f and then estimate the parameters of the density using, for example, **maximum likelihood**. This parametric approach has excellent properties if the assumed density is the correct one, but can lead to grossly incorrect inferences if the assumed density is inappropriate.

Nonparametric **density estimation** methods avoid this problem by weakening the assumption on the true density to be that f is unspecified, except that it is assumed to be smooth (that is, at least a specified number of derivatives of f are square integrable, where that number is usually two or four). The nonparametric maximum likelihood estimator (MLE) of f is not a reasonable density estimator, since the maximizer of the nonparametric log likelihood is a set of (Dirac) spikes at the observations $\{x_i\}$. That is, it is not consistent with a smooth density because of its great roughness. Maximum penalized likelihood estimation modifies the log likelihood to discourage the roughness of the nonparametric MLE by penalizing the estimator if it becomes too rough. The maximum penalized likelihood estimator (MPLE) [3] is the maximizer of

$$L(f) = n^{-1} \sum_{i=1}^{n} \log f(x_i) - \Phi(f)$$

subject to $\int f = 1$, where $\Phi(f) \geq 0$ is a roughness penalty that decreases as f becomes smoother. The resultant estimator provides a tradeoff between fidelity to the data (from the log likelihood) and smoothness (from the roughness penalty). The estimator also has a **Bayesian** interpretation, with the **prior** for the density having the form $\exp[-\Phi(f)]$ and the posterior mode being the final estimate.

Different choices of Φ yield different estimators. A common strategy is to take $g = \log f$ and $\Phi(g) = \alpha \int [g^{(m)}(u)]^2 \, du, \alpha \geq 0$, where $g^{(m)}$ is the mth derivative of g [14, 15]. Then, $\hat{f} = \exp(\hat{g})$ (note that since the MPLE is defined through exponentiating an estimate of the log-density, it is nonnegative).

The smoothing parameter α controls the amount of smoothing, with larger α resulting in a smoother estimate. As $\alpha \to 0$, the MPLE approaches the nonparametric MLE of Dirac spikes, while as $\alpha \to \infty$, the MPLE becomes the MLE within a parametric family that depends on Φ. For example, if f is defined on the nonnegative numbers, and $\Phi(g) = \alpha \int [g''(u)]^2 \, du$, the limiting family is **exponential**, while if $\Phi(g) = \alpha \int [g'''(u)]^2 \, du$, the limiting family is Gaussian. If f is bounded away from zero, and $\int [f^{(2m)}(u)]^2 \, du$ is finite, then a roughness penalty based on mth order derivatives gives an estimator the **mean square error** (MSE) of which converges to zero at the rate $O(n^{-4m/(4m+1)})$. Note that the estimator does not achieve the usual parametric rate of $\text{MSE} = O(n^{-1})$. This deficiency can be viewed as being the price that one pays for weakening the parametric assumption merely to smoothness.

Penalized likelihood estimators are often called **spline** estimators, since many such estimators take the form of polynomial splines with knots at the order statistics. Asymptotically, the MPLE is approximately a local-bandwidth kernel estimator. If $\Phi(g) = \alpha \int [g''(u)]^2 \, du$, for example, then

$$\hat{f}(x) \approx \frac{f(x)^{1/4}}{n\alpha^{1/4}} \sum_{i=1}^{n} K\left[\frac{(x - x_i) f(x)^{1/4}}{\alpha^{1/4}}\right],$$

with kernel function

$$K(u) = \frac{1}{2} \exp\left(\frac{-|u|}{\sqrt{2}}\right) \sin\left(\frac{|u|}{\sqrt{2}} + \frac{\pi}{4}\right),$$

away from the boundary. Further theoretical analysis of the MPLE can be found in [1], [2], [7], and [8].

The MPLE is difficult to compute, and for that reason various adaptations of it have been proposed. Scott et al. [13] converted the penalized likelihood to one on discrete data by binning the observations, calling this the discrete maximum penalized likelihood estimator (DMPLE), and gave conditions where the DMPLE converges to the MPLE as the bins narrow. O'Sullivan [10] and Gu [6] described other spline-based density estimators.

Penalized likelihood methods also can be generalized to multivariate data, although with increasing

Table 1

	62	63	64	65	66	67	68	69	70	71	72	73	74	75	76
Staff	0	0	0	0	0	0	1	2	3	1	1	3	3	4	3
Trainee	1	1	0	0	1	0	1	3	5	4	0	2	5	0	0

computational difficulties. Natural roughness penalties take the form of sums of squared derivative terms (one for each dimension), such as (for bivariate data)

$$\Phi = \iint \left[\left(\frac{\partial f}{\partial u} \right)^2 + \left(\frac{\partial f}{\partial v} \right)^2 \right] \mathrm{d}u \, \mathrm{d}v$$

(Scott et al. [12], who used a discrete version of this penalty), or

$$\Phi = \iint \left[\left(\frac{\partial^2 \gamma}{\partial u^2} \right)^2 + \left(\frac{\partial^2 \gamma}{\partial v^2} \right)^2 \right] \mathrm{d}u \, \mathrm{d}v,$$

where $\gamma = \sqrt{f}$ [4]. Granville & Rasson [5] proposed and investigated a penalty based on $g = \log f$.

Penalized likelihood estimation has also proven valuable in the estimation of cell probabilities in large sparse **contingency tables**. Consider a K-cell **multinomial** vector $n_i, i = 1, \ldots, K$, with $\sum n_i = n$ and underlying cell probabilities $p_i, i = 1, \ldots, K$. Under the usual asymptotic model of a fixed number of cells K with $n \to \infty$, the frequency estimator $\overline{p}_i = n_i/n, i = 1, \ldots, K$, is **consistent** and fully **efficient**.

Tables in which the sample size is not large compared with the number of cells are called sparse tables, and the usual asymptotics (*see* **Large-sample Theory**) do not provide a reasonable model for them. Sparse asymptotics, where K and n both become infinite at the same rate, provide a theoretical framework for the analysis of large sparse tables. In this situation the frequency estimator is no longer useful, since its good properties require the number of observations in each cell to become infinite. The frequency estimator is not sparse asymptotic consistent, in the sense that

$$\sup_{1 \le i \le K} \left| \frac{\overline{p_i}}{p_i} - 1 \right| \neq o_p(1).$$

In contrast, maximum penalized likelihood estimation leads to a sparse asymptotically consistent estimator. The estimator is the maximizer of

$$\sum_{i=1}^{K} n_i \log p_i - \alpha \sum_{i=1}^{K-1} (\log p_i - \log p_{i+1})^2, \alpha > 0,$$

where α is the smoothing parameter. Assuming appropriate smoothness and boundary conditions on the underlying probability vector $\mathbf{p}$, the MPLE $\hat{\mathbf{p}}$ is sparse asymptotic consistent, with convergence rate [16]

$$\sup_{1 \le i \le K} \left| \frac{\hat{p}_i}{p_i} - 1 \right| = O_p[K^{-2/5} (\log K)^{2/5}].$$

An application of maximum penalized likelihood estimation to sparse categorical data is illustrated in Table 1. The data, originally from [9], and further analyzed in [11] and [17], represent the performance of staff and trainees in correctly interpreting diagnostic tests given to psychologically disturbed patients, as measured by counts of people at the different performance levels. The question of interest here is whether the performance of staff and trainees differs.

In Figure 1 are given the observed relative frequencies [part (a)], and the (smoothed) penalized likelihood estimates [part (b)] (staff probabilities are represented by solid lines connecting $\times$'s, while trainee probabilities are represented by dotted lines connecting $\circ$'s). Because of the roughness in the estimates, it is difficult to see from the unsmoothed relative frequencies what the relative shape of the distributions is. In contrast, the smoothed estimates clearly show multimodality in both group's scores, with lower scores (less than 72) more probable for trainees, and higher scores (greater than 72) more probable for staff members.

Notes

1. IMSL provides a Fortran subroutine to calculate a discrete maximum penalized likelihood density estimate.
2. RKPACK-II, a collection of Ratfor routines for penalized likelihood density estimation, is available using a World Wide Web browser at the URL, at `http://www.stat.purdue.edu/~chong/rkpk2.shar.gz`.

Penetrance

There is a relationship between the underlying **genotype** and the observed phenotype of an individual that must be defined in describing the genetic basis of a trait. The function that describes this relationship is called the *penetrance function*, and is defined in a general sense as the conditional probability that an individual with genotype g expresses phenotype y : $\Pr(y|g)$ for a discrete trait, or $\phi(y|g)$ for a continuous trait, where ϕ is the probability density function. Specification of such a penetrance function, along with associated parameter estimates, is a necessary component in computations that are based on **maximum likelihood** methods and requires relationships between genotypes and phenotypes (*see* **Genetic Counseling**; **Linkage Analysis, Model-based**; **Segregation Analysis, Complex**).

When the relationship between the genotype and the phenotype is simple, as is the case for most **blood groups**, this conditional probability is either 0 or 1, depending on the particular combination of genotype and phenotype. For many traits, however, the relationship between specified underlying genotypes and possible resulting phenotypes is not so clear. For these traits, the penetrance function can be thought of as a quantitative model that summarizes our lack of understanding about the underlying mechanisms relating genotype to phenotype. In defining the penetrance function in these cases, we make the implicit assumption that $\Pr(y|g)$ is an average over all possible individuals with genotype g, and that these individuals have been randomized for all factors that have an impact on this probability.

There are a number of commonly used penetrance functions. For some phenotype–genotype combinations, $\Pr(y|g) = k$, where $0 < k < 1$ but k is a constant. This model is called a *fixed-penetrance* model, and has been well described in experimental organisms. For example, in the fruit fly *Drosophila melanogaster* there is a **gene** for which 90% of homozygotes for allele i have an interrupted wing vein [5]. This *reduced penetrance* probability remains 90% in offspring of matings between obligate homozygotes for the i allele, regardless of whether the i/i parents have normal or interrupted wing veins. In humans, there are many genetic disorders that behave in a similar manner to this reduced penetrance example in flies. For example, in the autosomal dominant disorder split-hand deformity, $\Pr(\text{disease}|\text{genotype} = Dd) \cong 0.7$, where D is the disease allele and d is the normal allele [7]. For phenotypes that are easily dichotomized into normal vs. abnormal phenotypes, this narrower definition of penetrance is often used: that of the *penetrance* of a genotype, where it is specifically the penetrance $\Pr(y = \text{disease}|g)$ that is of interest, possibly for different underlying genotypes, g. This narrower definition of penetrance is used only in the context of inherited diseases (in humans) or unusual phenotypes (in nonhumans).

Frequently, the penetrance differs among individuals as a function of some identifiable **covariate**, which can then be incorporated into the model. Covariates might include such intrinsic characteristics of an individual such as age or sex, or might include extrinsic characteristics such as diet or exposure to some environmental factor. The penetrance function may then be defined as $\Pr(y|g, c)$, where c may be a vector of covariates. It is quite common, for example, to assume that males and females have different penetrance functions for certain phenotypes, such as the probability of baldness.

Age is a particularly common covariate in penetrance functions for human diseases. Examples include breast cancer, Alzheimer's disease, and Huntington's disease. For each, the probability that disease has developed increases with the age of the individual. Typically, either a cumulative **normal distribution**, or a straight-line penetrance function (with a minimum and maximum age of penetrance and a linear increase between them) is used. Other functions are also possible, including use of liability classes for age intervals, with fixed but increasing penetrance for each interval [6]. The parameters for the functions will vary across genotypes, including the possibility of 0% penetrance at all ages for some genotypes (e.g. the nonsusceptible genotype for Huntington's disease), or the possibility of sporadic forms of the disease with later mean onset than the "genetic" forms (e.g. early-onset Alzheimer's disease [3]). In model-based analyses of diseases with sporadic cases, computation of **likelihood** for linkage analysis (*see* **Linkage Analysis, Model-based**) or **genetic counseling** requires using the density function and age at onset for affected individuals, and the cumulative distribution function and age at last examination or at death for unaffected individuals [4] since ultimately what is desired is the reverse probability, $\Pr(g|y)$.

A disease with age-dependent penetrance can also be affected by other covariates. For example, $\varepsilon 4/\varepsilon 4$ homozygotes at the ApoE locus have a lower mean onset age of Alzheimer's disease than do individuals with other ApoE genotypes [2]. Separate age-dependent penetrance functions for different ApoE genotypes increased the likelihood in a linkage analysis [3], as is expected if this model fits the data better than one which did not account for this discrete covariate.

The penetrance function may, in principle, also take into account genotypes at multiple loci, e.g. $\Pr(y|g_1, g_2)$, where g_1 and g_2 are genotypes at two loci. In humans, relatively few such multilocus systems have been characterized well enough to define precise multilocus penetrance functions. Until the specific interacting loci have been identified, the penetrance function will generally be parameterized in terms of only one locus, which should be adequate for describing penetrance in unrelated individuals unless there is **linkage disequilibrium** at the population level between this locus and additional contributory loci. However, for computations on related individuals, the increased sharing of alleles identical-by-descent (*see* **Identity Coefficients**) in closely, vs. more distantly, related individuals means that a single-locus penetrance function will only approximate the correct penetrance probabilities in computations on pedigrees. While this has little effect on initial linkage analyses [1], the resulting model-misspecification may reduce the ease by which such a disease locus can be localized to a very small genomic region by **multipoint linkage analysis**.

Person-years at Risk

In follow-up studies of subjects subsequent to various treatments or exposures and in the study of chronic disease where the **incubation period** or length of illness may be months or years, consideration must be given to the time the subjects were under observation or to the time intervening between the initial exposure and the eventual outcome, e.g. recovery, onset of disease, or death. If the probability of a given outcome is related to time, outcome measures are affected by the length of the observational period [1].

Person-years at risk are units of measurement which combine persons and time by summing individual units of time (years and fractions of years) during which subjects in a study population have been exposed to the risk of the outcome under study. A person-year is defined as the equivalent of the experience of one individual for one year [2]. Each subject contributes only as many years as he or she has been actually observed (or exposed); a subject under observation for one year contributes one person-year; six months would contribute one-half person-year, etc. Person-years at risk frequently comprise the denominator of calculations of **incidence rates** measured over extended and variable time periods or of measures of morbidity and mortality resulting from chronic exposure to environmental hazards such as industrial toxic waste materials or cigarette smoke.

ROBERT A. ISRAEL

Person-years of Life Lost

For public health planning purposes it is important to have measures of the impact of particular diseases and of the potential impact of preventive measures, and one of the most useful and intuitive of such measures of impact is *person-years of life lost*, sometimes termed, *potential years of life lost*, and generally abbreviated as *PYLL*.

In principle, the measure is straightforward. In a stationary or **life table** population, the person-years of life lost due to a particular cause of death represents the difference between the expectation of life of the population and the expectation of life with the cause in question eliminated (*see* **Life Expectancy**). Standard methods are available for the calculation of cause-deleted life tables [2]. In an actual population, the PYLL are obtained by taking the deaths at each age due to the cause being examined, and calculating the years those people would have lived according to the cause-deleted life table [1]. Like life expectancy, the PYLL may be calculated from birth or any other age, or over any given age range. Also like life expectancy, it gives greatest weight to the deaths at the youngest ages.

In practice, there are a number of complications, arising from two main sources: judgments about the value of life at different ages; and the problem of **competing risks**.

Person-years of life lost is often used as a measure in cost-of-illness studies, and in this context it is common to restrict its calculation to the years of economically active life (e.g. between 15 and 65). In other contexts, it is generally calculated up to a particular upper age limit, e.g. 65, 70, etc. The use of such cutoffs is virtually universal, despite the obvious theoretical weakness in arbitrarily weighting or valuing all years lived (or lost) inside the limits at unity and all those lived outside the limits at zero.

One reason for excluding deaths at older ages is the problem of **competing risks** and the difficulty of determining a single cause of death in older people with multiple potentially lethal conditions. Competing risks are, in fact, an issue at all ages, and the various approximate methods which have been used to calculate the index differ principally in the extent to which they attempt to come to terms with competing causes of death. It is still common, for instance, to base the calculation on the assumption that, if the cause were eliminated, the individuals "saved" would all survive to the upper age limit being used (e.g. 65 years). That clearly overestimates the years lost, because in that period such individuals would remain at risk of dying from other causes. A second approximation involves applying the total mortality to the lives saved; this underestimates the PYLL, because it includes the cause that is meant to have been eliminated.

Apart from these technical issues, the principal shortcoming of the method is that basing it on cause-deleted tables incorporates an inadequate model of disease causation and prevention. Public health activities are principally aimed at elimination or reduction of risk factors rather than causes of death, and as in the case of smoking, one risk factor may result in deaths from a variety of causes. Where appropriate, the use of **attributable fractions** to convert PYLL due to particular causes to PYLL due to particular risk factors is a more realistic approach.

L. SMITH

Petty, William

Born: May 26, 1623, in Romsey, Hampshire, UK.
Died: December 16, 1687, in London, UK.

Petty was a precocious youth. His father was a clothier, and the young Petty learnt many of the skills of the business while he was learning Latin and Greek at school. At the age of 14 he became a cabin boy and attracted attention in France, during a period of recovery from a broken leg, as "le petit matelot anglais qui parle latin et grec". He spent a few years abroad, teaching English and navigation, and studying at the Jesuit College in Caen. He returned to England to join the Royal Navy, but in 1643, after the outbreak of the Civil War, he returned to the continent, studying medicine and mathematics in Utrecht, Amsterdam, and Leyden. After a period in Paris, he returned to England in 1646, joining his father's business. During this period, he sketched the idea of a national scientific society, later to be embodied in the Royal Society, of which he would become a founder member.

After a while, he moved to Oxford to continue his medical studies, and in 1649 he was made a Doctor of Physic and Fellow of Brasenose College. By 1651 he had become Professor of Anatomy and Vice-Master of Brasenose.

In about 1652 he was appointed Professor of Music at Gresham College, apparently with the influential help of his friend **John Graunt**. But almost immediately he left for Ireland, where the Commonwealth government was engaged in resettlement and in the forfeiting of estates of Irish landowners who were in debt to the government. For this purpose a survey of these estates was required, and Petty was entrusted with the task, which eventually expanded to the complete mapping of Ireland. He became involved in Commonwealth politics, but after the Stuart restoration in 1660 he found himself on good terms with the monarchists, and was knighted by Charles II on the granting of the Charter to the Royal Society in 1662. Petty had by now become a key figure in London intellectual circles.

In the meantime, Graunt, hitherto a prosperous trader, had become bankrupt, and Petty was able to repay Graunt's earlier generosity by giving him material support until Graunt's death in 1674.

Petty shared Graunt's interest in demographic matters (*see* **Demography**), and published many essays on **vital statistics**, inventing the term "political arithmetic". He was not a pioneer of Graunt's calibre, and earlier rumours that he had written Graunt's *Observations on the Bills of Mortality* appear to be unfounded. His economic writings include a *Political Anatomy of Ireland*, and *A Treatise of Taxes and Contributions*. For a modern statistician perhaps his greatest contribution was the advocacy of a national statistical office, to enumerate population (*see* **Censuses**), evaluate property, organize tax collection and improve the public health. His assessment of the importance of official statistics can perhaps be judged from this delightful quotation: "God sent me the use of things, and notions, whose foundations are secure and the superstructures mathematical reasoning; for want of which props so many Governments doe reel and stagger."

Greenwood's epitaph [2] is appropriate: "Careless, happy-go-lucky, tendentious; yes, all of that. But anyone who has felt the exhilaration ... in the doing of sums concerning biological problems, feels his heart warmed by the arithmetic knight errant who had so many statistical adventures" (see also [1] and [3]).

PETER ARMITAGE

Pharmaceutical Industry, Statistics in

Pharmaceutical statistics is an emerging discipline that is going through the classical stages of growth of a developing science: first, as a loose collection of topics; next, as a recognized subspecialty; and finally as a largely separate discipline. In this respect, it is following closely on the heels of medical statistics as it emerges from the science of statistics, which in its turn has followed the emergence of statistics from mathematics. These developments can be traced through the founding of journals devoted to these respective subjects. **Karl Pearson** founded ***Biometrika*** in 1900 because he found that his papers were too mathematical for the biologists and too biological for the mathematicians. ***Biometrics*** was started after World War II, amongst other reasons, because *Biometrika* was perceived as being too abstract for the life scientist. ***Statistics in Medicine*** has had a phenomenal growth since its beginning in the 1980s and this is surely at least partly due to the increasing numbers of statisticians working exclusively in medicine and with no interest (say) in agriculture. More recently, a new journal has appeared, ***The Journal of Biopharmaceutical Statistics***, and although we can expect that many papers on pharmaceutical statistics will continue to appear in *Statistics in Medicine* in the same way that papers on medical statistics continue to appear in *Biometrics*, no doubt we can expect to see a growth in this more specialist outlet for pharmaceutical statistics. Perhaps eventually we will even see the need for a specialist *Encyclopedia of Pharmaceutical Statistics*!

Obviously, there is still a considerable overlap between pharmaceutical statistics and medical statistics. There are, however, many topics which are given a different emphasis even if attention is restricted to a field of common interest: the design and analysis of **clinical trials**. For example, two of the most important topics of research in the statistics of clinical trials in the last quarter of the twentieth century have been **survival analysis** and group sequential (*see* **Data and Safety Monitoring**) methods. Although both of these are of some importance to pharmaceutical statistics, in fact it is only a small minority of trials in which survival is the main outcome, and even fewer which are run sequentially. On the other hand, **crossover trials** are much more important than in medical statistics generally and there are various other topics such as **pharmacokinetic** modeling that really apply only in connection with drug development [18].

Drug Development

Before describing the role of the statistician in drug development, it is appropriate to say something about drug development itself. It is the process of finding and producing therapeutically useful pharmaceuticals and of turning them into high-quality formulations of usable, effective, and safe medicines. It is also the process, however, of delivering valuable, reliable and trustworthy information about appropriate doses and dosing intervals and about likely effects and side effects of these treatments. Drug development is carried out by *sponsors* (mainly pharmaceutical companies), and its acceptability is judged by *regulators* such as the **Food and Drug Administration (FDA)** of the US or the **Medicines Control Agency (MCA)** in the UK. It is an extremely complex business and the risks are high, but the potential rewards are also considerable.

The phrase *drug development* is used in two different senses within the pharmaceutical industry. In its more general sense, it covers all the activities leading to the eventual marketing of a pharmaceutical. In a more restricted sense, a distinction is made between drug research, which covers the study of basic mechanisms of action and the identification of candidate substances, and drug development proper, which covers the business of producing suitable formulations and studying their effects in man.

It takes many years for a project to reach drug development proper. First, basic research must be undertaken to validate concepts and mechanisms. The choice of therapeutic areas to investigate will depend on commercial potential and this in turn requires a thorough understanding of disease areas and current therapies in order to establish unmet medical need. Intelligence reports regarding these matters will continue to be produced throughout the life of a project. Next, a lead compound must be identified for a particular indication. This will then be subject to a battery of screening tests to

assess its potential in terms of therapeutic activity. Back-up compounds will also be investigated. If a compound looks promising it will also be evaluated from both safety and practical points of view. Will it be easy to formulate? How many steps are involved in the synthesis? How difficult will it be to manufacture in large quantities? Before a treatment can go into development, not only must satisfactory answers have been obtained to all these questions, but a viable pharmaceutical formulation permitting further study must be available. This can be an extremely delicate matter, involving work to develop suitable solutions, pills, patches, or aerosols, as the case may be (*see* **Preclinical Treatment Evaluation**).

If and when a molecule is accepted into drug development proper, animal studies will be undertaken in order to check safety and to establish a dose at which studies in man may be undertaken. Once basic toxicological work has been undertaken, **phase I** may begin and the first such studies may start. These will be single-dose studies in which lower doses are tried first and cautiously increased until a maximum tolerated dose may be established. In many indications such studies are carried out on healthy volunteers but where the treatment is highly aggressive (and hence intended for serious diseases) patients will be used instead. In the meantime longer-scale toxicological studies with animals will have been completed. Pharmacokinetic studies in man will be undertaken in which the concentration–time profile of the drug in blood will be measured at frequent intervals in order to establish the rate at which the drug is absorbed and eliminated (*see* **Bioavailability and Bioequivalence**). These studies together, if successful, will permit multiple dose studies to be undertaken.

Once maximum tolerated doses have been established, **phase II** begins and dose-finding studies in patients are started. This is usually an extremely difficult phase of development but, if the drug proves acceptable, the object is that preliminary indications of efficacy should be available and that a firm recommendation for doses and dose schedules should emerge. Once these studies have been completed, the pivotal phase III studies can begin. These have the object of proving efficacy to a skeptical regulator and also of obtaining information on the safety and tolerability of the treatment.

A successfully completed development program results in a dossier: an enormous collection of clinical trial and other reports, as well as expert summaries covering not only the clinical studies as regards efficacy and safety but also preclinical studies and other technical reports as well as details of the manufacturing process. The purpose of this dossier is to reassure the regulator as to quality, safety, and efficacy of the pharmaceutical. If successful, the package leads to registration, but even during the review process, phase IV studies may have been initiated in order to discover more about the effect of the treatment in specialist subpopulations, or perhaps with the object of providing data to cover price negotiations with purchasing authorities. These *reimbursers* may include national health services but also agents acting for private health care plans.

Once a drug has been launched on the market the process of monitoring and "pharmacovigilance" begins in earnest, since the drug will now be used by far more people than was ever the case in the clinical trials in phases I to III, and rare side effects, which could not be detected earlier, may now appear [18]. Some further phase IV **postmarketing surveillance** studies may be initiated and further work extending indications or preparing new formulations may be undertaken.

It is important to stress that all this work is carried out to an extremely high standard [1, 5, 9, 18]. A sponsor will have standard operating procedures to cover all aspects of the trial, from informed consent for patients (*see* **Ethics of Randomized Trials**), to report writing, passing such diverse matters as the handling of human specimens, monitoring, drug disposal and accounting, source data verification, database management (*see* **Data Management and Coordination**), and, of course, statistical analysis en route. These, in turn, will reflect regulatory guidelines [2]. The results will be closely examined by regulators and this examination will, in some cases, involve reanalysis of the data and even study-site visits [4, 5, 9] (*see* **Drug Approval and Regulation**). Of course, in-house quality control and assurance also receives a great deal of attention and the typical sponsor will have a number of auditors and monitors, who, although not necessarily statisticians, will make important contributions to data quality. The net result is that the average standard that applies to clinical trials within the pharmaceutical industry is far higher than that which applies outside.

Statistics in Drug Development: The Current Position and Recent Past

A top pharmaceutical company will employ between 50 and 150 statisticians in a number of sites worldwide dealing with various aspects of drug development and research. Activities in which statisticians can become involved include [18]:

1. Optimization in chemical, pharmaceutical, or manufacturing development
2. Animal toxicology experiments
3. Bioassay (*see* **Biological Assay, Overview**)
4. Project prioritization and portfolio management
5. Quality control
6. Pharmacoeconomics (*see* **Pharmacoepidemiology, Overview**)
7. Pharmacokinetics
8. Epidemiology and drug monitoring
9. Design and analysis of clinical trials.

The last of these has always been the most important area of activity for the pharmaceutical statistician but others, in particular epidemiology and pharmacoeconomics, are growing in importance. The potential for the statistician to contribute to portfolio management is also considerable [17, 18].

The randomized clinical trial (RCT) provides the *fiducial framework* which permits the regulator to mandate the sponsor to carry out drug development. The allocation of patients to treatment usually involves an element of **randomization**, thus reducing the sponsor's ability to manipulate results. Each trial has an extensive protocol covering all aspects of its conduct. It will also include a detailed description of the data which will be collected and the intended analysis and these must be presented or accounted for in the final report (*see* **Clinical Trials Protocols**). A concern, sometimes amounting to an obsession, with prespecified analyses is, in fact, one of the characteristic features of pharmaceutical statistics.

It is the norm, of course, for trials to be designed jointly by at least one physician and one statistician. Indeed, the Good Clinical Practice Guidelines of the European Union state, "Access to biostatistical expertise is necessary before and throughout the entire procedure, commencing with the design of the protocol and ending with completion of the Final Report." There has been a remarkable growth in the number of statisticians employed by the pharmaceutical industry since the 1970s. The first phase of this growth was in the primary industry, but latterly there has been an explosion in the secondary industry: the Contract Research Organizations (CROs) (*see* **Proprietary Biostatistical Firms**). This is illustrated by the change in membership of **Statisticians in the Pharmaceutical Industry (PSI)**, a UK-based body, since it was founded in the late 1970s. In the late 1980s, through the creation of the category of Associate Member, it was opened to those not working in the primary industry and they now exceed ordinary members in number.

This growth in pharmaceutical statistics has taken place both in North America and in Europe and, as regards the statistical expertise available to sponsors, there is no disparity between the two regions. (Japan, although actively involved in the harmonization of drug regulations, has lagged behind in this respect.) As regards regulators, however, until recently the discrepancy was considerable. The FDA employs about 120 statisticians in human health but until the 1990s there were none in the European Union. The **Royal Statistical Society** (RSS) was so concerned by this state of affairs that it issued a report in an attempt to encourage statistical representation in drug regulation [12]. The position has now improved considerably, with statisticians, for example, in Germany, Sweden and the UK. This is a welcome development, since employing physicians to consider statistical arguments is clearly an inefficient and ineffective use of resources.

Statistical topics which have been of particular interest to pharmaceutical statisticians, whether working for regulators or sponsors, are:

1. Design and analysis of crossover trials [16]
2. **Equivalence** testing [18]
3. Pharmacokinetic and pharmacodynamic models [10, 14, 21]
4. Repeated measures
5. Dose finding [22]
6. **Bayesian methods**
7. **Nonlinear random effect** modeling [10, 21]
8. Professional and practical statistical matters [1, 5].

Two Examples

Statisticians employed in the industry can be involved in a wide variety of tasks. Two examples are given here to illustrate the breadth.

Formoterol

The first concerns the development of a new formulation of a drug, formoterol (eformoterol in the UK) [19]. Formoterol is a beta-agonist used to treat asthma and a series of trials carried out over a number of years had succeeded in demonstrating that it had a rapid onset and 12 hours duration of action [11]. This was a considerable improvement over the drugs then available, which had a 4–5 hour duration.

A single-dose dry powder formulation had been developed and it was desired to show that a dry powder multidose formulation would be equivalent. Normally, one would attempt to do this by measuring concentration–time profiles of the active substance in the blood, but this was impossible because (a) at 12 μg for a standard dose (80 000 doses weigh less than a gram), formoterol is not detectable by bioassay, and (b) even if it were, 90% of it is swallowed and although some of this is eliminated in "the first pass", the portion that remains might be a large (but irrelevant for efficacy) part of what you would detect. Hence, it is necessary to study the effects in patients to compare the formulations.

This raises an issue of sensitivity, however, and to show that equivalence is not falsely concluded simply because the top of the **dose–response** curve has been reached for each formulation, it is necessary to compare various doses of each formulation: a parallel groups design. It is also necessary to include a placebo (*see* **Blinding or Masking**). As a result, it was decided to compare three doses of each formulation with a placebo. There were thus seven treatments. **Sample size calculations** showed that for a parallel group trial 200 patients per group would be needed for the target precision. For these sorts of numbers, however, one might as well start a development from scratch. On the other hand, a seven period crossover was out of the question: for reasons of patient compliance, five was the most periods that could be contemplated.

In the end an **incomplete blocks design** was chosen in 21 sequences replicated six times and five periods chosen in such a way that each patient received five different treatments. Each treatment appeared equally often in each period, so that each pair of treatments was equally represented amongst the 126 patients. The design proved to be a considerable success but the new formulation was not. The trials showed unequivocally that the new formulation was less potent: at least 24 μg of the multidose dry powder were necessary to show the same effect as 6 μg of the single-dose formulation.

Project Prioritization

The second example concerns work on project prioritization: how does one choose which drug development projects to pursue [17]? Everyone agrees that probability of success, cost to develop, time to develop, and potential sales are the important considerations, but there is no general consensus on how to combine them.

A simple insight is sufficient to show, however, that it is necessary to dig deeper into projects to establish their worth. If two drugs have identical overall probabilities of success, identical overall costs to develop, identical rewards and so forth, any index based on weighting these factors would have to score them identically. However, if one project were such that it would fail early if it failed it would be much more valuable than another which would fail late if it failed. Hence, what is needed is an index that goes into the cost and probability architecture of the projects. Such indices can be based on **decision analysis**, a subject developed originally by statisticians, and it is thus just as important to the pharmaceutical industry for statisticians as for marketers to be involved in this problem.

Statistics, Drug Development, and the Future

The pharmaceutical industry is currently facing a strong economic challenge as a consequence of rapidly increasing health care costs and price curtailment policies. This has various implications for the work of the pharmaceutical statistician. First, price regulation is forcing sponsors to consider pharmacoeconomics and to provide reimbursers with evidence regarding "value for money". There has been a rapid growth in the number of pharmacoeconomic studies. Many of these have been carried out through the medium of the RCT. The RCT is not, however, ideally suited to this and it will be necessary in the future to combine information from a number of sources using complex models, whereby current knowledge is used to predict the probable health effects and cash flow resulting from introduction of

a pharmaceutical. This will be a great collaborative opportunity for the statistician. Since the fiducial framework of the RCT does not cover this, it is doubtful that reimbursers will be able to mandate sponsors to carry out these studies and as a consequence we shall see the rise of third party analysis. Of course, the industry will also have to carry out these analyses, if only to predict what conclusions others will come to.

Secondly, specialization is the order of the day, and more and more work of all kinds, including statistical work, is being subcontracted by sponsors. The CROs seem to provide sponsors with an attractive option to disinvest: something which is only done with difficulty with your own staff. However, business is value added and if the CROs are adding the value, this is an area of business lost to the primary industry. Where will it all end? Will CROs eventually become the commissioning partners and trawl the primary industry for molecules to develop? Will the major pharmaceutical companies gradually turn themselves into nothing more than the providers of venture capital?

The third economic concern of the industry is speed. All sponsors are trying to shorten development times. One consequence for statistics is that the time available to complete the final analysis has been reduced from weeks to days. This means, of course, that all computer programs have to be developed before the trial is over and validated and run on blinded data before finally being applied to the "cleaned" and decoded database. The irony is that this practice, a reflection not only of economic but also of regulatory pressure for prespecified analyses, means that at a time when **exploratory data analysis** has never been easier, it has been rendered virtually obsolete. This development is not all bad: far from it. Exploratory data analysis has always carried with it the danger of overinterpretation. Far more attention will have to be given to prior specification, whether the framework is frequentist or **Bayesian** (*see* **Inference**). Nevertheless, the trend is worrying and many companies would do well to consider the possibility of creating secondary databases for nonregulatory analyses: the sort that could be carried out at leisure and whose results could inform the design of further trials. More serious, however, is that some companies are reducing development times by moving towards doing activities in parallel. This is extremely costly when a project fails and what is needed is to carry out the sort of statistical decision analysis described above to see if it is justified.

Finally, the new concern with economics means marketing will have to change. The golden era of the "detail man" is over and marketing will be carried out by highly qualified sellers to a few specialist buyers. Evidence (which in this context is just another word for data and statistical analysis) will become more important in selling the product and the need for statistical support for marketing will increase.

Subgroup analysis (*see* **Treatment-covariate Interaction**) will become more important. Recently, the **National Institutes of Health (NIH)** and FDA have insisted that women and minorities be adequately represented in clinical trials [7, 8]. This is not as simple as it might seem. If a highly effective treatment for lung cancer is found it will have been found on the basis of studies where most patients were male. (To insist that the same numbers of females should be represented would simply delay recruitment and the eventual proof of efficacy). Can it then only be prescribed for men? Must further trials be run until the same number of women have been studied? Bayesian methods or frequentist approaches which consider **mean square error** will be needed to deal with this problem [18]. The issue can only become more important since the Human Genome Project will deliver ever more ways (and perhaps more relevant ways) of classifying patients into subgroups [15]. (It may, of course eventually deliver a host of novel therapies, although there are reasons for not hoping for too much in the near future from this quarter [3].)

An important movement affecting clinical practice is **evidence-based medicine** [13], an idea which originated at McMaster with Sackett and colleagues. This requires the individual physician to integrate global information on the efficacy of treatment into his or her daily medical practice by formulating precise questions concerning the care of the individual, searching medical databases (*see* **Administrative Databases**) for the answer, critically appraising the evidence, deciding on a treatment, and carrying out a follow-up evaluation. A president of the RSS has even suggested that it should be extended to public policy making generally [20]. If it does it will only increase the pressure and need for more information. The quality of information available in dossiers submitted to regulatory authorities far exceeds that in

published reports. This raises an interesting possibility: will there soon be a requirement that regulatory dossiers, together with standard summaries, be made available on-line? If so, will there be commercial organizations whose sole purpose is to "surf the Web" and produce analyses which they will then sell to health care purchasers (*see* **Internet**)? Will the industry statistician be constantly looking over his or her shoulder, knowing that all analyses will eventually be repeated and modified by others who come after?

So far potential developments in pharmaceutical statistics have been looked at from the point of view of the requirements of the user. What of statistics itself? Here, various trends can be discerned. The first is the rapid rise in the use of Bayesian methods. The next few decades will show whether these are so successful that frequentist methods completely disappear by the time the DeFinetti–Lindley limit of 2020 has been reached [6]. However, whether or not we all become Bayesians, there are two Bayesian lessons that all pharmaceutical statisticians are having to learn. The first is the importance of **random effects** models; for example, models that permit appropriately combining information obtained from repeated measures on a given patient in a particular center with further information on the response of all patients in that center, and even with information on all patients in the trial, in order to produce better descriptions of the effect of the treatment for him or her. The second lesson is the importance of using prior knowledge, in particular biological knowledge, when choosing models for analysis (*see* **Model, Choice of**).

One of the advantages brought by progress in computing is that more difficult calculations can be undertaken. Currently there is a lack of satisfactory methods for dealing with **missing data**, patients who take rescue medication, noncompliance, and so forth. Some of the difficulties are inherent, but in some cases the pharmaceutical statistician is held back simply because computation is too difficult. These are topics that will receive more attention in the future simply because the ability to deal with them increases. Also included under this heading are nonlinear models, as used for example in repeated measure designs for pharmacodynamic dose–response.

Thus, a forecast of the duties of the pharmaceutical statistician and the nature of pharmaceutical statistics during the next decade might suggest:

1. That (s)he will have to know more about Bayesian methods.
2. Random effect models will be extremely important in his or her work.
3. In general, he or she will more often have to carry out complex and nonlinear modeling than is currently the case.
4. The incorporation of biological and pharmacological insights in planning and analysis will be more important.
5. The RCT will continue to be important but the proportion of statisticians not working on planning and analyzing RCTs but instead in health and economic modeling, epidemiology, and so forth will rise.
6. The statistician will become more involved in producing the clinical expert report (the overall summary of evidence for an application) [5].
7. There will be a much greater chance that the statistician will not be working in the primary industry.
8. Communication will be of the essence.

Pharmacoepidemiology, Adverse and Beneficial Effects

Pharmacoepidemiology has been defined as "the study of the distribution and determinants of drug-related events in populations and the application of this study to efficacious drug treatment" [26]. Similar definitions have been given by several authors [37, 53]. The term "drug" in the definition is generally understood to include biologics, such as vaccines, and the populations are understood to be human. The emphasis is on studies of the safety and effectiveness of drugs used for medical purposes. Both randomized (*see* **Clinical Trials, Overview**) and nonrandomized (**observational**) designs are used, with the latter being more common, especially for the study of adverse effects. Pharmacoepidemiology may be regarded as a subdiscipline of both **clinical epidemiology** and clinical pharmacology [53]. However, clinical pharmacologists typically use small, carefully controlled studies to examine drug **pharmacokinetics** (absorption, distribution, metabolism, and excretion) and pharmacodynamics (the relationship between the drug level and drug effects), while pharmacoepidemiologists typically examine drug effects in larger populations under conditions more representative of clinical practice. Pharmacoepidemiology is an essential component of risk management of pharmaceutical products. Risk Management "encompasses processes for identifying and assessing the risks of specific health hazards, implementing activities to eliminate or minimize those risks, communicating risk information, and monitoring and evaluating the results of the interventions and communications" [56].

Current US federal regulations require evidence of both safety and effectiveness of drugs prior to approval for marketing (*see* **Drug Approval and Regulation**). However, such evidence is limited by the extent, duration, and patient characteristics of preapproval clinical trials. In addition, unexpected potentially beneficial effects are sometimes found after marketed use and questions may arise about the effectiveness of various drugs under conditions of use and in patient populations not included in premarketing clinical trials. A well-known international guideline on the extent of patient exposure to assess the clinical safety of drugs intended for chronic use in the treatment of non-life-threatening conditions summarized limitations of preapproval information on safety by noting, first, that it is expected that short-term adverse events with a cumulative 3-month incidence of about 1% or more should be well characterized prior to approval; secondly, that events where the rate of occurrence changes over a longer period of time may need to be characterized depending on their severity and importance to the risk–benefit assessment of the drug; and thirdly, that adverse events occurring in less than one in 1000 patients treated are not expected to be characterized prior to market approval [22]. Thus, it is often necessary to conduct pharmacoepidemiologic studies of risks and benefits of drugs and vaccines under conditions of marketed use (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**).

To design and interpret such studies it is essential to understand the clinical pharmacology of the drug and the pathophysiology and natural history of the diseases which the drug is used to treat or prevent. It is also essential to understand basic principles of epidemiologic study design (*see* **Pharmacoepidemiology, Study Designs**) and to identify and avoid potential sources of **bias**.

Some Common Sources of Bias in Pharmacoepidemiologic Studies

In the epidemiologic literature *bias* refers to an error which causes an estimate of a parameter to differ in a systematic way from the true value [26] in the source population, also known as the *study base*, whose person-time experience (*see* **Person-years at Risk**) the study is designed to sample [31, 57]. Numerous authors have provided methodologic approaches by which sources of bias in epidemiologic studies may be categorized [41, 43, 51] (*see* **Bias in Case–Control Studies**; **Bias in Cohort Studies**; **Bias in Observational Studies**; **Bias, Overview**). We will briefly discuss some of the more common sources of bias in epidemiologic studies of drug effects.

Selection bias refers to errors arising because the estimated exposure effect among subjects included in the study differs from that which would have been obtained from including the entire study base [41]. For example, selection bias may occur when the

cases included in a study represent a nonrandomly selected subset of all of those arising from the study base [45]. Selection bias may also occur in **hospital-based case–control studies** if the drug exposure is related either positively or negatively to the diagnoses used to select **controls** or the drug exposure in the catchment population of the diagnoses used to identify cases differs from that in the catchment population of the diagnoses used to identify controls [57]. Differences in catchment populations are a particular problem with hospital-based studies because in many teaching hospitals patients may be drawn from hundreds of miles away for treatment of certain illnesses requiring particular skill in management and from only the immediate surrounding few miles for treatment of common disorders that are often used to select controls (*see* **Hospital Market Area**). Selection bias can produce serious distortions in estimates of disease natural history or treatment outcomes of patients drawn from referral centers [1, 28].

Confounding in epidemiologic studies occurs when exposure groups differ with respect to an extraneous factor related to the outcome. Estimates of exposure effects that fail to account appropriately for the imbalance are subject to bias. A full discussion of the assessment and control of confounding is beyond the scope of the present article and may be found in standard textbooks and in the current literature [41, 58, 60]. However, it is useful to mention *confounding by indication*, a particularly problematic form of confounding in studies of medical interventions when an indication for the intervention is itself a risk factor for the outcome under study [44, 59]. Studies in which confounding by indication has been an important consideration include mortality among asthma patients using long-acting inhaled beta agonists [7], myocardial infarction among hypertensive patients prescribed calcium channel blockers [38], and renal cell carcinoma in association with the use of diuretics [19]. A common way to avoid some obvious confounding by indication is to compare adverse outcomes of two drugs used for the same indication [7, 38]. However, even when the nominal indication is the same for two drugs, there may be subtle differences in patient characteristics and clinical judgments which lead to the choice of one drug over the other, are not documented in medical records, and yet which may be risk factors for the outcome.

A form of bias, which is closely related to but conceptually distinct from confounding by indication is *protopathic bias* [12, 44]. This occurs when early symptoms of a disease which is present but not yet recognized lead a patient to take a drug, which then appears to be the cause of the disease when it is eventually diagnosed. A classic example of this form of bias was seen in early studies of the antiulcer drug cimetidine, where a higher than expected incidence of gastric carcinoma was found among users than among nonusers. It is likely that many of the cancers were present but undiagnosed at the time the cimetidine was started. Subsequent studies with this class of drug have shown that elevations in gastric cancer risk diminish with duration of follow-up, returning to baseline with long-term use [23]. Not only protopathic bias but also confounding by indication was likely present in the association between cimetidine and gastric carcinoma. Peptic ulcer is both an indication for cimetidine and a risk factor for gastric carcinoma, with Helicobacter pylori being causally related to both peptic ulcer disease and gastric carcinoma.

Information bias arises from inaccuracies in the information collected on subjects in the study, resulting in **misclassification** of exposure, outcomes, or **covariates**. For example, patient recall of previous drug exposures has been shown to be subject to error, with the extent of inaccuracy differing by medication type, duration of therapy, recall interval and patient age [25, 61] (*see* **Recall Bias**). The misclassification of outcome is said to be *differential (nondifferential)* with respect to exposure if the misclassification probability differs (does not differ) depending on exposure. **Differential** and **nondifferential** misclassification of exposure with respect to outcome are defined similarly (*see* **Bias, Nondifferential**). In a simple cross-classification of exposure and outcome, nondifferential misclassification creates a **bias toward the null** [41]. However, even slight deviations from completely nondifferential misclassification can produce large biases away from the null [3].

When both exposure and outcome are misclassified and the misclassifications are **correlated**, the bias may be in either direction even when the misclassifications are nondifferential [4]. With more than two exposure levels, nondifferential misclassification will bias the most extreme category to the null but can bias intermediate levels of exposure in either direction [2]. Bias due to misclassification of **confounders** results in loss of ability to control confounding and

cannot be adequately dealt with by methods used to control confounding [13]. One practical conclusion from all of these findings is that it is *not* correct to conclude that risks of adverse drug effects estimated from inaccurate information are likely to represent underestimates simply because the misclassification may be presumed to be nondifferential.

Misclassification is a particular problem in epidemiologic studies using hospital discharge diagnosis codes to define outcomes and confounders, because the codes often do not correctly reflect discharge diagnoses recorded in the medical records [20]. This may occur through miscoding, use of nonspecific codes, omissions of codes in complicated patients with many different diagnoses, or failure to modify a code for an admission to "rule out" a condition when the condition was ruled out. For example, in a sample of about 1000 hospitalizations with the discharge diagnosis of acute myocardial infarction (AMI), medical record review found that 26% did not meet clinical criteria for AMI. Most were hospitalizations to rule out AMI in which the code remained even though AMI had been ruled out [20]. One approach which avoids some of problems with information bias is to use computer-based discharge diagnosis codes to identify potential cases and to confirm these by medical record review [40].

Adverse Drug Effects

Pharmacologic Classification

To help guide evaluation of adverse drug effects, clinical pharmacologists have classified them into two types, designated A and B, depending on their relationship to known pharmacological properties of the drug [39]. Type A ("augmented") effects are caused by exaggerated pharmacological actions of a drug. Such effects are also sometimes called "mechanism-based" adverse effects. They are somewhat predictable on the basis of the pharmacology of the drug and are typically dose-dependent. Examples include hypotension with anti-hypertensive drugs and gastrointestinal hemorrhage with nonsteroidal anti-inflammatory drugs [14]. Most type A effects are likely to have been at least identified before market approval. However, the predisposing factors, **dose–response** relationships, warning signs, spectrum of severity and long-term consequences may not have been adequately characterized at the time of initial marketing. Subsequent studies may reveal an increased risk in some patients with impaired metabolic clearance, concomitant use of drugs with competing metabolism, or increased target-organ sensitivity. Pharmacoepidemiologic studies of type A effects should be aimed not only at quantifying risks but also at finding ways to anticipate and reduce the risk through identification of predisposing factors and improved dosing guidelines [8].

Type B ("bizarre") effects are those that are not expected from the known pharmacologic properties of a drug given in usual doses to patients who metabolize the drug in a normal way [39]. Such effects include idiosyncratic, immunologic, allergic, pseudo-allergic, teratogenic, or carcinogenic reactions for which mechanisms are often unknown. Type B effects are typically rare, serious, unpredictable, not dose-dependent, and unlikely to have been adequately characterized or even recognized before market approval. The liver, blood, and skin are among the most common sites of type B reactions to drugs, while some vaccines have been associated with type B reactions of the nervous system [16, 21, 24, 36, 42, 55, 64]. Both drugs and biologics have been associated with rare allergic and pseudo-allergic type B reactions [9]. Pharmacologic studies of type B effects are typically constrained by the rarity of the events, but should attempt to identify patient subgroups at increased risk whenever this can be done.

Perhaps the most comprehensive example of using epidemiologic information to identify risks and benefits in different patient subgroups and providing this information to patients and physicians is given by the US prescribing information for oral contraceptives [34]. A more limited example is given by studies of agranulocytosis in association with the angiotensin-converting enzyme inhibitor captopril; it was found that the risk was extremely low except in well-defined subgroups in whom use of the drug could generally be avoided [5].

Timing of Adverse Effects in Relation to Duration of Therapy

One of the most important aspects to consider in both the clinical and epidemiologic evaluation of adverse drug effects is the timing in relation to duration of therapy [15, 17, 52, 54, 62]. Some effects, such as angioedema with angiotensin-converting enzyme inhibitors, are more common early in

therapy [50]. Others, such as tardive dyskinesia with phenothiazines, are typically seen only after prolonged exposure to the drug. For some effects there may be a time window of highest risk. For example, onset of Guillain–Barré syndrome following the so-called "swine flu" vaccine was highest 17 days after vaccination and declined thereafter [46]. Serum-sickness-like reactions to drugs typically occur from 7 to 21 days after starting therapy [9]. Depletion of susceptibles may also affect the hazard function for adverse events in relation to duration of therapy [62]. Accounting for timing of adverse effects in relation to duration of therapy requires collecting information on timing of the event not only in relation to last exposure to the drug but also in relation to duration of therapy. Failure to account properly for timing may result in over- or underestimation of risks and can create artifactual treatment-by-subgroup **interactions** when comparing patient groups with different temporal patterns of usage [15].

Beneficial Effects

Intended Beneficial Effects: Efficacy, Effectiveness and Outcomes Research

Efficacy refers to the benefits of an intervention as measured under ideal circumstances in a randomized, controlled clinical trial conducted in a homogeneous set of patients with careful attention to the protocol. Clinical trials conducted to provide demonstrations of drug efficacy needed for drug approval are typically conducted under conditions which maximize internal validity of the trial itself at the possible expense of external validity – generalizability to usual clinical practice [48] (*see* **Validity and Generalizability in Epidemiologic Studies**). *Effectiveness* refers to the benefits of the intervention as measured under conditions intended to resemble closely the settings and patient populations where the intervention will be used in clinical practice. Effectiveness depends not only on efficacy but also on ease of administration, acceptability to patients and prescribers, compliance, and impact on use of health care resources. Consequently, effectiveness of an intervention depends not only on the intervention, but also on the setting in which it is delivered.

Recently there has been an increased emphasis on judging the results of health interventions in terms of their ability to improve *health outcomes*, i.e. changes in health status noticeable by patients, rather than exclusively in terms of their ability to improve laboratory tests or physiological parameters [10, 11, 48]. The field of **outcomes research** seeks to evaluate the overall effects of different interventions on health outcomes in clinical practice [10, 11, 27].

Because of the difficulty and expense of conducting randomized clinical trials in a clinical practice setting, observational studies are often used for the comparison of treatment outcomes [11, 27]. Observational studies of drug effectiveness are subject to selection bias, which may be impossible to control because the factors which lead to the choice of one therapy over another may not be fully reflected in any data source [6, 12, 28–30, 32, 59]. Selection bias in the study of intended effects of drugs may be more difficult to overcome than in the study of unintended effects [30]. Confounding by the indication for therapy must be considered in all pharmacoepidemiologic studies, and is particularly difficult to control in observational studies of intended drug effects [30, 59, 63]. Because most differences in effectiveness between active agents are likely to be moderate, observational studies are especially prone to distortion caused by bias and confounding [30, 32, 63]. This cautionary note also applies to observational studies of vaccine effectiveness, though to a lesser extent, because the effect sizes are typically much larger than for effectiveness studies of drugs [33, 47] (*see* **Vaccine Studies**). As an alternative to observational studies of drug effectiveness in clinical practice, randomized effectiveness trials have been conducted [35, 49]. Such studies have the potential for producing more valid estimates of effectiveness than can be obtained from observational studies.

Unintended Beneficial Effects

Some current indications for drug treatment began with the serendipitous finding of an unexpected **association** between drug exposure and a beneficial effect. The initial hypothesis of a beneficial drug effect usually arises from **case series** or laboratory observations, followed by formal epidemiologic studies. As useful as such studies have been in providing quantitative estimates of benefit, randomized clinical trials are essential for **hypothesis testing**. For example, data from randomized clinical trials of beta-carotene

in the prevention of lung cancer have not confirmed findings of earlier observational studies which had suggested a protective effect [18].

Pharmacoepidemiology, Overview

Pharmacoepidemiology, the study of patterns of medication use in the population and their effects on disease, is a new field. The need for this area of research became evident in 1961, during the thalidomide catastrophe, when it was realized that drugs prescribed for therapeutic purposes could produce unexpected risks. The entry of thalidomide, a new hypnotic drug, on the market was accompanied by a sudden sharp increase in the frequency of rare birth defects, characterized by the partial or complete absence of limbs [29, 31]. Consequently, several countries either instituted agencies to regulate drugs or expanded the mandate of existing agencies [51]. These agencies were previously interested only in the demonstration of a drug's efficacy, but now required proof of a drug's safety before it was tested in humans let alone before it was marketed for use by the general population (*see* **Drug Approval and Regulation**). These proofs of safety, based on toxicologic and pharmacologic studies, were necessary before randomized controlled trials (RCTs) (*see* **Clinical Trials, Overview**) could be conducted on human subjects, primarily to demonstrate the efficacy of a drug.

The use of the epidemiologic approach to characterize population patterns of medication use and to assess their effects developed as a complement to RCTs for several reasons. First, RCTs were designed to assess the efficacy and effectiveness of a drug, providing as well some data on its safety with respect to commonly arising side-effects. However, rare side-effects typically cannot be identified in clinical trials because of their small size. For example, to detect a **relative risk** of 2, for a side-effect having an **incidence** of 1 per 100, we would require a two-arm trial with over 3000 subjects per arm ($\alpha = 0.05$, $\beta = 0.1$). If the incidence of the side-effect is 1 per 10 000, the sample size per arm would need to be over 300 000. Clearly, these sample sizes are rarely if ever used in RCTs, yet the number of people who will be using these drugs will be in the millions.

Secondly, RCTs usually restrict the study subjects to people without coexisting disease, who are therefore not taking other medications that could interact with the study medication. They are also restricted with respect to age, rarely including children and elderly subjects. Yet, the elderly will be major consumers of most of these medications, along with other medications they are using for coexisting diseases (*see* **Co-morbidity**; **Drug Interactions**).

Thirdly, RCTs will usually be based on a short follow-up that typically assesses medication use for a period of 3–12 months. Yet, again, subjects may be using these medications for years, so that the effect of the prolonged use of these medications remains clearly unknown from the RCT data. Finally, there are situations where the RCT is either unethical or inapplicable. For example, it would be ethically unacceptable today in North America or Europe to assess the long-term effects of a new anti-hypertensive agent against placebo in an RCT, although this has been done in China [12] (*see* **Ethics of Randomized Trials**). Yet, a large number of hypertensive patients from the general population are either untreated or do not comply with their treatment (*see* **Compliance Assessment in Clinical Trials**). They could be used as the reference group for a **nonrandomized** study based on a **cohort study** design.

Although pharmacoepidemiology can be simply regarded as an application of epidemiologic principles and methods to the field of medications, it is now developing as a discipline of its own because of the special nature of drugs. Indeed, the ways by which drugs are prescribed, employed, marketed and regulated impose certain constraints on epidemiologic research into their use and effects. This field poses challenges that often require special solutions not found in other domains of application, such as cancer, cardiovascular, occupational or infectious disease epidemiology; medications are marketed rapidly, practice patterns of prescribing by physicians are variable and profiles of drug use by patients are complicated by varying compliance patterns. This complex and dynamic context in which pharmacoepidemiology is situated, as well as the available sources of data, have given rise to unique statistical challenges. The fact that the lifetime of a drug on the market is relatively short and can suddenly be shortened still further by a regulatory or corporate withdrawal, often imposes major constraints on studies of its effects. These studies must be conducted rapidly and use existing data in an efficient way without compromising validity (*see* **Validity and Generalizability in Epidemiologic Studies**).

In this article we describe several areas where biostatistical input has served to advance pharmacoepidemiology. Although the last two decades have witnessed an explosion of methodologic advances put forward by biostatistics in the design and analysis of epidemiologic studies, most of these have been fundamental to the field of epidemiology in general. We do not discuss these areas here since they are dealt with extensively elsewhere (*see* **Analytic Epidemiology**; **Descriptive Epidemiology**). Instead, we focus on the biostatistical aspects that produced unique methodologic advances, specific to problems posed by pharmacoepidemiologic research.

The Case–Crossover Design

When conducting a **case–control study**, the selection of **controls** is usually the most challenging task. The fundamental principle is that selected controls should be representative of the source population which gave rise to the cases [33] a principle often difficult to implement in practice, especially when dealing with acute adverse events and transient exposures.

For example, we may wish to study the **risk** of ventricular tachycardia in association with the use of inhaled beta agonists in asthma. This possible effect has been hypothesized on the basis of clinical study observations of hypokalemia and prolonged Q-T intervals as measured on the electrocardiogram in patients after beta agonist exposure [1]. These unusual cardiac deviations were observed only in the 4-hour period following drug absorption. Thus, a case–control study of this issue would first select cases with this adverse event and investigate whether the drug was taken during the 4-hour span preceding the event. For **controls**, on the other hand, the investigator must define a time point of reference for which to ask the question about use of this drug in the "past 4 hours". However, if, for example, the drug is more likely to be required during the day, but controls can only be reached at home in the evening, the **relative risk** estimate will be **biased** by the differential timing of responses for cases and controls.

Consequently, when dealing with the study of transient drug effects on the risk of acute adverse events, Maclure [30] proposed the *case–crossover design*, which uses the cases as their own controls. The case–crossover design is simply a **crossover** study in the cases only. The subjects alternate at varying frequencies between exposure and nonexposure to the drug of interest until the adverse event occurs, which does for all subjects in the study since all are cases by definition. Each case is investigated to determine whether exposure occurred within the predetermined effect period, namely within the 4 hours previous to the adverse event in our example. This occurrence is then classified as having arisen either under drug exposure or nonexposure on the basis of the effect period. Thus, each case is either exposed or unexposed. For the reference information, data on the average drug use pattern are necessary to determine the probability of exposure in the time window of effect. This is done by obtaining data for a sufficiently long period of time to derive a stable estimate. In our example, we might determine the average number of times a day each case has been using beta agonists (two inhalations of 100 μg each) in the past year. This will allow us to estimate the proportion of time that each asthmatic is usually spending as "exposed" in the 4-hour effect period. This proportion is then used to obtain the number of cases **expected** on the basis of time spent in these "at-risk" periods, for comparison with the number of cases observed during such periods. This is done by forming a **two-by-two table** for each case, with the corresponding control data as defined above, and combining the tables using the **Mantel–Haenszel** technique as described in detail by Maclure [30]. The resulting **odds ratio** is then given by $OR = \sum a_i N_{0i} / \sum (1 - a_i) N_{1i}$, where a_i is 1 if case i is exposed, 0 if not, N_{0i} is the expected number of unexposed periods and N_{1i} the expected number of exposed periods during the reference time span.

Table 1 displays hypothetical data from a case–crossover study of 10 asthmatics who experienced ventricular tachycardia. These were all queried regarding their use of two puffs of inhaled beta agonist in the last 4 hours and on average over the past year. The fact of drug use within the effect period is defined by a_i with three cases having used beta agonists in the 4-hour period prior to the adverse event. The usual frequency of drug use per year is converted to a ratio of the number of exposed periods to the number of unexposed periods, the total number of 4-hour periods being 2190 in one year. Using the Mantel–Haenszel formula to combine the 10 two-by-two tables, the estimate of the odds ratio is 3.0, and the 95% **confidence interval** (1.2, 7.6).

Table 1 Hypothetical data for a case–crossover study of beta agonist exposure in last 4 hours and the risk of ventricular tachycardia in asthma

Case no.	Beta agonist use[a] in last 4 hours (ai)	Usual beta agonist use in last year	Periods of exposure (N_{1i})	Periods of non-exposure (N_{0i})
1	0	1/day	365	1825
2	1	6/year	3	2184
3	0	2/day	730	1460
4	1	1/month	12	2178
5	0	4/week	208	1982
6	0	1/week	52	2138
7	0	1/month	12	2178
8	1	2/month	24	2166
9	0	2/day	730	1460
10	0	2/week	104	2086

[a]Inhalations of 200 μg: 1 = yes, 0 = no

The case–crossover design depends on several assumptions to produce **unbiased** estimates of the odds ratio. Greenland [14] presented examples where the odds ratio estimates from this approach can be biased. For example, the probability of exposure cannot vary over the time. Similarly, **confounding** factors must be constant over time. Finally, there cannot be **interaction** between unmeasured subject characteristics and the exposure. Nevertheless, this approach is being used successfully in several studies [38, 43]. It has also been adapted for application to the **risk assessment** of vaccines [11].

Confounding Bias

Because of the lack of **randomization**, the most important limitation of **observational studies** in pharmacoepidemiology is whether an important confounding factor is biasing the reported relative risk estimate. A factor is considered a confounder if it is associated, at each level of drug exposure, with the adverse event, and with exposure to the drug itself. Two approaches exist to address the problem of confounding variables, which we describe in the context of the case–control design, although they apply equally well to a cohort design. The first is to select controls that are matched to the cases with respect to all confounding factors and to use the appropriate corresponding techniques of analysis for matched data, usually **conditional logistic regression** (*see* **Matched Analysis**; **Matching**). This approach, although often appropriate, has been shown to be susceptible to bias from residual confounding due to coarse matching [5]. The second solution is to select controls unmatched with respect to these confounding factors, but to measure these confounders for all study subjects and use statistical techniques based on either **stratification** or **multiple regression**, permitting removal of their effect on the risk from the effect of the drug under study. This approach can also lead to residual confounding if the confounder data are not analyzed properly. For example, the risk of venous thromboembolism has been found to be higher among users of newer oral contraceptive drugs than users of older formulations [22, 41, 52], after controlling for the effect of age. A recent study, however, showed that when confounding by the woman's age is analyzed using finer age bands, the relative risk is substantially reduced [10].

Beyond such difficulties generic to epidemiology, the context of pharmacoepidemiology has produced several situations where confounding requires particular statistical treatment. Some are described in this section.

Missing Confounder Data

It is at times impossible to obtain data on certain important confounding variables. A frequent situation encountered in pharmacoepidemiology is that of complete data for the cases and incomplete data for the controls of a case–control study. This is often encountered in "computerized database" studies based on **administrative databases** where cases have likely been hospitalized and thus have an extensive medical dossier. For these cases, the investigator will thus have access to ample information on potential confounding variables. However, if the controls are population-based (*see* **Case–Control Study, Population-based**), it is unlikely they were hospitalized and will not provide comparable data on confounders in the absence of medical charts. Consequently, confounder data will only be available in the cases, and not in the controls.

We can assess whether a factor is a confounder on the basis of data available solely for the cases, so that if the factor is deemed not to be a confounder, then the final analysis of the risk of the drug under study will not need to be adjusted. The approach is described by Ray & Griffin [37] and was

used in the context of a study of nonsteroidal anti-inflammatory drug (NSAID) use and the risk of fatal peptic ulcer disease [15]. The strategy is based on the definition [5] of a confounder C (C+ and C− denote presence and absence) in the assessment of the **association** between a drug exposure E (E+ and E− denote exposure or not to the drug) and an adverse condition D (D+ and D− denote cases and controls, respectively). Confounding is present if both following conditions are satisfied:

1. C and E are associated in the control group (in D−).
2. C and D are associated in E+ and in E−.

Assuming, in the absence of **effect modification**, a common odds ratio between E and D (OR_{ED}) in C+ and in C−, condition 1 becomes equivalent to: C and E are associated in the case group (D+). Thus, if in the cases we find no association between the potential confounder and drug exposure, confounding by this factor can be excluded outright, without having to verify condition 2. In this instance, the analysis involving drug exposure in cases and controls can be performed directly without any concern for the confounding variable. This strategy for assessing confounding is extremely valuable for several case–control studies in pharmacoepidemiology, since if confounding is excluded by this technique, crude methods of analysis can be used to obtain a valid estimate of the odds ratio. However, this is not often the case.

As an example, we use data from a case–control study conducted using the Saskatchewan computerized databases to assess whether theophylline, a drug used to treat asthma, increases the risk of acute cardiac death [46]. In this study, the 30 cases provided data on theophylline use, as well as on smoking, possibly an important confounder. However, the 4080 controls only had data available on theophylline use and not on smoking. Table 2 displays the data from this study. The crude odds ratio between theophylline use and cardiac death is 4.3((17/13)/(956/3124)). Because of the **missing data** on smoking, it is only possible to partition the cases, but not the controls, according to smoking. The odds ratio between theophylline use and smoking among the cases is estimable and found to be 7.5((14/5)/(3/8)), thus indicating that smoking is indeed a strong confounder.

Table 2 Data from a case–control study of theophylline use and cardiac death in asthma, with the smoking confounder data missing for controls

	Cases		Controls	
	E	$\overline{E}$	E	$\overline{E}$
Notation:				
Combined	a	c	b	d
Stratified by smoking:				
Smokers	a_0	c_0	[a]	[a]
Nonsmokers	a_1	c_1	[a]	[a]
Data:				
Combined	17	13	956	3124
Stratified by smoking:				
Smokers	14	5	[a]	[a]
Nonsmokers	3	8	[a]	[a]

[a]These frequencies are missing for controls.

An approach was recently developed to permit the estimation of the *adjusted* odds ratio of the theophylline by cardiac death association, in the absence of confounder data among the controls [45]. The adjusted odds ratio is given by

$$OR_{\text{adj}} = \frac{P_0(w-y)}{(1-P_0)y}, \tag{1}$$

where $y = \{v - [v^2 - 4(r-1)rwx]^{1/2}\}/[2(r-1)]$, $v = 1 + (r-1)(w+x)$ when $r \neq 1$ (and $y = wx$ when $r = 1$), r is the odds ratio between exposure and confounder among the cases, x is the probability of exposure among the controls, P_0 is estimated by $a_0(a_0 + c_0)$, and w is the **prevalence** of the confounder among the controls [45]; w is the only unknown and must be estimated from external sources. An estimate of the variance of OR_{adj} in (1) exists in closed form. For the illustrative data, an external estimate of smoking prevalence among asthmatics, obtained from a Canadian general population health survey, is 24%. Using this estimate, the adjusted odds ratio is 2.4, much lower than the crude estimate of 4.3, with 95% confidence interval (1.0, 5.8).

This statistical approach was developed specifically to address the frequent problem of missing confounder data in pharmacoepidemiology. When using computerized databases, these data are more often missing only in the control series of a case–control study. This technique, based on statistical reasoning, allows us to derive adjusted estimates of relative risk with few assumptions. Extensions of this type

of approach to a **regression** context will expand its usefulness.

The Case–Time–Control Design

Case–control studies in pharmacoepidemiology that assess the intended effects of drugs are often limited by their inability to obtain a precise measure of the indication of drug exposure. Adjustment for this crucial confounding factor becomes impossible and an unbiased estimate of the drug effect is unattainable [49]. This bias, arising from confounding by indication, is a major source of limitation in pharmacoepidemiology [32]. Here again, a within-subject approach, similar to the case–crossover design, has been developed. By using cases and controls of a conventional case–control study as their own referents, the *case–time–control design* eliminates the biasing effect of unmeasured confounding factors such as drug indication [44]. This approach is applicable only in situations where exposure varies over time, which is typically often the case for medications.

The correct application of the case–time–control design is based on a specific model for the data, a model that entails inherent assumptions and imposes certain conditions for the approach to be valid. The model, based on a case–control sampling design, is presented for a dichotomous exposure that varies over time and that is measured only for two consecutive time periods, the current period and the reference period. The logit of exposure $L_{ijkl} = \text{logit}\{\Pr(E_{ijkl} = 1)\}$, is given by

$$L_{ijkl} = \mu + S_{il} + \pi_j + \Theta_k \qquad (2)$$

where E_{ijkl} represents the binary exposure for group i, period j, outcome k and subject l within group i, μ represents the overall exposure logit, S_{il} is the effect of study subject l in group i, π_j is the effect of period j and Θ_k is the effect of event occurrence k. More specifically, $i = 0, 1$ denotes the case–control group (1 = case subjects, 0 = control subjects), $j = 0, 1$ denotes the period (1 = current period, 0 = reference period), $k = 0, 1$ denotes the event occurrence (1 = event, 0 = no event) and $l = 1, \ldots, n_i$ designates the study subject within group i, with n_1 case subjects and n_0 control subjects. The confounding effect of unmeasured severity or indication is inherently accounted for by S_{il}.

The period effect, measured by the log of the odds ratio, is given by $\delta_\pi = \pi_1 - \pi_0$ and estimated from the control subjects. The net effect of exposure on event occurrence is given by $\delta_\Theta = \Theta_1 - \Theta_0$. The case subjects permit one to estimate the sum $\delta_\Theta + \delta_\pi$ so that the effect of exposure on event occurrence δ_Θ, is estimable by subtraction. The estimation of the odds ratio is based on any appropriate technique for matched data, such as conditional logistic regression.

Three basic assumptions are inherently made by this logit model. The first is the absence of effect modification of the exposure–outcome association by the unmeasured confounder, i.e. the exclusion of the $S_{il}\Theta_k$ interaction term in model (2). The second is the absence of effect modification of the exposure–outcome association by period, i.e. a null value for the $\pi\Theta_k$ interaction term. The third is the lack of effect modification of the exposure–period association by the confounder, represented by the absence of an $S_{il}\pi_j$ interaction term in model (2). Greenland [14] presented examples of the bias that can occur with this approach when the model contains the latter interaction.

The approach is illustrated with data from the Saskatchewan Asthma Epidemiologic Project [40], a study conducted to investigate the risks associated with the use of inhaled beta agonists in the treatment of asthma. Using databases from Saskatchewan, Canada, a cohort of 12 301 asthmatics was followed during 1980–87. All 129 cases of fatal or near-fatal asthma and 655 controls were selected. The amount of beta agonist used in the year prior to the index date was found to be associated with the adverse event. In comparing low (12 or less canisters per year) with high (more than 12) use of beta agonists. The crude odds ratio for high beta-agonist use is 4.4, with 95% confidence interval (2.9, 6.7). Adjustment for all available markers of severity, such as oral corticosteroids and prior asthma hospitalizations as confounding factors, lowers the odds ratio to 3.1, with 95% confidence interval (1.8, 5.4), the "best" estimate one can derive from these case–control data using conventional tools.

The use of inhaled beta agonists, however, is known to increase with asthma severity which also increases the risk of fatal or near-fatal asthma. It is therefore not possible to separate the risk effect of the drug from that of disease severity. To apply

the case–time–control design, exposure to beta agonists was obtained for the 1-year current period and the 1-year reference period. Among the 129 cases, 29 were currently high users of beta agonists and were low users in the reference period, while 9 cases were currently low users of beta agonists and were high users previously. Among the 655 controls, 65 were currently high users of beta agonists and were low users in the reference period, while 25 were currently low users of beta agonists and were high users previously. The case–time–control odds ratio, using these discordant pairs frequencies for a matched pairs analysis, is given by $(29/9)/(65/25) = 1.2$, with 95% confidence interval (0.5, 3.0). This estimate, which excludes the effect of unmeasured confounding by disease severity, indicates a minimal risk for these drugs.

The case–time–control approach provides an unbiased estimate of the odds ratio in the presence of confounding by indication, a common obstacle in pharmacoepidemiology. This is possible despite the fact that the indication for drug use (in our example, disease severity) is not measured, because of the within-subject analysis. Nevertheless, as mentioned above, its validity is subject to several strict assumptions. This approach must therefore be used with caution.

Risk Functions Over Time

Most epidemiologic studies assessing a risk over time routinely assume that the hazards are constant or proportional. Rate ratios are then estimated by **Poisson regression** models or Cox's **proportional hazards** model [6]. Often, deviations from these simplifying assumptions are addressed at the design stage, by restricting the study to a specific follow-up period where the assumptions are satisfied. For instance, to study the risk of cancer associated with an agent considered to be an initiator of the disease, the first few years of follow-up after the initiation of exposure will not be accounted for in the analysis, to allow for a reasonable **latency period**. On the other hand, if the agent is suspected to be a cancer promoter, these same first years will be used in the analysis. Since such considerations are mostly dealt with at the design stage, little attention has been paid to the analytic considerations of this issue.

In pharmacoepidemiology, the risk of an adverse event often varies strongly with the duration of use of a drug. Figure 1 shows three different risk profiles, typical of drug exposure. Figure 1(a) displays the usual profile of risk associated with an acute effect. The drug will affect susceptible subjects early, reflected by the early sharp rise in the curve, and once these subjects are eliminated from the cohort, the remaining subjects will return to some lower constant baseline risk. The peak can occur almost immediately, as with allergic reactions to antibiotics, or may take a certain time to affect the organ, as with gastrointestinal hemorrhage subsequent to NSAID use. This profile of risk was used to explain variations in the risk of agranulocytosis associated with the

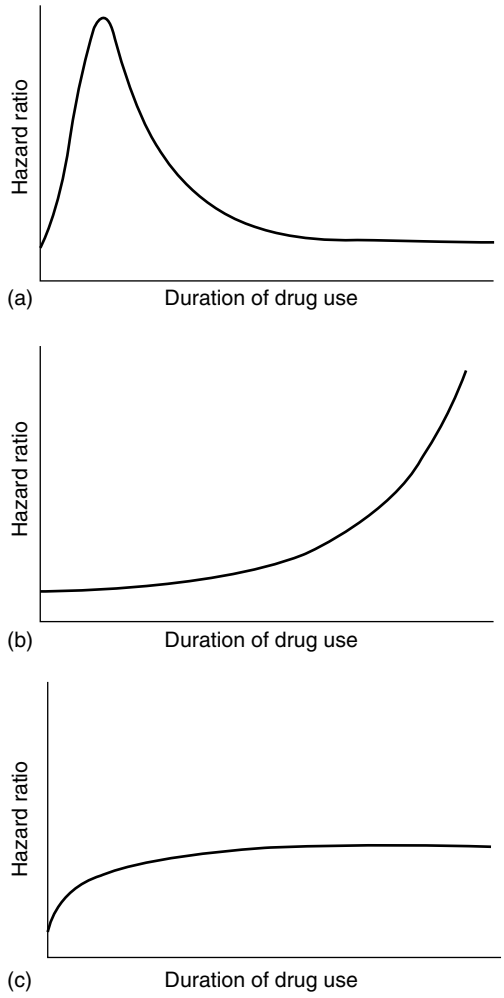

Figure 1 Different risk profiles by duration of drug use: (a) acute effect; (b) increasing risk; (c) constant risk

use of the analgesic dipyrone [16]. It has recently been used to assess the risk profile of oral contraceptives [47]. Figure 1(b) shows a gradually increasing model of risk, associated with diseases of longer latency such as cancer. Figure 1(c) displays the constant hazard model, after a rapid rise in the risk level.

Unfortunately, such graphs are not part of the analysis plan of most pharmacoepidemiologic studies at this point, despite the existence of appropriate techniques [9, 16]. The next few years should see an increasing use of **spline functions** and other similar tools to model the risk of drugs by their duration of use. The wider access to newer statistical software such as **S-PLUS** [42] among researchers in pharmacoepidemiology, as well as the publication of papers that simplify the understanding of these sophisticated approaches [13, 16], will encourage their wider use in a field where they are clearly pertinent.

Probabilistic Approach for Causality Assessment

The traditional epidemiologic approach to assess whether a drug causes an adverse reaction is based on the Hill criteria [18], that require the association to be biologically plausible, strong, specific, consistent and temporally valid (*see* **Hill's Criteria for Causality**). These criteria are applied to the results of pharmacoepidemiologic studies and, depending on the number of criteria satisfied, provide a level of confidence regarding causality of the drug (*see* **Causation**). The result of this exercise will be, if a drug is judged to cause an adverse reaction, that all exposed cases, or at least some etiologic proportion of these cases [39], are due to the drug. This approach is valuable for **inferences** to the population, but does not allow cases to be assessed individually, does not incorporate the specifics of the case, and does not entirely address the unique features of drugs as an exposure entity in epidemiology.

The study of individual cases of adverse reactions has been the mainstay of national pharmacovigilance centers throughout the world for several decades [3, 51] (*see* **Postmarketing Surveillance of New Drugs and Assessment of Risk**). When a case report of a suspected drug-associated adverse event is received, the natural question is whether the drug actually caused the event. Several qualitative approaches have been proposed to answer this question [20, 25]. Recently, however, a formal quantitative approach using biostatistical foundations has been put forward [26–28]. It is based on **Bayes' theorem**, which can be used in the following way:

$$\Pr(D \rightarrow E|B, C) = \frac{\Pr(D \rightarrow E|B)\Pr(C|D \rightarrow E, B)}{\Pr(C)},$$

where $D \rightarrow E$ denotes that the drug D causes the adverse event E, B represents the background characteristics of the case that are known to affect the risk, while C represents the case information.

This Bayes' theorem approach allows us to estimate the posterior probability that an adverse event was caused by a drug by separating the problem into two components. The first component is the **prior probability** of the event given the baseline characteristics of the patients. This is estimated from existing data obtained from clinical trials or epidemiologic studies. The second component is the probability of case information given that the drug caused the event.

The primary limitation of this approach is the scarcity of data available to estimate the two components. In many instances, it is difficult to find the clinical and epidemiologic data necessary to estimate the prior probability, especially for rare clinical conditions that have not been the object of extensive population-based research. The same limitation applies to the second probability component because of the problems of finding cases relevant to proven drug causation. **Case series** that apply directly to the case being assessed are often difficult to find. These limitations are real but not limited to the Bayesian approach – they are a general problem in the assessment of individual cases. The authors of these methods suggest that the primary purpose of the Bayesian approach is to provide a framework in which subjective judgments relevant to assessment of an individual case are coherently combined.

To facilitate the use of the Bayesian method, the equation is usually expressed in terms of **odds** rather than probabilities. This formulation simplifies somewhat the need for data, since epidemiologic studies more frequently report odds ratios than absolute probabilities. The relative **likelihood** may also be easier

to estimate subjectively. This equation formulated in terms of odds is given as

$$\begin{aligned}\text{posterior odds} &= \Pr(D \rightarrow E|B, C)/\Pr(D \not\rightarrow E|B, C)\\ &= [\Pr(D \rightarrow E|B)/\Pr(D \not\rightarrow E|B)]\\ &\qquad \text{prior odds}\\ &\times[\Pr(C|D \rightarrow E, B)/\Pr(C|D \not\rightarrow E, B)]\\ &\qquad \text{likelihood ratio.}\end{aligned}$$

This approach was applied on several occasions [19, 23, 24, 34] and was recently made user-friendly by computerizing [21]. The increasing amount of new epidemiologic data on disease distribution and risk factors combined with new clinical and pharmacologic insights on drug effects will make this probabilistic approach more effective in future uses.

Methods Based on Prescription Data

One of the distinguishing features of pharmacoepidemiology is the use of computerized administrative health databases to answer research questions reliably and with sufficient rapidity. The usual urgency of concerns related to drug safety makes these databases essential to perform such risk assessment studies. In particular, databases containing only information on prescriptions dispensed to patients, and no outcome information on disease diagnoses, hospitalizations or vital status, have been the object of interesting statistical developments. These standalone prescription drug databases, that do not require to be linked to outcomes databases, are more numerous and usually more easily accessible than the fully linked databases. They provide a source of data that allows the investigation of patterns of drug use that can yield some insight into the validity of risk assessment studies as well as generate and test hypotheses about these risks. In this section we briefly review some of the resourceful uses of these drug prescription databases in pharmacoepidemiology.

A technique that was developed specifically for the context of drug databases is prescription sequence analysis [36]. Prescription sequence analysis is based on the situation when a certain drug A is suspected of causing an adverse event that itself is treated by a drug B. To apply this technique, the computerized drug database is searched for all patients using drug A. For these subjects, all patients prescribed drug B in the course of using drug A are identified and counted. Under the **null hypothesis** that drug A does not cause the adverse event treated by drug B, this number of subjects should be proportional to the duration of use of drug A relative to the total period of observation. This extremely rapid method of assessing the association between drug A and drug B is assessed for its **random error** with a **Monte Carlo** simulation analysis. This technique was applied to assess whether patients using the antivertigo or antimigraine drug flunarizine (drug A) causes mental depression, as measured by the use of antidepressant drugs (drug B). The authors found that the number of patients starting on antidepressant drugs during flunarizine use was in fact lower than expected [36]. They thus concluded, using this rapid approach based solely on drug prescription data, that this drug probably does not cause mental depression. An extension of prescription sequence analysis, called prescription sequence symmetry analysis, was recently proposed [17]. Using a population of new users of either drug A or B, this approach compares the number of subjects who used drug A before drug B to that using B before A. Under the null hypothesis, this distribution should be symmetrical and the numbers should be equal.

Another function of these databases is to use the prescriptions as **covariate** information to explain possible confounding patterns. The concept of *channeling* of drugs was put forward as an explanation of unusual risk findings [48]. For example, a case–control study conducted in New Zealand found that fenoterol, a beta agonist bronchodilator used to treat asthma attacks, was associated with an increased risk of death from asthma [8]. Using a prescription drugs database, it was found that severe asthmatics, as deemed from their use of other asthma medications prescribed for severe forms of the disease, were in fact channeled to fenoterol, probably because fenoterol was felt by prescribers to be a more potent bronchodilator than other beta agonists [35]. This phenomenon of channeling can be assessed rapidly in such databases, provided medications can be used as proxies for disease severity. This approach can be subject to bias, however, as it has been used with **cross-sectional** designs that cannot differentiate the directionality of the association. An application of channeling using a **longitudinal** design was recently presented [4]. It indicated that channeling can vary according to the timing of exposure, i.e. that disease severity was not associated with first-time use of a

drug, but subsequently severe patients were more likely to be switched to that drug. This type of research into patterns of drug prescribing and drug use can be very useful in understanding the results of case–control studies with limited data on drug exposures and subject to confounding by indication (*see* **Pharmacoepidemiology, Adverse and Beneficial Effects**).

These prescription drug databases have also been used to study patterns of interchange in the dispensing of NSAIDs. Such research is important because switching patterns permits the identification of brands that may not be well tolerated and result in the prescription of another agent. By using a **stochastic** approach, Walker et al. [50] estimated the **transition** probabilities from one NSAID to another. For a set of k different brands of NSAID, they derived the expected marginal distributions of the transition matrix that corresponds to a global equilibrium state by solving a system of $k + 1$ equations with $k + 1$ unknowns. By comparing these expected values with the observed marginals of the transition matrix, it was possible to assess whether this population had reached this stable state and for which drugs. Such models can be used rapidly to assess patterns of interchange and identify potentially harmful agents.

Finally, these prescription drugs databases may in certain situations provide all the necessary data for a conventional cohort or case–control study. For instance, the use of beta blockers to treat hypertension and other cardiac diseases has been hypothesized to cause depression. A prescription for an antidepressant drug can be used as a proxy for the outcome of depression. In this way, a standalone prescription drug database can provide data on exposure to beta blockers, on the outcome of depression, as well as on covariate information from other medications [2, 7].

S. SUISSA

Pharmacoepidemiology, Study Designs

The field of **pharmacoepidemiology** includes the study of the use of and effects of pharmaceuticals in populations [10]. In general, the study designs used in pharmacoepidemiology are the same as those used in other areas of **clinical epidemiology**. There are three key differences, however.

First, because pharmacoepidemiology studies are usually performed after drug marketing, and because 500–3000 patients are generally studied prior to drug marketing, pharmacoepidemiology studies usually must include substantially larger numbers of patients in a **cohort study** or, alternatively, tap an equivalently sized population for a **case–control study**, in order to contribute new useful information.

Secondly, because at least one randomized **clinical trial** was already performed prior to drug marketing, pharmacoepidemiology studies are less likely to use randomized clinical trial study designs; many of the same limitations which the premarketing randomized clinical trials were subject to would apply as well to any postmarketing randomized clinical trial, and so they would not be able to contribute new useful information. For example, because of the need for huge sample sizes, randomized clinical trials are not an efficient means of studying uncommon adverse effects, or the effects of drugs in types of patients commonly excluded from such trials.

Thirdly, because pharmacoepidemiology questions often arise as regulatory, commercial and public health crises, answers must often be obtained very quickly.

This need for rapidly performed studies of massive sample size has led to a series of special approaches which have characterized the field of pharmacoepidemiology, and will be the primary focus of this article. Other analytic issues which are special to pharmacoepidemiology include the need for special attention to the drug regimen. In many other areas of clinical epidemiology, "exposure" is frequently treated as a dichotomous variable. Even when studying drugs, most randomized clinical trials specify a single fixed dose of the drug of interest. In contrast, once a drug is on the market, questions of how its effects vary with different doses, different durations of therapy, and different regimens (e.g. intermittent vs. continuous administration) are often the questions which are of greatest clinical importance. For reasons of space, these have not been discussed here. The reader is referred elsewhere for such considerations [2].

Data Resources Used in Pharmacoepidemiology

Historically, the primary data resource used in pharmacoepidemiology was the spontaneous reporting system [1, 18]. This is a nonsystematic collection of case reports (*see* **Case Series, Case Reports**) of adverse events following use of drugs, considered by the treating physician as possibly due to the drug. These are reports to the medical literature but, more voluminously, to regulatory bodies (*see* **Drug Approval and Regulation**). As case reports, they are useful primarily for generating rather than testing hypotheses. For example, case reports of acute flank pain following the use of suprofen generated formal studies which tested and confirmed the resulting hypothesis [14], while analogous spontaneous reports of anaphylactic reactions to tolmetin were not confirmed when these hypotheses were formally tested [13].

Another approach to pharmacoepidemiology studies uses **vital statistics** data and **drug utilization** data to perform analyses of secular trends, searching for whether trends in drug exposure over time or across geographic areas correlate with trends in disease occurrence [9]. For example, with the marketing of oral contraceptives, mortality rates from pulmonary embolism increased, but only in women of reproductive age [5]. While this type of study is easy to perform, it obviously is prone to many difficulties, including the limitations inherent in vital statistics data as well as identifying which of the possible **correlations** truly reflect cause vs. simply coincidence (*see* **Hill's Criteria for Causality**). For example, in a study using data from 18 different cancer registries around the world to investigate the relationship between sales of methyldopa and the development of biliary carcinoma [12], the results from one of the cancer registries showed an artifactual association, caused by changes in coding practices in that registry.

Over the past two decades, pharmacoepidemiology has been to the fore in scientific fields using automated databases of claims information (*see* **Administrative Databases**) for its research [7, 11].

In clinical epidemiology studies, the largest expense of the study is generally that of data collection, and this is particularly problematic in the very large studies of pharmacoepidemiology. However, using these automated databases (*see* **Database Systems**), the substantial cost of data collection for these very large studies is borne by the underlying insurance system, rather than the study. A large proportion of pharmacoepidemiology studies are now using such systems. However, given the relatively small number of exposed diseased individuals relative to unexposed diseased individuals, in using an automated database to implement such a study one needs to obtain a huge number of medical records of diseased individuals, relatively few of whom are exposed. Inasmuch as most of the cost of this type of study is the cost of obtaining these medical records, this is inefficient, and new methods are needed to enable one to sample from unexposed diseased individuals. The major weakness of these systems is the uncertain validity of the data, especially the diagnosis data [11]. Furthermore, these systems can lack information about key potential **confounding** variables, if they do not come to medical attention. Thus, there is increasing interest in the exploration of medical record databases, as opposed to claims databases, for such research [3].

Historically, there have been a few ongoing systems of *ad hoc* data collection, tailored for pharmacoepidemiology research. One of these has been a hospital-based system of collecting drug exposures and outcomes in hospitals, pioneered by the Boston Collaborative Drug Surveillance Program [4]. This system has the advantage of known **incidence rates** and high-quality data collected on site in the hospital, but an inability to study either the many important drugs used in outpatients, or uncommon adverse reactions, even if serious. New data collection in this system was abandoned many years ago, although a few hospitals have mounted analogous systems elsewhere.

Another such system has been the system of case–control surveillance developed by the Drug Epidemiology Unit, now the Slone Epidemiology Unit at Boston University [8]. This also focuses on hospitals, but collects information on prior drug exposures as possible causes of the hospitalization, performing **hospital-based case–control studies**. This system suffers from the uncertain validity of the drug exposure data obtained from patients and from restriction to hospital-based case–control studies, with the inherent problems of **selection bias**. In recent years, data collection for this system has been curtailed.

Finally, many pharmacoepidemiology studies are still designed as *ad hoc* clinical epidemiology studies, whether cohort or case–control. The choices among these designs are discussed elsewhere.

Special Methodological Approaches Used to Apply These Resources

In applying the special resources described above, unique challenges are confronted by pharmacoepidemiologists, in part because of the nature of the information being collected, and in part because of the large sample sizes required. These are each discussed in turn below.

Validity of Exposure and Outcome Data

In order to perform a valid epidemiologic study, one obviously must have valid information on both exposure and outcome. This can be very problematic in pharmacoepidemiologic studies. The best measures of disease occurrence are medical records, as patients often do not understand the details of the diseases which they have. Case–control studies have a major advantage here, as patients can be identified from their health care providers. However, medical records are very poor sources of information about prior drug use, as drugs tend to be recorded very incompletely [15]. Obtaining drug histories directly from patients can be problematic, however, as most patients cannot identify the drugs they are on now, even less the drugs they took in the past. Special techniques have been developed by pharmacoepidemiologists in order to maximize the validity of the drug data collected from patients as part of case–control studies, e.g. the use of indicator prompts and pictorial handouts. The details of these approaches are beyond the scope of this article, but the reader is referred elsewhere for them [17]. However, suffice it to say that much work remains to be done on these issues.

In contrast, data on drug exposure from claims databases are extremely valid, as they represent documentation of the exact drugs dispensed to patients. Reimbursement by insurance carriers varies according to the identity and amount of the drug [11]. While

this does not assure compliance with the dispensed drug, it is a level better than prescribing information, as many prescribed drugs are never dispensed. In contrast, however, the diagnosis information in these databases is of uncertain validity, as reimbursement generally does not depend on diagnosis and, especially, on correct and precise diagnoses [11]. As such, in studies using these databases, considerable attention needs to be paid to obtaining validation of these diagnoses.

Special Study Designs Used to Increase Efficiency

Because of the large numbers of individuals included in many pharmacoepidemiology studies, even when using claims databases, pharmacoepidemiologists seek special study designs to enable the data processing and, especially, any medical record review to be more efficient. In general, pharmacoepidemiologists are studying diseases of low incidence. Furthermore, any given drug is used by a small proportion of the population. As such, one is investigating a low **prevalence** of exposure and a low **incidence** of disease. To the degree one includes general population samples, therefore, one collects information on a large number of people who do not contribute much additional statistical information to the investigation. Case–control studies can be useful toward this end, when the prevalence of exposure is high. However, for many drugs this is not applicable.

Another approach which is used is the **nested case–control study**. In this design, an investigator first creates a cohort of exposed individuals and then, within that cohort, identifies cases and a **random sample** of noncases for the study. This design is efficient and allows one to use conventional statistical methods for the analysis of case–control studies, which is a major advantage. However, it can result in logistical problems in identifying the sample of noncases, as they must be at risk of developing the disease at the same time as the case, and identifying these risk sets can be difficult [16].

Another design beginning to be used by pharmacoepidemiologists is the **case–cohort study**, an approach pioneered in **occupational epidemiology** [6]. In this situation, one identifies a cohort of exposed subjects in advance, and the subset of people who are cases, as with the nested case–control study. However, instead of sampling randomly from the known noncases those at risk of developing the disease at the same time as the case, one randomly samples from the entire cohort, creating a subcohort, which also can include some of the cases. Then, the distribution of exposures and **confounders** in the case group can be compared for analytic purposes to the distribution in the subcohort. This approach has the advantage of achieving much smaller sample sizes with a simple sampling scheme. Also, one can study multiple outcomes within the same study. It has the disadvantage of requiring analyses different from those of normal case–control studies. Instead, a modified Cox **proportional hazards** approach is used and, until recently, software was not available to implement this.

Conclusions

In conclusion, pharmacoepidemiologists use the same methods of study design as do other clinical epidemiologists. However, because of the special characteristics of the field, there are special issues of study design and analysis which arise. These have been discussed briefly in this article.

Pharmacogenetics

Most **complex diseases** are syndromes rather than distinct diseases, and probably have multiple environmental and genetic determinants [3, 13, 29]. A component of this complexity in diseases that can be treated with pharmacotherapy is often a highly variable response to pharmacological therapy among individual patients [21]. Pharmacogenetics is the study of the role of genetic determinants in the variable response to therapy. Ideally, we would be able to stratify a population needing treatment into those likely, or unlikely, to respond to treatment as well as those likely, or unlikely, to experience adverse side-effects [24].

Variability in individual drug treatment response may be due to many factors, including the severity and type of disease, treatment compliance, the presence of other illness, the use of other drugs (drug–drug **interaction**), environmental exposures, sex and age. However, family-based studies have suggested that genetic factors underlie a significant proportion of the observed treatment **variance** in many diseases [11].

Although many pharmacogenetic mechanisms are possible, specific **DNA** sequence variants may alter response to drugs in three main ways (Table 1) [12]:

1. Variation in the metabolism of a drug among individuals, especially in enzymes involved in the catabolism or excretion of a drug. An important example is the highly genetically diverse cytochrome P450 system, known to have many pharmacogenetic effects [10, 27].
2. Variation among population members with respect to drug adverse effects that are not based on the drug's action.
3. Variation in the drug treatment target or target pathways. In this category, a population is conceptually divided into responders and nonresponders, and analysis of genetic variants (*see* **Genotype**) is used in an attempt to distinguish these groups [24].

Table 1 Possible pharmacogenetic mechanisms[a]

Genetic variants associated with:	Type of mechanism
Altered uptake, distribution or metabolism of the drug administered	Pharmacokinetic
An unintended action of a drug outside of its therapeutic indication	Idiosyncratic
Alterations in the drug target or a component of the drug pathway leading to altered drug efficacy; or	Pharmacodynamic
Differences in the expression of a physiological phenotype (*see* **Genotype**) such that a given target may not be disease-associated in a given patient

The current trend in genetic analysis of complex human diseases is away from family-based strategies using microsatellite **markers** towards single nucleotide polymorphisms (SNPs) [SNPs are discussed in the article, Markers] genotyping and different analytical strategies based on **association** and **haplotype analysis** [14, 18, 20]. Since response to drug treatment generally varies with age, and the number and type of medications for a given disease is changing rapidly, it is unlikely that family-based treatment data will be available in the foreseeable future for most complex diseases. In the absence of these data, **case–control** association studies are the approach of choice (*see* **Disease-marker Association**). Case–control association analyses are now recognized as being well suited for localizing susceptibility loci [23], and they are intrinsically more powerful than **linkage analyses** in detecting weak genetic effects [3].

Pharmacogenetic studies have generally investigated associations between drug response phenotypes and genotyped DNA sequence variants, most commonly "SNPs". The last decade has seen dramatic increases in molecular genetic technologies that can potentially be used to understand the biologic basis of pharmacogenomics [22]. Because of their potential biologic importance, the common SNPs in the human genome increasingly have been the subject of large-scale cataloguing projects funded by both government and industry groups [2, 5, 9] (*see* **Human Genome Project**). Limitations related to cost and the current incomplete status of SNP databases has meant that the association analysis of SNPs in pharmacogenomics has so far been limited to polymorphisms within biologically plausible candidate loci (*see* **Gene**).

Although genetic information has only recently begun to be integrated into the clinical trial setting, there is now a growing list of candidate genes being investigated for association with treatment response in many different diseases [30]. Most pharmacogenomic studies published to date have essentially been *post hoc* genetic studies undertaken using DNA and phenotypic data from subjects who had been enrolled in a conventional clinical trial.

Statistical Issues

The testing of large numbers of SNPs for association with one or more traits raises important statistical issues regarding the appropriate false-positive rate of the tests and the level of statistical significance to be adopted given the multiple testing (*see* **Multiple Comparisons**) involved [19]. Many relevant areas of genetic statistics are under active methodological development [18, 25]. Two major potential statistical issues in pharmacogenetics relate to population **stratification** and statistical power.

Genetic Heterogeneity and Population Stratification

In addition to variation in allele frequencies, there is also a high degree of variation in the strength of **linkage disequilibrium** in a given chromosomal region among populations of different origins [31] and also between different genomic regions [6, 26]. Such genetic heterogeneity is a major challenge to the discovery of genes that modulate pharmacogenetics pathways. An important limitation of case–control association studies related to heterogeneity is the potential that undetected population stratification will produce misleading evidence of association.

Population stratification may cause spurious associations in a case–control study when allelic frequencies vary across subpopulations in a study cohort. For example, if there is an imbalance in ethnic group representation between the case and control cohorts, one could detect a spurious association [4]. Such population stratification may result from recent **admixture** or from poorly matched cases and controls. Genotyping of unlinked panels of SNPs, chosen without regard to the phenotype of interest, can be used to ensure that case and control populations are genetically homogeneous. Methods have recently been developed to assess population stratification and, if necessary, to test correctly for association in the presence of such stratification [15–17]. However, neither systematic testing for population stratification nor application of these new statistical methods has yet been incorporated into the great majority of pharmacogenetic studies of complex human diseases.

Statistical Power

Growing experience with complex disease genetics has made clear the need to minimize type I error in genetic studies [7, 18]. Table 2 shows some simple

Table 2 Sample size requirements for case–control analyses of SNPs (one control per case; detectable difference of OR $\geq$ 1.5; power = 80%)

	Dominant model[c]			Recessive model[d]		
		Sample size required[e]			Sample size required[e]	
Allele frequency[a]	Exposure[b]	$\alpha = 0.05$	$\alpha = 0.005$	Exposure[b]	$\alpha = 0.05$	$\alpha = 0.005$
10%	19%	1162	1934	1%	16 730	27 822
20%	36%	834	1388	4%	4370	7366
30%	51%	818	1360	9%	2094	3484
40%	64%	936	1556	16%	1316	2188
50%	75%	1200	1994	25%	980	1630
60%	84%	1732	2882	36%	834	1388

[a]Frequency of risk-increasing allele in controls.
[b]Exposure (=prevalence) in controls assuming a diallelic locus with a dominant or recessive allele at the **Hardy–Weinberg equilibrium**.
[c]OR of 1.5 between cases and controls for possession of at least one copy of disease-associated SNP by case.
[d]OR of 1.5 between cases and controls for possession of two copies of disease-associated SNP by case.
[e]Required sample size = cases plus controls.

estimation of required sample sizes needed to detect a true **odds ratio** (OR) of 1.5 with 80% power and type I error probability (α) of either 0.05 or 0.005. Both mode of inheritance (dominant, recessive) (*see* **Genotype**) and allele frequency can have dramatic effects on required sample sizes (Table 2). Even for the "best case scenario" – a common SNP acting in a dominant fashion – a relatively large sample size of more than 800 subjects is required at an α of 0.05 (Table 1).

Multiple testing issues are likely in many genetic association studies of candidate loci where either multiple SNPs in one gene, multiple SNPs in several loci, or both [28] are tested, suggesting that a lower α such as 0.005 is probably more realistic than an α of 0.05. Using an α of 0.005 or assuming an uncommon SNP (allele frequency $\leq$0.10) that acts in a recessive fashion points to the need for very large sample sizes, i.e. more than 10 000 cases. Finally, Table 2 assumes an effect size (OR = 1.5) which, in the context of common, multifactorial diseases, may be quite large. Assuming a smaller effect may be more realistic for many genes, and would lead to concomitantly higher required sample sizes. **Simulation** studies have also suggested that genes of small effect are not likely to be detectable by association studies in sample sizes of less than 500 [8].

While these power calculations are simple and fairly conservative, they suggest that the sample sizes used in many of the small case–control pharmacogenetic association studies conducted to date had insufficient power to detect even a large effect associated with a SNP. This suggests that larger-scale studies than most of those currently being performed using data derived from standard clinical trials will be needed. As other researchers have suggested [1], the integration of genetic information into clinical trials will likely require a paradigm shift in the conduct and design of clinical trials. A central problem has been that the parameters of the **mutation**(s) affecting drug response (mode of inheritance, allele frequency, effect size) are not generally known at the start of a clinical trial. Study design remains one of the areas most in need of attention in pharmacogenetics.

Future Directions and Issues

The ultimate goal of pharmacogenetics is to understand the role that sequence variation among individuals and populations plays in the variability of responses to pharmaceuticals. The frequency and **penetrance** of a sequence variant affecting responsiveness to a particular drug and potential interactions with other genetic and environmental factors must ultimately be assessed in multiple population-based samples. A SNP must be relatively common and have a significant impact upon phenotype to be important at the population level in determining treatment response. These criteria become particularly important when extrapolating from specific clinical trials to general clinical use in the highly heterogeneous populations that are the current major markets for drug therapeutics. It is clear that large well-characterized cohort studies of population-based and ethnically diverse samples will be critical to the future success of any diagnostic SNP-based pharmacogenetic tests and for cost-effectiveness studies.

Thus far, pharmacogenetics studies have been limited to the **candidate gene** model. A new direction that is technically feasible at present, but as yet remains unexplored in pharmacogenomics, are SNP-based whole genome screens for variants associated with variation in drug response [31]. Other future directions include the use of pharmacogenomic data for the study of **gene–environment interactions** in determining response to pharmacologic therapy and for homogeneity testing and improving study design [12].

Pharmacokinetics and Pharmacodynamics

The final stage of establishing the safety and efficacy of a new drug, prior to submitting an application for marketing approval, typically involves one or more randomized **clinical trials** comparing the drug's effect to that in an appropriate control group. Sample size requirements in these pivotal (Phase III) trials may dictate that the number of treatment arms be kept to a minimum. As a result, it is not uncommon to study just one dose level of the new drug in pivotal trials. In this situation it is essential that adequate investigation of possible dosing strategies be carried out in earlier stages of clinical development to allow determination of the "best" dose for inclusion in Phase III testing.

Pharmacokinetic (PK) and pharmacodynamic (PD) modeling are key tools in proper dose selection. *Pharmacokinetics* attempts to characterize the fate of the drug in the body following dosing, primarily by sampling its concentration–time profile in the circulation. *Pharmacodynamics* investigates the relationship between the response induced by the drug and its circulating concentration. A common mnemonic is that pharmacokinetics deals with "what the body does to the drug", while pharmacodynamics focuses on "what the drug does to the body". Whereas the response of interest in PK modeling is always concentration of the drug and/or its metabolites, there is often more flexibility in the choice of response in PD models. Typically, it is some relevant biochemical or physiological marker of drug activity, that can be measured easily during the early stages of clinical development. In some cases this may be the intended final clinical endpoint (e.g. reduction in blood pressure). More commonly, the PD response, while providing some measure of the drug's biological activity, serves only as a **surrogate** for the clinical outcome ultimately of interest.

PK/PD modeling plays a role not only in human studies, but also in animal experiments conducted during drug development. Although animal studies involve certain unique aspects, the main issues in model derivation and fitting parallel those encountered with human data. Accordingly, the exposition here considers modeling of data from human subjects only. Understanding the PK and PD characteristics of a new drug is important, not only to identify promising dosing regimens to be tested in pivotal efficacy trials, but also to obtain information needed for labeling, to allow the prescribing physician to use the drug sensibly in clinical practice.

Pharmacokinetic Modeling

Objectives

Underlying most dosage regimens is the idea of a "therapeutic window", i.e. a range within which drug concentrations should be maintained to achieve clinical benefit. Concentrations that are too low may not achieve efficacy, whereas higher levels may result in undesirable side-effects. For instance, most antibiotics require a certain minimum inhibitory concentration (MIC) to be sustained to maintain efficacy against a particular target organism, but concentrations too far in excess of the MIC may be toxic. An effective dosing regimen should aim to reach concentrations within the therapeutic window as quickly as possible, and to stay within the desired range by suitable choices of maintenance dose and dosing interval. On the basis of the drug's PK characteristics in a "typical" subject, a dosing strategy can be designed which should maintain concentrations in the desired range (*see* **Minimum Therapeutically Effective Dose**).

For some classes of agents, assuming a common therapeutic window for all patients may be an oversimplification. Subject-specific genetic, physiologic, or demographic factors may alter the relationship between drug concentration and effect to such a degree that the desirable concentration range may differ substantially across patients, particularly if the therapeutic window is narrow. Even if the target concentration range is the same for all subjects, if differences in their PK characteristics are sufficiently marked it may be necessary to use different dosing strategies for some subjects to maintain concentrations in that range. For PK/PD modeling to provide useful guidance for dosing patients, it is thus a matter of practical importance that the models capture not only "typical" PK/PD behavior; they also need to explain variation in this behavior as fully as possible.

Following the target concentration paradigm described above, the primary clinical application of PK information is the development of a dosing regimen that maintains circulating drug concentrations

within the therapeutic window appropriate for a given patient. The relevant concentration range may be derived from an understanding of the PD relationship, if available. In the earliest stages of clinical testing, some guidance on the appropriate range may be obtained from preclinical work (e.g. from efficacy studies in a relevant animal model, or from theoretical considerations involving binding affinity and targeted receptor occupancy).

To use the drug in clinical practice, three fundamental questions must be answered: (i) *How* should the drug be administered? (ii) *How much* should be given? (iii) *How often* should it be given? In addition to these three basic questions, two auxiliary issues often need to be investigated prior to approval of a drug. These are: characterization of potential interactions with other drugs likely to be used in the target population, and identification of patient characteristics such as sex, weight, ethnic group, or renal function, which exert an effect on the kinetics of the drug substantial enough to warrant dose adjustment.

The main goal of PK modeling is to address these issues, using information obtained in clinical studies. Developing a *model* to describe the kinetic properties of a drug allows one to go beyond purely empirical conclusions, based on dosing regimens that have actually been studied, to predict outcomes for regimens that have not been tested. Evaluating the effects of subject characteristics, changes in physiology or disease state, or other drugs, on kinetic behavior is also naturally accomplished within a suitable model framework.

Design Aspects of Pharmacokinetic Studies

The fundamental data in any PK study are concentration measurements at timepoints following single or multiple doses of the drug. A prerequisite, therefore, is the availability of an accurate and reproducible assay to determine drug levels in any biological matrix of interest. This requirement is not trivial, but lies beyond the scope of this review, and we shall assume that a reliable assay is available. Conceptually, one might be interested in drug concentrations over time in any one of several target tissues. However, ethical and practical considerations limit the ability to obtain concentration measurements in human subjects, so that data are generally available only for blood (serum or plasma concentrations), and possibly urine. Even if biopsies can be obtained for other tissues, reliable determination of concentration is difficult as homogeneous distribution of the drug is unlikely for many tissues. To simplify the exposition, in what follows we consider drug or metabolite concentrations obtained in blood, as this covers most PK studies. We refer to "plasma concentrations", although in some cases drug levels may be assayed in serum, or in whole blood. When available, urine concentration data can provide further insight into elimination characteristics.

It is helpful to identify two broad categories of studies where PK data may be generated. In the first of these, characterization of the kinetic behavior is a primary goal. Such "classical" PK studies involve intensive sampling of the concentration–time profile in a relatively small number of subjects, often healthy volunteers. In contrast, most clinical studies do not have PK as the main focus, but some concentration measurements may be obtained during their conduct. In this situation, relatively few concentration measurements are available for a given subject, but the number of subjects is often considerably larger than that in a classical PK study, and information is obtained in patients, the target population of interest. Occasionally in clinical studies, more intensive sampling may also be carried out in a subgroup of subjects; this is quite common in Phase II trials, but not usual in Phase III.

Some Fundamental Pharmacokinetic Concepts

Studies carried out primarily to address pharmacokinetic issues are often referred to as ADME studies, since they are designed to characterize four fundamental aspects of a drug's kinetics: absorption, distribution, metabolism, and excretion.

Absorption refers broadly to the process by which the drug proceeds from the site of administration to the site of measurement within the body, typically the bloodstream. An understanding of absorption characteristics is important for drugs intended for extravascular routes of administration, e.g. oral agents, or drugs given by subcutaneous injection. Both the rate and extent of absorption are of practical interest. The rate may have implications for time to symptom relief, the extent provides information on the efficiency of the proposed route of administration.

Distribution deals with the question: Where does the drug go? Because of practical constraints in measuring drug levels in tissues, detailed information on

distribution is difficult to obtain directly in humans. Assessment of distribution is typically carried out most extensively in preclinical animal studies, using a radioactively labeled drug. The relevance of such preclinical results to humans is subject to the usual uncertainties surrounding interspecies extrapolation.

Metabolism refers to the conversion of one chemical species to another. It typically plays an important role in the elimination of drugs from the body, as very few drugs are excreted unchanged. The liver is a major site of drug metabolism, through microsomal enzymes which act upon the drug; metabolism in the gastrointestinal system is also common. In some cases it is of interest to characterize the kinetics of major metabolites as well as those of the original drug, particularly if these metabolites exhibit significant pharmacologic or toxic activity.

Excretion refers to the loss of unchanged drug from the body. The term *elimination*, used to describe any loss of drug, encompasses both metabolism and excretion. Elimination occurs primarily, though not exclusively, through the kidneys and the liver. Physiological or demographic factors, as well as the presence of other medications, can frequently affect elimination. It is important to understand which factors exert a substantial effect on elimination patterns to facilitate any dose adjustments that might be necessary as a result.

The key data obtained in any PK study are samples taken post-dosing from the concentration–time curve. Appropriate summaries calculated from this profile can provide information on specific ADME characteristics of the drug. Table 1 summarizes key PK quantities pertaining to absorption, distribution, and elimination that can be calculated from the concentration profile (*see* **Bioavailability and Bioequivalence**). Rates (e.g. of absorption or elimination) are usually defined in terms of *first-order kinetics*. This corresponds to an assumption that the rate of change of drug concentration at a particular time is

Table 1 Common pharmacokinetic parameters

Parameter	Explanation	Remarks
Area below the curve, AUC	Area below the concentration–time curve	Often taken as a measure of total exposure to the drug
Clearance, Cl	Volume of plasma cleared of drug per unit time	$Cl = \text{dose/AUC}$
Volume of distribution, V	The volume that would be occupied if the total amount of drug in the body were at the same concentration as that in the plasma	Gives an idea of the extent to which drug is distributed to tissues. If $V \gg$ plasma volume, then this indicates extensive distribution outside the plasma
Peak concentration, $C_{\max}$	Maximum achieved plasma concentration	Values of $C_{\max}$ that are "too high" may have implications for toxicity
$T_{\max}$	Time at which peak concentration occurs	Mainly relevant for extravascular administration; gives some information on the rate of absorption
Absorption rate, k_a	Fractional rate of drug absorption if first order kinetics are assumed	Relevant for extravascular routes of administration.
Elimination rate, k_{el}	Fractional rate of drug elimination from the body during the terminal phase	$k_{el} = \text{Cl}/V$
Terminal half-life, $t_{1/2}$	Time taken for the plasma concentration to fall by one half during the elimination phase	$t_{1/2} = \log 2/k_{el}$
Bioavailability, F	Exposure relative to that for the same dose given IV. Exposure is measured by the total AUC	$F = \text{AUC}_{\text{other route}}/\text{AUC}_{\text{IV}}$

proportional to the drug concentration at that time, which is approximately true in many cases. The concept of an elimination half-life that is independent of concentration also presupposes first-order elimination. *Zero-order kinetics*, reflecting a constant rate of change of drug concentration, sometimes obtain, for example, intravenous infusion at a constant rate, or in the absorption of certain drugs from the gastrointestinal tract.

The relationships between the quantities shown in the table are model-independent, unless stated otherwise. That is, their validity does not rest on any particular parametric model to describe the underlying concentration profile. Estimation of these quantities from experimental data is discussed below.

Compartmental Modeling

If intensive sampling of individual PK profiles has been conducted, significant progress can be made in estimating the PK parameters described in Table 1, without assuming a specific parametric functional form for a given subject's response profile. If the goal is to go beyond simple summarization of the data at hand, for instance to project PK behavior for other dosage regimens, then a more sophisticated model framework is usually invoked. Similarly, stronger assumptions about the form of the model describing individual subject profiles are generally needed to make progress on inference in the sparse data case. A suitable basis to support derivation of relevant parametric models is provided by the theory of compartmental modeling. Data analyses are classified as noncompartmental or compartmental, according to the underlying assumptions.

The basic idea in compartmental modeling is to represent the body as a system of compartments that communicate reversibly with each other. One should think of a "compartment" in this context not so much as a particular anatomic or physiologic region, but rather as a tissue or group of tissues with similar blood flow and drug affinity. For example, the liver and kidneys, being highly perfused organs, are often considered as being in the same compartment as the circulation. Compartments are assumed to be "well-mixed", assuring uniform distribution of drug throughout. On the basis of such a representation, a mathematical model can be derived to describe drug disposition over time in different compartments. Such models usually assume that drug transfer in and out of compartments follows *linear kinetics*, with transfer rates that are linear in concentration (i.e. zero or first order). This leads to a system of linear differential equations describing the transfer of drug between compartments. The associated PK rate constants are parameters that will generally need to be estimated from experimental data.

An illustration is the case of a two-compartment model to describe drug kinetics following a single intravenous (IV) bolus injection. This model is illustrated in the central part of Figure 1. Following essentially instantaneous absorption of the drug into the circulation, it is assumed to distribute into two compartments. The central compartment represents the blood, extracellular fluid and highly perfused organs and tissues. The second (peripheral) compartment may be thought of as other, poorly perfused, tissues. For the case shown in Figure 1, elimination is assumed to occur from the central (plasma) compartment only. The rate constants, k_{10}, k_{12}, and k_{21}, referred to as *microconstants* in the PK literature, govern the assumed first-order kinetic transfers into and out of the relevant compartments.

For this model, writing the differential equations to describe the system, and solving, shows that the function describing the concentration of drug in the plasma at time t after dosing may be written in

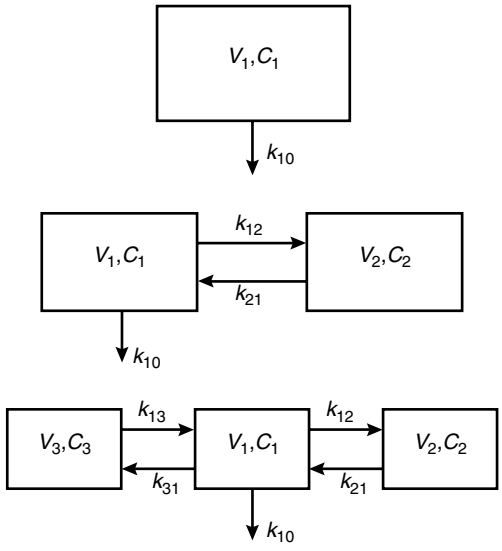

Figure 1 One-, two-, and three-compartment models to describe drug kinetics following a single intravenous bolus injection

biexponential form:

$$C(t) = A_1 \exp(-\lambda_1 t) + A_2 \exp(-\lambda_2 t). \quad (1)$$

Here the parameters λ_1 and λ_2 satisfy the relationships $\lambda_1 + \lambda_2 = k_{12} + k_{21} + k_{10}$ and $\lambda_1 \lambda_2 = k_{21} k_{10}$. The secondary parameters, A_1 and A_2, satisfy $A_1 = [D(\lambda_1 - k_{21})]/[V_P(\lambda_1 - \lambda_2)]$ and $A_2 = [D(k_{21} - \lambda_2)]/[V_P(\lambda_1 - \lambda_2)]$, where D and V_P represent the amount of drug administered and the volume of the plasma compartment, respectively. Solving the linear differential equations that arise in compartmental models, for which transfers follow linear kinetics, is most naturally accomplished using Laplace transforms. Details for the most common cases are given in Gibaldi & Perrier [6].

If the model above is a reasonable description of the system, then we would expect the concentration–time profile for a subject to decline in two distinct exponential phases. During the *distribution phase* there may be a relatively rapid disappearance of the drug from the plasma compartment as it distributes to the tissues. After equilibrium is reached between the plasma and tissue compartments, elimination exerts the dominant effect on plasma concentration, resulting in a shallower decline during the *(terminal) elimination phase*. This type of behavior is evident in Figure 2; these data, taken from a larger study, represent concentrations of indomethacin measured in four subjects following a single IV bolus dose. The constraint $\lambda_1 > \lambda_2$ is sometimes implemented to ensure **identifiability** of the model; nonnegativity of all four parameters in the model is required to yield sensible interpretations. The model is nonlinear in λ_1 and λ_2; nonlinearity in certain parameters is the norm for compartmental models. Following intravenous dosing, assuming linear kinetics, a general representation of the function describing plasma concentration is as a sum of exponential terms, the number of exponentials corresponding to the number of compartments.

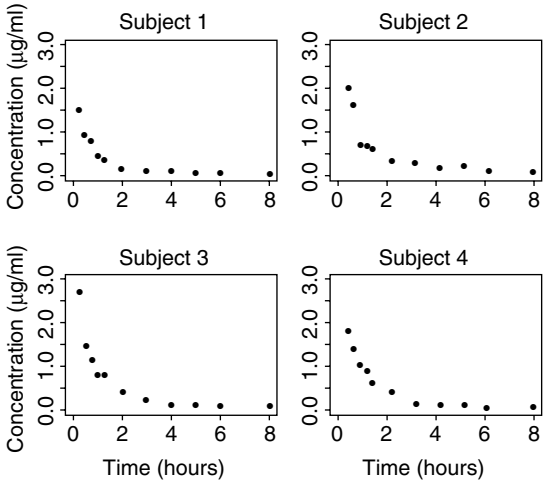

Figure 2 Concentrations of indomethacin in four subjects, following a single intravenous bolus injection

Use of the two-compartment model described above is particularly common. Modification to incorporate elimination from the tissue compartment is straightforward. If distribution to tissues is minimal, a single (plasma) compartment model may be adequate to describe the concentration profile. If distribution to tissues occurs very rapidly, and few sampling times fall in the distribution phase, then it is possible to miss the fact that two compartments are appropriate, as the observed concentration profile will likely appear to follow a monoexponential decline. Where the data indicate three distinct exponential decay phases, the usual interpretation is that tissues fall into two groups, one for which the movement of drug from the plasma to tissue occurs at a moderate rate, the second ("deep tissue compartment") consisting of very poorly perfused tissues such as bone and fat. The distribution of drug from the plasma compartment to these tissues is markedly slower.

Another important extension of the two-compartment model given above is to accommodate extravascular routes of administration such as oral dosing, or subcutaneous or intramuscular injection. In such cases the model is adjusted to include an absorption phase. If absorption occurs from the gastrointestinal tract, a lag time is sometimes included as well. A general method for adjusting the expected plasma concentration function following bolus IV dosing (instantaneous input) to account for a different input process is described by Gibaldi & Perrier[[6], Appendix B]. One multiplies the Laplace transform of the concentration function for IV dosing by that of the input function, and takes the inverse Laplace transform of the product. Application of this method to the case of a two-compartment model with first-order absorption into, and first order elimination from, the plasma compartment yields a function for the plasma concentration at time t that may be written

as the sum of three exponential terms:

$$C(t) = A_1 \exp(-\lambda_1 t) + A_2 \exp(-\lambda_2 t) + A_3 \exp(-k_a t), \quad (2)$$

where the six parameters in the model are known functions of the microconstants and other PK parameters. Inspection of this function suggests the possibility of identifiability problems, depending on the relative magnitudes of the absorption rate constant, k_a, and those associated with the distribution and elimination phases (λ_1 and λ_2, respectively). For most drugs, one expects that $k_a > \lambda_2$. For certain drugs with very rapid elimination, fitting techniques may sometimes interchange the two, a phenomenon referred to as "flip-flop" behavior. In general, k_a may be larger or smaller than λ_1, so that distinguishing between them cannot be done on any theoretical basis. A further difficulty arises if $k_a \approx \lambda_1$. In that case it is likely that the data support fitting only two exponential terms. This would correspond to a one-compartment model with first-order absorption, even though experience from other routes may suggest two compartments are needed. Thus, it is not always possible to determine k_a unambiguously from concentration data following oral administration only. Infrequent sampling during the absorption phase often compounds the problem. In theory, any ambiguity can be resolved by also characterizing kinetics following IV administration in the same subject; this may not always be practicable.

Nonlinear Kinetics

In many cases, linear kinetics obtain in only part of the concentration range. Differences in kinetic behavior may occur at higher concentrations, often due to some type of saturation phenomenon, e.g. of plasma protein or tissue binding, or of some capacity-limited metabolic process. Elimination kinetics are frequently affected. For example, suppose that clearance of the drug occurs primarily through metabolism in the liver, and that the activity of a particular enzyme involved acts as a rate-limiting step. Then the rate of metabolism may be linear over a portion of the concentration range, but reach a plateau at higher concentrations. Borrowing from standard modeling approaches in enzyme kinetics, this type of behavior is usually described by a rectangular hyperbola, with parametric form given by the **Michaelis–Menten equation:**

$$\frac{dC(t)}{dt} = \text{rate} = \frac{V_m C}{K_m + C}, \quad (3)$$

where V_m represents the maximal rate and K_m the concentration at which half the maximal rate is attained. Capacity-limited metabolism can also give rise to nonlinear absorption kinetics, e.g., in the case of drugs that undergo a significant degree of metabolism in the liver before being absorbed into the circulation (the so-called *first pass effect*). If one or more transfer rates in a compartmental model obey Michaelis–Menten kinetics, then the associated system of differential equations will be nonlinear. In this situation, an analytic solution for concentration functions is not possible, except in certain special cases. Saturable, or otherwise nonlinear, kinetics are to be expected at very high concentrations of a drug. Nonlinear kinetic behavior within the therapeutic concentration range is less frequent and its existence can complicate dosing considerably.

Multiple Dosing

Most drugs require multiple administration to maintain effect. If fixed doses are given, separated by a constant dosing interval, then peak plasma levels following later doses will usually be higher than that occurring after the first dose, a phenomenon known as *accumulation*. The degree of accumulation following successive doses attenuates until an eventual steady state is reached for the plasma profile. At the steady state, average input and output over the dosing interval are the same. It is straightforward to show that the average concentration at steady state is proportional to the half-life divided by the length of the dosing interval. The time to reach steady state is a function solely of the drug half-life; to attain 90% of steady-state concentration requires about 3.3 half-lives. Only in the case of intravenous infusion at a constant rate is the expected concentration at steady state actually constant; for an input function corresponding to discrete doses at regular intervals, a "sawtooth" pattern about some overall average steady-state level is expected. If fixed doses are given, at constant intervals, then the size and frequency of doses must be balanced to preclude excessive fluctuations in level between doses. More frequent dosing reduces the

degree of fluctuation between peak and trough levels, but must be balanced against practical aspects such as patient compliance.

If one makes the assumption that the kinetic behavior following a single dose is unchanged, regardless of how many other doses may already have been given, then it is straightforward in principle to predict plasma concentration following multiple doses. One applies the *principle of superposition*, which simply adds the expected contribution of the new dose to the concentration at any timepoint to the expected concentration at that time from all preceding doses. Proceeding recursively, the expected concentration is then simply a sum of terms, one per administered dose, of the concentration function evaluated at the time post-dosing for each of the individual doses. If doses are given at times t_k, and f is the function describing plasma concentration after a single dose, then

$$C(t) = \sum_{k:t_k<t} f(t - t_k). \tag{4}$$

It is important to recognize that the principle of superposition represents an *assumption*, which may or may not be true in practice. Quite often it applies until concentrations exceed the range where linearity of kinetics is preserved. Measurement of concentrations following multiple dosing is needed to provide an empirical check on the validity of models derived from the principle of superposition.

Further Reading

Several texts cover various aspects of PK in more depth. Gibaldi & Perrier [6] provide mathematical details of derivations for the most commonly used compartmental models. A more applied perspective is taken by Rowland & Tozer [13]. Other approaches that have been suggested for modeling PK data include the use of physiologically based models [1], and of stochastic compartmental models (e.g. [11]). A partial list of current and future issues in applying PK to clinical therapeutics includes: development of controlled release formulations, differential PK behavior of stereoisomers, use of stable isotopes in determining bioavailability, appropriate dosing of therapeutic proteins manufactured by recombinant DNA technology, and the challenges in delivery and dosing that accompany the promise of gene therapy.

Statistical Aspects

The development so far has focused on derivation of theoretically based models to describe the expected plasma concentration profile. In practice, concentration values sampled from a subject's profile will be subject to measurement error. Estimation of underlying model parameters is necessarily based on *observed* concentration data and involves the explicit or implicit assumption of a *statistical model*, characterizing the variability in the data. To be useful in practice, statistical modeling must also reflect the design and the analysis objectives accurately. These are generally sufficiently different for the "intensive" and sparse sampling cases that distinct modeling issues arise in the two situations. We now consider each case separately.

Individual PK Modeling and Inference

Objectives

For early **Phase I** studies, with intensive sampling of kinetic profiles, the primary objectives in analysis are usually: (i) to establish the correct functional form of the relevant PK model (e.g. one or two compartments) and (ii) to obtain a preliminary idea of typical values of the model parameters. A subsidiary objective may be characterization of the variability in concentration measurements about the postulated mean function. Intersubject variation in PK characteristics is also of some interest, but estimating this variability on the basis of a relatively small number of subjects who may not be representative of the target patient population clearly has the potential to mislead.

Noncompartmental Analysis

For data from "classical" studies, where relatively frequent samples are taken from the concentration profile, considerable progress can be made in estimating subject-specific PK parameters using noncompartmental methods. For instance, the area under the curve for a given subject can be estimated by application of the trapezoidal rule to the subject's observed profile. For curves exhibiting two distinct phases of exponential decay, a plot of log(concentration) against time should reveal two separate phases of approximately linear decline. Fitting a straight line

to later concentration measurements on this plot yields an estimate of the terminal rate of exponential decline. The terminal half-life may then be estimated by dividing log 2 by this slope estimate. Other parameters may be estimated by exploiting relationships such as those shown in Table 1. Quantifying the uncertainty associated with such noncompartmentally derived parameter estimates, e.g. by calculation of standard errors, is not straightforward, however. The absence of replication precludes calculation of any type of "pure error" estimate of within-subject variation to be used in calculating standard errors. Furthermore, although such methods do provide empirical summaries of the observed concentration profiles, they do not facilitate prediction of concentrations for other dosing regimens, without the assumption of a specific model form.

Compartmental Analysis

In estimating subject-specific parameters within a compartmental modeling framework, the key statistical techniques are those used in heteroscedastic nonlinear regression problems. Denote the jth concentration measurement for the ith subject, taken at time t_{ij}, by y_{ij}, $j = 1 \ldots m_i$, $i = 1 \ldots n$. For convenience, use the vector $\mathbf{x}_{ij}$ to summarize covariate information pertinent to the response y_{ij}; typically, this involves the measurement time, t_{ij}, and information on dosing history for the ith subject up to that time. Assume that

$$\mathrm{E}(y_{ij}|\boldsymbol{\beta}_i) = f(\mathbf{x}_{ij}, \boldsymbol{\beta}_i); \quad \mathrm{cov}(\mathbf{y}_i|\boldsymbol{\beta}_i) = \mathbf{R}_i. \qquad (5)$$

Here, f is a function whose form is known from the relevant compartmental model and which depends nonlinearly on $\boldsymbol{\beta}_i$, a $p \times 1$ vector of unknown PK parameters, specific to the ith subject. The within-subject **covariance matrix** $\mathbf{R}_i$, is assumed to have the same form for all subjects. We restrict attention here to the case where $\mathbf{R}_i$ is diagonal; **serial correlation** in the within-subject concentration measurements is certainly possible, but methods commonly used in PK modeling do not account for it. In contrast, heterogeneity of variance in concentration usually is accommodated when specifying the form of $\mathbf{R}_i$. Typically, a pattern of increasing variance is seen as the mean concentration increases, suggesting that variance might be modeled as a smooth function of the mean. The most common implementation of this idea in the PK literature assumes that the variance is proportional to some power of the mean, corresponding to diagonal elements of $\mathbf{R}_i$ of the form $\mathrm{var}y = \sigma^2\mu^{2\theta}$. The value of θ appearing in the exponent may be known, or may need to be estimated from the data.

Estimating the subject-specific parameters $\boldsymbol{\beta}_i$ from the ith subject's data is thus a **nonlinear regression** problem. Ordinary **least squares** fitting is one possibility, but the heterogeneity of variance in concentration measurements suggests adopting a weighted approach instead, with weights w_{ij} chosen to be inversely proportional to the response variance: $w_{ij} = \sigma^2/\mathrm{var}y_{ij}$.

If the weights are considered to be known constants, then the weighted least squares (WLS) estimate of $\boldsymbol{\beta}_i$ is the value that minimizes $\sum_{j=1}^{n_i} w_{ij}\{y_{ij} - f(\mathbf{x}_{ij}, \boldsymbol{\beta}_i)\}^2$. In practice, the correct choice of weights, w_{ij}, will not be known. However, a simple extension of the WLS approach is to use *estimated* weights in a scheme such as the following (assuming θ known). First obtain a preliminary unweighted estimator $\boldsymbol{\beta}_i^{\mathrm{p}}$, e.g. by ordinary least squares. On the basis of this estimate, form estimated weights $\hat{w}_{ij} = 1/(\hat{\mu}_{ij}^{2\theta})$, where $\hat{\mu}_{ij} = f(\mathbf{x}_{ij}, \boldsymbol{\beta}_i^{\mathrm{p}})$. Use these weights to reestimate $\boldsymbol{\beta}_i$ by weighted least squares. Update the weights on the basis of the new estimate of $\boldsymbol{\beta}_i$ and iterate until convergence. Denote the final estimate by $\hat{\boldsymbol{\beta}}_i^{\mathrm{GLS}}$. This method is known as generalized least squares (GLS), or sometimes as iteratively reweighted least squares (IRLS) (*see* **Generalized Linear Model**).

If θ is unknown, then it may be estimated from the data. An overview of methods for estimating variance parameters in the context of GLS regression may be found in Carroll & Ruppert [2]. An alternative method, commonly used by pharmacokineticists in fitting individual profile data, is to maximize the normal theory **likelihood** for the ith subject's data jointly in $\boldsymbol{\beta}_i$, θ, and σ; this method is referred to in the PK literature as *extended least squares* [12].

In practice, it is important to implement *some* type of weighting scheme in estimating the regression parameters, as failure to do so may give insufficient weight to lower concentration values, resulting in poor estimation of parameters pertaining to the terminal phase. Weights based on predicted rather than observed concentrations are preferable to avoid misbehavior due to one or two "bad" observed y values, and some iteration is desirable to wash out the effect

of poor initial weights. Small deviations from the "optimal" weighting scheme are unlikely to affect inference very much, so exact characterization of the value of θ is not critical. With this in mind, a less formal procedure is simply to examine plots of weighted Studentized residuals following GLS fits for a small grid of possible values of θ (e.g. 0, 0.5, and 1.0), and choose the value which most nearly corrects for the heterogeneity of response variance. Investigating the pattern of within-subject heteroscedasticity on the basis of **residuals** from a preliminary fit has the advantage that it is straightforward to pool the within-subject residuals across all subjects to obtain a single estimate of θ. This presupposes that a common value of θ is appropriate for all subjects, which is likely to be reasonable for PK data, provided assay procedures for determining concentrations are comparable.

In compartmental modeling, the parameters $\boldsymbol{\beta}_i$ appearing in the polyexponential functions usually employed in fitting plasma concentration data are not always the quantities of primary interest. Pharmacokinetic parameters that may be of more practical interest are generally expressible as some known (possibly nonlinear) function, h say, of the elements of $\boldsymbol{\beta}_i$. For example, the terminal half-life in the case of a two-compartment model following intravenous bolus dosing may be calculated as $\log 2/\beta_{4i}$, where β_{4i} is the exponential decay rate for the elimination phase. Estimation of such derived PK parameters is straightforward: one simply substitutes the estimate of $\boldsymbol{\beta}_i$ obtained by GLS, or other method of choice, into the appropriate expression. That is, an estimate of $h(\boldsymbol{\beta}_i)$ is given by $h(\hat{\boldsymbol{\beta}}_i)$.

Approximate expressions for estimating standard errors for the $\hat{\boldsymbol{\beta}}_i$, or functions of $\hat{\boldsymbol{\beta}}_i$, may be obtained by suitable application of standard asymptotic theory for weighted nonlinear regression. Details may be found in most nonlinear regression texts (e.g. [14]). In the context of parameter estimation based on data from only a single subject, where one may be attempting to estimate five or six parameters from only a dozen or so data points, the quality of such approximations may be quite poor.

Estimates of subject-specific PK parameters may be used for subsequent analyses in a number of ways. They may form the basis of prediction of achieved concentrations for different dosing regimens contemplated in future studies. If population modeling is of interest, then subject-specific estimates may be used as raw data for certain types of population analyses.

Software

Nonlinear regression routines with the flexibility to allow iterative reweighting are available in most major statistical packages (*see* **Software, Biostatistical**). These routines generally require explicit specification of the regression function, and possibly its first derivatives with respect to the parameters. More specialized packages, such as NONLIN or ADAPT, widely used by pharmacokineticists, allow the user to choose from a library of preexisting models. This obviates the need for explicit specification of the regression function and derivatives, which can be particularly helpful in situations where complex multiple dosing schemes have been used, or where explicit solution of the differential equations is not possible. Generally, these programs also allow iterative reweighting, with a few different options for the form of the dependence of the variance on the mean.

Practical questions which may arise, no matter what fitting routine is used, are the determination of suitable starting values, conventions for handling concentration values below the assay detection limit, possible model identifiability problems, and suitable choice of parameterization. In addition, convergence to sensible values, and the reliability of standard error estimates based on asymptotic approximations, always tricky issues in nonlinear regression, can be especially troublesome in fitting compartmental models.

Population PK Modeling and Inference

Objectives

For sparse concentration data obtained in the clinical setting, different statistical approaches are usually needed. In part, this follows from the design; obtaining individual estimates from each subject's data is generally not feasible. Analysis objectives also differ, with greater emphasis on characterizing differences in kinetic behavior among subjects. Population analysis thus has two primary goals: (i) estimation of subject-specific PK parameters, and (ii) understanding inter-subject variation in PK characteristics.

Population Modeling

Noncompartmental techniques are generally less useful in the population setting; the extra structure that

follows from a compartmental modeling approach is typically necessary to make much progress. Accommodation of two levels of random variation, within and between subjects, is also necessary. The relevant statistical techniques are those associated with mixed-effect models. A **two-stage** model framework proves useful; we first present this model in fairly general form, and then explain the interpretation of its different components. Let $\mathbf{x}_{ij}$, y_{ij}, $\mathbf{y}_i$, $\boldsymbol{\beta}_i$, $\mathbf{R}_i$, and f have the same interpretations as before, and consider the following model:
Stage 1:

$$\mathbf{y}_i = f(\mathbf{x}_i, \boldsymbol{\beta}_i) + \mathbf{e}_i,$$
$$\mathrm{E}(\mathbf{e}_i|\boldsymbol{\beta}_i) = \mathbf{0}; \qquad \mathrm{cov}(\mathbf{e}_i|\boldsymbol{\beta}_i) = \mathbf{R}_i. \tag{6}$$

Stage 2:

$$\boldsymbol{\beta}_i = \mathbf{A}_i\boldsymbol{\beta} + \mathbf{b}_i,$$
$$\mathrm{E}(\mathbf{b}_i) = \mathbf{0}; \qquad \mathrm{cov}(\mathbf{b}_i) = \mathbf{D}. \tag{7}$$

Interpretation of stage 1, which models data for the ith subject, $i = 1, \ldots, m$, is as before. The second stage models the intersubject variation in $\boldsymbol{\beta}_i$. In the first term, $\mathbf{A}_i\boldsymbol{\beta}$, the systematic component of the variation, is modeled in terms of a $k \times 1$ vector of fixed effects, $\boldsymbol{\beta}$, and a $p \times k$ matrix $\mathbf{A}_i$ incorporating subject-specific covariate information. The second term, $\mathbf{b}_i$, is a $p \times 1$ vector of random effects, reflecting residual (unexplained) variation in the PK parameters $\boldsymbol{\beta}_i$. In the simplest possible case, $\mathbf{A}_i = \mathbf{I}$, so that $\boldsymbol{\beta}_i = \boldsymbol{\beta} + \mathbf{b}_i$, corresponding to the situation where all of the variation in $\boldsymbol{\beta}_i$ is considered random, about an overall population average $\boldsymbol{\beta}$, with covariance matrix $\mathbf{D}$. If possible, one would like to identify subject-specific covariates that account for some of the variation in $\boldsymbol{\beta}_i$. This can be done by a suitable choice of the "design matrix" $\mathbf{A}_i$.

To fix ideas, suppose that the PK parameters $\boldsymbol{\beta}_i$ correspond to the bivariate vector of clearance and distribution volume for the ith subject, (Cl_i, V_i). We might wish to investigate the belief that clearance for a given subject depends on the subject's age. One possibility would be to formulate a model that postulates a linear dependence of clearance on age. Suppose none of the measured subject-level covariates plausibly affects the volume of distribution, so that all between-subject variation in that parameter is considered unexplained. Then, writing β_{1i} and β_{2i} for clearance and volume of the ith subject, respectively, this situation would be described by the following model:

$$\beta_{1i} = \beta_1 + \beta_3\mathrm{Age}_i + b_{1i},$$
$$\beta_{2i} = \beta_2 + b_{2i}. \tag{8}$$

Thus, at the second stage, one attempts to build a parametric regression model, where the subject-specific PK parameter is the response and the model attempts to separate the variation in this response into a systematic component, predictable by measured covariates, and a residual (random) component. As in any regression model, the residual variation will reflect both the true random variation in the population, as well as any variation attributable to covariates that have not been measured. In the case above the regression model is linear in the fixed-effect parameters, $\boldsymbol{\beta} = (\beta_1, \beta_2, \beta_3)'$. For the example described above, $\mathbf{A}_i$ is the following 2×3 matrix:

$$\begin{bmatrix} 1 & 0 & \mathrm{Age}_i \\ 0 & 1 & 0 \end{bmatrix}.$$

Dependence on other covariates would be incorporated by adding columns to $\mathbf{A}_i$ and corresponding elements to the vector of fixed-effect parameters, $\boldsymbol{\beta}$, as necessary.

The need to accommodate both within-subject and intersubject variation correctly in population analysis, and the potential utility of mixed-effects modeling as a way of doing this, was first recognized by Sheiner et al. [15].

Inference

The two-stage model above is quite similar to the two-stage mixed-effects model, described by Laird & Ware [8], used to derive inferential methods for *linear* repeated measurement data. This suggests adapting inferential methods for the linear case for use in fitting population PK models. This approach forms the basis of most commonly used methods for population PK modeling. In the linear case, normality of $\mathbf{e}_i$ and $\mathbf{b}_i$, and linearity of the model in $\mathbf{b}_i$, allow the marginal distribution of $\mathbf{y}_i$ to be derived explicitly. **Multivariate normality** of this marginal distribution allows application of standard **maximum likelihood** or **restricted maximum likelihood** methods.

In contrast, nonlinear dependence of f on $\boldsymbol{\beta}_i$, and consequently on $\mathbf{b}_i$, makes exact derivation of the

marginal impossible, as the necessary integration over the random-effects distribution cannot be performed analytically. Dependence of the covariance matrix $\mathbf{R}_i$ on $\mathbf{b}_i$ complicates matters further. Most inferential methods for PK modeling of sparse data within the framework above rely on approximations to the marginal likelihood. Specifically, a Taylor series expansion in $\mathbf{b}_i$ is used to provide an approximation that is linear in $\mathbf{b}_i$, yielding an approximation to the marginal likelihood. One can then apply methods for linear mixed-effects models to carry out approximate inference on the parameters $\boldsymbol{\beta}$ and $\mathbf{b}_i$, and the independently varying components of the matrices $\mathbf{R}_i$ and $\mathbf{D}$.

Most of the commonly used methods are based on some variation of one of two approximations. The first of these involves a Taylor series expansion in $\mathbf{b}_i$ about zero, the mean of the random effects distribution, giving a first-order approximation to the likelihood. This approximation was first suggested by Sheiner et al. [15], and is referred to as the *first-order* (FO) method in the PK literature. Lindstrom & Bates [9] suggested a refinement, wherein accuracy of the approximation may be improved by expanding about the current estimate of the subject-specific random effect in an iterative fashion. A variation of their method has been adopted by pharmacokineticists; the resulting inferential techniques being referred to as *first-order conditional estimation* (FOCE). At the time of writing, these methods are implemented in two software packages: NONMEM, a package widely used by pharmacokineticists, developed in the early 1980s, and a more recent suite of contributed functions to **S-PLUS**, `nlme`, which implement the method of Lindstrom & Bates.

Application of these methods allows inference on the fixed-effects and the independently varying covariance components. In addition, empirical Bayes estimates of the individual random effects $\mathbf{b}_i$ (and thus of the subject-specific PK parameters $\boldsymbol{\beta}_i$) are obtained. By analogy with the linear mixed-effects model, the random-effect estimates may be viewed as subject-level residuals, and thus prove useful in screening covariates for inclusion in the second-stage model to account for intersubject variation. Formal testing of the need to include particular covariates may be implemented using **likelihood ratio test** techniques.

Other inferential methods have been proposed in the recent statistical literature. Each assumes some type of **hierarchical model** framework; most attention has focused on relaxing assumptions pertaining to the second-stage (random-effects) distribution. Among the proposed approaches are completely nonparametric estimation of the random-effects distribution [10], and a semiparametric alternative, developed by Davidian & Gallant [3]. Recent advances in using **Markov chain Monte Carlo** (MCMC) techniques to deal with computational complexities have allowed practical implementation of Bayesian analysis in the context of hierarchical regression models. Wakefield [17] illustrates application of these methods in the context of population PK modeling. Two recent texts that review modeling and inference in nonlinear hierarchical regression are Davidian & Giltinan [4], and Vonesh & Chinchilli [16].

PD Modeling

Objectives

The primary goal of PD modeling is to characterize the concentration–effect relationship for some appropriate measure of response (*see* **Dose-response in Pharmacoepidemiology**). This can be used to deduce the appropriate target concentration range to guide dosing. Just as subjects may exhibit different PK behavior resulting from genetic or physiological characteristics, their response to circulating concentrations may also differ. Substantial differences might result in a need for subject-specific target concentration ranges – particularly if the separation between toxicity and efficacy response curves is narrow. In such cases an understanding of the factors giving rise to differential sensitivity to the drug may be important in order to allow accurate prediction of the correct target concentration range for a new patient.

Design Aspects

Data suitable for PD modeling are most often obtained in a setting where PK (concentration) data are also being collected. The goal is to characterize the relationship between response and concentration, so that concentration plays the role of "independent variable" in PD modeling. Sometimes, concentration values are obtained concurrently with the measurement of the PD response, but sampling schedules

for PK and PD measurements may differ. Conceptually, this can be accommodated by incorporating an appropriate lag term in the model, or by using predicted concentration values, from subject-specific PK parameter estimates, at the PD measurement timepoints. Some studies employ a dose–titration design, in which each subject receives multiple dose levels of the drug, separated by a washout period. More commonly, each subject is dosed at only one of the possible levels, although multiple dosing at the particular level assigned may occur. In this case, concentration determinations may be made at several timepoints post-dosing, ensuring some variation in the achieved concentrations, but any one subject is unlikely to achieve concentration levels that span the entire range of interest. Thus, unlike PK modeling, it is rarely possible to characterize the full concentration–effect profile for a particular subject on the basis of that subject's data only. As a result, population-based fitting methods are usual in PD modeling.

Model Derivation

In comparison to PK modeling, both theoretical and practical aspects of PD modeling are less well developed. This is not surprising; given the potential variety in the choice of PD endpoints, development of a unified theory for modeling may be too much to expect. Potential issues in PD modeling include (i) choice of pharmacologic endpoint – factors to be considered in making this choice include clinical relevance, ease and variability of measurement, and sensitivity to changes in drug concentration; (ii) possible lag between changes in plasma concentration and PD effect, a phenomenon known as *hysteresis*; (iii) error in concentration measurements; (iv) the possibility of diurnal or other temporal variation in response; (v) feedback loops resulting in up- or downregulation of response; and (vi) possible formation of metabolites affecting response. This list is not exhaustive.

The most commonly used model relating PD response to concentration is the so-called sigmoid $E_{\max}$ model, proposed by Holford & Sheiner [7]. There are several possible parameterizations; the following is common:

$$y = E_0 + \frac{E_{\max} - E_0}{1 + (\mathrm{EC}_{50}/C)^{\gamma}}. \tag{9}$$

This model is also referred to as the four-parameter logistic function. The parameters have the following interpretation. E_0 and $E_{\max}$ are the response at zero concentration and the maximal response, respectively. EC_{50} is the concentration eliciting a response halfway between E_0 and $E_{\max}$, and γ (the *Hill coefficient*) is a parameter governing the steepness of the concentration–effect relationship.

In some situations the biochemistry or physiology of response is such that a definite lag occurs between a change in the circulating concentration of the drug and a change in response. One possible view is that it is the drug concentration at the site where it elicits its effect (e.g. by binding to receptors in the target tissue) that is important, more than plasma concentrations. Measurement of drug levels at the effect site is generally infeasible, of course, so plasma concentrations act as a surrogate. The lag may be interpreted as the time it takes for changes in plasma concentrations to be propagated to the effect site. Adopting this view, one approach to modeling the lag in response is to incorporate a hypothetical "effect-site compartment", with a term that describes the absorption process required for the drug to reach this compartment (see, for example, [7]). Recent work by Jusko and colleagues [5] develops a more general approach, resulting in a family of *indirect pharmacodynamic models*. The flexibility of the indirect modeling approach is appealing; given its relatively recent introduction, there have been few reported applications in the literature to date.

Inference

The data structure in PD modeling problems usually parallels that in population PK analysis: relatively infrequent repeated measurements on each of a number of subjects, according to an unbalanced design. A similar two-stage model is appropriate, with the first stage modeling concentration–response data for each subject, and the second stage describing intersubject variation in parameters of the first-stage PD model. Since this model is nonlinear in certain parameters, inferential methods for nonlinear mixed effects models are appropriate for population PD modeling, as well as for population PK modeling. Either sequential or simultaneous fitting of population PK and PD models is possible. Details are beyond the scope of this article; a more extensive discussion may be found in Davidian & Giltinan [4].

In contrast to PK modeling, there is no requirement that the response variable in a PD model be continuous. For discrete or binary responses, existing

methods for population PK analysis will generally not be appropriate. The natural model framework in these cases is that of generalized mixed models; see, for example, [16]. This is an area of considerable interest in the current statistical literature. Given the interest in characterizing intersubject variation in PD parameters, subject-specific modeling is more suitable than methods that focus on marginal inference. **Bayesian** hierarchic modeling, implemented by appropriate **Markov chain Monte Carlo** (MCMC) methods, appears particularly promising in this context.

Conclusion

Pharmacokinetic and pharmacodynamic modeling address an important practical need during drug development, namely that of learning how to dose a drug sensibly to achieve therapeutic benefit. Several factors can make this a challenging problem: a steep concentration–effect relationship, poor separation of the dose–response curves for efficacy and toxicity, and high intersubject variability in PK or PD characteristics. Drugs that exhibit good separation of the efficacy and toxicity curves are generally easy to use in practice – even in the presence of high intersubject variation it may be possible to find a single dosing regimen that is suitable for all patients. If the therapeutic window is not so wide, then some individualization of dosing may be required, depending on the degree of intersubject variation. Ideally, simple adjustments to dosing based on easily measured subject characteristics, such as age, sex, or weight, are adequate. For drugs where simple adjustments prove inadequate, a possible recourse is to implement some degree of therapeutic concentration monitoring initially. With this approach a patient might be started out on a dosage regimen based on "typical" kinetic behavior. One or two blood draws are taken and assayed for drug concentration, thereby allowing an assessment of how different the subject's concentration profile is from the norm. Beliefs about the values of the subject's kinetic parameters may be updated in a Bayesian fashion, and possible dose corrections may be implemented. Since therapeutic concentration monitoring is somewhat resource-intensive, its use is generally limited to drugs with a narrow therapeutic window, and a high degree of unexplained intersubject variability in kinetics, such as theophylline, digoxin, or phenytoin. At the most challenging end of the dosing spectrum are drugs with poor separation of efficacy and toxicity, a high degree of intersubject PK and PD variability, and with few covariates of predictive value. If no measure of a patient's sensitivity is available to guide a sensible choice of target concentration range, it is sometimes possible to titrate dose to a specific effect level. This requires the availability of an easily measured PD endpoint upon which dose titration can be based. In many situations it may not be practicable to dose a drug in this manner, though in some cases this approach can be successful. The anticoagulating agent coumadin, frequently titrated for an individual subject according to the coagulation parameter prothrombin time, represents an example of a drug dosed in this fashion. The distilled grain extract Stolichnaya is another.

Phase I Trials

The initial phase of human experimentation in the development of chemotherapeutic drugs involves finding a dose that produces an acceptable level of toxicity. What is acceptable obviously depends on the disease in question: in diseases with significant morbidity and mortality, particularly cancer, the acceptable level of toxicity is quite high. Indeed, the toxicity of the drug may be to some extent a measure of its potential efficacy. That any toxicity is acceptable is an acknowledgment that, in the absence of any information regarding the optimal therapeutic dose of the drug, the maximum benefit is presumed to occur at the highest possible dose.

The Phase I trial has, as a general objective, the determination of the maximum dose of a drug, either alone or as part of a combination, that will, when administered by a specific schedule and route, produce an acceptable level of toxicity. This dose is usually referred to as the maximum tolerable dose (MTD), although in animal studies the same acronym may refer to the largest dose that will not kill any animals. A typical definition of acceptable toxicity (for an anticancer agent) might be, for example, "toxicity of grade 3 or worse in not more than one out of three patients", where grade 3 toxicity is further defined according to criteria that are as objective as possible. An occurrence of toxicity that is unacceptable is said to be a dose-limiting toxicity (DLT). The MTD is most frequently defined in terms of the frequency of occurrence of the **binary** outcome associated with the presence/absence of DLT. Mathematically, if Y denotes the binary response with $Y = 1$ denoting the occurrence of DLT, then one seeks a dose x_{MTD} where $\Pr(Y = 1|x_{\mathrm{MTD}}) = q_0$, where q_0 is usually in the range $0.1-0.4$ (although this is often not explicitly defined). However, in cases where toxicity is almost always restricted to a single quantitative parameter; for example, white blood count (WBC), it would be possible to define the MTD in terms of the WBC itself; for example, the highest dose where the median nadir WBC is at least 2000 (see the section on continuous outcomes below). One must also define the time period over which the evaluation of toxicity is to be performed. The MTD is typically defined only with respect to relatively acute toxicities, such as those occurring within three to four weeks of drug administration.

Once an MTD is established, one presumes that this dose will be used in further evaluations of efficacy in **Phase II trials**; however, this logical progression is complicated by the fact that patient populations in Phase I and II trials are likely to be dissimilar.

Traditional Methods

When defined in terms of the presence or absence of DLT, the MTD can be defined as some **quantile** of a tolerance distribution or **dose–response** curve. For a given sample size, the most effective way of estimating this quantile would be to determine, for each patient in the sample, the exact dose of the agent in question at which DLT first appears. Such data are nearly impossible to gather, however, as it is impractical to give each patient more than a small number of discrete dosages. Furthermore, the data obtained from sequential administration of different doses to the same patient would almost surely be **biased**, as one could never distinguish the cumulative effects of the different doses from the acute effects of the current dose level. Extended washout periods (*see* **Crossover Designs**) between doses are not a solution, since the condition of the patient, and hence the response to the drug, is likely to change rapidly for the typical patient in a Phase I trial. For this reason, almost all Phase I trials involve the administration of only a single dose level to each patient and the observation of the frequency of occurrence of DLT in all patients treated at the same dose level.

There are two significant constraints on Phase I trial design. The first is the ethical requirement to approach the MTD from below, so that one must start at a dose level believed almost certainly to be below the MTD, and gradually escalate upward. The second is the fact that the number of patients typically available for a Phase I trial is relatively small, say $15-30$, and is not driven traditionally by rigorous statistical considerations requiring a specified degree of precision in the estimate of MTD. The pressure to use only small numbers of patients is large – literally hundreds of drugs per year need to be tested, and each combination with other drugs, each schedule, and each route of administration

requires a separate trial. Furthermore, the number of patients for whom it is considered ethically justified to participate in a trial with little evidence of efficacy is limited (*see* **Ethics of Randomized Trials**).

As a consequence of the above considerations, the traditional Phase I trial design utilizes a set of fixed dose levels that have been specified in advance; that is, $x \in \{a_1, a_2, \ldots, a_K\}$. The choice of the initial dose level a_1, and the dose spacing, are discussed in more detail below. Beginning at the first dose level, small numbers of patients are entered, typically three to six, and the decision to escalate or not depends on a prespecified **algorithm** related to the occurrence of DLT. When a dose level is reached with unacceptable toxicity, then the trial is stopped.

Initial Dose Level and Dose Spacing

The initial dose level is generally derived either from animal experiments if the agent in question is completely novel, or by conservative consideration of previous human experience if the agent in question has been used before but with a different schedule, route of administration, or with other concomitant drugs. A common starting point based on the former is from 1/10 to 1/3 of the mouse LD_{10}, the dose that kills 10% of mice, adjusted for the size of the animal on a per kilogram basis or by some other method.

Subsequent dose levels are determined by increasing the preceding dose level by decreasing fractions, a typical sequence being $\{a_1, a_2 = 2a_1, a_3 = 1.67a_2, a_4 = 1.5a_3, a_5 = 1.4a_4$, and thereafter $a_{k+1} = 1.33a_k, \ldots\}$ Such sequences are often referred to as "modified Fibonacci". (In a "true" Fibonacci sequence the increments are approximately 2, 1.5, 1.67, 1.60, 1.63, and then 1.62 thereafter, converging on the golden ratio.) With some agents, particularly biological agents, the dose levels may be determined by log (i.e. $\{a_1, a_2 = 10a_1, a_3 = 100a_1, a_4 = 1000a_1, \ldots\}$) or half-log (i.e. $\{a_1, a_2 = 3a_1, a_3 = 10a_1, a_4 = 30a_1, a_5 = 100a_1, \ldots\}$) spacing.

Escalation Algorithms

A wide variety of dose escalation rules may be used. For the purposes of illustration, we describe the following:

1. Evaluate three patients at a_k:
   - (i) if zero of three has DLT, then increase dose to a_{k+1} and go to step 1;
   - (ii) if one of three has DLT, then go to step 2;
   - (iii) if more than one of three have DLT, then go to step 3.
2. Evaluate an additional three patients at a_k:
   - (i) if one of six has DLT, then increase dose to a_{k+1} and go to step 1;
   - (ii) if more than one of six have DLT, then go to step 3.
3. Discontinue dose escalation.

If the trial is stopped, then the dose level below that at which excessive DLT was observed is the MTD. Some protocols may specify that if only three patients were evaluated at that dose level, then an additional three should be entered, for a total of six, and that process should proceed downward, if necessary, so that the MTD becomes the highest dose level where no more than one toxicity is observed in six patients. The actual q_0 that is desired is generally not defined when such algorithms are used, but clearly $0.17 \leq q_0 \leq 0.33$, so we could take $q_0 \approx 0.25$.

While such an algorithm makes common sense, only brief reflection is needed to see that the determination of MTD on rigorous statistical grounds is extremely tenuous. Consider a trial where the frequency of DLT for three consecutive dose levels following the algorithm above is, respectively, zero of three, one of six, and two of six. Ignoring at this point the sequential nature of the escalation procedure, the pointwise 80% **confidence intervals** for the rate of DLT at the three dose levels are, respectively, 0 – 0.54, 0.02 – 0.51, 0.09 – 0.67. Although in such an outcome the middle dose would be taken as the estimated MTD, there is not even reasonably precise evidence that the toxicity rate for *any* of the three doses is either above or below the implied target rate of approximately 0.25.

A more rigorous statistical analysis of this problem would produce simultaneous confidence intervals for the three dose levels, account for the sequential sampling algorithm (*see* **Sequential Analysis**), and also account for the fact that the toxicity rates are presumably nondecreasing with increasing dose. Such an analysis is quite complex for even such a simple example, and would not alter the basic point regarding the lack of precision about toxicity rates. Furthermore, even the latter analysis does not

quantify the imprecision in the estimate of MTD itself.

Crude comparisons among different dose escalation algorithms can be made by examining the level-wise operating characteristics of the design, i.e. the probability of escalating to the next dose level given an assumption regarding the underlying probability of DLT at the current dose level. Usually, this calculation is a function of simple **binomial** success probabilities. For example, in the algorithm described above, the probability of escalation is $B(0, 3; p_x) + B(1, 3; p_x)B(0, 3; p_x)$, where $B(r, n; p_x)$ is the probability of r successes (toxicities) out of n trials (patients) with underlying success probability at the current dose level p_x. When the probability of escalation is plotted over a range of p_x, one can characterize algorithms as relatively "aggressive" or "conservative".

More useful comparisons need to involve consideration of the entire dose–response curve, which, of course, is unknown. Many features of traditional dose escalation algorithms can be studied by formulating the design as a discrete **Markov chain** [11]. The states in the chain refer to treatment of a patient or group of patients at a dose level, with an absorbing state corresponding to the stopping of the trial. If the design can be formulated such that one has constant transition probabilities for various assumptions about the true dose–response curve, then much information, such as the number of patients treated at each dose level, can be calculated exactly by carefully computing the appropriate quantities summarized from successive powers of the transition probability matrix **P**. Usually, however, **simulation** studies are a more practical tool for this purpose. As with exact computations, one needs to specify a range of possible dose–response scenarios, and then simulate the outcome of a large number of trials under each scenario. Many different aspects of the algorithm can be compared, such as the mean and variability of x_{MTD} (or, more usefully, the probability of DLT at x_{MTD}), the average number of patients treated, and the percentage of patients treated at doses where p_x is either undesirably small or large. In particular, one can study the sensitivity of the design to features of the dose–response curve that will be unknown in practice, such as the number of dose levels between the starting dose and the true MTD, and the steepness of the dose–response curve near the MTD.

Alternative Approaches

A Bayesian Approach: The Continual Reassessment Method

The small sample size and low information content in the data derived from traditional methods have suggested to some the usefulness of Bayesian approaches (*see* **Bayesian Methods**) to estimate the MTD. In principle, this approach allows one to combine any prior information available regarding the value of the MTD with subsequent data collected in the Phase I trial to obtain an updated estimate reflecting both.

The most clearly developed Bayesian approach to Phase I design is the continual reassessment method (CRM) proposed by O'Quigley and colleagues [7, 9] From among a small set of possible dose levels, say $\{a_1, \ldots, a_6\}$, experimentation begins at the dose level that the investigators believe, based on all available information, is the most likely to have an associated probability of DLT equal to the desired q_0. It is assumed that there is a simple family of monotone dose–response functions ψ such that for any "dose" x and desired probability of toxicity q there exists a unique θ where $\psi(x, \theta) = q$ and, in particular, $\psi(x_{\mathrm{MTD}}, \theta_0) = q_0$. An example of such a function is $\psi(x, \theta) = [(\tanh x + 1)/2]^{\theta}$. Note that ψ is not assumed to be necessarily a dose–response function relating a characteristic of the dose levels to the probability of toxicity. That is, x does not need to correspond literally to the dose of the drug. The uniqueness constraint implies, in general, the use of single-parameter models, and explicitly eliminates popular two-parameter dose–response models like the logistic (*see* **Quantal Response Models**).

A **prior distribution** $g(\theta)$ is assumed for the parameter θ such that for the initial dose level; for example, a_3, either $\int_0^{\infty} \psi(a_3, \theta) g(\theta)\, \mathrm{d}\theta = q_0$ or, alternatively, $\psi(a_3, \mu_a) = q_0$, where $\mu_a = \int_0^{\infty} \theta g(\theta)\, \mathrm{d}\theta$. The particular prior used should also reflect the degree of uncertainty present regarding the probability of toxicity at the starting dose level; in general, this will be quite vague.

After each patient is treated and the presence or absence of toxicity observed, the current distribution $g(\theta)$ is updated along with the estimated probabilities of toxicity at each dose level, calculated by either of the methods above. The next patient is then treated at the dose level minimizing some measure of the distance between the current estimate of the

probability of toxicity and q_0. After a fixed number, n, of patients have been entered sequentially in this fashion, the dose level selected as the MTD is the one that would be chosen for a hypothetical $n + 1$st patient. Confidence intervals for the probability of toxicity at the selected dose level are available [6], though not for x_{MTD} itself, although some consistency results are available [10].

Although the prior distribution $g(\theta)$ can be chosen to be extremely vague, some practitioners object philosophically to the Bayesian approach, and it is clear in the Phase I setting that the choice of prior can have a measurable effect on the estimate of MTD [4]. However, the basic framework of CRM can be adapted easily to a non-Bayesian setting and can conform in practice more closely to traditional methods [10]. For example, there is nothing in the approach that prohibits one from starting at the same low initial dose as would be common in traditional trials, or from updating after groups of three patients rather than single patients. Allowing for some ad hoc deterministic rules to start the trial off, the Bayesian prior can be abandoned entirely and the updating after each patient can be fully **likelihood** based [8].

Storer's Two-stage Design

Storer [11, 12] has explored a combination of more traditional methods implemented in such a way as to minimize the numbers of patients treated at low dose levels and to focus sampling around the MTD; these methods also utilize an explicit dose–response framework to estimate the MTD.

The design has two stages and uses a combination of simple dose-escalation algorithms. The first stage assigns single patients at each dose level, and escalates upward until the first toxicity is reached; then, the dose is decreased one level and the second stage begun. The second stage incorporates a fixed number of cohorts of three patients; successive cohorts are entered at the next lower, same, or next higher dose level, respectively, according to whether the current cohort experiences two or more, one, or zero dose-limiting toxicities. After completion of the second stage a dose–response model (*see* **Dose-response in Pharmacoepidemiology**; **Dose–Response Models in Risk Analysis**) is fit to the data and the MTD estimated by **maximum likelihood**. For example, one could use a **logistic** model where logit $\Pr[Y = 1|x] = \alpha + \beta x$, whence the estimated MTD is $x_{\mathrm{MTD}} = (\mathrm{logit} q_0 - \hat{\alpha})/\hat{\beta}$.

The particular second-stage algorithm described above is designed with a target percentile of $q_0 = 0.33$ in mind. Although other percentiles could be estimated from the same estimated dose–response curve, a target q_0 different from 0.33 would probably lead one to use a modified second-stage algorithm.

Extensive simulation experiments using this trial design in comparison with a more traditional design demonstrated the possibility of reducing the variability of point estimates of the MTD, and reducing the proportion of patients treated at very low dose levels, without markedly increasing the proportion of patients treated at dose levels where the probability of DLT is excessive; say, 0.5. Storer [12] also evaluated different methods of providing confidence intervals for the MTD. Standard likelihood-based methods that ignore the sequential sampling scheme (a **delta method**, a method based on **Fieller's theorem**, and a **likelihood ratio** method) are often markedly anticonservative. More accurate confidence sets can be constructed by simulating the distribution of any of those test statistics at trial values of the MTD; however, the resulting confidence intervals are often extremely wide. Furthermore, the methodology is purely frequentist, and may be unable to account for minor variations in the implementation of the design when a trial is conducted.

With some practical modifications, the two-stage design described above has been implemented in a real Phase I trial [2]. The major modifications included: (i) a provision to add additional cohorts of three patients, if necessary, until the estimate of β in the fitted logistic model becomes positive and finite; (ii) a provision that the recommended Phase II dose is not higher than the highest dose level at which patients have actually been treated, in the event that the estimate of x_{MTD} is above that dose; and (iii) a provision to add additional intermediate dose levels if, in the judgment of the protocol chair, the nature or frequency of toxicity at a dose level precludes further patient accrual at that dose level.

Continuous Outcomes

Although not common in practice, it is useful to consider the case where the major outcome defining toxicity is a continuous measurement; for example, the nadir WBC. This may or may not involve

a fundamentally different definition of the MTD in terms of the occurrence of DLT. For example, suppose that DLT is determined by $Y < c$, where c is a constant, and we have $Y \sim \mathrm{N}(\alpha + \beta x, \sigma^2)$. Then $x_{\mathrm{MTD}} = [c - \alpha - \Phi^{-1}(q_0)\sigma]/\beta$ has the traditional definition that the probability of DLT is q_0. The use of such a model in studies with small sample size makes some distributional assumption imperative. Some sequential design strategies (*see* **Sequential Analysis**) in this context have been described by Eichhorn & Zacks [3].

Alternatively, the MTD can be defined in terms of the mean response, i.e. the dose where $\mathrm{E}(Y) = c$. For the same simple linear model above, we then have that $x_{\mathrm{MTD}} = (c - \alpha)/\beta$. Fewer distributional assumptions are needed to estimate x_{MTD}, and **stochastic approximation** techniques might be applied in the design of trials with such an endpoint [1]. Nevertheless, the use of a mean response to define MTD is not generalizable across drugs with different or multiple toxicities, and, consequently, has received little attention in practice.

A recent proposal for a design incorporating a continuous outcome is that of Mick & Ratain [5]. This is also a two-stage study, which for a hypothetical study of etoposide assumes a simple **linear regression** model relating dose to the WBC nadir $\ln(\mathrm{WBC}) = \alpha + \beta_1 \ln(\mathrm{WBC_{pre}}) + \beta_2 x$, where $\mathrm{WBC_{pre}}$ is the pretreatment WBC. The first phase uses cohorts of two patients. Ad hoc rules for dose escalation are determined by the toxicity experience in the current cohort; however, the model is fit each time and cohorts of two are added until at least eight patients have been treated and β_2 is significantly different from 0 at the 0.05 level of significance. In the second stage of the study, the dose for the next cohort of two patients is determined by fitting the regression model to the accumulated data and estimating the dose that leads to a mean nadir WBC of 2.5; that is, $a_{k+1} = [\ln(2.5) - \hat{\alpha} - \hat{\beta}_1 - \ln(\mathrm{WBC_{pre}})]/\hat{\beta}_1$. This continues until at least eight patients have been treated and β_2 is significantly different from 0 at the 0.001 level of significance.

Simulation studies of this design using a **pharmacokinetic model** and historic database demonstrated a clear increase in precision in the MTD estimated from the model-based dose escalation method, as compared with the MTD estimated from a more traditional design. The average sample size was also measurably smaller. Though such results are promising, the method applies only to situations where the dose limiting toxicity is a single continuous outcome. Furthermore, the simulation studies that are needed to establish the usefulness of the method in specific situations often require the use of human pharmacokinetic data that may not yet be available.

Phase II Trials

Clinical trials of new medical treatments may be classified into three successive phases. **Phase I trials** typically are small studies to determine the maximum safe dose of a drug, biological agent or combination regimen [26]. Once a dose and schedule of a new experimental regimen E have been determined, its therapeutic activity is evaluated in a Phase II trial. Phase II trials in cancer are usually single-treatment-group studies whose primary goal is to determine whether E has a level of anti-disease activity sufficiently promising to warrant further development. Phase II results also frequently serve as the basis for additional single-treatment-group studies involving E in combination with other drugs or in other dosage schedules. Phase II trials are important because they are the primary means of selecting treatments for more rigorous evaluation in Phase III trials.

Phase II trials can be categorized broadly with regard to objectives. The objective of most single-agent Phase II trials in oncology is to determine whether the agent has any anti-disease activity. This is a Phase IIA trial. Gehan [15] proposed the first Phase IIA design, a two-stage design in which n_1 patients are treated in stage 1, the trial is stopped if there are no successes in the first stage, and otherwise an additional n_2 patients are treated in stage 2. The stage 1 sample size is chosen to control type II error probability β (*see* **Hypothesis Testing**), specifically $n_1 \geq \log(\beta)/\log(1-p_1)$ (see Phase IIA trials below). The stage 2 sample size is chosen to obtain an estimate of the success probability, having **standard error** no larger than a given magnitude. The size of n_2 depends on the number of successes in the first stage, since that stage provides the estimate of success probability on which to base computation of the **binomial** standard error.

Often, the goal of a Phase II trial of a combination regimen E is to determine whether the new treatment is promising, compared with a standard treatment S. This is a Phase IIB trial. In this case, E is already known to be active. An important consideration in IIB trials is that it is clinically undesirable to continue a trial of an experimental treatment that proves not to be promising compared with S, to make way for potentially more promising new treatments. It is also important to recognize the comparative aspect of Phase IIB trials, which may lead to formal use of historical data on S in the evaluation of E, and possibly to a randomized trial [31].

Short-term response is usually used as the measure of treatment effect in Phase II trials. In oncology, partial tumor response often is not a validated measure of patient benefit. In general, the comparison of survival between responders and nonresponders is not valid for demonstrating that treatment has extended survival for responders [1]. Because response is often viewed as a necessary but not sufficient condition for extending survival, response may be used in Phase II trials for screening promising treatments. To evaluate the effectiveness of a regimen in prolonging survival, however, a Phase III trial of survival is required.

Phase IIA Trials

Single-stage Designs

The simplest Phase II design is a single-arm (i.e. treatment group) single-stage trial in which patients are treated with E. Treatment success typically is defined as a **binary** variable such as greater than 50% tumor shrinkage. The data consist of the **random variable** Y_n, the number of successes, and n, the number of patients evaluated. Y_n is **binomial** in n and the unknown success probability p. The sample size is determined so that, given a fixed standard response rate p_0 and a target response rate $p_1 = p_0 + a$, which represents a medically important improvement over p_0, a test of $H_0 : p \leq p_0$ vs. $H_1 : p \geq p_1$ has type I error probability (significance level) $\leq \alpha$ and type II error probability $\leq \beta$. The test is determined by a cutoff, r, with H_0 rejected if $Y \geq r$ and H_1 rejected if $Y < r$. The consequences of a type I error are that an uninteresting or even inferior treatment is likely to become the basis for a Phase III trial. The consequence of a type II error is that a promising treatment has been lost or its detection delayed. The required sample size n and test cutoff r are determined by specifying α, β, p_0 and δ. Reasonable values for δ are usually 0.15 to 0.20, since $\delta < 0.15$ usually leads to unrealistically large n, while $\delta > 0.20$ leads to a trial yielding very little information about E.

An alternative method of designing a single-stage trial is to choose n to obtain a **confidence interval** of given width and level (coverage probability) to estimate p. Ghosh [16] provides a good approximate

confidence interval, or the exact binomial confidence interval of Clopper & Pearson [6] may be used.

Multi-stage Designs

The most serious limitation of the single-stage design is that it has no provision for early termination if the interim observed response rate is unacceptably low. The first multistage design introduced was Gehan's two-stage design described above. Schultz et al. [23] and Fleming [13] provide a general multistage framework for Phase II trials in which n_j patients are accrued at the jth stage and a decision is made to stop or continue the trial at the end of each stage (*see* **Sequential Analysis**). At stage j, H_1 is rejected and the trial is terminated if S_j, the cumulative number of successes up to that point, $\leq a_j$. H_0 is rejected and the trial is terminated if $S_j \geq r_j$. The trial continues to the next stage if $a_j < S_j < r_j$. If the trial continues to the Kth (final) stage, then one of the two hypotheses must be rejected; hence, $a_K = r_K - 1$. The sample sizes in each stage and test cutoffs must be chosen to provide overall test error rates α and β. The actual sample size is thus random. Fleming [13] provides an explicit method for determining the test cutoffs to satisfy the error probability constraints, although the number of stages and division of patients among the stages are somewhat arbitrary. Bellisant et al. [3] present a simulation study evaluating several multistage Phase II designs.

Therneau et al. [39] provide an efficient enumeration **algorithm** that provides optimal $\{a_j, r_j\}$ boundary values for given $K, n_1, \ldots, n_k, \alpha, \beta, p_0$ and p_1.

Simon [24] derives two-stage designs that either (i) minimize the expected sample size (the optimal design) under the **null hypothesis** or (ii) minimize the maximum sample size (the **minimax** design) for given α, β, p_0, and p_1. One need not specify n_1 or n_2 because these are viewed as design parameters to be optimized. An important distinction between the two-stage version of the Fleming design and Simon's designs is that the latter allow only rejection of H_1 or continuation, but not rejection, of H_0 at the interim test. Simon [24] tabulates design parameters and operating characteristics for a broad range of parameter values, and a computer program to obtain these values is available on Statlib (OTSDEXEC.ZIP)

Garnsey-Ensign et al. [14] provide an optimal three-stage design that is essentially a combination of the Gehan [15] and optimal Simon [24] designs. At stage 1, the design stops with rejection of H_1 if there are no successes at that point; otherwise, it continues to stage 2 and (possibly) stage 3. Rejection of H_1 is possible at any stage, but H_0 may be rejected only at the final test. The design is optimal in that the expected sample size under the null hypothesis is minimized for given α, β, p_0 and p_1 subject to the requirement that $n_1 \geq 5$.

When computing a confidence interval for the response probability, one should account for interim decision rules (*see* **Data and Safety Monitoring**). Methods for adjusting one-sample confidence intervals for a binomial parameter computed after trials with interim stopping rules (*see* **Sequential Analysis**) have been discussed by a number of authors, including Jennison & Turnbull [18], Atkinson & Brown [2], and Duffy & Santner [10].

Bayesian Designs

Sylvester [29] proposes **decision-theoretic Bayesian methods** for Phase II clinical trials. He optimizes the sample size and decision cutoff of a single-stage design to determine whether a new drug is active by minimizing the Bayes risk. The approach assumes that $\Pr[\Theta_E = p_0] = 1 - \Pr[\Theta_E = p_1]$, with $p_1 > p_0$, where Θ_E is the response rate of regimen E, and p_1 and p_0 are response rates at which E would and would not be considered promising, respectively, i.e. they assume that Θ_E may take on two possible values. A more general approach is given by Brunier & Whitehead [4], who use a **beta prior distribution** for Θ_E and derive optimal Bayesian designs based on a **utility** function that accounts for both cost and the number of patients treated in a future Phase III trial.

Herson [17] proposes the use of predictive probability (PP) as a criterion for early termination of Phase II trials to minimize the number of patients exposed to an ineffective therapy. The PP of an event, such as concluding that E is or is not promising according to some decision rule, is the conditional probability of that event given the current data, computed by averaging over the posterior distribution of the parameter, which is Θ_E in the present context. Mehta & Cain [21] provide charts of early stopping rules based on the posterior probability of $\Theta_E > p_1$, where p_0 is a fixed level at which E would be considered active.

Phase IIB Clinical Trials

Most Phase IIB trials evaluate one or more new treatments relative to a standard therapy S; hence, they are inherently comparative even though a standard treatment arm usually is not included. In the designs described above, it is common to assume that p_0 is a known constant and to determine n to obtain a test of $p = p_0$ vs. $p = p_0 + \delta$ for given type I and type II error rates, α and β. For Phase IIB trials, where p_0 represents the activity level of available regimens, the numerical value of p_0 used in this computation is often a statistical estimate $\hat{p}_0$ based on historical data, rather than a known constant. The empirical difference $\hat{p} - \hat{p}_0$, which is the basis for the test, is thus the difference between two statistics and has variance larger than the assumed $p(1-p)/n$. Consequently, the sample size computed under a model ignoring the fact that $\hat{p}_0$ is a statistic is incorrect.

Makuch & Simon [19] derived single-stage Phase II designs for binary endpoints that take into consideration the number of patients in a single historical control series (*see* **Nonrandomized Trials**). Similar results were presented by Dixon & Simon [9] for time-to-event endpoints. Thall & Simon [31] derived optimal single-stage Phase II designs that incorporate historical data from one or more trials of S and account for the variability inherent in $\hat{p}_0$. They considered both binary and **normally distributed** responses. Because the variability between historical studies sometimes exceeds what is predicted by a binomial model for binary responses, they used a **beta-binomial** model to account for possible extra binomial variation. Their results indicate that it is sometimes best to randomize (*see* **Randomization**) a proportion of patients to S, and they derived the total sample size and optimal proportions for allocation to E and S that minimize $\text{var}(\hat{p} - \hat{p}_0)$. Their results indicate that an unbalanced randomization may be superior to a single-arm trial of E alone. When the uncertainty in historical control outcomes is great, either because of interstudy variability or lack of historical controls, the traditional single-arm Phase IIB trial used in oncology is not reliable. They also showed that ignoring the variability in $\hat{p}_0$ may lead to trials with actual values of α and β much higher than their nominal values.

The above method for dealing with the variability of an estimate of p_0 may be regarded as a particular approach to a more general problem. Given that in a Phase II trial the success rate of E ultimately must be compared to that of S, and that uncertainty regarding the response rate of S will always exist, the general problem is to account for this uncertainty when planning the trial and interpreting its results. A different statistical approach is based on the Bayesian framework, in which the success probabilities of E and S are regarded as random rather than fixed parameters. To underscore this distinction, we denote the random response probabilities by Θ_E and Θ_S.

Thall & Simon [32, 33] present a Bayesian approach to Phase II clinical trials in which patient response is binary and the accumulating data are monitored continuously. Their designs require an informative beta prior for Θ_S, a flat or weakly informative beta prior for Θ_E, a targeted improvement for Θ_E over Θ_S, and lower and upper bounds m and M on the allowable sample size. The maximum sample size M is chosen to obtain a given level of reliability in the posterior distribution of Θ_E. Depending upon the specific objectives, the posterior distribution of Θ_E is updated when each patient response is observed. The trial may be terminated if E is shown with high posterior probability to be either promising or not promising compared with S, or if the predictive probability of either conclusion is small. Otherwise, the trial continues. Although the framework for determining early termination bounds and M is Bayesian, the operating characteristics of the design are evaluated using frequentist criteria, and the design parameters are determined on that basis. An alternative design stops early only if E is not promising compared with S, and does not stop early if E is promising. This design would be preferred when it is desirable to continue the trial if the new treatment is promising, rather than terminate it early. A menu-driven computer program "Multcomp" to implement this design is available via anonymous FTP from `odin.mdacc.tmc.edu` in directory/pub/source.

Randomized Phase II Trials

The response rates obtained in different Phase II trials of the same treatment often vary widely. Simon et al. [25] cite a number of factors as the sources of this variability, including patient selection, definition of response, inter-observer variability in response

evaluation (*see* **Observer Reliability and Agreement**), drug dosage and schedule, reporting procedures, and sample size. To deal with these problems, they propose randomizing patients among several experimental treatments in Phase IIA trials, with **ranking** and selection methods used to interpret results. They do not require that a standard treatment arm be included. Specifically, they propose that sample size be computed to ensure that, if one group of treatments has response rate $p_0 + \delta$ and the rest have rate p_0, then a "select-the-best" strategy will choose one of the superior treatments with a desired probability. For example, 44 patients in each of three arms will ensure a 90% chance of choosing a treatment with response rate 0.35 when the other two treatments have response rate 0.20.

Randomized strategies for Phase IIB evaluation of new treatments have been considered by Whitehead [40, 41], Strauss & Simon [28], and Thall & Estey [30]. Whitehead assumes that the success rates of the experimental treatments are random and may be considered as independent draws from a beta prior distribution. Given the total number of patients, N, he derives the number of treatments, k, and number of patients per treatment, n, which maximize the expected success probability of the treatment selected based on the largest observed success rate. The constraint is that $nk = N$.

Strauss & Simon [28] study properties of a sequence of randomized Phase II trials. At each of k stages, $2n$ patients are randomized between a new experimental treatment and the better of the two treatments from the previous stage, starting with a known standard S at stage 1. The better of the two treatments at each stage, the "winner", thus becomes the new standard, and is then compared with the next experimental treatment. The goal is to select a single treatment of Phase III evaluation. Similar to Whitehead [40], Strauss & Simon assume that the success probabilities of the experimental treatments are independent draws from a beta prior distribution, either with fixed mean equal to that of S or with distribution adapted to the data in that its mean equals that of the latest winner.

Multiple Outcomes

The designs discussed in the preceding sections are based on a single binary outcome. Patient response in clinical trials is an inherently multidimensional phenomenon, however, with the possibility of both adverse events and efficacy outcomes (*see* **Multiplicity in Clinical Trials**). In addition to evaluating treatment efficacy, a Phase II trial must determine whether an experimental treatment is sufficiently safe to allow its evaluation in a large randomized trial.

Thall et al. [34, 37] present a general Bayesian strategy for monitoring multiple outcomes in single-arm clinical trials. Each patient's response is characterized as a **multinomial** variable that records the specific combination of events occurring for the patient in the course of the trial. This includes both adverse events and efficacy outcomes, possibly occurring at different study times. They use a Dirichlet–multinomial model to accommodate general discrete multivariate responses (*see* **Multivariate Distributions, Overview**), and they provide Bayesian decision criteria for early termination of studies with unacceptably high rates of adverse outcomes or with low rates of efficacy outcomes. Each stopping rule is constructed either to control the rate of an adverse event or to achieve a specified level of improvement of an efficacy event rate for the experimental treatment, compared with that of standard therapy. They avoid explicit specification of costs and a loss function, and evaluate the joint behavior of the multiple decision rules using frequentist criteria. Their approach accommodates a broad range of clinical situations, including settings in which observation of certain endpoints is conditional on the occurrence of earlier events. They illustrate the approach with a variety of single-arm cancer trials.

Etzione & Pepe [12] propose a Bayesian criterion for monitoring two adverse outcomes in a pilot toxicity study, in the case where the occurrence of one event precludes the occurrence of the other.

Bryant & Day [5] extend Simon's [24] minimax design to the setting with an efficacy endpoint and a toxicity endpoint. They determine two-stage designs that minimize the maximum expected number of patients entered when the treatment is unacceptable either in terms of clinical response or toxicity. Conaway & Petroni [7, 8] also propose Phase II designs accounting for both efficacy and toxicity, and formulate hypotheses in terms of tradeoffs between these outcomes.

Discussion

In oncology, nearly any clinical trial that is not a dose-finding study and that does not contain a randomized control group is called a Phase II trial. Consequently, the Phase II category is quite heterogeneous with regard to objectives and characteristics. Unfortunately, these differences are not always recognized, and statistical designs developed for one type of Phase II trial are sometimes inappropriately applied to another type.

Until recently, most statistical designs developed for Phase II clinical trials were applicable primarily to the objectives of Phase IIA trials. These include the designs of Gehan [15], Schultz et al. [23], Fleming [13], Simon [24], and Therneau et al. [39]. These and other Phase II designs are reviewed by Mariani & Marubini [20]. Phase IIB trials have the objective of determining whether a new regimen has a level of anti-disease activity that is promising relative to the best available regimens. In dealing with combination regimens, sometimes involving a complex sequential treatment program for the patient, it is not relevant to show that the regimen is active. Rather, the focus often is on determining whether the combination regimen under test is sufficiently active, compared with the activity level of the best available standard therapy, to warrant a Phase III trial. Hence, Phase IIB trials are inherently comparative. Although Phase IIA designs can be used for Phase IIB trials if the response probability for the best available regimen is known accurately, this is seldom the case. Usually, the comparative aspects of Phase IIB trials are either suppressed or not addressed directly. This can have two undesirable effects. The first is that the results with the experimental regimen may appear so promising that a Phase III trial is difficult to conduct, since randomization to a control arm appears unethical. The second is that the results are inappropriately interpreted as promising and a Phase III trial is conducted when it is not warranted. In general, we believe that the comparative aspects of Phase IIB trials should be addressed directly, that specific control groups should be identified, and that uncertainties arising from the use of nonrandomized control groups of finite size should be quantified. The designs of Thall & Simon [31–33] and Thall et al. [34, 37] address this. These designs are, however, quite different from those developed for the simple Phase IIA trials.

An alternative to conducting a Phase IIB trial is to use a Phase III randomized design, allowing one or several experimental regimens, with early termination of a treatment arm if early results with that regimen are sufficiently discouraging. The designs described by Ellenberg & Eisenberger [11], Thall et al. [38], Thall et al. [35, 36], Wieand & Therneau [42], Schaid et al. [22], and Storer [27] are of this type. It is often difficult to organize a Phase III trial of an experimental regimen, however, without some earlier Phase II experience with that regimen.

Phase-type Distributions in Survival Analysis

When studying time to failure of some sort, it is often natural to imagine that the process goes through a number of stages, or phases. In cancer epidemiology, this is an old recognition; the **multistage model** of Armitage & Doll [2] postulated that development of cancer went through a number of stages corresponding to a simple homogeneous Markov model (*see* **Markov Processes**). This assumption fits very well with the **Weibull** hazard function that is often observed for cancer incidence as a function of age. The Armitage–Doll model has been an inspiration in the understanding of carcinogenesis, although it has now been overtaken by more complex models.

The Armitage–Doll model is a special case of a phase-type distribution. In general, consider a time-continuous **Markov chain** with a finite number of states and constant transition intensities. One state is supposed to be absorbing, the remaining states being transient. Assume that the Markov process starts somewhere in the transient space, and consider the time until absorption. A transition time defined in this way is said to have a phase-type distribution.

Considerable attention has been paid to this kind of distribution in probability theory, especially in **queuing** theory where they are a means for developing computationally manageable models. Some basic references are [3, 5, 9], and [10]. Estimation problems have been considered by Asmussen et al. [4] and Olsson [11]. Phase-type distributions may also be of use in **survival analysis**, both for the insights they give and as an estimation tool; see [1]. In particular, phase-type models can deepen our understanding of **hazard** functions. An important modern use of a simple phase-type model has been given by Longini et al. [8].

The Armitage–Doll and Longini distributions are so-called series models (see Figure 1, where the αs are constant transition intensities). Such simple series models may help in answering the question: Why do hazard functions often increase with time? This is observed very often, like the increasing incidence of cancer and heart disease and of general mortality as a function of age. Phase-type theory tells us that the hazard function for the time to move from the initial to the final state in a series model is always increasing with time, and reaching a maximum level equal to the smallest transition intensity. This increase is in spite of the constant transition intensities, so no aging in the sense of increasing intensities is needed to see an increasing hazard. This point has been made repeatedly in cancer epidemiology [6], but may have a more general validity.

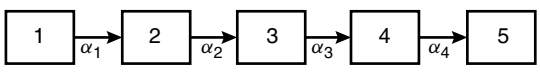

Figure 1 Series model with five states

However, hazard functions do not always increase inexorably; sometimes they decrease, or they have an initial increase followed by a decline. In the phase-type framework such phenomena can also be explained. To do this, one must introduce the concept of *quasi-stationary distribution* on the transient state space. If the Markov chain starts out with this initial distribution, then the hazard function of the time until absorption is constant. A quasi-stationary distribution often exists [1, 7], and can be considered as a suitable normalized limiting distribution on the transient state space.

Under certain assumptions (like irreducibility of the transient state space) the hazard function of any phase-type distribution will approach the constant value consistent with the quasi-stationary initial distribution. For some typical processes, allowing movements back and forth between states, the following will be observed [1]: if the process starts out in a state close enough to the absorbing one, then the hazard function will be monotonically decreasing. If the process starts out in an intermediate distance from the absorbing state, then one will observe a hazard function that first increases and then declines. If the starting state is far enough out, then the hazard function will be monotonically increasing.

In general, there are two forces influencing the Markov process: one is the "pull" of the absorbing state, and the second is the diffusion on the transient state. It is the balance of these two forces that determines the shape of the hazard function.

Physicians' Health Study

The Physicians' Health Study was a randomized, double-blind, placebo-controlled, 2×2 factorial trial of aspirin (325 mg every other day) and β-carotene (50 mg every other day) among 22 071 apparently healthy US male physicians. The aspirin arm was terminated early, on 25 January 1988 (median treatment and follow-up, five years) due primarily to the emergence of a statistically extreme ($P < 0.00001$) 44% reduction in risk of a first myocardial infarction. The β-carotene arm ended as scheduled on 31 December 1995 (median treatment and follow-up, 12 years), and showed no overall benefit or harm of β-carotene supplementation on cancer or cardiovascular disease. The Physicians' Health Study cohort continues to provide important information regarding the causes and prevention of cardiovascular disease, cancer, and other chronic diseases.

Background and Rationale

A critical element that must be considered when designing a trial is the balance between the evidence supporting the hypothesis being tested and the gap in knowledge that may be filled by the results. Achieving this balance is a particularly delicate matter in randomized clinical trials. For both ethical and practical reasons, there must be sufficient belief in the potential of the agent to be tested to justify exposing half of the subjects to it, just as there must be sufficient doubt about the agent to allow withholding treatment from the other half [15].

In the late 1970s, we viewed these conditions to be applicable to the use of aspirin in the primary prevention of myocardial infarction and the use of β-carotene in the primary prevention of cancer. For aspirin, a plausible Nobel prize-winning mechanism [38] had been advanced for the possible use of aspirin in the treatment and prevention of cardiovascular disease [33, 34]. The epidemiologic evidence, however, was not consistent. A large case series from California [10], two case–control studies [5, 18], and a prospective cohort study had suggested a possible small beneficial effect of aspirin in men and women [12], while another case–control study had found no association between aspirin use and fatal coronary disease [17]. With respect to β-carotene, more than 20 epidemiologic studies conducted in various parts of the world had generally found reduced risks of cancers at various sites associated with higher intakes of dark green and yellow vegetables, which are abundant in β-carotene [26]. In addition, the use of β-carotene-containing multivitamins or supplements was increasing rapidly, with as many as one-third to one-half of US adults reporting daily vitamin consumption [39], based largely on the belief, unsupported by randomized trials, that β-carotene could prevent cancer.

Thus, randomized trials testing whether aspirin and β-carotene conferred benefits were both important and timely. The Physicians' Health Study was designed to accomplish these and other objectives.

Methods

Detailed descriptions of the Physicians' Health Study have been published elsewhere [16, 28, 29]. In brief, from 1981 to 1984, invitation letters, consent forms, and enrollment questionnaires were sent to 261 248 male physicians between 40 and 84 years of age residing in the US who were registered with the American Medical Association in 1981. Of these, 59 285 were willing to participate in the trial, 26 062 of whom were excluded because they indicated on the baseline questionnaire a history of myocardial infarction, stroke, or transient ischemic attack; cancer (except nonmelanoma skin cancer); current renal or liver disease; peptic ulcer; gout; or contraindication to or current use of either aspirin or β-carotene. The remaining 33 223 willing and eligible physicians were enrolled in an 18-week run-in phase to assess willingness to participate and compliance. Of these, 22 071 physicians were randomized using a 2×2 **factorial design** to one of four treatment groups: aspirin, β-carotene, both, and neither. A total of 11 037 physicians were randomized to aspirin and 11 034 to aspirin placebo; 11 034 physicians were randomized to β-carotene and 11 037 to β-carotene placebo. Active aspirin consisted of one 325 mg tablet (as Bufferin, supplied by Bristol-Myers Products) to be taken every other day. Active β-carotene consisted of one 50 mg capsule (as Lurotin, supplied by BASF AG) to be taken every other day.

Follow-up

All follow-up was conducted by mailed questionnaire. The initial follow-ups were at 6 and 12 months, then yearly thereafter.

Endpoints

Endpoints (*see* **Outcome Measures in Clinical Trials**) were considered confirmed or refuted only after an endpoints committee made up of two internists, a cardiologist, and a neurologist, all of whom were blinded to the treatment assignments, had examined all available information, including medical records.

Blood Samples

Kits containing Vacutainer tubes containing ethylenediamine tetraacetic acid, complete instructions for blood draws, polypropylene cryopreservation vials, and coldpacks were mailed to all 33 223 physicians participating in the run-in phase. They were asked to have their blood drawn into the Vacutainer tubes, to fractionate the blood by centrifugation, and to return the samples in the coldpack by prepaid overnight courier. Upon receipt in the laboratory, each sample was divided into aliquots and stored at -82°C. Specimens were received from 14 916 (68%) of the randomized physicians. None of the samples collected between 1982 and 1984 has inadvertently thawed during storage.

Results

Aspirin

The aspirin component of the trial was terminated early in 1988, after an average follow-up of 60.2 months, due primarily to the emergence of a statistically extreme benefit on risk of a first myocardial infarction. Aspirin takers had a 44% reduction in risk of a first myocardial infarction, with significant benefits on fatal and nonfatal events [28, 29]. As a consequence of early termination, there were insufficient numbers of strokes upon which to draw firm conclusions. However, the available data did not suggest any reduction in stroke, and there was, in fact, a possible but not statistically significant 19% increase in nonfatal stroke. Because of aspirin's effect on platelet aggregation, a particular concern with its use is a possible increase in hemorrhagic stroke. For this subgroup of strokes, there was the suggestion of a possible increased risk in the aspirin group (23 events vs. 12 events), although the numbers were small and did not achieve conventional statistical significance ($P = 0.06$). There were also too few cardiovascular deaths upon which to draw firm inferences.

β-carotene

Virtually no early or late differences in the overall incidence of malignant neoplasms or cardiovascular disease, or in overall mortality, were observed between the β-carotene and placebo groups. In the β-carotene group, 1273 men had a malignant neoplasm (except nonmelanoma skin cancer), as compared with 1293 in the placebo group (relative risk, 0.98; 95%, 0.91 to 1.06). There were also no significant differences in the number of cases of lung cancer (82 in the β-carotene group vs. 88 in the placebo group); the number of deaths from cancer (386 vs. 380), deaths from any cause (979 vs. 968), or deaths from cardiovascular disease (338 vs. 313); the number of men with myocardial infarction (468 vs. 489); the number with stroke (367 vs. 382); or the number with any one of the previous three endpoints (967 vs. 972). Among current and former smokers, there were also no significant early or late differences in any of these endpoints. There were, however, suggestions that among the prospective subgroup of men with the lowest blood levels of β-carotene at randomization (*see* **Treatment-covariate Interaction**), β-carotene reduced the risk of total and prostate cancer, and also reduced the risk of subsequent vascular events among the subgroup of men with angina at baseline.

Discussion of Results
