Medical record linkage poses problems of data **confidentiality** and privacy, because the linked data are comprehensive and the techniques use personal identifying data. Most analytic studies do not require access to patient identifiable data once the linkages have been made. For administrative data sets, strict controls need to be in place to ensure that the data are not released to individuals and used for purposes other than those registered in government legislation.

The issue of infringing civil liberties, by invasion of privacy through wrongful use of information, is currently taxing most governments. Researchers need to be aware of legislation and appropriate use of data. For example, in Scotland, access to identifiable data is controlled by medically qualified data holders, and a Privacy Advisory Committee [10] has been established, with membership drawn from senior medical officers, legal professions, and the public, to ensure that ethical approval is in place for record linkage studies.

Evidence-Based Medicine

The perception remains that descriptive epidemiology has little to contribute to the development of **evidence-based medicine** with its focus on randomized **clinical trials** (see McPherson [12]). Probability-based record linkage techniques can make a major contribution in assessing the efficacy of treatment regimes at the macro level. For example, using exact

matching on health service administration numbers, Evans et al. [4] at the Tayside Medicines Monitoring Unit are able to use **case–control** methodology to review the association of topical nonsteroidal anti-inflammatory drugs with hospital admission for upper gastrointestinal bleeding and perforation. The Scottish Health Service are now automating the linkage between prescribing data, patient hospitalization, and death profiles. This will establish a facility for **post-marketing surveillance**, in which possible adverse drug reactions can be quickly analyzed and assessed before the public are alarmed by the media (*see* **Pharmacoepidemiology, Overview**).

Another area in which linkage is being used effectively is the follow-up of very low birthweight children and the impact of their improved survival on health care costs. In California [2], probability-linked data from the California Birth Cohort and Medicaid claims in years after birth have been used to evaluate competing hypotheses for racial and ethnic differences (*see* **Ethnic Groups**) in mortality and health care costs, and to assess the need for hospital services from the improved neonatal survival of these children.

Outcome Measurement

Evaluating the effects of medical care is not a new idea, but it has received increased emphasis over the past decade because of concerns for the quality and cost of medical care (*see* **Quality of Care**). While most attention has been placed on determining the effectiveness of new treatment regimes through randomized control trials, the inclusion criterion for patients can be so selective (*see* **Eligibility and Exclusion Criteria**) that the true efficacy of the treatment can only be assessed when it comes into general usage. Application of record linkage techniques using **administrative databases** for follow-up of cohorts of patients with specific disease patterns, or procedures, permits analysis of outcomes measures which would otherwise be prohibitively expensive.

The Clinical Resource and Audit Group of the Scottish Office Department of Health have pioneered the publication of routine clinical outcome measures in the UK since 1993. The three reports [17] to date have been produced following detailed consultation with health service professionals, to gain consensus on the measures and to assess the feasibility of using them to monitor the effectiveness and appropriateness of health purchasing strategies. Without a unique patient identifier, probability linkage is the key to determining readmission rates, including to other institutions, and postoperation survival after discharge.

While the measures tend to be presented as interval estimates (*see* **Estimation, Interval**), standardized for **confounding** factors, such as age, sex, deprivation, and co-morbidities, administrative data do not yet contain **robust** measures of severity of disease. As with all descriptive epidemiology techniques, the outcome measures highlight topics for more detailed investigation via randomized controlled trials or clinical audit.

Survival Rates

As the search continues for new, meaningful outcome measures, one of the main uses of record linkage has been analysis of survival patterns for disease, especially for cancer (*see* **Survival Analysis, Overview**). Most civil registration authorities provide an exact matching service for bona fide researchers. However, increased computing power has meant that this process can now be automated to include probability or "fuzzy" matching techniques, which increase the reliability of the links. Within the Scottish Cancer Registry, we found that exact matching with manual techniques under-ascertained almost 5% of deaths [16], because the procedures were built on zero tolerance of **false positive** rates. This resulted in one study for the nuclear industry showing a "healthy worker" effect (*see* **Occupational Epidemiology**), until another three deaths were determined by automated probability linkage among the cohort of employees.

The availability of population-based data in specific **diseases registers**, such as cancer, diabetes, and renal failure, with linkage to death registrations enables the development of survival tables [16] (*see* **Life Table**), which are of use not only to the professional dealing with individual patients but also to the patients and their carers. Society is becoming more attuned to the concepts of **risk**, and one of the most common questions asked when life-threatening disease is diagnosed is "What is my chance of surviving 1 year, 5 years, or 10 years?". Insurance companies are very interested in improved estimates of

actuarial risk (*see* **Actuarial Methods**) for health care policies.

Changing Treatment Patterns in Hospital Care

Access to databases containing linked patient episodes over long time periods (15+ years) helps to identify the changing treatment patterns and use of hospital resources by cohorts of patients with specific disease. For example, the protocol for clinical treatment of asthma in children has changed considerably over the past 20 years, and Strachan et al. [18] used linked data for children with their first hospital admission for asthma between 1980 and 1984 to explore the increase in subsequent emergency admissions for the disease during the following 10 years (*see* **Health Care Utilization Data**).

In mental health (*see* **Psychiatry**) the impact of policies for shifting care from the acute sector to the community can be monitored from linked data sets. Geddes & Juszczak [5] argue that trends in increased suicide rates for recently discharged female psychiatric patients may well be related to changes in discharge protocols due to implementation of government policy and new clinical practice. In a similar vein, the Scottish Health Service is currently linking mental health discharge records to the general hospital patient database, to investigate if the policy of early discharge from psychiatric institutions has resulted in psychiatric patients being readmitted to acute care after a short period in the community.

The effect on emergency readmission rates from early hospital discharge and associated **quality of care** have been identified by Henderson et al. [8] and Thomas & Holloway [19]. Investigation of Scottish data demonstrates "like" Trusts which have significantly different medical emergency readmission rates, with inversely related bed occupancy rates and lengths of continuous inpatient stay. Instead of focusing on efficiency (high throughput, and short length of hospital stay) commissioners of health care can consider the effect of a 50% variation in the risk of emergency readmissions: Does this provide acceptable levels of value for money versus quality of care for the patient?

One of the roles of descriptive epidemiology is to aid the understanding of uncertainty. McPherson [12] uses the example of 5 year mortalities following treatments for prostatectomy, reported from analysis of large linked databases, to highlight the impact of changing clinical practice without the rigors of assessment trials, and the concerns raised amongst patients when consensus cannot be reached amongst clinicians on the effect of different treatments.

Health Service Planning

The potential of taking data created routinely as part of a government's system for paying for medical care and turning it into information on health needs and the health of the population is well demonstrated by the work of Roos & Shapiro [14] and Roos et al. [15] and his team at the Manitoba Center for Health Policy and Evaluation (*see* **Health Services Research, Overview**). The research attempts to move beyond medical care policy initiatives (e.g. insuring availability, quality of care, and efficiency) to health policy initiatives of improving longevity and **quality of life**. As pressures grow, throughout Europe and North America, to contain the costs of health care by reducing investment in acute sectors, health planners are looking to such population health information systems for quantitative trend data on which to base their decisions. Evidence is needed to answer questions such as:

1. Are high risk populations poorly served or do they have poor health outcomes despite availability of services?
2. Can we shift resources from acute care to primary care?
3. What services can be rationed without jeopardizing at-risk populations?

Lack of population morbidity information leads epidemiologists to use hospitalization rates as proxy measures for underlying morbidity. Improved availability of **general practice** diagnosis and treatment data from administrative systems in the surgery allows estimation of the true level of demand in communities, which can be linked with hospital discharge data at a patient level. This is invaluable for needs assessment work in public health, where commissioners of services attempt to balance supply with demand within small geographic areas (*see* **Small Area Variation Analysis**).

Longitudinal and Cohort Studies

Many of the most renowned epidemiologic studies, such as **Framingham** [20] and Whitehall [11], used the manual tracking systems available from civil death registries. The advent of computer technology has made automated follow-up of survey data for alternative endpoints other than death a simple process – provided that informed consent is obtained by the subject for access to computerized medical records.

In 1973–76, a cohort of the population in the west of Scotland towns of Paisley and Renfrew, aged 45–64 years, took part in a cardiovascular survey of mid-life health, the MIDSPAN [6] project. Participants gave written consent to their medical records being used for follow-up, and the data set now includes details of all episodes of hospital care and death registrations for participants as they have aged over the past 20 years. It can be used for prospective **case–control studies** to investigate determinants of good and poor health from baseline lifestyle variables and clinical measurements.

The West of Scotland Coronary Prevention Study (WOSCOPS) [21] demonstrated the value of automated linkage in a randomized–controlled trial compared to prospective follow-up using direct contact with patients. An accuracy check of the study's own independent records of deaths and hospitalizations for the study population with data available from the Scottish Medical Record Linkage Database showed that while almost 100% accuracy was achieved for deaths, the study records under-ascertained hospitalizations for cardiovascular disease.

In the US, the Veterans Affairs database [1] has formed the source for **multicenter** randomized and quasi-randomized health service trials, which are much easier to plan and conduct in a centralized state system than in the private sector.

The UK Case–Control Study for Childhood Cancers will report findings in 1997. One of the methodological issues which has arisen from the study, access to case notes, has demonstrated the value of conducting applied research within the health administration system of the country rather than solely in an academic environment. The study is investigating hypotheses for cause and effect of cancer in children, covering ionizing radiation, chemical exposure, preconception and *in utero* exposure, parental occupational hazards, electromagnetic fields, and infectious exposure.

Summary

This article has described the main applications of record linkage techniques in epidemiology: from follow-up studies in randomized controlled trials and surveys to outcome measurement and survival following hospital care in the general population.

The Chief Medical Officer of the UK government [3] recently identified the need to use better descriptions of public health risk. We have demonstrated that, within health administration systems, much of the data already exists. When integrated using linkage techniques, these data can be used to build the knowledge base to identify these risks and to quantify them in both relative and attributable ways.

The use of such linked databases for descriptive epidemiology brings the following benefits:

1. data ascertainment, validity, and quality are documented within the administrative system;
2. linkage can be performed by computer at low cost relative to staff costs;
3. completeness of linkage is greater than by manual methods;
4. research efforts can focus on the analyses and interpretation of the data rather than data collection.

Provided that privacy and confidentiality rules are strictly applied, and users remember that in any linkage system, be it exact match or probability-based, one cannot be 100% certain that the correct data have been linked, there are vast data repositories available waiting to unlock the answers to key epidemiologic questions.

MARY SMALLS & STEVE KENDRICK

Reduced Rank Regression

Given a set of predictors (**explanatory variables**), $x_1, x_2, \ldots, x_p$, and a response variable, y, the **multiple linear regression** procedure finds the best **least squares** linear prediction of the response variable given all of the predictors. If $\mathbf{X}$ is an $n \times p$ matrix of n observations on the predictor variables and $\mathbf{y}$ is an $n \times 1$ vector of observations on the response variable, the multiple regression model would be

$$\mathbf{y} = \mathbf{Xb},$$

where $\mathbf{b}$ is a $p \times 1$ vector of regression coefficients. The ordinary least squares estimator for $\mathbf{b}$ is

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y},$$

and the lack-of-fit of this estimator is given by the standard error of estimate,

$$\left(\frac{\mathbf{y}'\mathbf{y} - \mathbf{b}'\mathbf{X}'\mathbf{y}}{n - p - 1}\right)^{1/2}.$$

Among the many problems associated with multiple regression is the difficulty of *multicollinearity* of the predictor variables (*see* **Collinearity**). Multicollinearity means that two or more predictor variables are highly correlated (*see* **Correlation**) or that there are one or more linear constraints on these variables. In the latter case, $\mathbf{X}'\mathbf{X}$ does not have an inverse. Even if these variables are not completely collinear but are still correlated, the following problems may arise:

1. obtaining a stable inverse for $\mathbf{X}'\mathbf{X}$ may be difficult.
2. as the predictor variables become more correlated, the standard errors of the regression coefficients increase in size and the regression coefficients become more and more correlated. These conditions make it difficult to interpret these coefficients.

A number of procedures have been designed to deal with these problems. Early solutions include elimination of predictor variables in the model by various sequential procedures such as stepwise regression or the investigation of combinations of subsets of variables (*see* **Variable Selection**). Another procedure is **ridge regression**, which enhances the chances of getting a good inverse of $\mathbf{X}'\mathbf{X}$ at the expense of introducing bias into the regression coefficients. Most of these are rather ad hoc procedures. There are also some straightforward multivariate solutions.

Principal Components Regression

Principal components regression is a technique which requires the predictor variables to be transformed into **principal components** which, in turn, become the predictors in the least squares solution. Principal components regression deals directly with the problem of multicollinearity. If some of the predictors are perfectly correlated and/or other linear constraints exist, then the principal components analysis will produce one or more characteristic roots (**eigenvalues**) equal to zero. The characteristic vectors (**eigenvectors**) associated with these roots may be used to identify these situations (see, for example, [1]). This may suggest the deletion of some variables so that a stable regression solution can still be obtained. In many cases, the ordinary least squares solution may experience near-multicollinearity. Because the principal components are uncorrelated, there is no problem in principal components regression with matrix inversion. The regression coefficients are also uncorrelated and there is no inflation of their standard errors. This regression equation may then be restated back in terms of the original correlated predictor variables.

In addition to transforming correlated variables into uncorrelated ones, principal components analysis also allows one to approximate the original data with $k < p$ components to obtain a more **parsimonious** description of the structure of the original variables. Principal components regression may be carried out with this reduced set of components but the resultant regression coefficients, in terms of the original variables, would only be estimates of the ordinary least squares solution, and the corresponding standard error of estimate would be larger. However, if there is not much increase in this quantity and the principal components are interpretable, then this could be a useful prediction equation, particularly if k is small relative to p. This is the goal of principal components regression.

Principal components regression has been widely used in many fields, particularly with a reduced set of components. However, caution should be used with this technique. The principal components are

obtained sequentially in order by the amount of variability of the original variables they account for. Various stopping rules are available to determine how many components to retain, the general assumption being that the variability unaccounted for is inherent variability. There is no reason to assume that the components accounting for the most variability will be the best predictors of the response variable, and there are many examples in the literature where this is not so. This would suggest the use of *stepwise* principal components regression (see, for instance, [2]) but more effort has been directed towards some other methods.

Latent Root Regression

Latent root regression [5, 11] differs from principal components regression in that the response variable is included in the principal component analysis. Any component that has a zero characteristic root has a linear constraint among the variables, and the corresponding vector should indicate what that would be. Latent root regression is recommended for this purpose as well as to select variables which would make the best predictors. Reviews of these techniques are given by Gunst [4] and Mason [7].

Partial Least Squares Regression

The main criticism of principal components regression is that there is no guarantee that the larger components will be the best predictors, so some ad hoc scheme must be employed. For this reason, there has been considerable use in the last few years of a technique called *partial least squares regression* [12]. This technique is similar to principal components regression in that it produces a set of vectors for the predictor variables but does take the response variable into account. As each vector is obtained, it is immediately related to the response and the reduction in variability among the predictors. The estimation of the next vector takes that information into account. The very nature of partial least squares regression would indicate that it should do at least as well as principal components regression for the same number of retained components.

At the present time, partial least squares regression has been most widely used by analytical chemists, and most of the relevant information on applications is in the **chemometrics** literature. An algorithm for performing partial least squares regression may be found in [3]. Stone & Brooks [8] proposed a technique called *continuum regression* in which ordinary least squares, principal components regression, and partial least squares regression all fall out as special cases.

Multiple Responses

In addition to multiple predictors, there may also be multiple responses. Ordinary least squares and principal components regression treat each response as a separate regression problem, neither of them taking into account the relationships among the response variables. Partial least squares regression does take these relationships into account. As partial least squares regression sequentially establishes a set of vectors for the predictor variables, it simultaneously establishes a corresponding set of vectors for the response variables. For this reason, partial least squares regression has been referred to as "criss-cross" regression.

Maximum Redundancy

Being confronted with *sets* of both predictor and response variables might suggest the use of **canonical correlation**, a technique which obtains sets of vectors for each set of variables whose corresponding components will have maximum correlation. That technique will not produce an optimum prediction equation but an optimum solution can be obtained by a similar technique, *maximum redundancy* [9, 10], where *redundancy* is defined as the trace of the explained **covariance matrix** of the responses divided by the trace of the covariance matrix of the responses. Most of the applications of maximum redundancy have been in the fields of psychology and education.

Summary

A number of procedures have been suggested as alternatives to ordinary least squares to enhance the interpretation of the relationship between the predictor and response variables and/or to resolve problems associated with multicollinearity among the predictor variables. Although the most popular alternative, historically, has been principal components

regression, it does have some weaknesses and is being replaced by techniques such as partial least squares regression and maximum redundancy. Because partial least squares regression and maximum redundancy have been developed widely in different fields of application, it has not yet been established what the relative merits of them are. A unified treatment of the methods discussed in this article along with computational details may be found in [6].

J. EDWARD JACKSON

Regression to the Mean

Regression to the mean (RTM) can broadly be described as the tendency of observations that are extreme by chance to move closer to the **mean** when repeated. The importance of this in biostatistics is that causality (*see* **Causation**) – rather than RTM – may erroneously be inferred when there is improvement after a treatment or change after an intervention.

Examples of RTM are common in clinical medicine. For example, a patient is noted to have a higher than average blood cholesterol on an initial screening exam. A repeat measurement will also likely be high but will on average be closer to normal even if the patient was not given medication. As Turner et al. [5] note in the context of pain problems, most acute and some chronic pain will resolve regardless of treatment. Since many individuals seek treatment or agree to enroll in trials when symptoms are more extreme, any change is likely to be an improvement, making any treatment appear effective – even if it is useless.

To define RTM further suppose we are interested in the ability of a drug to lower blood cholesterol and compare a patient's initial value x and posttreatment value y. Figure 1 is a hypothetical graph of x and y assuming a pretreatment mean μ. For simplicity, we assume that x and y are both **normally distributed** with common **variance** σ^2 and **correlation** ρ and that the drug has no effect.

A patient with a high pretreatment value, x, will have an expected posttreatment cholesterol level that is also high. The expected value, $\mathrm{E}(Y|x)$, will not be x but instead will be the lower value $\mathrm{E}(Y|x) = x - (1-\rho)(x-\mu)$. The difference, $(1-\rho)(x-\mu)$, is the effect of RTM, and this increases for both larger values of $x-\mu$ and for smaller values of ρ. In other words, the magnitude of the RTM varies directly with the variability of the process being observed and the correlation between the two measurements.

When there is a treatment effect, τ,

$$\mathrm{E}(Y - x|x) = \tau - (1-\rho)(x-\mu).$$

In this case the apparent treatment effect, $\mathrm{E}(Y-x|x)$ will be due in part to the actual treatment effect, τ, and to the relative size of both $1-\rho$ and $x-\mu$.

In **clinical trials**, regression to the mean can **bias** the estimate of the treatment effect. Suppose that we now conduct a trial in which a sample of n patients is taken from the population and compare the average posttreatment cholesterol values, $\overline{y}$, with the pretreatment values, $\overline{x}$. If the sample is a **simple random sample**, the difference $\overline{y} - \overline{x}$ is an **unbiased** estimate of τ because $\overline{x}$ will have expected value μ.

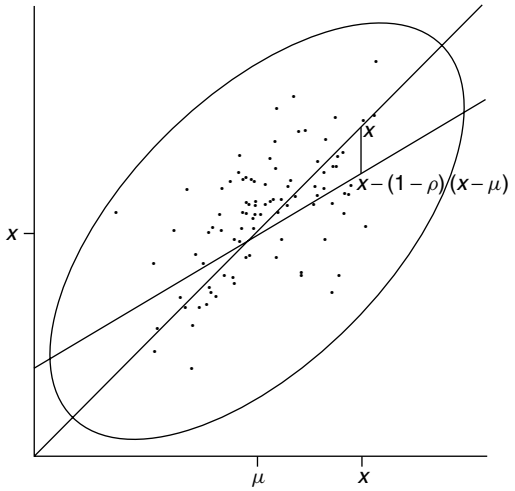

Figure 1 Hypothetical graph of posttreatment vs. blood cholesterol level pretreatment

However, most clinical trials are different in that we select from only a subset of the population – those with disease or, in this case, those with a cholesterol level above some cutoff, say c. In this case $\overline{y} - \overline{x}$ does not estimate the true treatment effect, but instead

$$\mathrm{E}(\overline{Y} - \overline{X}|X \geq c) = \tau - (1-\rho)\left(\frac{\sigma\phi\left(\frac{c-\mu}{\sigma}\right)}{1-\Phi\left(\frac{c-\mu}{\sigma}\right)}\right),$$

where ϕ and Φ are the density and cumulative density function for the normal distribution. Again, for extreme values of $c-u$ or small values of ρ the unadjusted treatment effect is biased. Results using this formula are presented in Table 1, which presents the effect of regression to the mean for various combinations of selection percentile, x, and correlation, ρ.

Suppose that patients are selected to be enrolled in a drug trial if their cholesterol levels are high, say above the 75th percentile. The average percentile for such patients is the 90th percentile. Assuming that pre- and posttreatment values have a correlation coefficient of 0.8, the posttreatment average will have dropped to the 85th percentile even in the absence

Table 1 Expected posttreatment percentile for a given pretreatment cutoff percentile and ρ (see text)

	Selection percentile			
ρ	50th	75th	90th	95th
0.0	0.50	0.50	0.50	0.50
0.2	0.56	0.60	0.64	0.66
0.4	0.63	0.69	0.76	0.80
0.6	0.68	0.78	0.85	0.89
0.8	0.74	0.85	0.92	0.95
1.0	0.79	0.90	0.96	0.98

of treatment effect. If $\rho = 0.6$, then the average will drop to the 78th percentile. If $\rho = 0$, then the expected posttreatment value will be at the 50th percentile for any pretreatment selection percentile. If $\rho = 1$, then there is no bias from RTM.

The term "placebo effect" has been defined by Turner et al. [5] as the nonspecific effects of treatment attributable to factors other than the active drug, including physician attention, patient expectations, changes in behavior, etc. Benefits from taking a placebo are often attributed to these factors, but RTM alone can produce such apparent benefits. Regression to the mean, then, is distinct from a "placebo effect". McDonald & Mazzuca [3] reviewed 30 randomly selected clinical trials in which the outcome was either a biologic, physiologic, or anatomic measurement. The authors noted that the improvement observed in placebo-treated patients and that of the estimate that would occur in biochemical variables due to regression to the mean were "remarkably similar".

Since RTM is a consequence of a correlation between two measurements, x and y, strategies consist of either eliminating the correlation or correcting it. McDonald & Mazzuca [3] suggest repeating the pretreatment measurement. In the cholesterol example, we would admit patients into the trial if x_1 were above the 90th percentile. A repeat pretreatment cholesterol, x_2, would be compared with a posttreatment y_1. Senn [4] shows that under restricted conditions, $\mathrm{E}(y_1 - x_2|x_1) = \tau$ is independent of x_1. A second possibility is to adjust for the correlation. When the underlying population from which the selected sample is drawn is large, Chen & Cox [1] suggest using the population to estimate the correlation and thereby adjust the treatment estimate. Hayes [2] examines various graphical methods. A third strategy is to conduct a randomized placebo-controlled clinical trial. This option will yield the most accurate results, since it involves no conditions or distributional assumptions.

In an experiment in which before and after measurements are made in order to evaluate some intervention, regression to the mean can account for some and possibly all of the estimated treatment effect. The extent of **confounding** will depend on the actual treatment effect, the sampling procedure used for patient selection, and the correlation between the two measurements. Methods of analysis and sampling techniques are available to adjust for regression to the mean, although direct estimation of treatment effects in trials is probably best.

Regression

The use of the term *regression* in statistics originated with **Francis Galton**, to describe a tendency to mediocrity in the offspring of parent seeds, and was used by **Karl Pearson** in a study of the heights of fathers and sons. The sons' heights tended on average to be less extreme than the fathers, demonstrating a so-called "**regression towards the mean**" effect (for details and a description of the most widely used form of regression analysis, *see* **Linear Regression, Simple**; **Multiple Linear Regression**). The term is now used in a wide variety of analysis techniques which examine the relationship between a **response variable** and a set of **explanatory variables**. The nature of the response variable usually determines the type of regression that is most natural (for a very general formulation of regression models and examples *see* **Generalized Linear Model**).

VERN T. FAREWELL

Regressive Models

Regressive models are designed for the analysis of correlated and naturally ordered data. They are **regression** models with **explanatory variables** including functions of preceding outcomes. Autoregressive models (*see* **ARMA and ARIMA Models**) are special cases with regression on the immediately preceding outcomes and are therefore conveniently indexed by the order, p say, indicating how far back the lagged values of the series itself should be regressed on. Thus, a **Markov process** is a first-order autoregressive model including only the regression on the first most immediately preceding outcome; a **Yule process** is second-order involving the two immediately preceding outcomes; and so on. Autoregressive models have been extensively studied in the context of long time, or spatial, series in which **stationarity**, seasonality, and the possibility of change points (*see* **Change-point Problem**) are of most interest. In the more general case of regressive models, the regression may involve just the first or all the preceding outcomes, as in a study of successive pregnancy outcomes, or the outcomes of natural links in branching structures, as, for example, parental disease status in human pedigree studies.

The emphasis in the present summary is on **likelihood** models for studying biological phenomena allowing for dependence among the outcomes. The nature of the measured outcome largely determines the measure of dependence used. Thus, for continuous outcomes, the **correlation** coefficient is natural, whereas for binary outcomes a regression coefficient that measures the change in the logarithm of the odds is a more natural measure.

Continuous Outcomes

The regressive model for n correlated and naturally ordered continuous outcomes $y_1, y_2, \ldots, y_n$ can be constructed following [6] using the **Gram–Schmidt** orthogonalization

$$\begin{aligned} z_1 &= y_1, \\ z_2 &= y_2 - b_{21}y_1, \\ z_3 &= y_3 - b_{31}y_1 - b_{32}y_2, \\ &\vdots \\ z_n &= y_n - b_{n1}y_1 - b_{n2}y_2 \cdots - b_{n,n-1}y_{n-1}, \end{aligned} \tag{1}$$

i.e. $\mathbf{z} = \mathbf{B}\mathbf{y}$ where $\mathbf{B}$ is a lower triangular matrix with 1s along the diagonal and is chosen so that the $\mathbf{z}$s are uncorrelated. Letting $\mathrm{var}(\mathbf{y}) = \mathbf{V}$, the covariance matrix of z is the diagonal matrix $\mathbf{W} = \mathbf{B}\mathbf{V}\mathbf{B}' = \mathbf{D}[w_i]$, w_i scalar. The Jacobian of the transformation is unity. Let the density function of a p-variate normal distribution (*see* **Multivariate Normal Distribution**) with mean zero and covariance matrix $\mathbf{\Sigma}$ be written as

$$\phi(\mathbf{t}, \mathbf{\Sigma}) = (2\pi)^{-p/2}|\mathbf{\Sigma}|^{-1/2} \exp\left(-\tfrac{1}{2}\mathbf{t}'\mathbf{\Sigma}^{-1}\mathbf{t}\right).$$

The density function of $\mathbf{y}$ can thus be written as a product of univariate normal densities:

$$\phi(\mathbf{y}, \mathbf{V}) = \phi(\mathbf{z}, \mathbf{W}) = \prod_{i=1}^{n} \phi(z_i, w_i). \tag{2}$$

In the language of **multiple linear regression**, for $i = 1, 2, \ldots, n$, z_i is y_i adjusted for $y_1, y_2, \ldots, y_{i-1}$; $b_{i1}, b_{i2}, \ldots, b_{i,i-1}$ are the partial regression coefficients; and w_i is the conditional variance of y_i given $y_1, y_2, \ldots, y_{i-1}$. Let $\mathbf{V}_{i-1} = (\sigma_{st})$ and $\mathbf{R}_{i-1} = (\rho_{st})$ denote the variance matrix and correlation matrix of $y_1, y_2, \ldots, y_{i-1}$, with respective inverses $\mathbf{V}_{i-1}^{-1} = (\sigma^{st})$ and $\mathbf{R}_{i-1}^{-1} = (\rho^{st})$. Then

$$\begin{aligned} b_{ij} &= \sum_{s=1}^{i-1} \sigma_{is}\sigma^{sj} = \left(\frac{\sigma_{ii}}{\sigma_{jj}}\right)^{1/2} \sum_{s=1}^{i-1} \rho_{is}\rho^{sj}, \\ w_i &= \sigma_{ii} - \sum_{j=1}^{i-1} \sigma_{ij}b_{ij} = \sigma_{ii}\left(1 - \sum_{j=1}^{i-1} \rho_{ij}b_{ij}^*\right) = \sigma_{ii}w_i^*, \end{aligned} \tag{3}$$

where

$$b_{ij}^* = \left(\frac{\sigma_{ji}}{\sigma_{ii}}\right)^{1/2} b_{ij} \quad \text{and} \quad w_i^* = \frac{1}{\sigma_{ii}}w_i.$$

The computation of b_{ij} and w_i becomes trivial once $\mathbf{R}_{i-1}^{-1}$ is computed, yielding explicit formulas for b_{ij}^* and w_i^*.

Consider the case in which $y_1, y_2, \ldots, y_{i-1}$ can be put into exactly two subgroups, A and B. Let the correlation of y_i and the elements of class A be η, the correlation of y_i and elements of class B be α, all the ys in A have the same correlation ρ, all those in B have the same correlation γ, and every y in A have a correlation of τ with every y in B. Using the notation $\mathbf{I}_i$ for an identity matrix of order n_i, $\mathbf{1}_i$ for a column

vector of n_i ones, and $\mathbf{J}_{ij}$ for an $n_i \times n_j$ matrix of ones, the correlation matrix of $y_1, y_2, \ldots, y_i$ is

$$\mathbf{R}_i = \begin{bmatrix} \mathbf{R}_{i-1} & | & \eta\mathbf{1}_1 \\ & | & \alpha\mathbf{1}_2 \\ \eta\mathbf{1}_1' \quad | \quad \alpha\mathbf{1}_2' & | & 1 \end{bmatrix}$$

$$= \begin{bmatrix} (1-\rho)\mathbf{I}_1 + \rho\mathbf{J}_{11} & | & \tau\mathbf{J}_{12} & | & \eta\mathbf{1}_1 \\ \tau\mathbf{J}_{21} & | & (1-\gamma)\mathbf{I}_2 + \gamma\mathbf{J}_{22} & | & \alpha\mathbf{1}_2 \\ \eta\mathbf{1}_1' & | & \alpha\mathbf{1}_2' & | & 1 \end{bmatrix}.$$

The inverse of $\mathbf{R}_{i-1}$ is

$$\mathbf{R}_{i-1}^{-1} = \begin{bmatrix} p_{11}\mathbf{I}_{11} + q_{11}\mathbf{J}_{11} & p_{12}\mathbf{J}_{12} \\ p_{21}\mathbf{J}_{21} & p_{22}\mathbf{I}_{22} + q_{22}\mathbf{J}_{22} \end{bmatrix},$$

where

$$p_{11} = \frac{1}{1-\rho}, \quad q_{11} = -\frac{\lambda_2\rho - n_2\tau^2}{(1-\rho)(\lambda_1\lambda_2 - n_1n_2\tau^2)}$$

$$p_{12} = p_{21} = -\frac{\tau}{\lambda_1\lambda_2 - n_1n_2\tau^2},$$

$$p_{22} = \frac{1}{1-\gamma}, \quad q_{22} = -\frac{\lambda_1\gamma - n_1\tau^2}{(1-\gamma)(\lambda_1\lambda_2 - n_1n_2\tau^2)},$$

$$\lambda_1 = 1 + (n_1 - 1)\rho \quad \text{and} \quad \lambda_2 = 1 + (n_2 - 1)\gamma.$$

Then

$$b_{ij}^* = \begin{cases} \dfrac{\lambda_2\eta - n_2\tau\alpha}{\lambda_1\lambda_2 - n_1n_2\tau^2}, \\ \qquad \text{if } y_j \text{ is in subgroup A} \\ \dfrac{\lambda_1\alpha - n_1\tau\eta}{\lambda_1\lambda_2 - n_1n_2\tau^2}, \\ \qquad \text{if } y_j \text{ is in subgroup B,} \end{cases}$$

and

$$w_i^* = 1 - \frac{n_1\eta(\lambda_2\eta - n_2\tau\alpha) + n_2\alpha(\lambda_1\alpha - n_1\tau\eta)}{\lambda_1\lambda_2 - n_1n_2\tau^2}.$$

Some special cases are as follows:

1. $n_1 = n_2 = 1, \eta = \alpha$. Then

$$b_{ij}^* = \frac{\eta}{1+\tau} \quad \text{and} \quad w_i^* = 1 - \frac{2\eta^2}{1+\tau}.$$

2. If $y_1, y_2, \ldots, y_i$ belong to class A and class B is empty, then $n_1 = i - 1, n_2 = 0, \gamma = 0, \eta = \rho$, so that

$$b_{ij}^* = \frac{\rho}{1 + (i-2)\rho} \quad \text{and}$$

$$w_i^* = 1 - \frac{(i-1)\rho^2}{1 + (i-2)\rho}.$$

3. If $\alpha = n_1\tau\eta/\gamma_1$, then

$$b_{ij}^* = \begin{cases} \dfrac{\eta}{\lambda_1}, & \text{if } y_j \text{ is in class A,} \\ 0, & \text{if } y_j \text{ is in class B,} \end{cases}$$

and

$$w_i^* = 1 - \frac{n_1\eta^2}{\lambda_1}.$$

The orthogonal variate z_i in (1) is then a linear combination of y_i and the ys for class A members only. Here, class A may be taken as all those measurements immediately preceding the ith measurement. The results are then relevant to the study of autoregressive models. For example, $n_1 = 1$ and $\tau = \eta = \rho$ give $\alpha = \rho^2$, the well-known condition for a Markov type of dependence. If $n_1 = 2$, we have a Yule type of dependence.

Regressive Logistic Models for Correlated Binary Outcomes

In the case of **binary** outcomes $Y_j = 1, 0$ with associated covariates $\mathbf{X}_j$, one can consider the regression on the preceding outcome $Y_{j-1}^* = 2Y_j - 1$, or the first outcome (Y_1^*), and on the sum of preceding positives $S_{j-1}^+ = \sum_{s=1}^{j-1} Y_s$, preceding negatives $S_{j-1}^- = \sum_{s=1}^{j-1}(1 - Y_s)$, and the other covariates $\mathbf{X}_j$. The model is defined by a **logistic** function; thus

$$\theta_j = \log[\Pr(Y_j = 1|Y_1, \ldots, Y_{j-1}, \mathbf{X}_j)/ \Pr(Y_j = 0|Y_1, \ldots, Y_{j-1}, \mathbf{X}_j)]$$
$$= \gamma_0 + \gamma_1 Y_1^* + \gamma_2 Y_2^* + \cdots + \gamma_{j-1} Y_{j-1}^* + \beta X_j,$$

where for convenience we have included only one component of $\mathbf{X}$. To postulate parsimonious versions so that only a few γs need to be estimated, consider the following model introduced by Bonney [7]:

$$\gamma_t = \begin{cases} \gamma^+ + \gamma, & \text{if } t = j-1, Y_{j-1}^* = 1, \\ \gamma^- + \gamma, & \text{if } t = j-1, Y_{j-1}^* = -1, \\ \gamma^+, & \text{if } t < j-1, Y_{j-1}^* = 1, \\ \gamma^-, & \text{if } t < j-1, Y_{j-1}^* = -1. \end{cases}$$

This parameterization allows the immediately preceding outcome to increase or decrease the logarithm of the odds of the current outcome by an amount γ

more than an increase or decrease from a more remote outcome. The logit of the current outcome becomes

$$\theta_j = \gamma_0 + \gamma Y^*_{j-1} + \gamma^+ S^+_{j-1} + \gamma^-(-S^-_{j-1}) + \beta X_j.$$

The modeling problem is therefore reduced to that of regression on the immediately preceding outcome, the number of preceding positives (1s), the number of preceding negatives (0s), and other covariates. There is no problem replacing Y^*_{j-1} by Y^*_1 so that the first outcome has a different effect on the current outcome. Some old approaches are special cases. Thus, for Markov dependence of order 1 as in [14, 15], and [18], $\gamma^+ = \gamma^- = 0$. The suggestion in [14] of regressing on the cumulative sum of preceding successes corresponds to $\gamma^- = 0$. Therefore we have a sufficiently general model against which the simpler models may be tested. It incorporates the natural explanatory variables one would consider in analyzing a sequence of binary outcomes. If it fits the data, then we have accounted for covariates of interest as well as the dependence in the sequence of observations in terms of a model that is easy to fit and interpret. Moreover,

$$S^+_{j-1} + S^-_{j-1} = j - 1,$$

so S^+_{j-1}, S^-_{j-1}, and the serial order j are perfectly **collinear**. Hence, any two of them are sufficient in the regression analysis. If, on the other hand, only one of them is included, then we have omitted a critical covariate that may show up as residual dependence. Table 1 displays an example.

Furthermore, in the case of equally spaced outcomes, regression on time is the same as regression on the serial order. In unequally spaced studies, actual time may replace serial order, as is commonly done. However, it is likely that significant collinearity with S^+_{j-1} and S^-_{j-1} may remain. Moreover, many unequally spaced serial observations are made at convenient periods, e.g. baseline, six months, 12 months, and 24 months. In such cases a few **dummy variables** describing the periods may be better than the more common linear function of time.

The results for binary outcomes generalize naturally to **polytomous** outcomes [2, 9].

With regard to the performance of the regressive models, a large computer **simulation** study [13] showed the following:

1. If the regression on preceding outcomes is ignored as in standard **logistic regression**, then the bias in the estimation of the regression coefficient of a covariate is increased by at least 12% in samples of sizes 200–500 and dependent groups of size two, and can be as bad as 25% in groups of size five if the true state of nature is Markov of order 1, and 30%–60% in the equally predictive case. In samples of sizes greater than 500, the bias is negligible only if the regression

Table 1 Frequencies of spontaneous abortion[a]

[a]Extracted from [22].

[b]0 = live birth; 1 = spontaneous abortion.

Equivalent models [7]: $\theta_i = 5.9157 + 1.5408 S^+_{i-1} - 0.0835 S^-_{i-1} + 0.5322 X_2 - 0.3124 X_3$, and $\theta_i = -6.6443 + 0.8121 S_{i-1} + 0.7285 X_1 + 0.5322 X_2 - 0.3123 X_3$, where S^+_{i-1} is the number of spontaneous previous abortions, S^-_{i-1} is the number of previous live births, X_1 is the serial pregnancy number, $X_2 = 1$, $X_3 = 0$ for Leridon, $X_2 = 0$, $X_3 = 1$ for Roman, $X_2 = 0$, $X_3 = 0$ for MRH, and $S_{i-1} = S^+_{i-1} + S^-_{i-1}$.

coefficient of the covariate and the dependence are both positive or both negative.
2. Modeling the dependence leads to more robust estimates of regression parameters, with the equally predictive model being generally more robust than the Markov model.
3. Caution should be exercised when the sample size is small because, while the regressive model can correct the bias of desired regression estimates, the additional parameters can increase problems of noncovergence, infinite variances, and nonunique estimates. Thus, for a sample size of 50 and group size two, the mean square error associated with the regressive model that fits an extra parameter can often be larger than that of the standard logistic.

Regressive Models in Family Studies

The design of the regressive models for family data [3, 4, 7, 8] was based on the following observations on pedigrees (see Figure 1):

1. Dependence among relatives arises from the biologic relationships, whether genetic or environmental in origin.
2. Pedigrees are structures evolving in time: grandparents appear before parents, who in turn appear before grandchildren, and so on. The time ordering along vertical lines of descent is evolutionary.
3. A pedigree, however complex, is made up of distinct sibships joined through the common parents. Thus, it is natural to consider models in which different sibships are conditionally independent given the intervening parents.

In view of these observations, the regressive models account for patterns of dependence in family data by specifying a regression relationship between a person's phenotype (Y), the phenotypes of ancestors and older relatives ($\mathbf{Y}_A$), the **genotype** (g), if any, at some postulated genetic loci, and other explanatory variables ($\mathbf{X}$). In essence the classical **penetrance** function is generalized to include ancestral phenotypes. The generalized penetrance function is the conditional probability of Y given g, $\mathbf{Y}_A$, and $\mathbf{X}$, i.e.

$$\Pr(Y|g, \mathbf{Y}_A, \mathbf{X}).$$

For a continuous trait, this is replaced by the probability density function. Including $\mathbf{Y}_A$ in the regression allows for unspecified (or residual) factors, such as spouse correlations, unspecified genes, and cultural and other environmental effects. Broad patterns of dependence are possible with $\mathbf{Y}_A$ including only a few relatives, which simplifies the calculations greatly. In the class A pattern of dependence parents alone account for residual correlations among sibs, so that $\mathbf{Y}_A$ includes only the phenotypes of mother ($\mathbf{Y}_M$), father ($\mathbf{Y}_F$), and spouse ($\mathbf{Y}_S$) if spouse correlations are not zero; class B adds the oldest sibs, class C adds the immediately preceding sibs, and class D includes all preceding sibs. An example of the penetrance function is given in Figure 2.

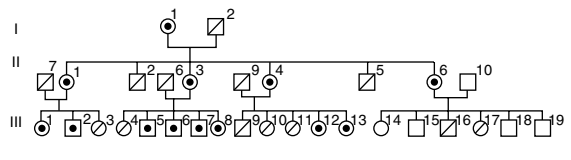

Figure 1 A three generational human family or pedigree

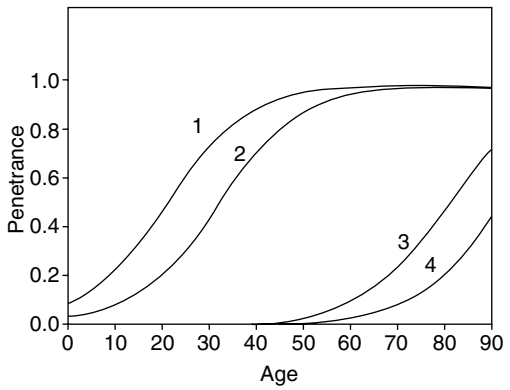

Figure 2 Estimated penetrance functions for a single gene in a family study of chronic atrophic gastritis [5]: 1. homozygous recessive (AA), mother affected; 2. homozygous recessive (AA), mother unaffected; 3. carrier (AB) or noncarrier (BB), mother affected; 4. carrier (AB) or noncarrier (BB), mother unaffected, where penetrance $= [1 + \exp[\theta(g)]]^{-1}$, $\theta(\mathrm{AA}) = -3.33 + 0.65Z_M + 0.12X$ for AA persons, $\theta(\mathrm{AB/A'B}) = -10.25 + 0.65Z_M + 0.12X$ for AB or BB persons, $Z_M = 1$ if mother is affected and $Z_M = -1$ if mother is unaffected, and $X =$ age at examination. Reproduced from Bonney et al. [5] by permission of John Wiley & Sons Ltd

Using Correlations to Describe Familial Dependence [6]

Suppose that the vector $\mathbf{y} = (y_1, y_2, \ldots, y_n)'$ comprises n measurements on members of a nuclear family: father, mother, and $n-2$ offspring (sibs), in that order. We use the following notation:

μ_i = mean of x_i,
σ_i^2 = variance of x_i,
ρ_{FM} = father–mother correlation,
ρ_{PO} = parent–offspring correlation, and
ρ_{SS} = sib–sib correlation.

Usually the means, μ_i, and sometimes the variances, σ_i^2, are modeled as linear functions of explanatory variables including major genotypes, if any are postulated. The orthogonalization process (1) yields

$$z_1 = x_1 - \mu_1, \quad \text{and}$$

$$z_i = (x_i - \mu_i) - \sum_{j=1}^{i-1} b_{ij}(x_j - \mu_j)$$

$$= (x_i - \mu_i) - \sum_{j=1}^{i-1} \frac{\sigma_i}{\sigma_j} b_{ij}^*(x_j - \mu_j), \; i = 2, \ldots, n,$$

and $\text{var}(z_i) = w_i = \sigma_i^2 w_i^*$, where

$$w_i^* = 1,$$

$$b_{21}^* = \rho_{\text{FM}}, \qquad w_2^* = 1 - \rho_{\text{FM}}^2,$$

$$b_{31}^* = b_{32}^* = \frac{\rho_{\text{PO}}}{1+\rho_{\text{FM}}}, \qquad w_3^* = 1 - \frac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}.$$

For $i > 3$, we are adjusting x_i for xs from individuals who could be either parents or sibs, i.e. we have a two-class case. Letting $n_1 = 2$, $n_2 = i-3$, $\rho = \rho_{\text{FM}}$, $\gamma = \alpha = \rho_{\text{SS}}$, and $\tau = \eta = \rho_{\text{PO}}$, we obtain:

$$b_{ij}^* = \begin{cases} \dfrac{\rho_{\text{PO}}}{1+\rho_{\text{FM}}}\left[1 + \dfrac{i-3}{1-\rho_{\text{SS}}}\left(\rho_{\text{SS}} - \dfrac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}\right)\right]^{-1}, \\ \quad \text{if } j \text{ is parent}, \\ \dfrac{1}{1-\rho_{\text{SS}}}\left(\rho_{\text{SS}} - \dfrac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}\right) \\ \times \left[1 + \dfrac{i-3}{1-\rho_{\text{SS}}}\left(\rho_{\text{SS}} - \dfrac{\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}\right)\right]^{-1}, \\ \quad \text{if } j \text{ is a sib}, \end{cases}$$

and

$$w_i^* = 1 - \left[\frac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}} + \frac{(i-3)\rho_{\text{SS}}}{1-\rho_{\text{SS}}}\left(\rho_{\text{SS}} - \frac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}\right)\right] \times \left[1 + \frac{i-3}{1-\rho_{\text{SS}}}\left(\rho_{\text{SS}} - \frac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}\right)\right]^{-1}.$$

For a class A regressive model, Bonney [3] gave the correlation among sibs due to common parentage as $2\rho_{\text{PO}}^2/(1+\rho_{\text{FM}})$, so that in the absence of other sources of correlation, $\rho_{\text{SS}} = 2\rho_{\text{PO}}^2/(1+\rho_{\text{FM}})$. Then the formulas reduce to

$$b_{ij}^* = \begin{cases} \dfrac{\rho_{\text{PO}}}{1+\rho_{\text{FM}}}, & \text{if } j \text{ is a parent}, \\ 0, & \text{if } j \text{ is a sib}, \end{cases}$$

and

$$w_i^* = 1 - \frac{2\rho_{\text{PO}}^2}{1+\rho_{\text{FM}}}.$$

Thus, the orthogonal variate z_i in (1) for a sib depends only on the ys for the parents. See [3] for the formulas for classes B, C, and D.

Using Variance Components to Describe Dependence

A popular example of the use of **variance components** with human family data was developed by Morton & MacLean [21], who proposed a model for polygenic inheritance in which variances (σ^2) are partitioned into $\sigma^2 = \sigma_{\text{a}}^2 + \sigma_{\text{e}}^2$ for parents and $\sigma^2 = \sigma_{\text{a}}^2 + \sigma_{\text{c}}^2 + \sigma_{\text{r}}^2$ for sibs, where

σ_{a}^2 = variance due to additive polygenic factors,
σ_{e}^2 = variance due to environmental factors,
σ_{c}^2 = variance due to common sibling environmental factors, and
σ_{r}^2 = variance due to random environmental factors on sibs such that $\sigma_{\text{e}}^2 = \sigma_{\text{c}}^2 + \sigma_{\text{r}}^2$.

Boyle & Elston [12] reviewed and extended the model to include other sources of variation. For this model of inheritance, the parent–offspring correlation is $\rho_{\text{PO}} = \frac{1}{2}\sigma_a^2/\sigma^2$ and the sib–sib correlation is $\rho_{\text{SS}} = (\frac{1}{2}\sigma_{\text{a}}^2 + \sigma_{\text{c}}^2)/\sigma^2$. Morton & MacLean assumed zero spouse correlations ($\rho_{\text{FM}} = 0$) and $\sigma_i^2 = \sigma^2$ for all i. Thus, in terms of the regressive models (1), the variance components model leads to

$$z_1 = x_1 - \mu_1, \, w_1^* = 1,$$

$$z_2 = x_2 - \mu_2, \, w_2^* = 1,$$

and

$$z_1 = (x_i - \mu_1) - \sum_{j=1}^{i-1} b_{ij}^*(x_j - \mu_j), \quad i \geq 3,$$

where

$$b_{ij}^* = \begin{cases} \left[\dfrac{\sigma^2}{\frac{1}{2}\sigma_a^2} + (i-3)\left(\dfrac{\sigma_c^2+\sigma_r^2}{\frac{1}{2}\sigma_a^2+\sigma_r^2} + \dfrac{\sigma^2\sigma_c^2}{\frac{1}{2}\sigma_a^2\left(\frac{1}{2}\sigma_a^2+\sigma_r^2\right)}\right)\right]^{-1}, \\ \quad \text{if } j \text{ is a parent,} \\ \left[(i-3) + \dfrac{\sigma^2\left(\frac{1}{2}\sigma_a^2+\sigma_r^2\right)}{\sigma^2\sigma_c^2 + \frac{1}{2}\sigma_a^2\left(\sigma_c^2+\sigma_r^2\right)}\right], \\ \quad \text{if } j \text{ is a sib,} \end{cases}$$

and

$$w_i^* = 1 - \left[\frac{1}{2}\left(\frac{\sigma_a^2}{\sigma^2}\right)^2 + (i-3) \times \frac{\frac{1}{2}\sigma_a^2+\sigma_c^2}{\frac{1}{2}\sigma_a^2+\sigma_r^2}\frac{\frac{1}{2}\sigma_a^2(\sigma_c^2+\sigma_r^2)+\sigma^2\sigma_c^2}{(\sigma^2)^2}\right] \times \left[1 + (i-3)\frac{\frac{1}{2}\sigma_a^2(\sigma_c^2+\sigma_r^2)+\sigma^2\sigma_c^2}{\sigma^2\left(\frac{1}{2}\sigma_a^2+\sigma_r^2\right)}\right]^{-1},$$

if $i \geq 3$.

Using these in (2) leads to a **likelihood** function which is a product of univariate normal densities.

Scope of the Regressive Models. Table 2 summarizes the scope of the regressive models for family studies and the relevant references for further reading.

Table 2 Scope of regressive models regression setup

Dependent variable		Explanatory variables		
	Phenotype Y	Genotype (specific) or major g	Ancestral phenotypes Y_A	Other covariates X
1. No causal scheme	Y		Y_A	X
2. Polygenic causal scheme	Y		Y_A	X
3. Genetic association (measured genotype)	Y	g	Y_A	X
4. Segregation analysis	Y	g		
Oligogenic complete penetrance	Y	g		
Incomplete penetrance	Y	g		X
More general (includes mixed models)	Y	g	Y_A	X
5. Linkage	Y	g (two or more loci)	Y_A	X
One trait One or more markers				
Two or more traits	**Y** (vector)	g (two or more loci)		
6. Pleiotropy	**Y** (vector)	g (one locus)	Y_A	X

Relationship Testing

Methods of genetic analysis generally assume relationships are known without error within families. Relationship misclassification due to factors such as false paternity, unknown adoption, and sample switches or duplications can compromise genetic analyses. Therefore, methods have been developed to detect misspecified relationships within a family and infer true relationships when putative ones are incorrect.

Depending on the pedigree structure, analysts often can detect relationship misspecification by observing Mendelian inconsistencies within a family: for example, a parent–offspring pair failing to share an allele (*see* **Gene**), or a sibship exhibiting more than four alleles. Identifying such inconsistencies often results from calculating a zero **likelihood** for pedigree data, or visually detecting logical inconsistencies in pedigree drawings. Algorithms also exist for detecting Mendelian inconsistencies and identifying the individual(s) most likely responsible for these errors [13, 15, 18]. Given smaller family subsets such as sibling pairs, it may not be possible to identify misspecified relationships with certainty. Still, with sufficient marker data, they may be identified probabilistically.

Many relationship inference methods analyze different pairs of relatives. In what follows, we focus on these relative-pair-based methods. These methods can be divided into three general categories: likelihood-based methods, expected allele-sharing methods, and continuous-data methods. We compare and contrast these categories of methods. All three categories distinguish different relationships using the pattern of alleles shared by the relative pair based on the principle that closely related pairs in general share more alleles than distantly related pairs.

Assumptions and Notation

We assume a noninbred relative pair is typed for a collection of M codominant **markers**. Assume marker k has n_k alleles with population frequencies $q_1, q_2, \ldots, q_{n_k}$. Let θ_k be the recombination fraction between markers k and $k+1$ $(1 \le k \le M-1)$. We assume θ_k is known without error and is the same for both sexes. If ***X*-linked** data are included, then we assume the sex of each individual is known. Let X_k be the pair of genotypes at marker k, and $X = (X_1, X_2, \ldots, X_M)$ be all the genotype data for the pair. Let ibd_k and ibs_k denote the number of alleles shared identical by descent (ibd) and identical by state (ibs), respectively, by the pair at marker k. Finally, let R_{Put} and R denote the putative relationship and true relationship for a relative pair (*see* **Linkage Analysis, Model-free** for more detail on ibd and ibs).

Likelihood-Based Methods for Relationship Inference

Likelihood-based methods for relationship inference are based on work by Thompson [19], who evaluated the probability, $\Pr(X_k|R)$, of a pair's data at marker k conditional on the pair's relationship. Using Bayes' rule,

$$\Pr(X_k|R) = \sum_{i=0}^{2} \Pr(X_k|\text{ibd}_k = i)\Pr(\text{ibd}_k = i|R). \tag{1}$$

$\Pr(X_k|\text{ibd}_k = i)$ is the conditional probability of the data X_k at marker k, given the pair shares i alleles ibd at that marker. This probability is a simple function of ibd_k and the allele frequencies $q_1, q_2, \ldots, q_{n_k}$, and is independent of the relationship R. These probabilities were evaluated for an autosomal marker by Thompson [19] and for an X-linked marker by Epstein et al. [8].

$\Pr(\text{ibd}_k = i|R)$ is the probability a pair of relationship R shares i alleles ibd at marker k; it is a simple function of R. For example, for an autosomal marker and $i = (0, 1, 2)$,

$$\Pr(\text{ibd}_k = i|R = \text{full sibs}) = \left(\tfrac{1}{4}, \tfrac{1}{2}, \tfrac{1}{4}\right)$$

and

$$\Pr(\text{ibd}_k = i|R = \text{parent–offspring}) = (0, 1, 0).$$

Similar probabilities may be calculated for other relationships and for X-linked data.

The joint probability for M unlinked markers is then [19]

$$\Pr(X|R) = \prod_{k=1}^{M} \Pr(X_k|R)$$

$$= \prod_{k=1}^{M} \left[\sum_{i=0}^{2} \Pr(X_k | \text{ibd}_k = i) \Pr(\text{ibd}_k = i | R) \right]. \quad (2)$$

One can determine the most likely relationship of a pair by evaluating $\Pr(X|R)$ under different relationships R and inferring the relationship that maximizes the joint probability (2). One can also obtain **maximum likelihood** estimates of $\Pr(\text{ibd}_k = i|R)$ for $i = 0, 1, 2$, and infer the relationship that is most consistent with these estimates [12, 19].

Equation (2) only applies to unlinked markers, which limits marker number and reduces the ability to distinguish different relationships. Göring & Ott [10] and Boehnke & Cox [2] independently extended the work of Thompson [19] to allow for linked markers. In particular, they noted that under the assumption of no genetic interference, $\text{ibd}_1, \text{ibd}_2, \ldots, \text{ibd}_M$ represent a **hidden Markov** chain for many relationships R. They then used Baum's algorithms [1] to evaluate $\Pr(X|R)$. Let $\alpha_k(i|R) = \Pr(X_1, X_2, \ldots, X_{k-1}, \text{ibd}_k = i|R)$ be the joint probability of the marker data at the first $k-1$ markers and that the pair shares i alleles ibd at marker k given the pair's relationship is R. For the first marker, $\alpha_1(i|R) = \Pr(\text{ibd}_1 = i|R)$, which is evaluated as before. For subsequent markers,

$$\alpha_{k+1}(j|R) = \sum_{i=0}^{2} \alpha_k(i|R) \Pr(X_k|\text{ibd}_k = i) \times \Pr(\text{ibd}_{k+1} = j|\text{ibd}_k = i; R). \quad (3)$$

$\Pr(\text{ibd}_{k+1} = j|\text{ibd}_k = i; R)$ is the transition probability that a pair of relationship R shares j alleles ibd at marker $k+1$ given they share i alleles ibd at marker k. These probabilities depend on θ_k and R. The transition probabilities for different relationships were presented for autosomal data by Risch [16] and for X-linked data by Epstein et al. [8]. One obtains $P(X|R)$ by the final summation

$$\Pr(X|R) = \sum_{i=0}^{2} \alpha_M(i|R) \Pr(X_M|\text{ibd}_M = i). \quad (4)$$

Boehnke & Cox [2] calculated $\Pr(X|R)$ under four different relationships [monozygotic (MZ) twin, full sib, half sib, and unrelated] and inferred the relationship that maximized this probability. Göring & Ott [10] assumed prior probabilities for full sibs, half sibs, and unrelated pairs in the study population and calculated the posterior probability, $\Pr(R|X)$, of each of these relationships using Bayes' rule.

McPeek & Sun [12] and Epstein et al. [8] extended the method of Göring & Ott [10] and Boehnke & Cox [2] to test additional relationships including parent–offspring, grandparent–grandchild, avuncular (e.g. aunt–niece) and first cousins. McPeek & Sun [12] evaluated $\Pr(X|R)$ and then used a **likelihood ratio** statistic to test the **null hypothesis** that the putative relationship of a pair is correctly specified against the **alternative hypothesis** that the putative relationship is misspecified. Under the alternative, they maximized the **likelihood** as a function of the probability from among the other tested relationships. Their likelihood ratio statistic is skewed, so they estimated significance by **simulation**. For more distant relationships such as avuncular and first cousins, McPeek & Sun [12] noted that $\{\text{ibd}_k\}$ no longer form a Markov chain [9], which complicates the likelihood calculation. They remedied this problem by calculating the likelihood for these more distant relationships under an augmented ibd Markov chain.

Epstein et al. [8] calculated $\Pr(X|R)$ for a variety of relationships and inferred the relationship that maximized this probability. Unlike McPeek & Sun [12], they chose to approximate $\Pr(X|R)$ for avuncular and first-cousin relationships by incorrectly assuming $\{\text{ibd}_k\}$ are Markovian. This approximate likelihood is an adequate substitute for the true likelihood in the inference of avuncular pairs and first cousins [12].

Broman & Weber [3] and Epstein et al. [8] extended these likelihood-based methods to allow for genotyping error. Failure to allow for genotyping error has only a modest impact for many relationships but often leads to incorrect classification of MZ twins and parent–offspring pairs. To model genotyping error, they let ε denote the probability that a genotype is chosen at random according to population genotype frequencies and let $1-\varepsilon$ be the probability that genotyping is done correctly with certainty. For this genotyping-error model, the only component altered is $\Pr(X_k|\text{ibd}_k = i)$. If either member of the pair is correctly genotyped for marker k, then $\Pr(X_k|\text{ibd}_k = i)$ remains the same. If either member is randomly genotyped, then the pair is effectively unrelated. Hence,

$$\Pr(X_k|\text{ibd}_k = i; \varepsilon)$$

$$= (1-\varepsilon)^2 \Pr(X_k | \text{ibd}_k = i; \varepsilon = 0) + \left[1 - (1-\varepsilon)^2\right] \Pr(X_k | \text{ibd}_k = 0; \varepsilon = 0). \quad (5)$$

While this random-genotype model is not a true representation of how genotype error occurs, it is computationally simple and can detect errors generated by more realistic error mechanisms [6].

Expected Allele-Sharing Methods for Relationship Inference

In contrast to likelihood-based methods, allele-sharing methods directly compare the observed allele sharing of a relative pair with that expected given the pair's putative relationship. These methods originated with Chakraborty & Jin [5]. Ehm & Wagner [7] and McPeek & Sun [12] proposed ibs-based test statistics to detect misspecified relationships based on a set of linked autosomal markers. Stivers et al. [17] derived an analogous ibs-based test statistic limited to unlinked markers.

Ehm & Wagner [7] only tested pairs of putative full sibs, although one could easily extend their method to test other putative relationships. They based their test on half the total number of alleles shared ibs by a pair across a series of M autosomal markers:

$$S_{\text{EW}} = \frac{1}{2} \sum_{k=1}^{M} \text{ibs}_k.$$

The authors standardized S_{EW} by subtracting the mean of S_{EW} and dividing by its standard deviation, where they calculated both the mean and variance assuming the putative relationship of full sibs.

McPeek & Sun [12] described essentially the same statistic generalized to any arbitrary putative relationship. Their test statistic relied on the average number of alleles shared ibs by the pair across a series of markers:

$$S_{\text{MS}} = \frac{1}{M} \sum_{k=1}^{M} \text{ibs}_k.$$

They also standardized the sum, again based on the putative relationship for the pair. For large M, the resulting standardized statistics Z_{EW} and Z_{MS} are approximately distributed as standard normal if the putative relationship is true.

Since ibd-based methods often are more powerful than ibs-based ones, McPeek & Sun [12] derived an analogous ibd-based allele-sharing statistic. This statistic, which they called the expected identical by descent (Eibd) statistic, is the average estimated number of alleles shared ibd by a pair at a series of markers, conditional on the marker genotypes and the putative relationship; it takes the form

$$\text{Eibd} = \frac{1}{M} \sum_{k=1}^{M} \text{E}(\text{ibd}_k | X_k; R_{\text{Put}}).$$

Eibd is approximately distributed as normal if the putative relationship is true.

McPeek & Sun [12] also created an ibd-based method that is conditional on ibs sharing. This statistic, which they called the adjusted ibs-sharing statistic (Aibs), has the form

$$\text{Aibs} = \frac{1}{M} \sum_{k=1}^{M} \text{Aibs}_k.$$

For marker k, the author calculated Aibs_k by summing over all four possible draws of an allele from each member of the relative pair. For a given draw, the authors evaluated the probability that the two alleles drawn from the pair are shared ibd given they are shared ibs and the putative relationship of the pair. Aibs approximately follows a normal distribution under the putative relationship.

For putative full sibs, Olson [14] presented an ibd-sharing statistic that infers the most likely relationship of a pair when the putative relationship is rejected. The method has some similarities with the Eibd statistic since both calculate the expected number of alleles shared ibd by a relative pair. However, while one calculates Eibd at a series of markers, Olson [14] considered any location along the genome. Let $\widehat{\text{ibd}}_s$ denote the estimated number of alleles shared ibd by the pair at some genomic location s, where $\widehat{\text{ibd}}_s$ is calculated using existing multipoint methods such as those described in Kruglyak et al. [11]. For full sibs, Olson [14] standardized $\widehat{\text{ibd}}_s$ as $Z_s = \sqrt{2}(\widehat{\text{ibd}}_s - 1)$, and calculated the expected ibd sharing along a chromosome as

$$Y_c = \frac{1}{L_c} \int_0^{L_c} Z_s \, \text{d}s,$$

where c denotes an autosomal chromosome of interest and L_c denotes the length of that chromosome. She

then calculated an overall statistic across all 22 autosomes as

$$Y = \left(\sum_{c=1}^{22} Y_c\right) \Big/ \left[\sum_{c=1}^{22} \mathrm{var}(Y_c)\right]^{\frac{1}{2}}.$$

Y approximately follows a standard normal distribution under the putative relationship of full sibs.

Since one does not estimate ibd sharing continuously along a chromosome, but rather at a number of points spaced at equal intervals, Olson [14] approximated Y_c by another statistic

$$\widehat{Y}_c = \frac{d\sqrt{2}\sum_{p=1}^{P}\left(\widehat{\mathrm{ibd}}_p - 1\right)}{P},$$

where P denotes the number of points where one estimates ibd and d denotes the distance between adjacent points. Then, she calculated the overall approximate $\widehat{Y}$ in the same analogous fashion as Y. Her simulations demonstrated that $\widehat{Y}$ often has smaller tail probabilities than a standard normal distribution. Therefore, Olson [14] calculated relationship critical values for $\widehat{Y}$, which are functions of the genome length and the average marker information content. Her method inferred the relationship based on these critical values.

Continuous-Data Methods for Relationship Inference

Both likelihood-based and expected allele-sharing methods use the allele sharing of a relative pair at discrete points along the genome to infer relationship. Continuous-data methods assume that, with advances in sequencing technology, it may soon be possible to observe ibd allele sharing continuously along a chromosome. Relationship inference methods based on continuous data should be more powerful than methods based on discrete data, since the patterns and lengths of the sharing provide information for distinguishing different relationships.

Browning [4] used **Monte Carlo methods** to estimate the likelihood of a particular relationship of a pair using simulated continuous-ibd gamete data. She calculated the likelihood for the observed data weighted by multiple crossover processes consistent with the data simulated from the particular relationship. She evaluated this likelihood under both the putative relationship and the alternative one and then constructed a likelihood ratio statistic for inference. As with other Monte Carlo procedures, this method is computationally intensive.

Zhao & Liang [20] developed a method to evaluate the exact likelihood for the continuous-ibd gamete data using the theory of continuous-time **Markov chains**. The authors developed a relationship-specific intensity matrix that denotes the transitions from ibd sharing to nonsharing and vice-versa along the genome. Using this intensity matrix and the observed lengths of ibd sharing and nonsharing along the chromosome, the authors calculated the exact likelihood for the data under the given relationship. The authors then constructed a likelihood ratio statistic to test the putative relationship against an alternative one.

Discussion

Likelihood-based and expected allele-sharing methods provide an efficient means of distinguishing a variety of relationships. Simulation studies have shown that likelihood-based methods tend to have greater power to reject an incorrect putative relationship than expected allele-sharing methods under a variety of marker and map situations [7, 12]. Likelihood-based methods can also infer the actual relationship of the relative pair if the putative one is rejected. With the exception of Olson [14], none of the expected allele-sharing methods infer the actual relationship of a pair if the putative one is rejected.

The likelihood-based and expected allele-sharing methods rely on several assumptions. They assume that intermarker recombination fractions and population marker allele frequencies are known and assume that crossover interference (*see* **Genetic Map Functions**) is absent. In principle, the violation of these assumptions might lead to biased results; in fact, this appears not to be the case. Epstein et al. [8] explored the effect of recombination fraction misspecification and found their likelihood-based method was robust to such error. McPeek & Sun [12] investigated the effect of misspecified allele frequencies and found their ibs-based statistics were more sensitive to error than their likelihood-based method and Eibd statistic. The authors also investigated the effect of crossover

interference and found that it had a trivial effect on their results.

In theory, continuous-data methods should have more power than the other methods to infer the most likely relationship, since they use more data. However, as of yet, scientists cannot readily apply these methods because continuous data with known ibd sharing and nonsharing are unavailable. The power of the continuous-data methods to differentiate commonly tested relationships such as full sibs, half sibs, and grandparent–grandchild is unknown. Browning [4] and Zhao & Liang [21] only applied their methods to relatively distant relationships, including greatgrandparent–greatgrandchild and first cousins.

This work concentrated on inference methods for pairwise relationships. Recently, Sieberts et al. [17] developed a likelihood-based method for relationship inference for trios of relatives. The addition of a third relative is valuable since it can increase the power to infer relationships correctly. The authors constructed their likelihood by extending the Baum algorithms [1] in (3) and (4) to accommodate trios. Their method also allowed for a general error model that makes no assumptions about the relationship between the observed marker phenotype and the true underlying marker genotype. The previous error models of Broman and Weber [3] and Epstein et al. [8] both made the unrealistic assumption that the observed marker phenotype and true marker genotype were independent conditional on the occurrence of an error. Sieberts et al. [17] applied their trio-based method to real data examples and showed their method has an increased ability to distinguish relationships and requires less marker data for proper inference compared to pairwise methods. While their method can be more computationally intense than pairwise methods (depending on the chosen error model), the extra amount of computer time generally should not prevent efficient analysis.

Conclusions

Relationship testing of relative pairs within families is important to ensure the validity of analysis results. We have presented a variety of inference methods that can be used to test the putative relationship of a pair. Some methods presented here can also infer the most likely relationship of the pair when the putative one is incorrect. Unless otherwise noted, these methods are accurate, computationally fast, and robust to model misspecifications. Software for these methods has been developed and can be downloaded, usually for free, from the World Wide Web [7, 8, 10, 14, 17].

Relative Hazard

The relative hazard is the ratio of two **hazard rate** functions at a given time. If this hazard ratio is constant, as is assumed in the **proportional hazards model**, it can be **consistently estimated** both from **cohort** and from time-matched **case–control studies** (*see* **Density Sampling**). Over a small time interval, the relative hazard can be estimated as the **incidence density** ratio, also known as the **incidence rate** ratio.

MITCHELL H. GAIL

Relative Odds

The relative odds, or **odds ratio**, is the ratio of the **odds** of disease in an exposed cohort divided by that in an unexposed cohort. The relative odds can be estimated not only from **cohort** data but also from **case–control** data, because the relative odds of exposure comparing cases with disease-free controls equals the relative odds of disease comparing exposed with unexposed [1]. For rare diseases, the odds ratio approximates the **relative risk**.

Relative Risk Modeling

Risk models are used to describe the hazard function (*see* **Hazard Rate**) $\lambda(t, z)$ for time-to-failure data as a function of time t and **covariates** $\mathbf{Z} = Z_1, \ldots, Z_p$, which may themselves be time dependent. The term "relative risk models" is used to refer to the covariate part $r(\cdot)$ of a risk model in a **proportional hazards** form

$$\lambda(t, \mathbf{Z}) = \lambda_0(t)\, r[\mathbf{Z}(t); \boldsymbol{\beta}], \tag{1}$$

where $\boldsymbol{\beta}$ represents a vector of parameters to be estimated. In the standard proportional hazards model, the **relative risk** term takes the **loglinear** form $r(\mathbf{Z}, \boldsymbol{\beta}) = \exp(\mathbf{Z}'\boldsymbol{\beta})$. This has the convenient property that it is positive for all possible covariate and parameter values, since the hazard rate itself must be nonnegative. However, in particular applications, some alternative form of relative risk model may be more appropriate.

First, an aside on the subject of time is warranted. Time can be measured on a number of different scales, such as age, calendar time, or time since start of observation. One of these must be selected as the time axis t for use of the proportional hazards model. In **clinical trials**, time since diagnosis or start of treatment is commonly used for this purpose, since one of the major objectives of such studies is to make statements about **prognosis**. In epidemiologic studies, however, age is the preferred time axis, because it is usually a powerful determinant of disease rates, but it is not of primary interest; thus, it is essential that its **confounding** effects be eliminated. However, other temporal factors, such as calendar date, or time since exposure began may still be relevant and can be handled either by treating them as covariates or by **stratification**.

Why Model Relative Risks?

Before proceeding further, it is worth pausing to inquire why one might wish to adopt the proportional hazards model at all. Certainly, there are examples of situations where some other form of model provides a better description of the underlying biologic process. Two alternative models that have received some attention are the **additive hazards model** $\lambda(t, \mathbf{Z}) = \lambda_0(t) + \mathbf{Z}'\boldsymbol{\beta}$ and the **accelerated failure-time model** $S(t, \mathbf{Z}) = S_0[t \exp(\mathbf{Z}'\boldsymbol{\beta})]$, where $S(t) = \exp[-\int_0^t \lambda(u)\, du]$ is the survival function. Although any risk model can be reparameterized in proportional hazards form, it may be that a more **parsimonious** model can be found using some alternative formulation. For example, the additive risk model could be written as $\lambda(t, \mathbf{Z}) = \lambda_0(t)(1 + \tilde{\mathbf{Z}}'\boldsymbol{\beta})$, where $\tilde{\mathbf{Z}} = \mathbf{Z}/\lambda_0(t)$ if the baseline hazard $\lambda_0(t)$ were some known parametric function, such as a set of external rates for an unexposed population. In this case, whether the proportional hazards or additive hazards model provides a more parsimonious description of the data depends on whether relative risk or the **excess risk** is more nearly constant over time (or requires the fewest time-dependent **interaction** effects).

The advantages of relative risk models are both mathematical and empirical. Mathematically, the proportional hazards model allows "**semiparametric**" estimation of covariate effects via **partial likelihood** without requiring parametric assumptions about the form of the baseline hazard. Furthermore, at least with the standard loglinear form of the relative risk model, asymptotic **normality** seems to be achieved faster in many applications than for most alternative models. Empirically, it appears that many failure-time processes do indeed show rough proportionality of the hazard to time and covariate effects, at least with appropriate specification of the covariates. Evidence of this phenomenon for cancer incidence is reviewed in Breslow & Day [2, Chapter 2]: age-specific **incidence rates** from a variety of populations have more nearly constant ratios than differences.

Data Structures and Likelihoods

Failure-time data arise in many situations in biology and medicine. In clinical trials, time-to-death or time-to-disease-recurrence are frequently used endpoints. In epidemiology, **cohort studies** are often concerned with disease incidence or mortality in some exposed population, and **case–control studies** can be viewed as a form of sampling within a general population cohort. All these designs involve the collection of a set of data for each individual $i = 1, \ldots, I$ comprising a failure or censoring time t_i (*see* **Censored Data**), a censoring indicator $d_i = 1$ if the failure time is observed (i.e. the subject is affected), zero otherwise, and a vector of covariates $\mathbf{z}_i$, possibly time dependent.

The appropriate **likelihood** depends on the sampling design and data structure. For a clinical trial or cohort study with the same period of observation for all subjects, but where only the disease status, not the failure-time itself, is observed, a **logistic model** for the probability of failure of the form $\Pr(D = 0|\mathbf{Z}) = [1 + \alpha r(\mathbf{Z}, \boldsymbol{\beta})]^{-1}$ might be used, where α is the odds of failure for a subject with $\mathbf{Z} \equiv 0$. Again, the standard form is obtained using $r(\mathbf{Z}, \boldsymbol{\beta}) = \exp(\mathbf{Z}'\boldsymbol{\beta})$. The likelihood for this design would then be

$$L(\alpha, \boldsymbol{\beta}) = \prod_i \Pr(D = d_i|\mathbf{Z} = \mathbf{z}_i; \alpha, \boldsymbol{\beta}) = \prod_i \frac{[\alpha r(\mathbf{z}_i; \boldsymbol{\beta})]^{d_i}}{1 + \alpha r(\mathbf{z}_i; \boldsymbol{\beta})}. \quad (2)$$

The same model and likelihood function would be used for an unmatched case–control study, except that α now involves the control sampling fractions as well as the baseline disease risk.

In a clinical trial or cohort study in which the failure times are observed, the proportional hazards model (1) leads to a full likelihood of the form

$$L[\lambda_0(\cdot), \boldsymbol{\beta}] = \prod_i \lambda_0(t_i)^{d_i} r[\mathbf{z}_i(t_i); \boldsymbol{\beta}]^{d_i} \times \exp\left\{-\int_{s_i}^{t_i} \lambda_0(t)\, r[\mathbf{z}_i(t); \boldsymbol{\beta}]\, \mathrm{d}t\right\}, \quad (3)$$

where s_i denotes the entry time of subject i. Use of the full likelihood requires specification of the form of the baseline hazard. Cox [6] proposed instead a "partial likelihood" of the form

$$L(\boldsymbol{\beta}) = \prod_{n=1}^{N} \frac{r[z_{i_n}(t_n); \boldsymbol{\beta}]}{\sum_{j \in R_n} r[z_j(t_n); \boldsymbol{\beta}]}, \quad (4)$$

where $n = 1, \ldots, N$ indexes the observed failure times, i_n denotes the individual who fails at time t_n and R_n denotes the set of subjects at risk at time t_n. This likelihood does not require any specification of the form of the baseline hazard; the estimation of $\boldsymbol{\beta}$ is said to be "semiparametric", as the relative risk factor is still specified parametrically (e.g. the **loglinear model** in the standard form). This partial likelihood can also be used to fit relative risk models for matched case–control studies (including nested case–control studies within a cohort), where n now indexes the cases and R_n indicates the set comprising the nth case and his matched controls.

For very large data sets, it may be more convenient to analyze the data in grouped form using **Poisson regression**. For this purpose, the total person-time of follow-up is grouped into $k = 1, \ldots, K$ categories on the basis of time and covariates, and the number of events N_k and person-time T_k in each category is recorded, together with the corresponding values of the (average) time t_k and covariates $\mathbf{z}_k$. The proportional hazards model now leads to a Poisson likelihood for the grouped data of the form

$$L(\lambda, \boldsymbol{\beta}) = \prod_{k=1}^{K} [\lambda_k T_k r(\mathbf{z}_k; \boldsymbol{\beta})]^{N_k} \times \frac{\exp[-\lambda_k T_k r(\mathbf{z}_k; \boldsymbol{\beta})]}{N_k!}, \quad (5)$$

where $\lambda_k = \lambda_0(t_k)$ denotes a set of baseline hazard parameters that must be estimated together with $\boldsymbol{\beta}$.

Approaches to Model Specification

For any of these likelihoods, it suffices to substitute some appropriate function for $r(\mathbf{Z}; \boldsymbol{\beta})$ and then use the standard methods of **maximum likelihood** to estimate its parameters (*see* **Estimation**) and test hypotheses (*see* **Hypothesis Testing**). In the remainder of this article, we discuss various approaches to specifying this function. The major distinction we make is between empiric and mechanistic approaches. Empiric models are not based on any particular biologic theory for the underlying failure process, but simply attempt to provide a parsimonious description of it, particularly to identify and quantify the effects of covariates that affect the relative hazard. Perhaps the best known empiric model is the loglinear model for relative risks, but other forms may be appropriate for testing particular hypotheses or for more parsimonious modeling in particular data sets, as discussed in the following section. With a small number of covariates, it may also be possible to model the relative risk **nonparametrically**. Mechanistic models, on the other hand, aim to describe the observed data in terms of some unobservable underlying disease process, such as the **multistage theory of carcinogenesis**. We touch on such models briefly at the end.

Before proceeding further, it should be noted that what follows is predicated on the assumption that the covariates $\mathbf{Z}$ are accurately measured (or that the exposure–response relationship that will be estimated refers to the measured value of the covariates, not to their true values). There is a large and growing literature on methods of adjustment of relative risk models for measurement error (*see* **Measurement Error in Epidemiologic Studies**).

Empiric Models

The loglinear model, $\ln r(\mathbf{Z};\boldsymbol{\beta}) = \mathbf{Z}'\boldsymbol{\beta}$, is probably the most widely used empiric model and is the standard form included in all statistical packages for logistic, Cox, and Poisson regression (*see* **Software, Biostatistical**). As noted earlier, it is nonnegative and it produces a nonzero likelihood for all possible parameter values, which doubtless contributes to the observation that in most applications, parameter estimates are reasonably normally distributed, even with relatively sparse data. However, the model involves two key assumptions that merit testing in any particular application:

1. for a continuous covariate Z, the relative risk depends exponentially on the value of Z; and
2. for a pair of covariates, Z_1 and Z_2, the relative risk depends multiplicatively on the marginal risks from each covariate separately (i.e. $r(\mathbf{Z};\boldsymbol{\beta}) = r(Z_1;\beta_1)r(Z_2;\beta_2)$).

Neither of these assumptions is relevant for a single categorical covariate with K levels, for which one forms a set of $K-1$ indicator variables corresponding to all levels other than the "referent" category. In other cases, the two assumptions can be tested by nesting the model in some more general model that includes the fitted model as a special case. This test can be accomplished without leaving the general class of loglinear models. For example, to test the first assumption, it may suffice to add one or more **transformations** of the covariate (such as its square) to the model and test the significance of its additional contribution. To test the second assumption, one could add a single product term (for two continuous or binary covariates) or a set of $(K-1)(L-1)$ products for two categorical variables with K and L levels respectively.

If these tests reveal significant lack of fit of the original model, one might nevertheless be satisfied with the expanded model as a reasonable description of the data (after appropriately testing the fit of that expanded model). However, one should then also consider the possibility that the data might be more parsimoniously described by some completely different form of model. In choosing such an alternative, one would naturally be guided by what the tests of fit of the earlier models had revealed, as well as by categorical analyses. For example, if a quadratic term produced a negative estimate, that might suggest that a linear rather than loglinear model might fit better; similarly, a negative estimate for an interaction term might suggest an **additive** rather than **multiplicative** form of model for joint effects. In this case, one might consider fitting a model of the form $r(\mathbf{Z};\boldsymbol{\beta}) = 1 + \mathbf{Z}'\boldsymbol{\beta}$. Alternatively, one might prefer a model that is linear in each component, but multiplicative in their joint effects, $r(\mathbf{Z};\boldsymbol{\beta}) = \prod_p (1 + Z_p\beta_p)$, or one that is loglinear in each component but additive jointly, $r(\mathbf{Z};\boldsymbol{\beta}) = 1 + \sum_p [\exp(Z_p\beta_p) - 1]$.

In a rich data set, the number of possible alternative models can quickly get out of hand, so some structured approach to model building is needed. The key is to adopt a general class of models that would include all the alternatives one might be interested in as special cases, allowing specific submodels to be tested within nested alternatives. A general model that has achieved some popularity recently consists of a mixture of linear and loglinear terms of the form

$$r(\mathbf{Z},\mathbf{W};\boldsymbol{\beta},\boldsymbol{\gamma}) = \exp(\mathbf{W}_0'\boldsymbol{\gamma}_0)\left[1 + \sum_{m=1}^{M} \mathbf{Z}_m'\boldsymbol{\beta}_m \exp(\mathbf{W}_m'\boldsymbol{\gamma}_m)\right], \quad (6)$$

where $\boldsymbol{\beta}_m$ and $\boldsymbol{\gamma}_m$ denote vectors of regression coefficients corresponding to the subsets of covariates $\mathbf{Z}_m$ and $\mathbf{W}_m$ included in the mth linear and loglinear terms, respectively. Thus, for example, the standard loglinear model would comprise the single term $m = 0$, while the linear model would comprise a single term $m = 1$ with no covariates in the loglinear terms. A special case that has been widely used in radiobiology (*see* **Radiation**) is of the form

$$r(\mathbf{Z},\mathbf{W};\boldsymbol{\beta};\boldsymbol{\gamma}) = 1 + (\beta_1 Z + \beta_2 Z^2) \times \exp(-\beta_3 Z + \mathbf{W}'\boldsymbol{\gamma}),$$

where Z represents radiation dose (believed from microdosimetry considerations to have a linear-quadratic effect on mutation rates at low doses multiplied

by a negative exponential survival term to account for cell killing at high doses) and **W** comprises modifiers of the slope of the **dose–response** relationship, such as attained age, sex, latency, or age at exposure. For example, including the log of latency and its square in **W** allows for a **lognormal** dependence of excess relative risk on latency (*see* **Poisson Regression in Epidemiology** for a discussion of software for fitting such models).

Combining linear and loglinear terms, using the same p covariates, would produce a model of the form $r(\mathbf{Z};\boldsymbol{\beta},\boldsymbol{\gamma}) = \exp(\mathbf{Z}'\boldsymbol{\gamma})(1+\mathbf{Z}'\boldsymbol{\beta})$ against which the fit of the linear and loglinear models could be tested with p df. Although useful as a test of fit of these two specific models, the interpretation of the parameters is not straightforward since the effect of the covariates is essentially split between the two components. It would be of greater interest to form a model with a single set of regression coefficients and an additional mixing parameter for the combination of the submodels. Conceptually the simplest such model is the exponential mixture [28]

$$r(\mathbf{Z};\boldsymbol{\beta};\theta) = (1+\mathbf{Z}'\boldsymbol{\beta})^{1-\theta}\exp(\theta\mathbf{Z}'\boldsymbol{\beta}), \qquad (7)$$

which produces the linear model when $\theta = 0$ and the loglinear model with $\theta = 1$. An alternative, based on the Box–Cox transformation, was proposed by Breslow & Storer [3], which also includes the linear and loglinear models as special cases. However, Moolgavkar & Venzon [20] pointed out both of these mixture models are sensitive to the coding of the covariates: for example, for binary covariates, relabelling the two possible values leads to different models, leading to different inferences both about the mixing parameter and the relative importance of the component risk factors. Guerro & Johnson [12] developed a variant of the Box–Cox model of the form

$$r(\mathbf{Z};\boldsymbol{\beta},\theta) = \begin{cases} \exp(\mathbf{Z}'\boldsymbol{\beta}), & \theta = 0, \\ (1+\theta\mathbf{Z}'\boldsymbol{\beta})^{1/\theta}, & \theta \neq 0, \end{cases} \qquad (8)$$

which appears to be the only model in the literature to date that does not suffer from this difficulty. These kinds of mixtures could in principle also be used to compare relative risk with additive (excess) risk models, although the interpretation of the β coefficient becomes problematic because it has different dimensions under the different submodels.

Although suitable for testing multiplicativity vs. additivity with multidimensional categorical data, these mixtures are less useful for continuous covariates because they combine two quite different comparisons (the form of the dose–response relationship for each covariate and the form of their joint effects) into a single mixing parameter. One way around this difficulty is to compare linear and loglinear models for each covariate separately first to determine the best form of model, then to fit joint models, testing additivity vs. multiplicativity. Alternatively, one could form mixtures of more than two submodels with different mixing parameters for the different aspects.

A word of warning is needed concerning **inference** on the parameters of most nonstandard models. Moolgavkar & Venzon [20] pointed out that for nonstandard models, convergence to asymptotic normality can be very slow indeed. Thus, the log-likelihoods are generally far from quadratic, leading to highly skewed confidence regions. For this reason, Wald tests and **confidence limits** should generally be avoided. Furthermore, as the parameter moves away from the null, the **standard error** increases more quickly than the mean, so that the Wald test can appear to become less and less significant the larger the value of the parameter [13, 34]. These problems are particularly important for the mixing parameters θ, for which inference should be based on the **likelihood ratio test** and likelihood-based confidence limits. For example, Lubin & Gaffey [15] describe an application of the exponential mixture of linear-additive and linear-multiplicative models [28] to testing the joint effect of radon and smoking on lung cancer risk in uranium miners; the point estimate of θ was 0.4, apparently closer to additivity than multiplicativity, but the likelihood ratio tests rejected the additive model ($\chi^2_1 = 9.8$) but not the multiplicative model ($\chi^2_1 = 1.1$). A linear mixture showed an even more skewed likelihood, with $\hat{\theta} = 0.1$ (apparently nearly additive) but with very similar likelihood ratio tests that rejected the additive but not the multiplicative model.

Models for Extended Exposure Histories

Chronic disease epidemiology often involves measurement of an entire history of exposure $\{X(u), u < t\}$ which we wish to incorporate into a relative risk model through one or more time-dependent covariates $\mathbf{Z}(t)$. How this is done depends upon one's assumptions about the underlying disease mechanism.

We defer for the moment the possibility of modeling such a disease process directly and instead continue in the vein of empiric modeling, now focusing on eliciting information about the temporal modifiers of the exposure–response relationship.

Most approaches to exposure–response modeling in epidemiology are based on an implicit assumption of *dose additivity*, i.e. that the excess relative risk at time t is a sum of independent contributions from each increment of exposure at earlier times u, possibly modified in some fashion by temporal factors. This hypothesis can be expressed mathematically as

$$r[t, X(\cdot); \boldsymbol{\beta}; \boldsymbol{\gamma}] = R[Z(t); \boldsymbol{\beta}],$$

where

$$Z(t) = \int_0^t f[X(u); \alpha]\, g(t, u; \boldsymbol{\gamma})\, \mathrm{d}u, \qquad (9)$$

and where $R(Z; \boldsymbol{\beta})$ is some known relative risk function such as the linear or loglinear models discussed above, f is a known function describing the modifying effect of dose rate, and g is a known function describing the modifying effect of temporal factors. The simplest weighting functions would be $f(X) = X$ and $g(t, u) = 1$, for which $Z(t)$ becomes cumulative exposure, probably the most widely used exposure index in epidemiology. For many disease with long latency, such as cancer, it is common to use lagged cumulative exposure, corresponding to a weighting function of the form $g(t, u; \gamma) = 1$ if $t - u > \gamma$, zero otherwise. Other simple exposure indices might include time-weighted exposure $\int_0^t X(u)\,(t-u)\,\mathrm{d}u$ or age-weighted exposure $\int_0^{t-\gamma} X(u)\,u\,\mathrm{d}u$, which could be added as additional covariates to $R(\mathbf{Z}; \boldsymbol{\beta})$ to test the modifying effects of latency or age at exposure. The function f can be used to test dose-rate effects (the phenomenon that a long, low-intensity exposure has a different risk from a short, high-intensity exposure for the same cumulative dose). For example, one might adopt a model of the form $f(X) = X^\alpha$ or $f(X) = X \exp(-\alpha X)$ for this purpose.

Models that do not involve unknown parameters α and $\boldsymbol{\gamma}$ are easily fitted using standard software by the device of computing the time-dependent covariate(s) for each subject in advance. Relatively simple functions of γ (such as the choice of lagging interval in the simple latency model) might be fitted by evaluating the likelihood over a grid of values of the parameter. For more complex functions $g(t, u; \boldsymbol{\gamma})$, such as a lognormal density in $t - u$ with unknown mean and variance (and perhaps additional dependence of these parameters on age, exposure rate, or other factors), it is preferable to use a package with the capability of computing $Z(t; \alpha, \boldsymbol{\gamma})$ at each iteration. This generally requires some programming by the user, whereas most of the likelihood calculations and iterative estimation are handled by the package. For example, using SAS procedure NLIN, one can recompute the covariates at each iteration by the appropriate commands inside the procedure.

Unfortunately, the additivity assumption has seldom been tested. In principle, this could be done by nesting the dose-additive model in some more general model that includes interactive effects between the dose increments received at different times. The obvious alternative model would simply add further covariates of the form

$$Z^*(t) = \int_0^t \int_0^u F[X(u)X(v); \alpha] \times G(t, u, v; \boldsymbol{\gamma}, \delta)\, \mathrm{d}v\, \mathrm{d}u, \qquad (10)$$

where F and G are some known weighting functions. However, one should take care to see that the dose-additive model is well fitted first before testing the additivity assumption (e.g. by testing for nonlinearities and temporal modifiers).

Nonparametric Models

The appeal of Cox's partial likelihood is that no assumptions are needed about the form of the dependence of risk on time, but it remains parametric in modeling covariate effects. Even more appealing would be a nonparametric model for both time and covariate effects. For categorical data, no parametric assumptions are needed, of course, although the effects of multiple covariates are commonly estimated using the loglinear (i.e. multiplicative) model, with additional interaction terms as needed. Similarly, continuous covariates are frequently categorized to provide a visual impression of the exposure–response relationship, but the choice of cutpoints is arbitrary. However, nonparametric smoothing techniques are now available to allow covariate effects to be estimated without such arbitrary grouping.

One approach relies only on an assumption of monotonicity. Thomas [29] adapted the technique of

isotonic regression to relative risk modeling, and showed that the MLE of the exposure–response relationship under this constraint was a step function with jumps at the observed covariate values of a subset of the cases. The technique has been extended to two dimensions by Ulm [33], but in higher dimensions the resulting function is difficult to visualize and can be quite unstable.

Cubic **splines** and other means of smoothing provide attractive alternatives which produce smooth, but not necessarily monotonic, relationships. The **generalized additive model** [14] has been widely used for this purpose. For example, Schwartz [26] described the effect of air pollution on daily mortality rates using a generalized additive model, after controlling for weather variables and other factors using similar models. A complex dependence on dew point temperature was found, with multiple maxima and minima, whereas the smoothed plot of the particulate air pollution was seen to be almost perfectly linear over the entire rate of concentrations.

With the advent of **Markov chain Monte Carlo methods**, **Bayesian techniques** for model selection and smoothing have become feasible and are currently an active area of research. A full treatment of these methods is beyond the scope of this article; see Gilks et al. [11] for recent reviews of this literature.

Mechanistic Models

In contrast with the empiric models discussed above, there are circumstances where the underlying disease process is well enough understood to allow it to be characterized mathematically. Probably the greatest activity along these lines has been in the field of cancer epidemiology. Two models in particular have dominated this development, the multistage model of Armitage & Doll [1] and the two-event model of Moolgavkar & Knudson [18] (*see* **Multistage Carcinogenesis Models**). For thorough reviews of this literature, see [17], [31], and [36]; here, we merely sketch the basic ideas.

The Armitage–Doll multistage model postulates that cancer arises from a single cell that undergoes a sequence of k heritable changes, such as point mutations, chromosomal rearrangements, or deletions, in a particular sequence. The model further postulates that the rate of one or more of these changes may depend on exposure to carcinogens. Then the model predicts that the hazard rate for the incidence of cancer (or more precisely, the appearance of the first truly malignant cell) following continuous exposure at rate X is of the form

$$\lambda(t, Z) = \alpha t^{k-1} \prod_{i=1}^{k} (1 + \beta_i X). \tag{11}$$

Thus, the hazard has a **power** function dependence on age and a polynomial dependence on exposure rate with order equal to the number of dose-dependent stages. It further implies that two carcinogens would produce an additive effect if they act at the same stage and a multiplicative effect if they act at different stages. If exposure is instantaneous with intensity $X(u)$, its effect is modified by the age at and time since exposure: if it acts at a single stage i, then the excess relative risk at time t is proportional to $Z_{ik}(t) = X(u)u^{i-1}(t-u)^{k-i-1}/t^{k-1}$ and for an extended exposure at varying dose rates, the **excess relative risk** is obtained by integrating this expression over u [8, 35]. More complex expressions are available for time-dependent exposures to multiple agents acting at multiple stages [30]. These models can be fitted relatively easily using standard software by first evaluating the covariates $Z_{ik}(t)$ for each possible combination of $i < k$ and then fitting the linear relative risk model, as described above. Note, however, that the expressions given above are only approximations to the exact solution of the stochastic differential equations [16], which are valid when the mutation rates are all small.

The Moolgavkar–Knudson two-stage model postulates that cancer results from a clone of cells of which one descendant has undergone two mutational events, either or both of which may depend on exposure to carcinogens. The clone of intermediate cells is subject to a birth-and-death process (*see* **Stochastic Processes**) with rates that may also depend on carcinogenic exposures. The number of normal stem cells at risk varies with age, depending on the development of the particular tissue. Finally, in genetically susceptible individuals, all cells carry the first mutation at birth. The predicted risk under this model (in nonsusceptible individuals) is then approximately

$$\lambda[t, X(u)] = \mu_1\mu_2[1 + \beta_2 X(t)] \int_0^t [1 + \beta_1 X(u)] \times \exp[\rho(t-u)]\,\mathrm{d}u, \tag{12}$$

where μ_k are the baseline rates of the first and second mutations, β_k are the slope of the dependence of the mutation rates on exposure, and ρ is the net proliferation rate (birth minus death rates) of intermediate cells. For the more complex exact solution, see [24].

There have been a number of interesting applications of these models to various carcinogenic exposures. For example, the multistage model has been fitted to data on lung cancer in relation to asbestos and smoking [30], arsenic [4], coke oven emissions [9], and smoking [5, 10], as well as to data on leukemia and benzene [7] and nonleukemic cancers and radiation [32]. The two-stage model has been fitted to data on lung cancer in relation to smoking [23], radon [21, 25], and cadmium [27], as well as to data on breast [22] and colon cancers [19]. For further discussion of some of these applications, see [31].

As in any other form of statistical modeling, the analyst should be cautious in interpretation. A good fit to a particular model does not of course establish the truth of the model. Instead the value of models, whether descriptive or mechanistic, lies in their ability to organize a range of hypotheses into a systematic framework in which simpler models can be tested against more complex alternatives. The usefulness of the multistage model of carcinogenesis, for example, lies not in our belief that it is an accurate description of the process, but rather in its ability to distinguish whether a carcinogen appears to act early or late in the process or at more than one stage. Similarly, the importance of the Moolgavkar–Knudson model lies in its ability to test whether a carcinogen acts as an "initiator" (i.e. on the mutation rates) or a "promoter" (i.e. on proliferation rates). Such inferences can be valuable, even if the model itself is an incomplete description of the process, as must always be the case.

Relative Risk

The relative risk is the ratio of the **risk** of disease in an exposed **cohort** over a defined time interval to the risk of disease in an unexposed cohort over this same time interval. Relative risk is synonymous with **cumulative incidence ratio**. Relative risk can be estimated both from cohort studies, and, for rare diseases, from **case–control studies**.

MITCHELL H. GAIL

Reliability Study

Reliability studies and **validation studies** provide information on **measurement error** in exposures or other **covariates** used in epidemiologic studies. Such information on the measurement error process is needed to obtain valid estimates and **inference** using methods such as regression calibration or **maximum likelihood** (*see* **Misclassification Error**). Reliability studies are based on repeating an error-prone measurement, and the validity of this method depends on a model for the errors given by (1) below. Validation studies are applicable to a broader class of error models, including models admitting **differential error**, but validation studies require that one be able to measure correct ("**gold standard**") covariate values on some subjects.

To define reliability sampling plans more precisely, let $\mathbf{Y}$ be the response variable, and let $\mathbf{X}$ be the true values of the variable which may be misclassified or measured with error. In some cases, $\mathbf{X}$ can never be observed and can be thought of as a *latent* variable. In other cases, $\mathbf{X}$ is a "gold standard" method of covariate assessment which is infeasible and/or expensive to administer to large numbers of study participants. Instead of observing $\mathbf{X}$, we observe $\mathbf{W}$, which is subject to error. Finally, there may be covariates $\mathbf{Z}$ upon which the model for response depends that are measured without error. In main study/reliability study designs, the main study consists of the data $(\mathbf{Y}_i, \mathbf{W}_i, \mathbf{Z}_i), i = 1, \ldots, n_1$. If the reliability study is *internal*, it consists of $(\mathbf{Y}_i, \mathbf{W}_{ij}, \mathbf{Z}_i)$, $j = 1, \ldots, n_i, i = n_1 + 1, \ldots, n_1 + n_2$ observations, and if the reliability study is *external*, it consists of $(\mathbf{W}_{ij})$, $j = 1, \ldots, n_i, i = n_1 + 1, \ldots, n_1 + n_2$ observations. Thus, there is only a single measurement for each main study subject, but replicate measurements for each subject in the reliability study.

The measurement error model for which a reliability study can be used is

$$\mathbf{W} = \mathbf{X} + \mathbf{U}, \tag{1}$$

where $\mathbf{U}$ is a mean zero error term with some variance–covariance Σ. The error $\mathbf{U}$ is assumed independent of $\mathbf{X}$. Note that model (1) implies that the error is **nondifferential**, not only with respect to $\mathbf{Y}$ but also with respect to $\mathbf{Z}$ because $f(\mathbf{W}|\mathbf{X}, \mathbf{Y}, \mathbf{Z}) = f(\mathbf{W}|\mathbf{X})$.

Under model (1), replicate data from a reliability study can be used for valid **estimation** and inference. This model has been applied to the analysis of blood pressure, serum hormones, and other serum biomarkers such as vitamin concentrations, viral load measurements, and CD4 cell counts.

We assume that subjects in an internal reliability study are selected completely at random. That is, if V is an indicator variable that equals 1 if a participant is in the validation study and 0 otherwise, then $\Pr(V = 1|\mathbf{Y}, \mathbf{X}, \mathbf{Z}, \mathbf{W}) = \Pr(V = 1) = \pi$.

To correct point and interval estimates relating $\mathbf{Y}$ to $\mathbf{X}$ for **bias** from measurement error in $\mathbf{W}$, it is necessary to estimate Σ and $\text{var}(\mathbf{X}) = \Sigma_{\mathbf{X}}$ using model (1). Estimates of the quantities, Σ and $\Sigma_{\mathbf{X}}$, are needed to correct the estimate of the parameter of interest describing the association between $\mathbf{Y}$ and $\mathbf{X}$, β, for bias due to measurement error. If an internal reliability sample is used one can estimate Σ from it. The quantity $\text{var}(\mathbf{W}) = \Sigma_{\mathbf{W}}$ can be estimated from the combined main study/internal reliability study data, and $\Sigma_{\mathbf{X}}$ can be estimated by $\hat{\Sigma}_{\mathbf{X}} = \hat{\Sigma}_{\mathbf{W}} - \hat{\Sigma}$. The same approach can be used if an external reliability sample is used except, in this case, $\Sigma_{\mathbf{W}}$ should be estimated from the main study only. This is because, under model (1), it is reasonable to assume that Σ may be transportable from one population to another, whereas $\Sigma_{\mathbf{X}}$, and hence $\Sigma_{\mathbf{W}}$, are likely to vary across populations. Because an internal reliability study ensures that Σ is correctly estimated and yields more efficient estimates of $\Sigma_{\mathbf{X}}$, it is preferred to an external reliability study.

In some applications, the goal of the research is simply estimation of the reliability coefficient, also known as the intraclass correlation coefficient, ρ, equal to $\Sigma_{\mathbf{X}}[\Sigma_{\mathbf{W}}]^{-1}$ (*see* **Correlation**). These applications arise, for example, in the evaluation of new medical diagnostic procedures such as new technology for ascertaining load of HIV in body tissue, or in assessing the consistency of different clinicians in evaluating the functional status of their patients. Designs of studies whose purpose is to estimate the reliability coefficient have $n_1 = 0$ and no data on $\mathbf{Y}$. In what follows, we will first discuss design of such reliability studies. Then, we will discuss the main study/reliability study design, where $n_1 > 0$ and $\mathbf{Y}$ is observed in the main study and possibly in the reliability study.

Design of Reliability Studies

A nontechnical introduction to reliability study design considerations appeared in a recent epidemiology

textbook by Armstong et al. [1]. A series of papers by Donner and colleagues [3, 4, 8] investigated design of reliability studies in considerable detail. The first and last of these provided formulas for the **power** to test $H_0 : \rho = \rho_0$, vs. $H_a : \rho = \rho_A$, where ρ is the intraclass correlation or reliability coefficient, equal to $\Sigma_{\mathbf{X}}/\Sigma_{\mathbf{W}}$, for a given (n_2, R), and where R is the number of replicates per subject. In addition, tables were given for power for fixed values of n_2 and R. The first paper was based upon exact calculations, and the last paper developed a less computationally intensive approximation to the exact formula which appears to work quite well. The total number of observations $(n_2 \times R)$ is minimized with a relatively small value for R, as long as the reliability is 40% or higher. In these cases, $R = 2$ or 3 is sufficient. Eliasziw & Donner [4] minimized reliability study cost with respect to n_2 and R, subject to fixed power to test H_0 vs. H_a as given above using the formula for power derived in [3]. Cost was taken as a function of the unit cost of replicating data within subjects, the unit cost of accruing subjects, and the unit cost related jointly to the number of replicates and the number of subjects. Tables were given for the optimal values of n_2 and R, for different unit cost ratios and different values of ρ_0. They found that for $\rho > 0.2$, the cost per subject is more influential than the cost per measurement. In addition, they found that the optimal n_2 and R were highly stable despite moderate changes in unit cost ratios.

Freedman et al. [5] investigated the design of reliability studies when **X** and **W** are **binary**. Reliability of W as a **surrogate** for X was parameterized by the probability of disagreement between the two replicate measures of X, W_1, and W_2, corresponding to the values obtained from two different raters (*see* **Agreement, Measurement of**). They gave tables for n_2 which assured a fixed **confidence interval** width around the estimated probability of disagreement when $R = 2$. For probability of disagreement between 0.05 and 0.40 and confidence interval widths of 0.1 to 0.2, sample sizes between 50 and 350 are needed. These authors also considered study design when the goal is to estimate the within-rater probability of disagreement as well as the between-rater probability of disagreement, and provided tables of power for scenarios in which there are two raters and two replicates per rater.

Design of Main Study/Reliability Studies

One can select various main study sizes (n_1), reliability study sizes (n_2), and numbers of replicate measurements (R) for each subject in the reliability substudy. An "optimal" main study/reliability study design will find (n_1, n_2, R) to achieve some design goal. One may wish to minimize the **variance** of an important parameter estimate, such as the log **relative risk**, β, subject to a fixed total cost. Alternatively, one may wish to minimize the overall cost of the study, subject to specified power constraints on the parameter of interest (*see* **Validation Study** for further discussion of choices of design optimization criteria). Liu & Liang [6] considered the optimal choice of R for internal reliability designs with $n_1 = 0$, that is, designs in which all subjects are in the reliability study. They studied **generalized linear models** for $f(\mathbf{Y}|\mathbf{X}, \mathbf{Z}; \beta)$ with the identity, log, probit, and logit link functions. They assumed the measurement error model for **X** described by (1) with **X** following a **multivariate normal distribution** $\text{MVN}(\mu_{\mathbf{X}}, \Sigma_{\mathbf{X}})$. The validity of their results required an additional approximation in the case of the logistic link function, which is the link function most commonly used in epidemiology. For scalar **X** and **W**, these authors derived a formula for **asymptotic relative efficiency** of β^*, the measurement-error corrected parameter describing the relationship between **Y** and **X**, as a function of $\Sigma/\Sigma_{\mathbf{X}}$ and R. They found that the precision of β^*, relative to the precision which would be obtained for estimating β if **X** were never measured with error, is little improved by increasing R above 4.

Rosner et al. [7] investigated the effect of changing n_2 and R on the variance of elements of a nine-dimensional vector β, where β is the log **odds ratio** relating coronary heart disease incidence to the model covariates in data from the **Framingham Heart Study** [2]. Four of the model covariates were measured with error (Figure 1). In this figure, n_1 was 1731, and Σ and Σ_x were assigned the values estimated in the analysis. When n_2 was greater than or equal to 100, the **standard error** of the four measurement-error corrected estimates reached an asymptote, indicating little or no gain in efficiency from increasing n_2 beyond that value. At that point, the gain in efficiency ranges between a 10%–20% reduction in the variance for the three variables measured with some error (BMI has little error, as

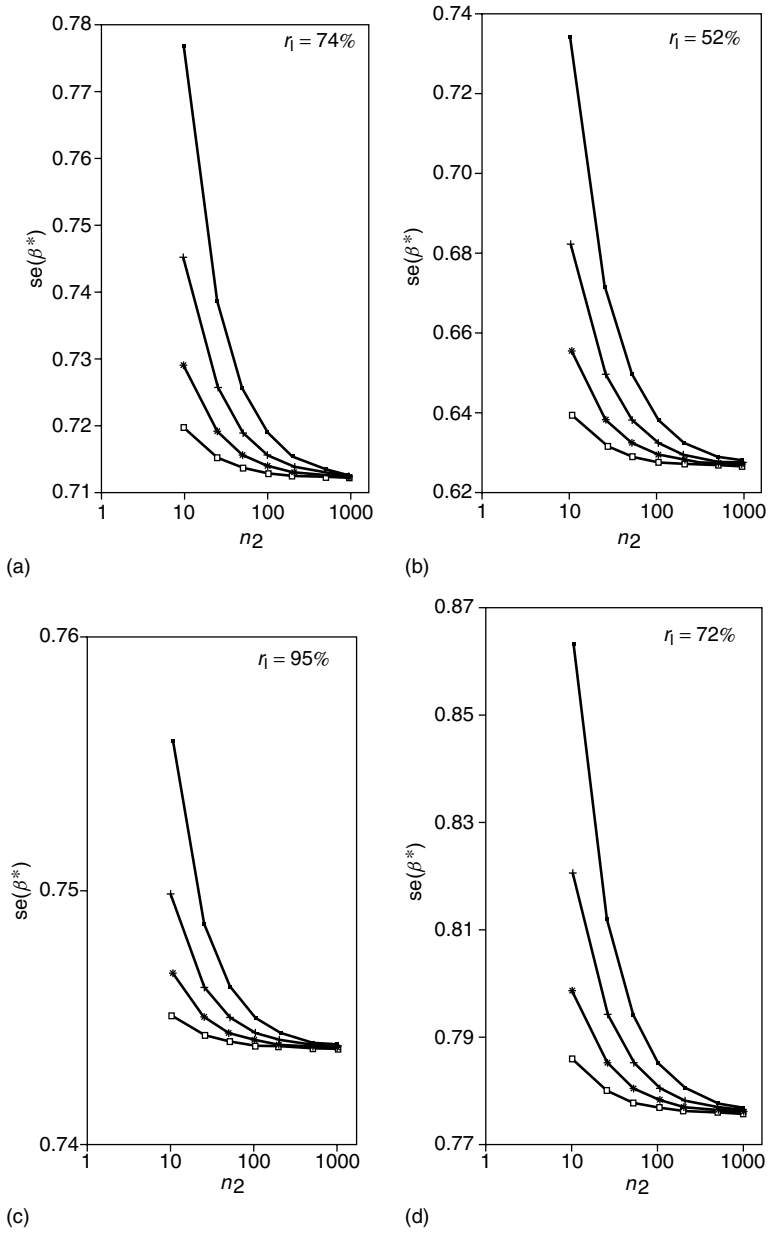

Figure 1 The relationship between the sample size (n_2) and the number of replicates per subject (R) in a reliability study, and the standard error of the measurement-error corrected logistic regression coefficient, β^*. Abbreviations and symbols used are: se for standard error and r_1 for the reliability coefficient $\text{var}(x)/\text{var}(w)$. Number of replicates, R: $\bullet = 2$; $+ = 3$; $* = 5$; $\square = 10$. (a) Cholesterol; (b) glucose; (c) body mass index; (d) systolic blood pressure

evidenced by the high reliability coefficient, $r_1 = 95\%$). Increasing the number of replicates decreased the standard errors of the estimates substantially when n_2 was small, but made little difference for larger reliability studies. For the three variables measured with error (cholesterol, glucose, and systolic blood pressure), the design ($n_2 = 10$, $R = 10$) was equally efficient as the design ($n_2 = 100$, $R = 2$). Although

the former requires fewer measurements, the latter may be more feasible, as it only requires two visits per subject.

Conclusion

Although model (1) is restrictive, there are many instances in biomedical research where it is considered reasonable. Methods of analysis under this model are well developed, but more research is needed on **optimal design**, and there is a need for user-friendly software for finding optimal designs.

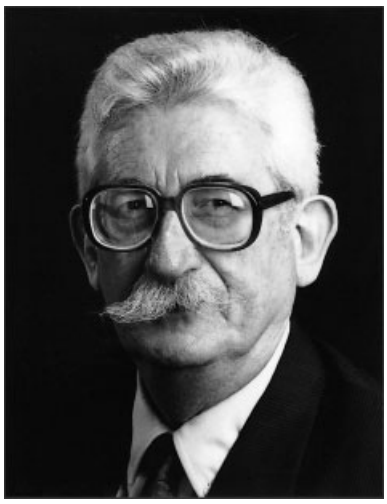
DONNA SPIEGELMAN

Remington, Richard D.

Born: August 2, 1931, in Nampa, Idaho.
Died: July 26, 1992, in Iowa City, Iowa.



As a leading public health statistician, Richard D. Remington played a major role in linking the quantitative fields of biostatistics and epidemiology to public health research and policy. His distinguished academic career reflects an extraordinary commitment to public health, particularly his advocacy of the vital role that biostatistical and epidemiologic thinking and research must play in the resolution of significant public health problems and in the development of national public health policy. He was a tireless, articulate advocate for his profession.

Richard Remington began his university studies pursuing the field of mathematics. He received a B.A. degree in mathematics with honors in 1952 and an M.A. in mathematics in 1954, both from the University of Montana. He entered the field of public health, first receiving an M.P.H. degree in 1957, then a Ph.D. in Biostatistics in 1958, both from the University of Michigan.

On receiving his doctoral degree, he was appointed to the faculty of the Department of Biostatistics at the University of Michigan School of Public Health, serving there through 1969, and earning the rank of full professor in 1965. During a sabbatical year in 1966, he was a Visiting Scholar at the London School of Hygiene and Tropical Medicine.

In 1969 he joined the faculty of the University of Texas School of Public Health, Houston, where he served through 1974 as Associate Dean for Research, Professor and Head of Biometry. In 1975, he returned to the University of Michigan as Professor of Biostatistics and Dean of the School of Public Health. In 1982, he was appointed as the University of Iowa Foundation Distinguished Professor of Preventive Medicine and Environmental Health, and from 1982 to 1988 served as Vice President for Academic Affairs and Dean of the Faculty at the University of Iowa, also serving as Interim President of the University of Iowa in 1987–1988. Following a sabbatical year in 1989 at the University of Texas School of Public Health, Professor Remington returned to the University of Iowa, and founded the Institute for Health, Behavior, and Environmental Policy, serving as the Institute's Director until his death in 1992.

During his tenure at the University of Texas School of Public Health, Professor Remington served as the Scientific Director of the Data Management and Analysis Coordinating Center for the National Heart, Lung, and Blood Institute (NHLBI)'s landmark Hypertension Detection and Follow-up Program (HDFP). HDFP, in a national, community-based, randomized controlled trial (*see* **Clinical Trials, Overview**) involving 10 940 persons with high blood pressure, compared the effects on five-year mortality of systematic antihypertensive treatment and referral to usual community medical therapy. In recognition of the significant research advances made by HDFP, Professor Remington, his research colleagues, and HDFP staff received the Albert and Mary Lasker Special Public Health Award, the highest award in the field of public health.

Several decades of Professor Remington's career were involved with fundamental inquiries into the public health impact of hypertension, the importance of its early detection and treatment, and, more broadly, its prevention. For this work, Professor Remington was recognized in 1992 as the Lewis Conner Memorial Lecturer of the American Heart Association, and the following year he received the Golden Heart Award, the most prestigious honor bestowed by the American Heart Association.

Professor Remington was an effective voice for public health research, policy, and training through his leadership of dozens of significant national and international committees, including membership on the NHLBI Clinical Trials Review Committee, one of

the most distinguished review groups of the **National Institutes of Health**, and chairmanship of the Committee for the Study of the Future of Public Health, a committee appointed by the Institute of Medicine of the National Academy of Sciences. As Chairman, Professor Remington was chief architect of the Institute of Medicine report, *The Future of Public Health* [1].

Professor Remington's contributions to biostatistics, epidemiology, and public health have been recognized by honors and his election to memberships in scientific academies. He was elected a fellow of the **American Public Health Association**, the **American Statistical Association**, the UK **Royal Statistical Society**, an elected member of the Institute of Medicine of the National Academy of Sciences, and was awarded an honorary doctor of science degree from the University of Montana in 1984.

Professor Remington was a prolific author, producing over 80 scholarly articles and two books. His text, coauthored with Professor M. Anthony Schork, [2] is widely used in introductory biostatistics and statistics courses.

Second only to public health was his love of music. As Dick Remington he was a virtuoso on the double bass and jazz tuba, always in demand to record with well-known Dixieland musicians and Dixieland bands.

Perhaps even more enduring than his contributions, publications, and music is his colleagues' memory of his altruism, warm embrace, and humanity. No matter what the occasion, Dick Remington always found time to listen to his colleagues and students, urge them on, and share with them his insight, zest, and dedication to the public health profession.

A memorial, *Tribute to Richard D. Remington*, was read in the Senate of the United States by the Honorable Tom Harkin, Iowa Senator, on the Legislative day of Tuesday, September 8, 1992.

R.F. WOOLSON

Renewal Processes

In a renewal process we study the occurrences, or recurrences, of an event "E" of interest, and the distribution of the corresponding **random variables**. Generally, a process depends on the complexity of the distributions of the random variables, and the distribution may change following the occurrence of an event. In the development of the theory of renewal processes, we make use of the repetitive pattern in many practical situations, and consider an event E to be a "renewal event" only if the underlying conditions of a process remain unchanged following an occurrence of E. Formally, a renewal event is defined by the following two conditions:

1. the occurrence or nonoccurrence of an event E in any given time interval is uniquely determined; and
2. the process following an occurrence of event E is a complete (independent) replica of the process following any other occurrence of E.

Let t_r be a time interval following the $(r-1)$th occurrence of E and including the rth occurrence of E, for $r = 1, 2, \ldots$. According to condition 2 above, $(t_1, t_2, \ldots)$ will be independent and identical distributed random variables. The time in the process may be discrete as in a random walk (*see* **Stochastic Processes**), or continuous as in a **Poisson process**. In this article we briefly review the distributions of the renewal processes for both the discrete and continuous cases. We also consider the number of renewals $N(t)$ within a given time interval $(0, t]$, and the age, excess life, and total lifetime of the component in use at time t. Some extensions of the basic ordinary renewal process are also outlined.

We illustrate the concept of renewal events with a few examples.

Example 1. Success in Bernoulli Trials

Let event E be "success" in a sequence of Bernoulli trials (*see* **Binary Data**). The result of a sequence of trials may appear as follows: FFFSFSSFFS, so that the event E occurs at the fourth, the sixth, the seventh, and the tenth trials, and $t_1 = 4, t_2 = 2, t_3 = 1$, and $t_4 = 3$.

Example 2. Return to Origin

Consider a one-dimensional random walk of a particle starting from the origin. The particle moves one step to the right or one step to the left after each trial. Let event E be "return to origin". Suppose that the result of a sequence of trials is: RL LR RRLL LLRR .... Event E occurs at the second, the fourth, the eighth, and the 12th trials.

Remark. The event "success" in Example 1 is a "single" event; its occurrence at a trial is independent of the preceding trials. In Example 2, "return to origin", RL, LR, RRLL, LLRR, etc. represents a pattern. The occurrence of E at a particular trial is dependent on the outcomes of the preceding trials. Nevertheless, both examples satisfy the conditions underlying a renewal process. So far as occurrence of an event is concerned, trials need not be independent. Sequences of trials following occurrences of an event are independent sequences.

Example 3. Failure and Renewal

When an electric bulb, an automobile tire, or a mechanical component fails, it is replaced with a new one. The renewal times are continuous random variables, and are assumed independent and identically distributed.

When a renewal is a result of a failure, the term *failure time* or *lifetime* is often used for *renewal time*.

The theory of renewal processes was developed mainly by Feller [5–8]. Other contributions to the theory of renewal processes include those in [1, 4, 8, 10, 12], and [13]. This article is based on the material in [2] and [11].

Discrete Time Renewal Processes

In discrete time renewal processes, the units of time t may be called "trials". The occurrence of event E at the nth trial is denoted by "$t = n$". For the ith trial, we define a random variable X_i such that $X_i = 1$ if event E occurs at the ith trial, and $X_i = 0$ if not. We let $f(n)$ be the (first) renewal probability, defined as follows:

$$f(n) = \Pr\{X_n = 1 \quad \text{and} \quad X_m = 0; m = 1, 2, \ldots, n-1 | X_0 = 1\}, \quad n = 1, 2, \ldots. \tag{1}$$

It is clear that

$$f(n) = \Pr\{t = n\}.$$

The sum

$$\sum_{n=1}^{\infty} f(n) = f(\cdot)$$

is the probability that event E will eventually occur.

Classification of Events

A renewal event may or may not be recurrent, depending on the probability $f(\cdot)$.

Transient Event. A renewal event E is a transient event if $f(\cdot) < 1$. In this case there is a positive probability $1 - f(\cdot)$ that event E will not occur in a finite number of trials.

Recurrent Event. A renewal event E is a recurrent event if $f(\cdot) = 1$. In this case, the sequence $\{f(n)\}$ forms a proper probability distribution. The expectation

$$\sum_{n=1}^{\infty} nf(n) = \mathrm{E}(t) = \lambda \tag{2}$$

is the mean recurrent time.

Recurrent Null Event. A renewal event E is a recurrent null event if $f(\cdot) = 1$ and $\lambda = \infty$.

Recurrent Nonnull Event. A renewal event E is a recurrent nonnull event if $f(\cdot) = 1$ and $\lambda < \infty$.

Periodic Event and Aperiodic Event. A renewal event E is a periodic event if there exists an integer $\alpha > 1$ such that E can occur only at trials $\alpha, 2\alpha, 3\alpha, \ldots$. The largest α with this property is the period of E. A renewal event E is aperiodic if $\alpha = 1$.

Let t_r be the number of trials following the $(r-1)$th occurrence of E and including the rth occurrence of E, for $r = 1, 2, \ldots$, as defined above. Each random variable t_r has the probability distribution:

$$\Pr\{t_r = n\} = f(n), \quad n = 1, 2, \ldots.$$

The sum $T_r = t_1 + t_2 + \cdots + t_r$ is the length of time required for r occurrences of E, and its probability distribution,

$$\Pr\{T_r = n\} = f_r(n) \quad \text{for} \quad n = r, r+1, \ldots \tag{3}$$

is the r-fold convolution of $f(n)$ with itself, or, in convolution notation,

$$\{f_r(n)\} = \{f(n)\}^{r*}.$$

The sum

$$f_r(\cdot) = \sum_{n=1}^{\infty} f_r(n)$$

is the probability of r occurrences of E in an infinite sequence of trials. For a transient event E where $f(\cdot) < 1$, the probability $f_r(\cdot)$ tends to zero as r becomes infinitely large. This means that, in an infinite sequence of trials, a transient event occurs a finite number of times, while a recurrent event occurs infinitely often.

For a renewal event E, there are two types of probabilities associated with the occurrence of E. In addition to the probability $f(n)$ introduced above, there is a probability $p(n)$ that the event E will occur at the nth trial regardless of its occurrences in the preceding trials. Formally, we define $p(n)$ as follows:

$$p(n) = \Pr\{X_n = 1 | X_0 = 1\}, \quad n = 1, 2, \ldots,$$

with $p(0) = 1$. These two types of probabilities have the relationship

$$p(n) = \sum_{j=1}^{n} f(j)p(n-j), \tag{4}$$

so that

$$f(n) = p(n) - \sum_{j=1}^{n-1} f(j)p(n-j).$$

Theorem 1. The sum of $p(n)$ and the sum of $f(n)$ are related by formulas

$$\sum_{n=0}^{\infty} p(n) = \frac{1}{1 - f(\cdot)}, \tag{5}$$

and

$$f(\cdot) = 1 - \frac{1}{\sum_{n=0}^{\infty} p(n)}.$$

Thus, $f(\cdot) = 1$ if the infinite sum $\sum_{n=0}^{\infty} p(n)$ diverges, and $f(\cdot) < 1$ if the infinite sum of $p(n)$ converges.

Corollary. The event E is recurrent if

$$\sum_{n=0}^{\infty} p(n) = \infty,$$

and E is transient if

$$\sum_{n=0}^{\infty} p(n) < \infty.$$

Theorem 2. If event E is recurrent non-null with period α, then

$$\lim_{n\to\infty} p(\alpha n) = \frac{\alpha}{\lambda},$$

where λ is the mean renewal time. If E is recurrent non-null and aperiodic, then

$$\lim_{n\to\infty} p(n) = \frac{1}{\lambda}. \tag{6}$$

If E is recurrent null or transient, then $p(n) \to 0$ as $n \to \infty$.

We illustrate the above results with an example.

Example 4. "Success" in Bernoulli Trials

Let E be "success" in an infinite sequence of Bernoulli trials, with the probability of success in a single trial denoted by π. Then $p(n) = \pi$ and $p(0) = 1$ by definition. Clearly, the event E is recurrent nonnull and aperiodic, and

$$f(n) = [1-\pi]^{n-1}\pi.$$

According to (4),

$$\pi = \sum_{j=1}^{n-1}[(1-\pi)^{j-1}\pi]\pi + (1-\pi)^{n-1}\pi,$$

which obviously is true. Furthermore, the infinite sum

$$\sum_{n=0}^{\infty} p(n) = \sum_{n=0}^{\infty} \pi = \infty,$$

and

$$f(\cdot) = \sum_{n=1}^{\infty} f(n) = \sum_{n=1}^{\infty} (1-\pi)^{n-1}\pi = 1,$$

consistent with the fact that E is recurrent. To verify (6) in Theorem 2, note that $p(n) = \pi$ is independent of n, so that

$$\lim_{n\to\infty} p(n) = \pi,$$

while the mean renewal time is

$$\lambda = \sum_{n=1}^{\infty} nf(n) = \sum_{n=1}^{\infty} n[1-\pi]^{n-1}\pi = \frac{1}{\pi}.$$

Thus, λ and π are reciprocal, as required by (6).

Delayed Renewal Processes

In many practical situations the renewal process is already in progress when a first observation is made. This type of renewal processes is called the *delayed renewal process*. The probability distribution of t_1, denoted by $k(n)$, is different from $f(n)$, the common distribution of t_2 or t_3, etc. Suppose that at the time of first observation, n_0 trials have taken place since the last occurrence of E. Then $k(n)$ is the conditional probability that E will occur for the first time at the $(n_0 + n)$th trial given that E does not occur in the first n_0 trials. This means that $k(n)$ and $f(n)$ satisfy

$$k(n) = \frac{f(n_0+n)}{1 - \sum_{j=1}^{n_0} f(j)}.$$

The main feature of a delayed renewal process is the first occurrence of E. After that, the ordinary renewal process returns.

Continuous Time Renewal Processes

In a continuous renewal process, each renewal time t_r of a system has the same density function $f(\tau)$ and the same distribution function $F(\tau)$, for $r = 1, 2, \ldots$. The sum $T_r = t_1 + t_2 + \cdots + t_r$ is the length of time needed for r renewals of the system. The density function of T_r is obtained from

$$f_r(\tau) = \int_0^{\tau} f_{r-1}(\tau - x) f(x)\, \mathrm{d}x, \quad r = 2, 3, \ldots, \tag{7}$$

and the distribution function of T_r from

$$F_r(\tau) = \int_0^{\tau} F_{r-1}(\tau - x)\, \mathrm{d}F(x), \quad r = 2, 3, \ldots, \tag{8}$$

with repeated integrations beginning with $r = 2$.

Delayed Renewal Processes

If, at the initiation of a study, the system has been in operation for a period τ_0, then we have a delayed renewal process. The first random variable t_1 is the residual lifetime of the system beyond "age" τ_0. The distribution function of t_1 is

$$K(\tau) = \frac{F(\tau_0 + \tau) - F(\tau_0)}{1 - F(\tau_0)}. \tag{9}$$

The density function of t_1 is

$$k(\tau) = \frac{f(\tau_0 + \tau)}{1 - F(\tau_0)}.$$

The formulas of the distribution function and the density function of T_r are the same as those in (7) and (26), except that $F_1(\tau) = K(\tau)$ and $f_1(\tau) = k(\tau)$.

Example 5. Exponential Distribution I

Suppose each t_r has an **exponential distribution** with

$$f(\tau) = \mu \exp(-\mu\tau) \quad \text{and} \quad F(\tau) = 1 - \exp(-\mu\tau). \tag{10}$$

The expectation and the variance of t_r are, respectively,

$$\mathrm{E}(t_r) = \frac{1}{\mu} \quad \text{and} \quad \mathrm{var}(t_r) = \frac{1}{\mu^2},$$

where the parameter μ is known as the force of mortality in **life table** analysis and the failure rate or **hazard rate** in **survival analysis**. Using (7) and (8) we find the density function and the distribution of T_r:

$$f_r(\tau) = \mu^r \frac{\tau^{r-1}}{\Gamma(r)} \exp(-\mu\tau),$$

and

$$F_r(\tau) = 1 - \exp(-\mu\tau) \sum_{i=0}^{r-1} \frac{(\mu\tau)^i}{i!}, \tag{11}$$

which is a **gamma distribution** with parameters μ and r. Note that when each t_r has the exponential distribution (10), the process of renewal times is a one-dimensional Poisson process with rate μ.

In the delayed renewal process where t_1 is the residual lifetime of the system beyond τ_0, the distribution function of t_1 is, from (9),

$$\begin{aligned} K(\tau) &= \frac{\{1 - \exp[-\mu(\tau_0 + \tau)]\} - [1 - \exp(-\mu\tau_0)]}{1 - [1 - \exp(-\mu\tau_0)]} \\ &= 1 - \exp(-\mu\tau) = F(\tau). \end{aligned}$$

Thus the residual lifetime t_1 has the same distribution as the total lifetime t_2 or t_3. This, however, is a special case. Here, the force of mortality, or the failure rate μ, is independent of the "age" of the system; the probability that the system will fail in a time element $(\tau, \tau + \mathrm{d}\tau)$ remains the same regardless of the length of time it has been in operation. A system that has been in operation up to time τ_0 will last as long as when it is new. The equality $K(\tau) = F(\tau)$ is justified.

A System with Components

Suppose that a system has s components which have the renewal times (or failure times) $(\tau_1, \tau_2, \ldots, \tau_s)$. Each τ_i has the same density function $h(\tau)$ and the distribution function $H(\tau)$. Let T be the renewal time of the system with the density function $f(\tau)$ and the distribution function $F(\tau)$. Obviously, the distribution of T is a function of $H(\tau)$ and the number s, but their exact relationship depends on the definition of the failure of the system. The following are two definitions of failure and the corresponding distributions.

Minimum Length of Life

An electric circuit with light bulbs connected in series fails as soon as one of the bulbs burns out. A chain is broken when its weakest link fails. Generally, a system with s components operating concurrently fails when the component with the shortest lifetime fails. Let us arrange the lifetimes of the components $(\tau_1, \tau_2, \ldots, \tau_s)$ in the order of magnitude: $[\tau_{(1)} < \tau_{(2)} < \cdots < \tau_{(s)}]$. The renewal time of the system is the first **order statistic** $\tau_{(1)}$. Therefore the density function of the renewal time of the system T is

$$f(\tau) = h_{(1)}(\tau) = s[1 - H(\tau)]^{s-1} h(\tau),$$

and the distribution function of T is

$$F(\tau) = H_{(1)}(\tau) = 1 - [1 - H(\tau)]^s.$$

Example 6. Exponential Distribution II

Suppose the common distribution of the s components is exponential as given in (10). The renewal time of the system has the density function

$$f(\tau) = h_{(1)}(\tau) = s\mu \exp(-s\mu\tau),$$

and the distribution function

$$F(\tau) = H_{(1)}(\tau) = 1 - \exp(-s\mu\tau),$$

which is an exponential distribution with parameter $s\mu$. The expected renewal time of the system is

$$\mathrm{E}(T) = \mathrm{E}[t_{(1)}] = \frac{1}{s\mu},$$

and the variance is

$$\mathrm{var}(T) = \mathrm{var}[t_{(1)}] = \frac{1}{(s\mu)^2}.$$

Maximum Length of Life

An electric circuit with s light bulbs connected in parallel fails only when all the bulbs are burned out. A room with s lights will not be dark unless all the lights are out. A system is still in operation so long as one of the components is working. In such cases, the renewal time of a system T is the maximum lifetime of $(\tau_1, \tau_2, \ldots, \tau_s)$, or the sth order statistic $\tau_{(s)}$. It follows that the distribution of the renewal time T is

$$F(\tau) = [H(\tau)]^s,$$

and the density function of t is

$$f(\tau) = s[H(\tau)]^{s-1} h(\tau)$$

Example 7. Exponential Distribution III

Suppose that the common distribution of the s components is exponential as in (10). Then the renewal time of the system has density function

$$f(\tau) = h_{(s)}(\tau) = s[1 - \exp(-\mu\tau)]^{s-1} \mu \exp(-\mu\tau),$$

and distribution function

$$F(\tau) = H_{(s)}(\tau) = [1 - \exp(-\mu\tau)]^s.$$

The expected renewal time of the system is

$$\mathrm{E}(T) = \mathrm{E}[\tau_{(s)}] = \frac{1}{\mu}\left(1 + \frac{1}{2} + \cdots + \frac{1}{s}\right),$$

and the variance is

$$\mathrm{var}(T) = \mathrm{var}[\tau_{(s)}] = \frac{1}{\mu^2}\left(1 + \frac{1}{2^2} + \cdots + \frac{1}{s^2}\right).$$

Number of Renewals *N(t)*

Thus far we have been discussing the length of time $\{t_r\}$ and $\{T_r\}$ needed for a given number of renewals to take place. Another aspect of renewal processes of considerable interest is the number of renewals $N(t)$ occurring within a given time interval $(0, t]$. In this case, the time interval $(0, t]$ is fixed, while the number of renewals $N(t)$ is a random variable. The main purpose here is to derive a formula for the probability distribution of $N(t)$,

$$\Pr\{N(t) = r\} = P_r(t), \quad r = 1, 2, \ldots.$$

It can be shown that

$$\sum_{r=1}^{\infty} \Pr\{N(t) = r\} = 1 \tag{12}$$

and $N(t)$ is a proper random variable.

Theorem 3. The probability distribution and the expectation of $N(t)$ are related to the distribution function $F_r(t)$ of the time of r renewals T_r as follows:

$$\Pr\{N(t) = 0\} = 1 - F_1(t) \tag{13}$$

$$\Pr\{N(t) = r\} = F_r(t) - F_{r+1}(t), \quad r = 1, 2, \ldots \tag{14}$$

and

$$\mathrm{E}[N(t)] = \sum_{r=1}^{\infty} F_r(t). \tag{15}$$

Proof. If the number of renewals occurring within the time interval $(0, t]$ is greater than or equal to r, then the length of time required for r renewals must be less than or equal to t, and vice versa. In other words,

$$N(t) \geq r \quad \text{and} \quad T_r \leq t$$

are equivalent, and the corresponding probabilities must be equal:

$$\Pr\{N(t) \geq r\} = \Pr\{T_r \leq t\} = F_r(t).$$

Therefore,

$$\begin{aligned}\Pr\{N(t) = r\} &= \Pr\{N(t) \geq r\} - \Pr\{N(t) \geq r+1\} \\ &= F_r(t) - F_{r+1}(t).\end{aligned}$$

When $r = 0$, (14) implies (13). To find the expectation $\mathrm{E}[N(t)]$, we write

$$\begin{aligned}\mathrm{E}[N(t)] &= \sum_{r=1}^{\infty} r \Pr\{N(t) = r\} \\ &= \sum_{r=1}^{\infty} r[F_r(t) - F_{r+1}(t)] \\ &= \sum_{r=1}^{\infty} F_r(t),\end{aligned}$$

and complete the proof.

Theorem 3 provides us with a simple method of obtaining the probability distribution and the expectation of $N(t)$ directly from the distribution function of the renewal time $F_r(t)$.

The function $M(t) = \mathrm{E}[N(t)]$ is called the *renewal function* and, when it exists, its derivative $m(t) = M'(t)$ is called the *renewal density*. Note from (15) that $m(t) = \sum_{r=1}^{\infty} f_r(t)$, so that, for small Δt, the probability that there is a renewal in the time interval $(t, t + \Delta t)$ is given by $m(t)\Delta t + o(\Delta t)$.

Theorem 4. If in an ordinary renewal process the renewal time t_r has a finite expectation $\mathrm{E}(t_r) = \lambda$ and a finite variance σ^2, then, as $t \to \infty$, the number of renewals $N(t)$ has an asymptotic normal distribution which has a mean t/λ and a variance $t\sigma^2/\lambda^3$.

Feller [6] originally established the theorem for the discrete case, where t is the number of trials. Takacs [13] proved the theorem for time - continuous processes. The following theorem is due to Smith [12].

Theorem 5. If the renewal time has a finite mean $E(t_r) = \lambda$ and a finite variance σ^2, then

$$\lim_{t\to\infty} \frac{\mathrm{E}[N(t)]}{t} = \frac{1}{\lambda}, \tag{16}$$

and

$$\lim_{t\to\infty} \frac{\mathrm{var}[N(t)]}{t} = \frac{\sigma^2}{\lambda^3}. \tag{17}$$

There is a fine difference between Theorems 4 and 5. Theorem 4 is regarding the asymptotic distribution of $N(t)$, whereas Theorem 5 concerns the moments of $N(t)$ as $t \to \infty$. Since convergence of a distribution does not imply convergence of moments, the two theorems are addressing two different issues.

To appreciate the above theorems, let us consider a specific distribution.

Example 8. Exponential Distribution IV

When the renewal time of a system t_r has an exponential distribution as given in (10) and the expectation and the variance of t_r are

$$\mathrm{E}(t_r) = \frac{1}{\mu} \quad \text{and} \quad \sigma^2 = \frac{1}{\mu^2}, \tag{18}$$

the interval of r renewals $T_r = t_1 + t_2 + \cdots + t_r$ has a gamma distribution with the distribution function given in (11):

$$F_r(t) = 1 - \exp(-\mu t) \sum_{i=0}^{r-1} \frac{(\mu t)^i}{i!}. \tag{11a}$$

According to Theorem 3, the probability distribution of the number of renewals in $(0, t)$ is

$$\Pr\{N(t) = r\} = F_r(t) - F_{r+1}(t). \tag{14}$$

Substituting (11) in (14) yields

$$\Pr\{N(t) = r\} = \frac{(\mu t)^r}{r!} \exp(-\mu t), \tag{19}$$

which is a **Poisson distribution** with parameter μt. It follows that the expectation and the variance of $N(t)$ are, respectively,

$$\mathrm{E}[N(t)] = \mu t \quad \text{and} \quad \sigma^2_{N(t)} = \mu t. \tag{20}$$

According to Theorem 5,

$$\mathrm{E}[N(t)] \longrightarrow \frac{t}{\lambda} \tag{16a}$$

and

$$\mathrm{var}[N(t)] \longrightarrow \frac{t\sigma^2}{\lambda^3}. \tag{17a}$$

Substituting formulas (18) for the expectation and the variance of t_r in (16a) and (17a), we recover the formulas of the expectation and the variance of $N(t)$ in (20). Verification of the theorems is complete.

Finally, the reader may wish to prove as an exercise the equation

$$\sum_{r=1}^{\infty} F_r(t) = \mu t,$$

where $F_r(t)$ is given in (11).

Backward and Forward Recurrence Times

Consider a continuous time renewal process with lifetimes t_r having $E(t_r) = \lambda < \infty$, density $f(\tau)$, and distribution function $F(\tau)$. Let $t > 0$ be a fixed point in time. The *backward recurrence time* A_t is the time since the last renewal, that is, the age of the component in use at time t, and the *forward recurrence time* E_t is the time until the next renewal, that is, the excess life of the component in use at time t. For most choices of density $f(\tau)$, the distributions of A_t and E_t cannot be determined explicitly, however, their asymptotic distributions are equal and given by (e.g. [11, Proposition 3.4.5])

$$\lim_{t\to\infty} \Pr\{E_t \le x\} = \lim_{t\to\infty} \Pr\{A_t \le x\} = \frac{1}{\lambda}\int_0^x [1 - F(u)]\,\mathrm{d}u. \quad (21)$$

Moreover, provided $\sigma^2 = \mathrm{var}(t_r) < \infty$, then (e.g. [11, Proposition 3.4.6])

$$\lim_{t\to\infty} E[E_t] = \lim_{t\to\infty} E[A_t] = \frac{\sigma^2 + \lambda^2}{2\lambda}. \quad (22)$$

It is easily verified that the mean of the distribution given by the right-hand side of (21) is $(\sigma^2 + \lambda^2)/(2\lambda)$. For $t > 0$, let $T_t = A_t + E_t$ be the *total lifetime* of the component in use at time t. Then, using (22),

$$\lim_{t\to\infty} E[T_t] = \lim_{t\to\infty} E[E_t] + \lim_{t\to\infty} E[A_t] = \frac{\sigma^2 + \lambda^2}{\lambda}. \quad (23)$$

Example 9. Exponential Distribution V

When the renewal time of a system t_r has the exponential distribution given by (10), it is easily verified that the limiting distributions of E_t and A_t are also given by (10) and that $\lim_{t\to\infty} E[T_t] = 2/\mu$. Thus, the limiting mean total lifetime of the component in use at time t is $2/\mu$ while the mean lifetime of a component is $1/\mu$! At first sight, this result, which is known as the *inspection paradox*, may seem surprising. However, it has a fairly simple explanation, which is given below in the general setting.

Arguing informally, considering the interval that covers the point t and letting $t \to \infty$ is equivalent to considering the interval covering a point chosen uniformly in $[0, t]$ and letting $t \to \infty$. In the latter, it is clear that an interval of length y is y times more likely to be sampled than an interval of length 1, so the limiting distribution of T_t as $t \to \infty$ has density $f_T(y)$ that is directly proportional to $yf(y)$. Since $\int_0^\infty f_T(y)\,\mathrm{d}y = 1$ it follows that $f_T(y) = \lambda^{-1} y f(y)$ $(y > 0)$. Note that

$$E[T] = \int_0^\infty y f_T(y)\,\mathrm{d}x = \int_0^\infty \lambda^{-1} y^2 f(x)\,\mathrm{d}x = \frac{\sigma^2 + \lambda^2}{\lambda},$$

agreeing with (23). Note also, that in the limit as $t \to \infty$, the sampled point is uniformly distributed within the interval containing it. Thus, denoting the limiting excess and total lifetimes by E and T, respectively, for $x > 0$, $\Pr\{E > x | T = y\} = (y - x)/y$ if $y > x$ and zero otherwise, so conditioning on T,

$$P(E > x) = \int_0^\infty \Pr\{E > x | T = y\} f_T(y)\,\mathrm{d}y = \int_x^\infty \lambda^{-1} f(y)(y - x)\,\mathrm{d}y. \quad (24)$$

Differentiating (24) with respect to x shows that E has density

$$f_E(x) = \lambda^{-1}\int_x^\infty f(y)\,\mathrm{d}y = \lambda^{-1}(1 - F(x)),$$

which corresponds to the right-hand side of (21).

Equilibrium Renewal Processes

Consider a delayed renewal process in which the first lifetime t_1 has density function given by

$$k(\tau) = \lambda^{-1}(1 - F(\tau)) \quad (25)$$

and distribution function given by

$$K(\tau) = \lambda^{-1} \int_0^\tau [1 - F(u)]\, du, \qquad (26)$$

where F is the distribution function of the subsequent lifetimes $t_2, t_3, \ldots$. Such a process is called an *equilibrium renewal process*. Note that if we start observing an ordinary renewal process at some fixed time $t > 0$, then the resulting process is a delayed renewal process in which the initial lifetime t_1 is given by the excess life E_t. Thus, for t large, it follows from (21) that the observed process will be very close to the equilibrium renewal process, and indeed equal to it in the limit as $t \to \infty$. It can be shown that the equilibrium renewal process is stationary, that for any $t > 0$, the excess life of the component in use at time t has the same distribution as t_1, (i.e. given by (25) and (26)), and that its renewal function and renewal density are respectively $\lambda^{-1}t$ and λ^{-1} ($t \geq 0$) (see, for example, [11, Theorem 3.5.2]).

Alternating Renewal Process

In an *alternating renewal process*, the even numbered renewal times $t_{2r}, r = 1, 2, \ldots$, have a different distribution to the odd numbered renewal times $t_{2r-1}, r = 1, 2, \ldots$. For example, consider a single machine that breaks down repeatedly. Suppose that the machine has just been repaired at time $t = 0$. Then $t_1, t_3, t_5, \ldots$ denote the lengths of successive working periods of the machine and $t_2, t_4, t_6, \ldots$ denote the lengths of successive repair times. Suppose that $t_1, t_2, \ldots$ are independent, $t_1, t_3, \ldots$ each have density $f_1(\tau)$ and mean λ_1, and $t_2, t_4, \ldots$ each have density $f_2(\tau)$ and mean λ_2. Then

$$\lim_{t\to\infty} \Pr\{\text{machine is working at time } t\} = \frac{\lambda_1}{\lambda_1 + \lambda_2}. \qquad (27)$$

In fact, (27) holds under the weaker assumption that (t_1, t_2), (t_3, t_4), ... are independent, that is, allowing for dependence between the lengths of a working period and the subsequent repair period (see, for example, [11, Theorem 3.4.4]). Further characteristics of the system, such as the limiting excess life distribution given that the machine is working at time t, can also be computed; (see, for example, [3, Chapter 7], and [11, Section 3.4.1].

Renewal Reward Process

Suppose that in a renewal process there is an award, R_i say, associated with the ith renewal. Then the total reward earned by time t is

$$R(t) = \sum_{i=1}^{N(t)} R_i,$$

where $N(t)$ is the number of renewals occurring in the time interval $(0, t]$ and the sum is zero if $N(t) = 0$. For example, suppose that claims come into an insurance company at the points of a renewal process $\{N(t), t \geq 0\}$. Then, if R_i denotes the value of the ith claim, $R(t)$ is the total value of all claims over $(0, t]$. Suppose that (t_1, R_1), (t_2, R_2), ... are independent and identically distributed, that $\lambda = E[t_1] < \infty$ and $\lambda_R = E[R_1] < \infty$. Then

$$\frac{R(t)}{t} \longrightarrow \frac{\lambda_R}{\lambda} \quad \text{almost surely as} \quad t \to \infty,$$

and

$$\frac{E[R(t)]}{t} \longrightarrow \frac{\lambda_R}{\lambda} \quad \text{as} \quad t \to \infty,$$

(see, for example, [11, Theorem 3.6.1]). Note that t_i and R_i are not assumed to be independent. The above results also hold if, instead of being earned en masse at the end of a lifetime the reward is earned gradually over the lifetime. As well as occurring naturally in many practical settings, renewal reward processes can also be used to analyze more complicated stochastic processes, such as queueing processes, where they arise as embedded processes, see, for example, [9, Section 10.5].

Repeated Events

Repeated or recurrent events often arise in **longitudinal** studies involving multiple subjects. Some examples are the occurrence of epileptic seizures [2], the recurrence of tumors in cancer patients or laboratory animals [5, 12], and coughing or wheezing episodes in persons with bronchial asthma [6]. Broad objectives in analyzing repeated events include (i) understanding and characterizing event occurrence processes for individual subjects, (ii) characterizing subject-to-subject variability and relating it to **covariates** or treatments, and (iii) assessing the relationship of **time-dependent covariates** or other processes to event occurrence. Several types of repeated events may be of interest in a single application but throughout most of this discussion, we assume that one specific type of event is being considered.

To set up a framework for analyzing repeated events, suppose that subjects $i = 1, \ldots, m$ are observed and that the times of occurrence of events are recorded. Assume that subject i is observed over the time period $(0, \tau_i]$; τ_i is sometimes referred to as a **censoring** or termination time. Let $t_{i1} \leq t_{i2} \leq \cdots$ denote the times of event occurrence for subject i and let $N_i(t)$ represent the number of events over $(0, t]$. Finally, let $t_{i0} = 0$ and $x_{ij} = t_{ij} - t_{i,j-1}$ $(j = 1, 2, \ldots)$.

In the following sections, we describe the modeling of repeated events, discuss methods of analysis, and present an example.

Models for Repeated Events

Let us temporarily drop the subscript i and consider events that occur in continuous time for an arbitrary subject. A full probability model for an orderly (no coincident events) process $\{N(t) : t \geq 0\}$ may be specified in terms of the complete intensity function [9, p. 9]; (*see* **Point Processes**). Define $H_t = \{N(s) : s < t\}$ as the "history" of the process up to time t, and let $\mathrm{d}N(t)$ denote the number of events over the small interval $[t, t + \Delta t)$. The intensity $\lambda(t; H_t)$ is defined by

$$\lambda(t; H_t) = \lim_{\Delta t \to 0} \frac{\Pr\{\mathrm{d}N(t) = 1 | H_t\}}{\Delta t}. \qquad (1)$$

The probability distribution of the point process $\{N(t) : t \geq 0\}$ over $(0, \tau]$ can be given in terms of $\lambda(t; H_t)$; see [3, pp. 57–58] or [4]. In particular, the probability density that exactly n events occur over the specified interval (τ_0, τ), and at times $t_1 < \cdots < t_n$, is

$$\prod_{j=1}^{n} \lambda(t_j; H_{t_j}) \exp\left[- \int_{\tau_0}^{\tau} \lambda(t; H_t)\, \mathrm{d}t \right] \qquad (2)$$

The formula (2) provides **likelihood** functions for **maximum likelihood** estimation and associated inference procedures for models in which the intensity is specified in terms of unknown parameters. When τ_o and τ are random, it also gives **partial likelihoods**, which can be used in the same way as likelihoods, provided that τ_o and τ are determined according to a process depending only on prior event history or covariates (see [1] or [3, p.59]).

Poisson processes, where the complete intensity (hereafter just the "intensity", for brevity) is of the form $\lambda(t; H_t) = \rho(t)$, or **renewal processes**, where it is of the form $h(t - t_{N(t^-)})$, are common models. The former is convenient when counts (i.e. numbers of events in various time intervals) are emphasized; for a Poisson process, the number of events occurring in time interval $(s, t]$ has a **Poisson distribution** with mean $\int_s^t \rho(u)\, \mathrm{d}u$, and the numbers of events in disjoint intervals are independent. Renewal processes are convenient when the intervals between events are of more direct interest. For a renewal process, the times $X_1, X_2, \ldots$ between successive events are independent and identically distributed with **hazard** function $h(x)$.

Fixed or time-varying covariates may be incorporated into the intensity function. We consider here only "exogeneous" covariates that are not affected by the event process, and condition on their realized values. If z is a vector of fixed covariates, then **multiplicative models** in which $\lambda(t; H_t, z) = \lambda_o(t; H_t)\phi(z)$ are often useful. Models with

$$\lambda(t; H_t, z) = \rho(t)\phi(z) \qquad (3)$$

$$\lambda(t; H_t, z) = h(t - t_{N(t^-)})\phi(z) \qquad (4)$$

for the Poisson and renewal cases, respectively, are easy to interpret and handle statistically. In (3) and (4), $\phi(z)$ is some positive-valued function that specifies the effect of z on the intensity. Time-varying covariates $z(t)$ may be incorporated in the same way.

When we specify an intensity function (1), we have a complete model for the repeated event process. As in ordinary **regression** or longitudinal data analysis, simple analyses of means or rates that avoid strong assumptions about the recurrent event process are often attractive, however. The rate of occurrence function is defined by $r(t) = \mathrm{d}E\{N(t)\}/\mathrm{d}t$, and the mean or expected count function $R(t) = \mathrm{E}\{N(t)\}$ is thus

$$R(t) = \int_0^t r(u)\,\mathrm{d}u. \tag{5}$$

For a Poisson process, the function $r(t)$ is also the intensity function but, in general, they are quite distinct, and $r(t)$ does not fully specify the process. Covariates z can be introduced into the rate or mean functions, the simplest way being by the multiplicative specification

$$r(t; z) = r_0(t)\phi(z) \tag{6}$$

A distinction should be made between fully parametric models that are specified solely in terms of a finite-dimensional parameter θ and **semiparametric** models, which involve arbitrary rate, mean, or intensity functions. For example, if in (3), we specify $\rho(t) = \exp(\gamma_0 + \gamma_1 t)$ and $\phi(z) = \exp(\beta z)$, the model is fully parametric; if we specify $\phi(z)$ thus but leave $\rho(t)$ an arbitrary positive-valued function, the model is semiparametric.

Poisson and renewal processes are fundamental in their simplicity and ease of interpretation but in many situations fail to represent event processes satisfactorily. Three broad approaches to modeling and analysis in such cases are (i) to seek satisfactory specification of the intensity processes by building in aspects of the event and covariate histories, (ii) to add **random effects** or time-varying covariates to Poisson or renewal models, and (iii) to generalize renewal models by incorporating serial dependence among the times between events.

Other types of models are discussed in books on point processes (e.g. [10] and [20]) and on **counting processes** (e.g. [3]).

Random effects are sometimes incorporated into Poisson or renewal models in order to represent unobservable heterogeneity among subjects. For example, if events for individual i occur according to a Poisson process, the counts $N_i(t)$ have Poisson distributions with means $R_i(t)$ and variances also equal to $R_i(t)$. Larger variances than means are often observed across individuals, however, and this **"overdispersion"** may signal unobserved heterogeneity.

One way of dealing with this (e.g. [6, 14]) is to assume that given (unobservable) random effects α_i, the processes $\{N_i(t), t \geq 0\}$ are Poisson with intensity functions $\alpha_i r_i(t)$. The α_i's are assumed to be independent random variables with mean 1 and variance σ_α^2. It is easily seen that $\mathrm{E}\{N_i(t)\} = R_i(t)$ and $\mathrm{Var}\{N_i(t)\} = R_i(t) + \sigma_\alpha^2 R_i(t)^2$. In addition, the event counts in nonoverlapping time intervals (s_1, t_1) and (s_2, t_2) for the individual are now **correlated**, with covariance $\sigma_\alpha^2 R_i(s_1, t_1) R_i(s_2, t_2)$, where $R_i(s, t) = R_i(t) - R_i(s)$. It is often convenient to assume that the α_i's have **gamma distributions**, in which case the $N_i(t)$'s have **negative binomial distributions**.

Aalen and Husebye [1], Lawless and Fong [16], and others discuss the incorporation of random effects into renewal processes, and Andersen et al. [3, Chapter 9] consider general counting processes.

The modeling approach taken with repeated events necessarily depends on one's objectives. Even so, more than one approach may be supportable in a given setting. A particularly interesting situation is when the comparison of treatments is a main objective. In this case, intensity-based comparisons may mask the treatment effects, and comparisons based on marginal rate or mean functions may be preferred. However, one might be interested in the relationship of treatment to patterns in events, and not just their frequency. For discussions along these lines, see [6] and [13, Chapter 9].

Statistical Methods

Likelihood and Partial Likelihood Methods

For models with a full probability specification, maximum likelihood is in principle available, although in some circumstances, it may be difficult or indeed impossible to implement. From (2), the likelihood based on n independent subjects observed over intervals (τ_{oi}, τ_i) is of the form (suppressing dependence on covariates in the notation and writing $H_i(t)$ for the history of subject i, including covariates)

$$\prod_{i=1}^{m} \left\{ \prod_{j=1}^{n_i} \lambda_i(t_{ij}; H_i(t_{ij})) \right\} \exp\left\{ -\int_{\tau_{oi}}^{\tau_i} \lambda_i(t; H_i(t))\,\mathrm{d}t \right\} \tag{7}$$

If the information necessary to evaluate the integrals in (7) is not available (e.g. values of covariates at all time points may not be available) or if the integrals are intractable, then they have to be approximated somehow for maximum likelihood to be feasible. For simple models, maximum likelihood is discussed in many references; for example, see [10] and [20] for Poisson and renewal processes, [1] and [14] for Poisson and renewal processes with random effects, and [3, 4], and [6] for general discussion.

Maximum likelihood based on (7) is most attractive when the model is fully parametric, in which case, standard large sample results concerning estimators, score (*see* **Likelihood**), and **likelihood ratio test** statistics apply as $m \to \infty$, and these can be used to obtain **hypothesis tests** or **confidence intervals**. Semiparametric methods may in many cases also be obtained from (7), although delicate mathematical points arise in a rigorous treatment. For semiparametric models, the most common approach is via multiplicative intensity Poisson models, which are analogous to **proportional hazards** models in survival analysis. In this case, the complete intensity is assumed to be of the form

$$\lambda(t; H_t) = \lambda_0(t)\phi[z(t); \boldsymbol{\beta}], \tag{8}$$

where $\lambda_0(t)$ is an arbitrary "baseline" intensity function and $z(t)$ is a vector of fixed or time-varying covariates.

The partial likelihood method of Cox [7, 8] (see **Cox Regression Model**) applies to models of the form (8). Define $\delta_i(t) = I(\tau_i \geq t \geq \tau_{oi})$ and note that if an event is observed at time t, then under (8), the probability it occurs for subject j is

$$\frac{\delta_j(t)\phi[z_j(t); \boldsymbol{\beta}]}{\sum_{i=1}^{m} \delta_i(t)\phi[z_i(t); \boldsymbol{\beta}]}, \tag{9}$$

which is independent of $\lambda_0(t)$. The partial likelihood for $\boldsymbol{\beta}$ is the product across all event times of terms of the form (9), and can be maximized to give an estimate $\hat{\boldsymbol{\beta}}$. Tests or confidence intervals for $\boldsymbol{\beta}$ follow by standard maximum likelihood methods. The cumulative baseline intensity function $\Lambda_0(t) = \int_0^t \lambda_0(u)\,\mathrm{d}u$ can be estimated by

$$\hat{\Lambda}_0(t) = \int_0^t \frac{\mathrm{d}N_{\cdot}(u)}{\sum_{i=1}^{m} \delta_i(u)\phi[z_i(u); \hat{\boldsymbol{\beta}}]}, \tag{10}$$

where $\mathrm{d}N_{\cdot}(u)$ is the total number of events observed at time u. Andersen et al. [3] give a comprehensive account of these methods.

In the special case in which there are no covariates, the right side of (8) is just $\lambda_0(t)$ so the process is Poisson. Then, the estimate (10) becomes

$$\hat{\Lambda}_0(t) = \int_0^t \frac{\mathrm{d}N_{\cdot}(u)}{\sum_{i=1}^{m} \delta_i(u)}, \tag{11}$$

which is termed the **Nelson–Aalen estimator**.

Owing to a connection with ordinary maximum likelihood, partial likelihood methodology can also be used with semiparametric renewal process models where

$$\lambda(t; H_t) = h_o[B(t)]\phi[z(t); \boldsymbol{\beta}], \tag{12}$$

where $B(t) = t - T_{N(t-)}$ is the time since the last event before t, and $h_o(s)$ is a baseline hazard function; see [11] and [19]. The models (8) and (12) can also be extended by allowing $z(t)$ to include functions of previous event history; these are sometimes referred to as modulated Poisson and renewal processes.

Estimating Function Methods for Rate and Mean Functions

The methods above are based on full probability models. Sometimes, it is attractive to model only the mean and rate functions for the repeated event, as in (5) and (6). It turns out that if the start and termination times τ_{oi} and τ_i for observation of individuals are determined independently of their event processes, then simple **robust** methods that are closely related to analysis under the Poisson model (8) can be used.

This approach follows from an observation of Nelson [23], who noticed that the Nelson–Aalen estimator (11) is a generally valid **nonparametric** estimate of a common mean function, $R(t) = \mathrm{E}[N_i(t)]$ for $i = 1, \ldots, m$. Lawless and Nadeau [17] subsequently provided methodology for parametric and semiparametric models including covariates; Pepe and Cai [25] consider related methods. Surveys of these and later developments are given in [6] and [18]. We outline here the methodology for the case of multiplicative semiparametric models, where the rate function (6) is given by

$$r(t; z) = r_o(t)\phi[z; \boldsymbol{\beta}] \tag{13}$$

with $r_o(t)$ an unspecified baseline rate function. Proofs for results stated below can be found in [17] and [21].

The key idea is to recognize that the maximum likelihood **estimating equations** for (13), which come from a Poisson process (in which case (13) is also the process intensity) are unbiased more generally, provided that the observation intervals (τ_{oi}, τ_i) are independent of the event processes. Thus, the estimates coming from these equations are consistent under the model (13), regardless of the underlying event process, and estimating equation theory may be used to give robust variance estimates and other tools for inference.

The Poisson maximum likelihood estimating equations for the semiparametric model (13) are [17]

$$\sum_{i=1}^{m} \int_o^{\tau} \delta_i(t)[\,\mathrm{d}N_i(t) - \mathrm{d}R_o(t)\phi(\boldsymbol{z}_i;\boldsymbol{\beta})] \times \frac{\partial \log \phi(\boldsymbol{z}_i;\boldsymbol{\beta})}{\partial \boldsymbol{\beta}} = \mathbf{0} \tag{14}$$

and

$$\mathrm{d}R_o(t) = \frac{\mathrm{d}N_{\cdot}(t)}{\sum_{i=1}^{m} \delta_i(t)\phi(\boldsymbol{z}_i;\boldsymbol{\beta})} \quad 0 \le t \le \tau \tag{15}$$

where $\tau = \max(\tau_i)$, we assume each $\tau_{io} = 0$ for simplicity, and $R_o(t) = \int_o^t r_o(s)ds$ is the baseline mean function. Inserting $\mathrm{d}R_o(t)$ from (15) into (14) produces the same estimating equation for $\boldsymbol{\beta}$ as given by the Cox partial likelihood for $\boldsymbol{\beta}$ based on the terms (9) in the Poisson model. Furthermore, insertion of the resulting estimate $\hat{\boldsymbol{\beta}}$ into (15) gives the generalized Nelson–Aalen estimate (10) as the estimate $\hat{R}_o(t)$. Thus, any software that implements the Cox Poisson regression model (8) for repeated events can be used to obtain the estimates $\hat{\boldsymbol{\beta}}$ and $\hat{R}_o(t)$ arising from (14) and (15). For example, for the common model in which

$$\phi(\boldsymbol{z};\boldsymbol{\beta}) = \mathrm{e}^{\boldsymbol{\beta}'\boldsymbol{z}}, \tag{16}$$

with $\boldsymbol{\beta}$ and $\boldsymbol{z}$ both $p \times 1$ vectors, the **S-Plus** function *coxph* with the "cluster" option for individuals can be employed.

Sandwich-type robust variance estimates for $\hat{\boldsymbol{\beta}}$, $\hat{R}_o(t)$, and estimated mean functions

$$\hat{R}(t;\boldsymbol{z}) = \phi(\boldsymbol{z};\hat{\boldsymbol{\beta}})\hat{R}_o(t) \tag{17}$$

can also be given ([17, 21]). Current **software** packages give the robust variance estimates for $\hat{\boldsymbol{\beta}}$ only, but more is planned for a forthcoming version of SAS.

In the case where there are no covariates, the common mean function $R_o(t) = \mathrm{E}[N_i(t)]$ is estimated from (15) with $\phi(\boldsymbol{z};\boldsymbol{\beta}) = 1$, which is the Nelson–Aalen estimator (11). For non-Poisson processes, the Poisson variance estimate for $\hat{R}_o(t)$ should be replaced with the robust estimate

$$\widehat{\mathrm{V}}\mathrm{ar}\{\sqrt{m}[\hat{R}_o(t) - R_o(t)]\} = \sum_{i=1}^{m} \left\{ \int_o^t \frac{\delta_i(s)}{\delta_{\cdot}(s)} \left[\mathrm{d}N_i(s) - \frac{\mathrm{d}N_{\cdot}(s)}{\delta_{\cdot}(s)} \right] \right\}^2, \tag{18}$$

where $\delta_{\cdot}(s) = \sum_{i=1}^{m} \delta_i(s)$.

Additional Considerations

It is, in general, important to consider the process that determines the observation periods $(0, \tau_i]$ for the various subjects. It has been noted that the robust methods require that the τ_i's are determined independently of the event processes, whereas for maximum likelihood methods based on a full intensity specification, the τ_i's may be determined randomly in a way that depends upon past event history but not on future events. Andersen et al. [3, Section 2.7] and Aalen and Husebye [1] give precise requirements for the observation periods (τ_{oi}, τ_i) of individual subjects. A practical requirement for the use of (7) is that the history $H_i(t)$ needed to compute the intensity function at time points in (τ_{oi}, τ_i) be available. Finally, the methods above do not require that the censoring or observation processes for individuals be modeled. If censoring can be modeled satisfactorily, it may be possible to use censoring weights (e.g. see [6] and [26]) to modify estimating functions for rate and mean functions so as to allow history-dependent censoring.

We now mention a few other topics of practical interest. First, events are sometimes recorded only at intermittent times, resulting in counts for specified time intervals rather than exact event times; see [6, Section 2.3] for a review and references to methodology. Secondly, in some settings, the repeated events process ceases with the occurrence of some terminating event, with which it may be associated; for example, events may be associated with the treatment of a specific illness and terminate when the illness ends or the patient dies. This area is reviewed in

[6, Section 5]. A third point is that we have discussed the analysis of one specific type of event. Multiple event types $j = 1, \ldots, J$ can be handled via intensity-based modeling by setting up counting processes $N_j(t)$ and complete intensities $\lambda_j(t; H_t)$ for each event type [3]. This allows association between event types through dependence of the intensities on prior events in H_t. Other approaches discussed in this article can also be extended to handle multiple events, in particular, the robust methodology for rate and mean functions [24].

We have emphasized **multiplicative models** like (8), (12), and (13). Multiplicative models for event occurrence are convenient, flexible, and easily interpreted, but other types are also useful in many settings. Fully parametric models of other types are easily handled, but semiparametric models can require some additional development beyond what has been given here. For example, see [13, p.289] and [22] for the case of **accelerated failure-time** models for rate and mean functions.

Finally, we have not discussed the very important topic of **model checking**. Specific methodology depends to some extent on the types of models under consideration, but a universal approach is to test base models against "expanded" models having additional parametric structure. **Graphical displays** involving the raw data, nonparametric and parametric estimates, and suitably defined **residuals** are also important. Andersen et al. [3] and Therneau and Grambsch [27] provide numerous examples for multiplicative intensity models.

The following rather simple example illustrates several of the points about modeling and methodology that have been discussed earlier. For more complex settings involving multiple covariates and more complicated observational patterns, see for example, illustrations and discussion in [6, 13, Chapter 9] and [27, Chapter 8].

An Illustrative Example

Gail et al. [12] presented data on the times to development of mammary tumors for 48 female rats in a carcinogenicity experiment (*see* **Tumor Incidence Experiments**). The animals were assigned randomly to two groups, treatment (23 animals) and control (25 animals), and the days on which new tumors occurred for each animal were recorded. All animals were observed over the time period $(0, \tau] = (0, 122]$ days. Although the data are given in discrete time units (days) and, in fact, animals were inspected for the presence of new tumors every two to four days, we will, for simplicity, treat the occurrence times as continuous; this does not affect the main conclusions; see [17] for methodology written in terms of discrete time processes. The main objective of the experiment was to compare the frequency of tumor occurrence for treatment and control animals.

A useful place to start is to plot nonparametric estimates (11) of the mean functions for animals in the two treatment groups. Figure 1 shows this and indicates that (i) there is no pronounced trend in the

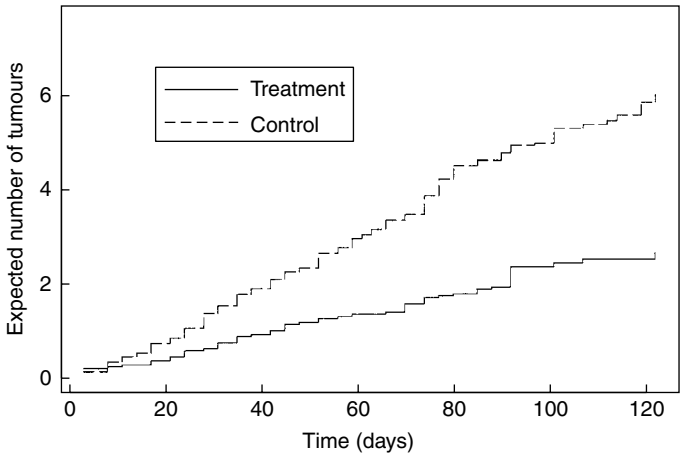

Figure 1 Estimates of mean functions for treatment and control groups

tumor occurrence rate for either group, and (ii) the rate and the expected number of tumors for control animals is about twice that for treatment animals.

To make a more thorough comparison, we might consider fitting Poisson processes to the events for the individual animals. However, there is evidence of overdispersion, particularly in the control group. Under a Poisson model, the total number of tumors $N_i(122)$ for each animal has a Poisson distribution. However, the sample means and variances for the treatment and control group animals are $\overline{N}_T = 2.65$, $s_T^2 = 3.62$ and $\overline{N}_C = 6.04$, $s_C^2 = 14.92$, respectively. Formal tests [14] provide evidence against the Poisson model.

To compare the rate functions for the two groups, Figure 1 suggests the multiplicative model (6) with $\phi(z) = \exp(\beta z)$, where $z_i = 0$ if animal i is in the control group and 1 if it is in the treatment group. Robust estimation of β, as described above (see (14) and (15)) and in [15] and [17] yields $\hat{\beta} = -0.82$ with a standard error of 0.21. This indicates a rather strong treatment effect; the tumor rate for treatment animals is estimated to be $\exp(-0.82) = .44$ times that for control animals. Inference based on a Poisson model with individual random effects for each animal [14] yields the same result. However, if we ignored the overdispersion and fitted Poisson processes to the two groups, we would obtain the same estimate $\hat{\beta} = -0.82$, but a smaller standard error of .15, thus overstating the strength of the treatment effect. A partial likelihood analysis yields the same inference for β as the Poisson model, and thus also overstates the treatment effect.

Other models may be considered for these data. For example, Gail et al. [12] fit renewal models in which times between successive events (tumors) for an animal are considered independent. Graphical and more formal methods may be used to check models that assume a specific probabilistic structure for the event processes (e.g. see [3, 10, 14, 27]). Plots involving both residuals and the raw data (e.g. [10]) are especially helpful.

Reproduction Number

The basic reproduction number (or ratio), R_0, is the expected number of secondary cases of an infection which one typical case could generate during its infectious period in a completely susceptible population. It is the most important theoretical concept in communicable disease epidemiology. If R_0 is greater than one, then a newly introduced infection may lead to a large epidemic in a completely susceptible population and a stable endemic level may persist if the host population is large enough such that new susceptibles are born into the population at a sufficiently high rate. If R_0 is less than one, then the total size of a newly introduced outbreak will remain small (*see* **Epidemic Thresholds**). In addition to this qualitative threshold property, R_0 has an important quantitative interpretation because it allows one to determine the amount of effort needed to reduce the incidence of a disease to zero: in a homogeneously mixing population the lower bound, c^*, for the necessary coverage with a vaccine that is 100% efficacious is given by the simple expression $1 - 1/R_0$, because for this coverage the number of secondary cases of one infective is reduced to the critical value of one $[R_0(1 - c^*) = 1]$ (*see* **Vaccine Studies**). This practical implication motivates epidemiologists to estimate R_0 from data about epidemics or endemic equilibria.

The notion, which has its origin in **demography**, was first introduced into the epidemiology of infectious diseases by Macdonald [13] in the context of malaria. Smith [15] applied it to the control of arboviruses, i.e. viruses which are transmitted from man to man or from animal to man by arthropods (e.g. yellow fever by mosquitoes). There is a parallel sequence of papers, started by Bharucha-Reid [5], followed by Neyman & Scott [14] and Bartoszýnski [3], in which the spread of infectious diseases in large populations is approximated by **branching processes**. In 1975 the concept was introduced independently and under different names in the context of directly transmitted virus diseases by Becker [4], Dietz [7], and Hethcote [12]. Currently, only the symbol has been standardized in epidemic theory, but R_0 is still being called by several names. The most natural one would be "basic reproduction *ratio*" or "basic reproduction *number*", since R_0 is a dimensionless quantity and does not deserve the affix "rate", which suggests a dimension "time^{-1}". A Dahlem Workshop [1] helped tremendously to popularize R_0 and the seminal paper by Diekmann et al. [6] provides a mathematically rigorous framework for its definition. The key reference is the dissertation of Heesterbeek [9], with its remarkably short title: "R_0". The most recent survey article is Heesterbeek & Dietz [11]. For an excellent description of the history of R_0, see review article by Heesterbeek [10].

Because of its important implications, it is essential to estimate R_0 on the basis of epidemiological data. A survey of estimation methods is given by Dietz [8]. R_0 depends on three parameters: (i) the contact rate, (ii) the duration of the infectious period, and (iii) the probability that a contact between an infective and a susceptible individual leads to an infection. The last parameter is sometimes broken down into two factors describing infectivity and susceptibility. For a homogeneously mixing population (*see* **Random Mixing**), the equilibrium proportion of susceptibles equals the inverse of the basic reproduction number, because in this situation on average one case produces one secondary case (*see* **Secondary Attack Rate**). For infections with lifelong immunity, the average age at first infection divided by life expectancy equals the proportion of susceptibles in the population, because this equals the fraction of life before the infection. Therefore, one can estimate a basic reproduction number by the ratio of life expectancy over the average age at first infection [7]. The comprehensive reference work on the mathematical approach to the epidemiology and control of human infectious diseases by Anderson & May [2] contains numerous estimates of R_0 for a wide variety of diseases in different geographical regions.

One can also estimate R_0 from the final size of an epidemic if one knows the number of individuals infected during the epidemic and the final proportion of individuals still susceptible. The following formula provides an estimate of R_0 for a homogeneously mixing population:

$$R_0 = (u_0 - u_\infty)^{-1}(\ln u_0 - \ln u_\infty),$$

where u_0 denotes the initial and u_∞ the final proportion of susceptibles.

The estimates of R_0 are highly dependent upon the assumptions about the contact structure in the population and the effects of immunity. If one only has

age-specific antibody prevalence data, it is impossible in principle to deduce the underlying mixing matrix. One frequent simplifying assumption is proportional mixing, which associates with each individual a certain contact rate. The probability that a contacted individual is infectious is then a weighted average of the prevalence using the contact rates as weights.

In spite of impressive theoretical progress, the practical application of R_0 is still in its infancy because of the intrinsic difficulties in applying this theoretical concept to real-life situations.

Reproduction

Human reproduction, fertility, sexuality, and family planning are central to our lives, and research into these areas has been under way for years. While this research uses methodologies and techniques that are common to many other branches of behavioral and biomedical science, there are a number of biostatistical challenges that are unique to the field. The main biostatistical problem is the assessment of fertility and pregnancy rates in different groups of users – ranging from men and women using highly effective methods to reduce their fertility, those using less effective methods, those living in "natural fertility" situations in which no fertility regulation methods are used at all, or to infertile couples who may be trying to increase their fertility. With a greater understanding of the factors that affect human fertility and the different ways in which these factors might be modified, clearer ideas have emerged on the most appropriate statistical measures to summarize information. Similarly, we now appreciate better the limitations of different research designs, the information generated by such designs and the types of data that need to be recorded.

The main biostatistical challenge is to summarize information on the effectiveness of different contraceptive methods in preventing pregnancy, the adverse and beneficial secondary effects associated with their use, and the reasons why people stop using their chosen method, switch to another method, or stop using any contraceptive method at all. Ideally, this information would be presented in such a way that an individual could freely choose the most appropriate method for his or her situation and reproductive intentions, and that this choice could be made with the fullest breadth and depth of knowledge available. In addition, the provider needs to know the risks, benefits, advantages, and disadvantages of different methods of fertility regulation in order to give appropriate advice and counseling on the most suitable methods to use. Similarly, policy makers, responsible for ensuring reproductive health and family planning services, need to have information relevant to their country or populations. Thus, not only is comprehensive information required on the characteristics of different methods, their reliability under ideal and typical conditions of use, their side effects, the type of advice, and the counseling to be given to potential or existing users, but also the extent to which this information can be generalized to women and men in different personal and social situations.

Comparisons between contraceptive methods within the same broad class are in general more straightforward and reliable than comparisons between widely different methods. For example, the comparative efficacy and rates of side effects of two types of intrauterine device (IUD) are relatively easy to establish, and to generalize to populations other than those studied. By contrast, comparative statements about methods that are widely different, for example periodic abstinence or withdrawal (coitus interruptus) and long-term methods such as five-year implants or sterilization, are much more problematic. However, this is exactly the information required.

To appreciate the biostatistical problems encountered in the study of human reproduction, fertility, and family planning, an understanding is necessary of the complex social, behavioral, and physiological processes that determine human fertility. A great deal is known about these and has been presented from different perspectives, and the following briefly summarizes those aspects that give rise to the unique and challenging problems for the biostatistician. Further details can be found in many good textbooks or reviews (see, for example, Gray et al. [8], Hatcher et al. [11], and Nieschlag & Behre [14]).

Key Factors in Male and Female Reproductive Physiology

The Female Partner

The physiological factors which determine whether a woman becomes pregnant include her ability to conceive (fecundity), the fertilizing capacity of her partner, the timing and frequency of intercourse, and the chances that the fertilized ovum will be implanted. Her fecundity is mainly determined by ovulation – whether or not it occurs and its regularity. These can be affected by many factors: ovulation only occurs naturally during the reproductive years, except during and soon after a pregnancy or during full breast feeding, and its regularity decreases with age. It can also be affected by extreme malnutrition or obesity, other physiological disorders, smoking, and strenuous exercise.

Successful fusion of oocyte and sperm and subsequent implantation require patent fallopian tubes which effectively transport the ovum from the ovary to the uterus. These may be adversely affected by pollutants such as smoking or damage caused by sexually transmitted diseases or other infections.

The regular human menstrual cycle has usual length of 28–30 days, although there is considerable variation in length both between women and within the same woman. The normal cycle is divided into the follicular phase, which leads up to ovulation around 14–18 days after the onset of menses, and the luteal phase, which lasts about 14 days. The endometrium (the lining of the uterus) is prepared to receive the fertilized ovum, and, in the absence of a successful implantation, is sloughed off at the onset of the next menstrual cycle. Typically an ovum can be fertilized up to one or two days following ovulation. A number of physiological changes, some of which can be comparatively easily observed, occur around the time of ovulation as the hormonal balance shifts from the follicular to the luteal phase. Examples include changes in cervical mucus quantity and quality around ovulation, a rise in basal body temperature (BBT) between 0.2 °C and 0.4 °C, or changes in the ratios of urinary metabolites that reflect circulating hormone levels.

There is a delay from the actual time of fertilization to the recognition of a pregnancy. Implantation occurs about six days following fertilization, at which time it is possible with very sensitive urinary assays to detect early signs of pregnancy [2]. Less sensitive tests, such as home pregnancy urinary testing kits, are only reliable two or more weeks after fertilization. Usually, the first recognizable sign of pregnancy is a delay in the expected onset of menstruation, although this is not a very specific indicator, as there are many other factors that can be responsible for menstrual delay. Clinical signs of pregnancy other than lack of menstruation are not apparent before six weeks.

The Male Partner

By contrast to the woman, who only ovulates once in each cycle, sperm production is a continuous process. The sperm are formed in the testes and stored in the epididymis ready to be released during ejaculation. A typical ejaculate contains between 100 million and 400 million sperm, only a small proportion of which are viable, motile, and able to swim towards the ovum. Only a few hundred actually reach the ovum and only a single sperm is required for fertilization. Sperm can survive in the female genital tract up to four or five days following ejaculation. The spermatogenic cycle (time from the formation of spermatogonia to the production of mature sperm capable of fertilization) takes about 90 days.

The factors that affect male fertility are less well understood than for the female. Male fertility declines naturally with age, and a number of environmental pollutants and toxic exposures can reduce sperm production and quality. In addition, there can be partial or complete blockage of the epididymis or vas deferens due to sexually transmitted diseases or other infections.

Opportunities for Contraceptive Methods

There are many factors that can disrupt the normal menstrual cycle, introduce variability, or prevent ovulation, fertilization, or implantation. Methods of fertility regulation target different stages of the process. For example, the method of periodic abstinence restricts intercourse to the infertile phases of the cycle; female hormonal methods reduce fecundity by blocking ovulation or implantation or changing the quality of cervical mucus to prevent the sperm ascending the genital tract. Barrier methods prevent contact between sperm and the ovum, while male hormonal methods reduce the production of spermatozoa. Sperm production is a complex process of precisely timed stages, any of which can be targets for the development of new methods of fertility regulation (see, for example, Hamilton & Saling [9]).

Some contraceptive methods act continuously and are permanent (e.g. male and female sterilization), some act continuously but are reversible (e.g. IUDs and hormonal methods), while others are used only around the time of intercourse (e.g. spermicides or barrier methods such as condoms and diaphragms). The coitus dependent methods require a high degree of compliance with correct method use to prevent pregnancy reliably, and it is difficult to separate the intrinsic efficacy of the methods from those factors that determine whether the method is used at all, and, if used, whether it is used correctly.

Biostatistical Challenges

The delay in recognition of pregnancy and the high rate of early pregnancy loss cause problems for estimating pregnancy rates and the efficacy of different contraceptive methods in **cohort studies**. First, when the decision to stop using a method is made, the woman may already be pregnant, although the pregnancy may not be recognized until later. It is unclear whether such an event should be counted as a contraceptive failure, or according to the expressed reason why the woman stopped using the method, or both. Some studies require an additional visit six to eight weeks after discontinuation of the method or release from the study to ensure that all pregnancies, including those not recognized at the time of discontinuation, are recorded. The second, though related, problem is to determine when fertilization actually occurred. In a cycle that does not result in pregnancy, menstruation usually starts about 14 days after ovulation, so the timing of ovulation can be made retrospectively. However, in a cycle in which fertilization and subsequent implantation occur, the exact time of ovulation cannot be determined accurately, unless there is daily monitoring of follicular growth or urinary metabolites [31]. In the absence of such methods, 14 days are usually added to the date of last menstrual period to give an "estimated date of conception", although this can be substantially in error if menstrual cycles are not regular. The third problem concerns the distinction between early "chemical" pregnancies detected by sensitive assays and clinically recognized pregnancies which can only be detected much later. About 20% of fertilized ova never reach the stage of implantation and a further 10% are lost before they result in clinically recognizable pregnancies. Thus, without a clear and consistent definition of pregnancy, rates reported from different studies are difficult to compare.

Some methods of fertility regulation are immediately effective while others require a delay before they become effective. Barrier methods, such as condoms or spermicides, which prevent contact between the sperm and ovum, are immediately effective and can be immediately reversed. Similarly, the IUD is effective from the moment it is inserted and its effect is rapidly reversed following removal. By contrast, currently available methods of male fertility regulation have a delayed effectiveness as the sperm production is stopped and the extra-testicular reserves of sperm are exhausted. This occurs with vasectomy, which prevents the sperm reaching the ejaculate, as well as with hormonal methods, which can reversibly suppress sperm production.

Many social, environmental, and personal factors determine which contraceptive methods are chosen and whether they are used correctly and consistently. These factors include the user's age, marital status, educational level, socioeconomic status, reproductive intentions, actual and perceived risks associated with use of different methods, access to appropriate family planning services, attitudes to unwanted pregnancy, and access to safe and appropriate methods for the termination of pregnancy. The interactions between these factors are complex and unique to each individual and vary according to time, personal circumstances, and place. While the goal is to develop biostatistical methods to assess contraceptive efficacy that can be generalized to other users, these factors are critically important in determining overall performance of a method. Moreover, the advantages and disadvantages of available methods will be weighed differently as individual circumstances evolve.

Historical Development

Effectiveness of a Method which is not Coitus-Related

The first comprehensive undertaking to record information systematically on large scale use of a contraceptive method was the Cooperative Statistical Program (CSP) for the Evaluation of Intrauterine Devices, which was established in the USA by the National Committee on Maternal Health in 1963 and supported by the Population Council. Although the IUD had been known and used since the 1930s, the CSP was the first attempt to evaluate the safety, effectiveness, and acceptability of a newly introduced contraceptive method by analysis of pooled data using uniform procedures and a systematic statistical approach. In 1970, the CSP reported on 23 917 insertions with 10 different devices [23] and showed features now known to be common to many different contraceptive methods. In particular, pregnancy and expulsion rates of the devices were higher in the first compared with subsequent years of use, pregnancy rates were higher among younger women, and removals due to medical reasons (primarily

complaints of increased pain and/or menstrual bleeding) were more common than removals for personal reasons. Thus, even with the early IUDs, their contraceptive efficacy was high (cumulative two-year pregnancy rates in the range 3–17%, compared with over 90% among women not using any method to avoid pregnancy), there were technical problems with the devices remaining in place (cumulative expulsion rates up to 30% at two years) but that "side effects" were the main factors leading to device removal (cumulative rates 15–40% at two years). About 60% of women still had the device in place two years after insertion.

Effectiveness of a Coitus-Dependent Method

The IUD is a device that is continuously effective (provided that it remains in place), does not interfere with sexual intercourse, and does not require any particular action by the user for its effectiveness. Thus the method effectiveness is the same as its effectiveness under typical conditions of use. By contrast, periodic abstinence methods require no external technology or devices. All rely for their effectiveness on rules of when to abstain from sexual intercourse in order to avoid pregnancy, and users may consciously or unconsciously depart from these rules. If the rules are not followed correctly, the efficacy of such coitus-dependent methods is much reduced, and this difference is reflected in two distinct measures of contraceptive efficacy – the method effectiveness under conditions of perfect use, and the method effectiveness under conditions of typical use. The distinction is important for methods which require a high degree of user compliance.

The recognition that fertile and infertile phases of a woman's menstrual cycle could be used to avoid pregnancy had been known since the 1930s [12, 15], but little work was done prior to 1970 with natural family planning (NFP) methods to study their effectiveness or investigate how their reliability and ease of use could be improved. In 1976, the **World Health Organization** initiated a five-country study of the ovulation method, which is based on recognizing changes in quantity and quality of cervical mucus to identify the fertile period [32]. A total of 869 volunteers of proven fertility with regular menstrual cycles kept daily records of menstruation, cervical mucus secretions, and acts of intercourse. Couples were instructed to abstain from intercourse during menstruation (because of possible early onset of the fertile period during the last days of menstrual bleeding), on alternate "dry days" prior to the onset of the fertile period (to minimize the difficulty of recognizing the onset of mucus secretion because of the presence of seminal fluid), and during the fertile period, which began on the first day of mucus secretion or the sensation of dampness or wetness detectable at the vulva. The "peak day" was defined as the last day on which fertile type mucus was recognized, and intercourse could be resumed on the fourth day after the peak day. Couples were thus required to abstain from intercourse for about half the menstrual cycle.

Almost 95% of women were able to identify accurately the fertile period of the menstrual cycle after an initial three-month training phase, and these entered a 12-month effectiveness phase. The cumulative discontinuation rate at the end of the effectiveness phase was 35.6%, the most common reasons for discontinuation being pregnancy (cumulative rate 19.6%) or desire for pregnancy (6.6%). Pregnancies were classified as method-related (all the rules for the method had been followed, and the peak day had been correctly identified), inadequate teaching or application of instructions (the record was only partially completed, the woman did not fully understand the method, had difficulty in recognizing the onset of wet days, or was confused as to which day following the peak was safe for resumption of intercourse), conscious departure from the rules (the couple knowingly made a decision to have intercourse, despite indications of fertility), or of uncertain classification. A total of 130 pregnancies were observed over 7514 cycles (22.5 pregnancies per 100 woman-years (*see* **Person-years at Risk**), assuming 13 cycles per year), of which 16 (2.8 per 100 woman-years) were method related, 22 (3.8 per 100 woman-years) were due to inadequate teaching or application of the method, 89 (15.4 per 100 woman-years) were due to conscious departure from the rules, and the remaining three were unclassified. The low pregnancy rate when the method was correctly used has stimulated further research into improved methods of identifying the fertile phase of the cycle, based for example on urinary metabolites [5, 13]. These would not require the couple to abstain from intercourse on alternate days prior to the onset of mucus secretion, and may be able to detect more accurately the timing of ovulation. They require less training in the recognition of

cervical mucus changes and no genital touching and therefore may be more accessible to a wider range of users. They may also require fewer days of abstinence and thus be less likely to result in departures from the rules and subsequent "user failures".

Method Failure or User Failure

Unfortunately, the method of analysis of pregnancy rates and assessment of contraceptive efficacy in this pioneering report were incorrect. The authors used the same denominator (total number of cycles of exposure) to compute all rates, but they divided pregnancies according to the different reported patterns of intercourse. The correct analysis requires each cycle also to be classified according to the reported pattern of intercourse. The number of pregnancies that occurred during correct method use should be compared with the number of cycles during which the method was correctly used, to derive the pregnancy or failure rate for correct method use. Similarly, the pregnancies that occurred following conscious departure from the rules need to be compared with the number of cycles when the rules were not followed, and not with the total number of cycles (*see* **Denominator Difficulties**). The only correct result in the original report is the overall pregnancy rate (22.5 pregnancies per 100 woman-years), the other rates given all being underestimates since the denominator is overestimated. However, the overall pregnancy rate is the most difficult to interpret and to generalize to other potential users of the method.

A major problem encountered with classifying each cycle according to the pattern of intercourse and rule breaking is that couples may be more likely to report acts of intercourse contrary to the rules in cycles in which a pregnancy in fact occurred, which would result in an overestimate of the pregnancy rate. For example, suppose there were 100 cycles during which intercourse occurred on a given fertile day, and these resulted in 30 pregnancies. If there is correct reporting of acts of intercourse in the pregnancy cycles, but only half of the acts in cycles that did not result in pregnancy are reported, the 30 pregnancies would apparently have occurred in 65 instead of 100 cycles. It is impossible to judge the extent to which this problem occurred with the WHO study, but the data collection methods were designed to minimize any such underreporting – volunteers were asked to maintain records on a daily basis and were visited by study staff monthly. In many cycles the visits would have taken place and the charts reviewed before any pregnancy had been recognized.

A subsequent reanalysis of the WHO study effectiveness phase data [24] showed that 16 pregnancies occurred in 6683 cycles of correct use, resulting in a "method failure" rate of 3.1 per 100 woman-years, about 12% higher than the originally computed method failure rate. However, the remaining 114 pregnancies occurred in 801 cycles in which rule breaking had been recorded, resulting in a pregnancy rate of 14.2% *per cycle* or 185.0 per 100 woman-years. Compare this result with the original report of 15.4 pregnancies per 100 woman-years for conscious departure from the rules. It is clear that the ovulation method does result in a low pregnancy rate when used correctly, but it is very unforgiving of any departure from the rules.

Overall Pregnancy Rate

The overall pregnancy rate is a weighted average of method failure rate and user failure rate, with weights proportional to the number of cycles of each type observed in the study. It is therefore difficult to interpret and generalize to other groups who may have a different proportions of perfect and imperfect use cycles. Better counseling of users, better teaching of how to use the method, different personal circumstances, and attitudes to an unplanned pregnancy would all change these proportions. Moreover, in the same population or group of volunteers these proportions may also be different, as the consequences of departures from the rules are known to them. Thus, not only can the overall pregnancy rate not be generalized to other groups, it does not even apply to a further study in the same cohort of volunteers! The other measures of failure – the pregnancy rate during perfect use, or the pregnancy rate when the rules were not followed – may be more applicable to other groups of users *when they adopt that particular pattern of intercourse*. The only assumption required to generalize these particular pregnancy rates to other groups is that the women have similar fecundity rates and their partners' fertility is comparable. We cannot be assured that this will be the case, and a rough assessment can only be made using indirect indicators of fertility. The women were of proven fertility, had regular menstrual cycles of length 23–35 days, were aged 34.5

(sd 6.2) years and their partners were aged 30.1 (sd 4.6) years. Thus the volunteers in the WHO study were selected so as to insure that only fertile couples were included, although the fertility of those who did not get pregnant during the study can only be presumed.

Pregnancy Rate Summary

During correct use of the ovulation method there were 16 pregnancies in 6683 cycles. This can either be expressed as a Pearl rate (usually pregnancies per 100 woman-years) or as the percentage of women who conceive within one year. Both statistics assume that the risk of conception in each cycle is constant (implying a **geometric distribution** for the number of cycles to conception) and when the **incidence rate** is low give very similar results. It is conventional to consider 13 cycles per year – in the WHO study the **median** cycle length was 27.7 days, corresponding to an average of 13.2 cycles per year. Thus the Pearl rate for correct method use is $16/6683 \times 1300$ or 3.11 pregnancies per 100 woman-years, with 95% **confidence limits** from the **Poisson distribution** (1.78, 5.05) pregnancies per 100 woman-years. The proportion of women conceiving within 13 cycles is $1 - (1 - p)^{13}$, where p is the probability of conception per cycle and gives the cumulative rate 3.07% (1.76%, 4.94%). When the incidence rate is low there is very little difference between the two statistics and it is often incorrectly assumed, by analogy with percentages, that the Pearl rate must lie in the range 0–100. However, when events are not rare, the two statistics give very different results. In the 801 cycles during which the rules were broken there were 114 pregnancies. Thus 14.2% (11.9%, 16.8%) of cycles resulted in pregnancy with corresponding Pearl rate 185 (155, 219) pregnancies per 100 woman-years. By contrast, the cumulative percentage of women conceiving within 13 cycles is 86.4% (80.7%, 90.9%). Thus the choice of statistic is important and the cumulative proportion conceiving within a specified period is preferred. It is also similar to the cumulative **life table** rate which is used to assess method failure and method discontinuation rates. However, the Pearl rate is simple to calculate and interpret, can be generalized to different types of exposure, and gives similar results when the incidence is rare. It thus has its uses, particularly when the incidence is low.

Constant or Decreasing Risks

Both statistics (Pearl rate and cumulative proportion conceiving within one year) assume that the **risk** (or **hazard rate**) of pregnancy in each cycle is constant, but, while this assumption may be appropriate for an individual, it is in general not true for a **cohort** of users. The cohort can be considered to consist of two types of women – those who adhere to the rules and those who do not. Since those who break the rules have a higher pregnancy rate than the others, they will drop from the risk set at a faster rate than those who adhere to the rules. After a number of cycles, the remaining cohort or risk set will have a smaller proportion of rule breakers and thus the cohort pregnancy risk will be lower. The problem of heterogeneity in time to event data is discussed in detail by Aalen [1]. This decreasing incidence rate applies not only to pregnancies in NFP studies, but also to other endpoints and other contraceptive methods. For example, in a cohort of IUD users, the younger, higher fertility women will become pregnant earlier, those prone to expel the device will drop from the cohort earlier, and those intolerant of or susceptible to side effects, such as menstrual disturbances, will discontinue method use earlier. Thus the study cohort changes in composition as the study progresses and event rates for all types of events decline with time. Within a limited time interval the cohort incidence rate may be constant, and the Pearl rate can provide a good summary measure in each interval. Similarly, annual cumulative life table rates, conditional on being at risk in the interval, can be computed to show how the incidence rate changes with time [33].

In the WHO NFP study, the overall pregnancy rate did decline with time, but the incidence rates were more nearly constant in the subgroups of women who adhered to the rules and among those who departed from the rules [24], illustrating how the changing composition of the cohort affects the overall incidence rate.

Possible Underreporting of Acts of Intercourse

The WHO study required daily records of mucus symptoms and menstruation as well as acts of intercourse. As a minimum, volunteers were required to record the last act before, all acts during, and the first act after the fertile period, with a note indicating whether all acts during the cycle had been

reported. A simpler design and instructions would have been to insist on all acts of intercourse being reported, irrespective of their timing relative to the fertile period. Although there were monthly reviews of the records by the study monitors and an assessment of the reliability of the information, there are strong suggestions in the patterns of pregnancy rates that substantial underreporting did occur. The percentage of imperfect use cycles which resulted in pregnancy were 12.6%, 7.7%, and 3.9% for women aged under 28 years, 28–34 years or 35–38 years, respectively, in Ireland, New Zealand, and the Philippines, while in India the corresponding pregnancy rates were 46.0%, 30.7%, and 16.8%, and in El Salvador they were 86.9%, 70.1%, and 45.4%, respectively. It is not plausible that the underlying fecundity of the volunteers is so different by country since the **eligibility criteria** were the same in all countries. Adjustment for other factors that might be related to pregnancy rates (such as reported frequency of intercourse) could not explain these large differences between countries. Moreover, the pregnancy rates among perfect use cycles were much more homogeneous between countries, and Trussell & Grummer-Strawn [24] concluded that acts of intercourse which occurred contrary to the rules were less likely to be reported when the cycle did not result in pregnancy, and the rate of such underreporting was higher in India and El Salvador than the other countries.

It is impossible to assess correctly perfect and imperfect use failure rates for methods which require a high degree of user compliance, such as the ovulation method, or male or female condoms, or the diaphragm, unless there is accurate, **unbiased** recording of all acts of intercourse and other features of coital behavior. The only statistic that does not require accurate records of coitus and method use is the overall pregnancy rate, but we have seen above that this rate is the most difficult to interpret. By contrast, the assessment of pregnancy rates for methods which are not coitus- or user-dependent, such as the IUD, can be made without the need for diaries, since the perfect use and overall pregnancy rates are the same.

The Steiner Model for Assessing Efficacy and Effectiveness

The importance of distinguishing between the efficacy of the contraceptive method when used correctly and the behavioral factors that determine whether the method is used correctly or at all was recognized by the authors of *Contraceptive Technology* [10]. A comprehensive review of the literature on contraceptive effectiveness [25] was undertaken and two main statistics were used to summarize the efficacy of different methods – the perfect use and typical use pregnancy rates.

This distinction has been widely used in subsequent publications (see, for example, Hatcher et al. [11]). More recently, Steiner et al. [21] proposed a theoretic model of contraceptive efficacy and contraceptive effectiveness that distinguishes clearly the different factors that govern the assessment of contraceptive methods. The couple's ability to conceive (fecundity of the female and fertilizing capacity of her partner) combined with the timing and frequency of intercourse determine the (unobservable) expected pregnancy rate R_{Exp} in the absence of contraception (see Figure 1). This expected pregnancy rate is reduced by the protection due to the contraceptive method under conditions of perfect use to yield the "perfect use pregnancy rate", $R_{\text{Obs,Perf}}$. The *efficacy* of the contraceptive method is defined as the

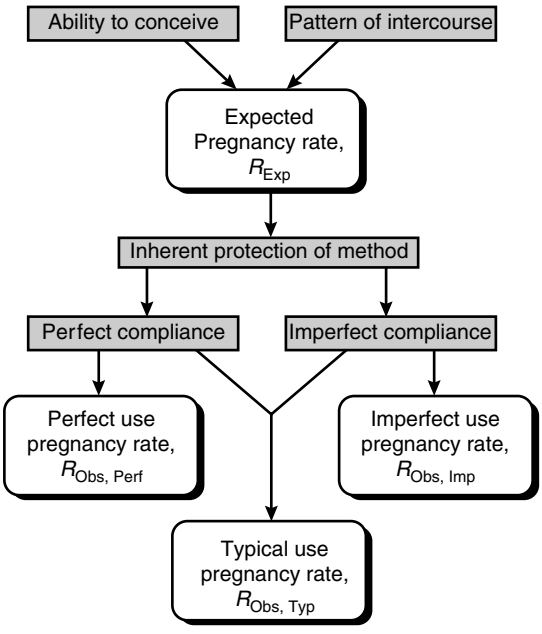

Figure 1 A conceptual model for contraceptive efficacy and contraceptive effectiveness (adapted from Steiner et al. [21])

preventable fraction under conditions of perfect use $1 - R_{\text{Obs,Perf}}/R_{\text{Exp}}$. When the method is used imperfectly, we observe the "imperfect use pregnancy rate", $R_{\text{Obs,Imp}}$. The difference between the two pregnancy rates is a measure of how unforgiving the method is of imperfect use. Similarly, the preventable fraction can be computed to give the efficacy of the method under conditions of imperfect use. In practice, there may be degrees of imperfect use, each with a different impact on the pregnancy rate, but only one type of imperfect use is shown in Figure 1 for simplicity. Most users or groups of users will have a mixture of perfect and imperfect use and we observe the "typical use pregnancy rate", $R_{\text{Obs,Typ}}$. The *effectiveness* of the method, the preventable fraction under conditions of typical use, is $1 - R_{\text{Obs,Typ}}/R_{\text{Exp}}$. Effectiveness is thus a measure that includes the degree of compliance with correct method use. The difference between efficacy and effectiveness rates depends not only on the pregnancy rates under conditions of perfect or imperfect use, but is also a function of the proportion of users who use the method perfectly, or the proportion of cycles in which the method is used perfectly. These proportions provide information on the degree of difficulty in using the method according to the rules for perfect use (assuming that subjects are trying to use the method perfectly to avoid pregnancy and do not deliberately use it imperfectly). Methods that do not require any particular intervention by the user, such as the IUD or sterilization, have the same typical and perfect use pregnancy rates, since the method cannot be used imperfectly. Thus IUD effectiveness is the same as IUD efficacy. However, oral contraceptives, which must be taken according to a fixed schedule, or coitus-dependent methods such as the condom, have a lower perfect than typical use pregnancy rate, and there can be a considerable difference between the efficacy and effectiveness of the method.

Contraceptive efficacy measures the inherent protection of the method and can thus be readily generalized to other populations and groups of users. In theory, the preventable fraction would be the same for users with different fecundity and patterns of intercourse. Similarly, the imperfect use pregnancy rate and preventable fraction under conditions of imperfect use can be generalized to other groups of users and can demonstrate the implications of imperfect use on pregnancy rates. By contrast, contraceptive effectiveness is very difficult to generalize, as the degree of compliance with correct method use (or proportion of perfect compliance users or cycles) depends on many factors that differ from one group to another, according to personal circumstances, and may also vary within the same couple from cycle to cycle. Although the typical use pregnancy rate is the easiest to observe, it is the most difficult to generalize.

The value of the model introduced by Steiner et al. [21] is that it focuses on what information is necessary to assess the different measures of a contraceptive method and generalize these to other users. Only in studies in which there is accurate recording of all acts of intercourse relative to the time of ovulation can the expected number of pregnancies be computed. Moreover, to distinguish between the effectiveness of the method under different patterns and types of use, accurate records of each use are required in an unbiased manner. In the NFP study, it was possible to classify cycles according to whether or not the rules for abstinence were correctly followed, and if not, according to the type of departure. However, a more complex example is the assessment of a barrier contraceptive method such as the diaphragm. If the day of ovulation and all acts of intercourse are accurately recorded, then the expected pregnancy rate R_{Exp} can be computed, but exact details of how the diaphragm was used for each act of intercourse (e.g. how long before intercourse it was inserted, how long it was left in place after intercourse, and whether spermicide was also used) are necessary to distinguish the different types of imperfect use, their associated pregnancy rates, and the efficacy of the method according to these different types of imperfect use.

Conceptions According to Different Times of Intercourse

To apply the Steiner model and estimate contraceptive efficacy, we need to know the probability of conception among couples not using any contraceptive method according to different patterns of frequency and timing of intercourse. Estimates of such conception probabilities have been derived from pregnancies among women who received a single insemination with donor sperm [19], from records of menstrual cycles, intercourse, and pregnancies among couples practicing the calendar method of NFP [4], and from records of couples planning pregnancies [31]. The analysis and interpretation of these conception probabilities is not straightforward, and there is currently

no consensus on the exact values for couples of normal fertility.

Donor Insemination

Schwartz et al. [19] reported on the success rate of artificial insemination with frozen donor semen among 529 presumed fertile women from infertile couples in which the male partner was either azoospermic or oligozoospermic (no or few sperm in the ejaculate). The day of ovulation was estimated from the basal body temperature (BBT) chart as the last day of hypothermia before the postovulatory rise. Data are available from 631 cycles with interpretable charts that resulted in 82 pregnancies. The proportion of cycles that resulted in a pregnancy (defined as at least three weeks of sustained hyperthermia from the BBT chart) is shown in Table 1 according to cycle day and show the highest pregnancy rate for inseminations on day -1. These results probably underestimate the chances of conception following coitus in couples of normal fertility, since the majority of infertile couples have some degree of fertility impairment in both partners [22]. While only couples with documented male factor infertility were included in the donor insemination series, reduced fecundity in the female partner is to be expected. Moreover, frozen donor semen may have a lower fertilizing capacity than fresh semen deposited during coitus.

The Barrett–Marshall Model

Conception probabilities according to cycle day among couples of normal fertility were obtained by Barrett & Marshall [4], who studied records of menstrual cycles, acts of intercourse and daily BBT charts for 241 couples, the majority of whom were practicing the calendar method of fertility regulation. Some couples also continued to record acts of intercourse and daily BBT charts in cycles in which they were attempting to achieve a pregnancy. By contrast to the donor insemination data, where there was only a single insemination per cycle, multiple acts of intercourse occurred in many cycles. Barrett & Marshall introduced a simple probability model for the probability of conception in a given cycle

$$P = 1 - \prod_i (1 - \pi_i)^{x_i}, \qquad (1)$$

where π_i is the probability of fertilization on day i and x_i is an indicator variable, which takes value 1 if intercourse takes place on day i and 0 otherwise. The results of the **maximum likelihood** fit are shown in Table 1 (using Schwartz' renumbering of the days before ovulation in preference to Barrett & Marshall's notation) and show reasonable agreement with the artificial insemination data.

A third set of conception probabilities was obtained by Vollman [29] from 74 couples who had been using periodic abstinence to avoid conception and then "agreed to have intercourse only once in the cycle for the next planned pregnancy". Although the data included cycles with more than a single act of intercourse, Vollman did not use model (1) but computed the conception probabilities directly from the number of conceptions that resulted from intercourse on a particular day by the number of cycles with intercourse on that day. This will have underestimated the conception probabilities.

These three sets of conception probabilities were smoothed by Dixon et al. [6] using a weighted **moving average** to reflect uncertainty in the exact time of ovulation which had been indirectly estimated from the BBT charts (Table 1). There is no theoretic reason or evidence that such smoothed estimates are more appropriate, and the highest chance of conception on day -1 is substantially less than that obtained from the original daily conception probabilities.

The Extended Schwartz–Barrett–Marshall Model

A limitation of model (1) is the assumption that the probabilities of conception from different coital acts in the same cycle are independent. If P_i is the probability of conception during a cycle with intercourse on day i, then the model implies that the probability P_{ij} of conception in a cycle with intercourse on days i and j is given by

$$P_{ij} = P_i + P_j - P_i P_j. \qquad (2)$$

Application of the independence model to cycles with multiple acts of intercourse leads to conception probabilities as high as 68% if intercourse takes place every day [18]. This appears to be too high, particularly in view of the rate of fetal loss within the first six weeks of pregnancy (the endpoint used by Barrett & Marshall). The model can be generalized to include

Table 1 Estimated conception probabilities relative to day of ovulation

Source	Data and model	Day of cycle (relative to day of ovulation)								
		−5	−4	−3	−2	−1	0	1	2	3
Schwartz [19]	Donor insemination (single insemination per cycle)		8%	20%	13%	21%	15%	11%	9%	
	Natural Family Planning cycles									
Barrett & Marshall [4]	Model (1)		13%	20%	17%	30%	14%	7%		
Dixon et al. [6]	Combined estimate (smoothed)	6%	10%	15%	17%	17%	14%	9%	5%	2%
Schwartz et al. [18]	Model (3)	4%	14%	20%	20%	34%	14%	7%		
	Direct estimates (cycles with a single coitus)	4%	20%	26%	15%	27%	15%	7%		
Royston [17]	Model (4)	4%	8%	16%	22%	22%	16%	7%	3%	1%
	Early Pregnancy Study									
Wilcox et al. [31]	Model (3)	10%	16%	14%	27%	31%	33%			
	Direct estimates (cycles with a single coitus)	8%	17%	8%	36%	34%	36%			

these other factors by writing the overall probability of pregnancy in a given cycle as $P = P_o P_f P_v$, where P_o is the probability of ovulation, P_f the probability that the ovum is fertilized, and P_v the probability that the fertilized ovum successfully implants and survives to the time of observation. Assuming that coital acts within the cycle are independent, we have, as before,

$$P_f = 1 - \prod_i (1 - \pi_i)^{x_i}.$$

The extended Schwartz–Barrett–Marshall model for the probability of conception in a cycle with coital pattern **x** is

$$P(\mathbf{x}) = kP_f = k\left[1 - \prod_i (1 - \pi_i)^{x_i}\right], \qquad (3)$$

where only the product $k = P_o P_v$ is estimable (*see* **Estimation**), since the probabilities of ovulation and ovum viability cannot be estimated separately from the observed pregnancies and coital patterns. Note that the probability of pregnancy in a cycle with intercourse on days i and j is now given by $P_{ij} = P_i + P_j - P_i P_j / k$ instead of (2) from the Barrett–Marshall model. The parameter estimates from model (3) obtained by Schwartz et al. to Barrett & Marshall's NFP data (extended by a small number of additional cycles; Table 1) are comparable to those from model (1). The combined ovulation/viability factor k was estimated to be 0.52, and the estimated probability of conception for a cycle in which intercourse occurs every day during the fertile period is reduced from 68% to 49%. Since all cycles included in the analysis had an ovulatory BBT pattern, the parameter k provides an estimate of P_v, the probability that the fertilized ovum survives to six weeks of pregnancy. There is also good agreement with the direct estimates of the conception probabilities from those cycles in which a single act of intercourse occurred in the fertile period (Table 1).

The model was further extended by Royston [17] who postulated that the probability of fertilization resulting from a single act of intercourse on the day of ovulation was 1 and declined **exponentially** according to the survival capacity of sperm and ovum for single acts before or after the day of ovulation. He also assumed that the viability of the fertilized ovum decreased linearly with the age of the woman. In addition, he allowed for uncertainty in the exact time of ovulation (indirectly estimated from the day of BBT shift) by averaging over an assumed **normal distribution** with **mean** 2 and **standard deviation** 1.25 days. The fitted conception probabilities (Table 1) show a maximum around days −2 and −1 with nonzero probabilities as far as day 3. Note that we have renumbered the days of the cycle so that day 0 corresponds to the last day before the BBT rise, instead of the first day of hyperthermia used in Royston's original paper. The viability of the fertilized ovum was estimated to be 0.48, close to that obtained in model (3), and declined by 0.022 for each additional year of the woman's age. The mean lifetime of the sperm was 1.47 days, twice as long as that of the ovum (0.70 days).

The Early Pregnancy Study

The fourth source of data on conception probabilities according to cycle day is records of couples enrolled in the Early Pregnancy Study [31]. This was a prospective study of 221 women planning pregnancy who kept coital and menstrual diaries and provided daily early morning urine samples for estimation of ovarian steroid metabolites. The exact day of ovulation was estimated from the rapid drop in the estrogen-to-progesterone ratio that occurs just before ovulation [3]. The primary objective of the study was to determine the **risk** of early pregnancy loss among healthy women, and thus a highly sensitive assay was used to detect pregnancies within six days of fertilization, around the time of implantation ("chemical pregnancies"). From a total of 199 chemical pregnancies, 48 ended within six weeks of last menstrual period and the remaining 76% were recognized clinically. The estimated conception probabilities obtained from these data for cycles in which a single act of intercourse took place are similar to those obtained from model (3) using all observed cycles (Table 1). The peak conception probabilities around the day of ovulation were in general higher than those seen with the donor insemination and NFP series, particularly for coitus on day 0 where the rates were more than twice as great. This is to be expected, since the study included chemical pregnancies. Interestingly, no pregnancies were observed for coital acts on the day after ovulation, although the authors could not exclude conception probabilities as

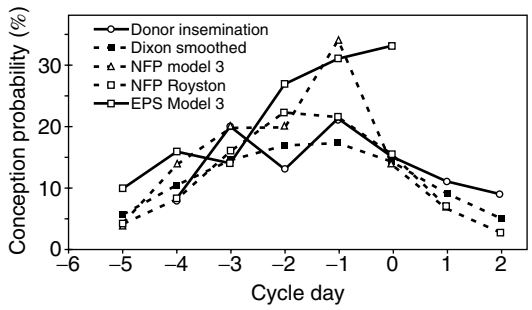

Figure 2 Estimated probabilities of conception arising from single acts of intercourse relative to the day of ovulation

high as 12% owing to the small number of total cycles observed.

Summary

The data described above are the only currently available sources of information on conception probabilities for acts of intercourse on different days of the cycle and some are plotted in Figure 2 for comparison. The artificial insemination data probably underestimate the true rates due to the potential for subfertility in the female. Similarly, the NFP data of Barrett & Marshall and Vollman are also probable underestimates, since they refer to couples who had been successfully using the method for some time and thus the highest fecundity couples will have either achieved a pregnancy or have changed to another contraceptive method. By contrast, the results from the Early Pregnancy Study are overestimates due to the inclusion of chemical pregnancies. A further analysis of these data considering only the clinically recognized pregnancies has recently been completed [27].

Studies of Emergency Postcoital Contraception

Emergency postcoital contraceptive methods protect against pregnancy after unprotected intercourse by reducing the viability of any fertilized ovum and preventing implantation. Although a variety of different hormonal regimens have been studied, the most widely used method is the Yuzpe regimen [34], which involves two high doses of estrogen and progestogen, the first taken within 72 hours of intercourse and the second 12 hours later. Each dose contains 500 μg of levonorgestrel and 100 μg of ethinylestradiol, which is about three times higher than the usual daily doses of hormones in the most widely used combined oral contraceptive pills (150 μg of levonorgestrel and 30 μg of ethinylestradiol). The majority of women request emergency contraception soon after a single act of unprotected intercourse during the fertile period, and thus the expected number of pregnancies can be estimated using the daily conception probabilities, either directly for a single act, or using model (3) if there were multiple acts. In general, the exact day of ovulation is not known and must be estimated from the usual menstrual cycle length and the date of onset of the previous menses. Any uncertainty in this estimate is not a problem for properly randomized comparative studies (*see* **Clinical Trials, Overview**) [30], since the comparison between treatment arms will not be biased. Similarly, differences between treatment arms will not be biased by calculations based on daily conception probabilities that are too low or too high (see, for example, Dixon et al. [6]), and the simple comparison of the number of observed pregnancies in the treatment arms [7] also provides a valid estimate of differences between the groups.

However, it is less easy to estimate the absolute efficacy of postcoital contraceptive methods. The overall pregnancy rate is a poor measure of the performance of such methods, since many cycles with unprotected intercourse will not result in pregnancy. A better measure is the preventable fraction, or efficacy rate, which has been estimated to be approximately 75% (95% confidence interval 68%–79%) by Trussell et al. [26], who reanalyzed data from ten studies of the Yuzpe regimen. However, the estimated efficacy rate for one study ranged from 55.3% to 67.1% according to which estimates of daily conception probabilities were used.

Estimating the Efficacy of Other Contraceptive Methods

While the conceptual model (Figure 1) and the estimates of conception probabilities (Table 2) clarify the information necessary to assess efficacy, these cannot provide estimates of efficacy for all contraceptive methods. Estimating the efficacy of emergency

contraception is straightforward, since the necessary information can be obtained by interview when the woman requests the method. Most users are exposed to a single act of unprotected intercourse and the method must be used within three days so that the timing of intercourse, usual length of menstrual cycle, and date of onset of the most recent menses can be accurately provided. This is by contrast to other coitus-dependent methods, for which information on coitus and menstruation is seldom sufficient.

Withdrawal (coitus interruptus) presents particular difficulties, since the method is used in ways that are difficult to observe – either it is used in emergency as a last resort when no other contraceptive methods are available, or it is used as a deliberate strategy for the prevention of pregnancy. The former type of user cannot be identified in advance, and any retrospective information collected on such users will be hopelessly biased by a greater reporting rate for cycles where pregnancy actually occurred. The second type of user will usually have poor access to reproductive health care services and will thus be difficult to identify. Nevertheless, any cohort of regular withdrawal users would be biased toward the better and more reliable users of the method. Information on the typical pregnancy rates of withdrawal must be obtained from other sources, such as **population based studies** or cohorts assembled for other reasons. For example, as part of the Romania 1993 Reproductive Health Care Survey, women provided information retrospectively on contraceptive and pregnancy history. These were combined to reconstruct periods of use of different contraceptive methods, the timing of any pregnancies, and the times and reasons for changing to another method. The 12-month cumulative life table pregnancy rate was found to be 30% [20]. This rate is more than four times higher than that estimated from a cohort of women participating in a long term prospective study conducted in England and Scotland by the Oxford Family Planning Association, which enrolled 17 000 British women aged 25–39 years using oral contraceptives, a diaphragm, or an IUD. In this cohort, the estimated pregnancy rate for withdrawal was 6.7 per 100 woman-years [28].

The wide discrepancy in estimated pregnancy rates from the UK cohort and the Romanian study illustrates the difficulties in assessing typical use pregnancy rates. The reproductive health care facilities in the two countries were widely different and the Oxford FPA cohort contained a large proportion of careful users. Indeed, a more representative group of married users in the UK yielded an estimated pregnancy rate of 21.9 per 100 woman-years [16] that is closer to the estimate from Romania. Note that it is almost impossible to obtain sufficient accurate information on menstruation and acts of intercourse among a group of withdrawal users to estimate the expected number of pregnancies. Thus the contraceptive efficacy of the method cannot be estimated, but only the typical use pregnancy rate.

Unresolved Problems

The first unresolved problem concerns estimates of daily conception probabilities. The extended Schwartz–Barrett–Marshall model has been shown to provide a good fit to data on conceptions and patterns of intercourse, and has proven its value for estimating conception probabilities according to different days relative to ovulation. It can also be applied to observed coital patterns to estimate the expected number of pregnancies in the absence of contraception and hence the contraceptive efficacy of different methods. The only outstanding issue is whether better or more data can be obtained on which to apply the model and derive more reliable estimates. Data on pregnancies arising from donor insemination or from users of natural family planning methods have their limitations, while studies of couples planning pregnancy, as in the Early Pregnancy Study, may yield more representative data. It is important to collect such information from a wide range of couples (different countries, age ranges, personal circumstances) to understand better the factors related to fecundity and fertilization probabilities. The availability of simple home testing methods to record urinary metabolites (see, for example, May [13]) would greatly simplify data collection and estimation of the day of ovulation.

The second unresolved problem concerns the efficacy of other coitus-dependent methods and the simultaneous use of combinations of methods. As we have seen, typical use pregnancy rates can be obtained for coitus-dependent methods, but the requirement to record coital acts and estimate the day of ovulation make it very difficult to collect unbiased data that would permit calculation of the efficacy of perfect use and of various types of imperfect use. Such efficacy estimates will be valuable

in counseling prospective users and predicting pregnancy rates among different types of user. An additional challenge is to establish typical use pregnancy rates and contraceptive efficacy of mixed method use; for example, use of a barrier method only during the fertile phase of the cycle. Theoretic typical use pregnancy rates can be estimated using the extended Schwartz–Barrett–Marshall and the contraceptive efficacy of barrier and natural family planning methods, but validation against observed data would be essential.

Resampling Procedures for Sample Surveys

One of the major statistical challenges in the development and application of complex **probability sample** designs is the valid **estimation** of sampling errors. Probability sampling theory and practice permits various departures from the **simple random, with or without replacement**, sampling model. These departures, which often take the form of **stratification**, **cluster sampling**, **multistage sampling**, and unequal probability of selection, are often used in order to produce sample designs that are both feasible and cost efficient. One of the drawbacks to these practical and efficient probability sample designs is the complexity and possible intractability that occurs with respect to the estimation of sampling errors. There are several basic methods linked to the general concept of resampling that have been developed for the estimation of sampling errors from complex (clustered and stratified) sample designs. These methods are discussed under three general headings: Simple Replication, **Jackknife** Repeated Replication, and Balanced Repeated Replication. It is interesting to note that while the use of a resampling technique known as the **bootstrap** has enjoyed wide use and acceptance in the general statistical literature, there have not been many attempts to apply simple bootstrap methods to complex applied probability sample designs. There has been some work by Rao and Wu [8], but they conclude that for certain classes of complex designs "the bootstrap variances estimators are less stable than those based on the linearization or the jackknife."

The basic approach of repeated replication in survey design was developed at the US Census [1] and built on the basic concepts of Mahalanobis [6]. McCarthy [7] introduced the idea of orthogonal balancing. It should be noted, however, that the use of replication in the form of "split-samples" was probably in use by psychologists prior to the development of probability sampling.

Simple Replication

The basic strategy of Simple Replication (*see* **Interpenetrating Samples**) or Replicated Subsamples involves four basic steps.

Assuming that the total sample is to consist of a primary selection (which will produce the desired sample size of n elements), a sample design is developed that will involve the selection of a/K primary sampling units. The value of K must be some integer greater than one and less than n (Deming [2] recommends the use of $K = 10$). A probability sampling design is formulated so that it may be repeated K times. Full flexibility is allowed in the sample design as long as the conditions required for probability sampling are satisfied. The sample design may be as simple as simple random or **systematic** selection of a/K elements with no stratification. It may be quite complex and involve stratification, clusters of unequal size, unequal probability of selection, and/or multiple stages of sampling.

Once the sample design has been specified, the actual sample selection process is carried out separately and independently a total of K times. Each repetition produces a replication or replicate. Let R_k denote the Kth replication or replicate. The set consisting of all K replicates constitutes the total sample $S : S = \{R_1, \ldots, R_k\}$.

Application of the estimation function $g(\cdot)$ for the particular survey estimate produces the total sample estimate $g(S)$. Let $g(R_k)$ denote the survey estimate produced from the kth replicate.

The simple replicated estimate of the sampling **variance** of $g(S)$ is

$$\text{var}_{\text{rep}}[g(S)] = \frac{1}{K(K-1)} \sum_{k=1}^{K} [g(R_k) - g(S)]^2. \quad (1)$$

The **standard error** of $g(S)$ is estimated as

$$\text{se}[g(S)] = \{\text{var}[g(S)]\}^{1/2}. \quad (2)$$

Confidence intervals based on this estimated standard error se$[g(S)]$ generally use the **Student's *t* distribution** with $K - 1$ "degrees of freedom".

It should be noted that (1) is an **unbiased** estimator of the sampling variance of $\overline{g(R_k)} = \sum g(R_k)/K$, the mean of the K estimates $g(R_1), \ldots, g(R_k)$. The use of (1) as a variance estimator for $g(S)$, the estimate derived from the total sample, depends upon the assumption that the **sampling distribution** of $g(S)$ is approximately equal to the sampling distribution of $\overline{g(R_k)}$. For certain simple statistics and simple sample designs, the two estimates $g(S)$ and $\overline{g(R_k)}$ are algebraically identical. This is the case for simple means

and proportions from simple random samples of fixed size n elements. For other more complex estimates (e.g. **regression** and **correlation** coefficients) and/or more complex sample designs (e.g. designs based on clusters of unequal size), these estimates may be different. For certain types of estimates based on **order statistics** (e.g. **medians** and percentiles (*see* **Quantiles**)) the impact of departures from this assumption may be substantial.

When first proposed, Simple Replicated Subsampling was seen as a sample design tool: that is, it was a model for sample designs that would permit simple and straightforward estimation of standard errors. The resampling took place in terms of generating K replications from the "sampling distribution". In many practical sample design situations, particularly those involving the presentation of legal evidence in either administrative or legal proceedings, the method has proven to be both simple and intuitively appealing for both statisticians and nonstatisticians. However, the method does have its limitations. The greatest limitation of the model is the limits that are placed on the complexity and efficiency of design. For example, a sample of 100 elements may, in its fullest complexity, utilize a stratification structure of 50 or even 100 strata. In a Simple Replicated Subsample Design which utilizes $K = 10$ replicates, the maximum number of strata is equal to 10.

The Simple Replicated Subsampling model is often used as a model for the computation of sampling errors, even in those situations in which it is not actually used in the sample design. That is, even when the sample is not selected in accord with the model, a pseudoselection model is formulated that reformulates the actual sampling process into a similar replicated subsampling process. This reformulation often involves a collapsing or combining of substrata within primary strata, after sample selection, for the purpose of standard error estimation. For example, a sample design might specify the selection of 100 elements from a population that is partitioned into 50 equal sized strata, with two elements selected per stratum. This design might be viewed as a replicated sample based on $K = 2$ or it might be reformulated, for purposes of sampling error estimation, into a design consisting of 10 strata with $K = 10$. The actual 50 strata would be collapsed or combined into 10 computational strata.

In most situations in which a design is reformulated for the purpose of standard error estimation, it is generally the case that the estimate of sampling error will be "conservative".

Jackknife Repeated Replication

Jackknife Repeated Replication (JRR) and Balanced Repeated Replication (BRR) are methods for standard error estimation that involve actual "resampling" or reuse of sample observations.

In their simplest forms, BRR and JRR assume a sample selection model based on a stratified design with two independent selections per stratum. This "paired selection" model assumes that the population is partitioned into $H = a/2$ strata, where a represents the total number of primary selections. Within each of these strata, it is assumed that there will be two independent primary selections. Following the first stage of sampling, there may be any number of subsequent stages, and selection may involve equal or unequal final probabilities for elements.

Jackknife Repeated Replication (JRR) estimates of sampling variance and standard error [3] are constructed as follows: we assume $H = a/2$ strata, each consisting of two primary stet units.

Let S denote the entire sample along with any weights that have been applied to the sample observations (including poststratification) associated with the full set of a primary selections.

Let J_h denote the hth jackknife replicate formed by including all sample observations not in the hth stratum, removing all sample observations associated with one of the two primary selections in the hth stratum, and including *twice* all sample observations associated with the other primary selection in the hth stratum.

Let CJ_h denote the hth complement jackknife replicate formed in the same way as the hth jackknife replicate J_h, *except* that the eliminated and doubled primary selections are interchanged.

Let $g(S)$ denote the total sample derived estimate for which a sampling variance is sought. Let $g(J_h)$ and $g(CJ_h)$ denote the same estimator applied to the hth jackknife replicate and complement jackknife replicate respectively. Note that it is assumed that any weighting process that has been applied to the total sample is applied to each jackknife and complement jackknife replicate as if they constituted the sample that was being used for estimation. (In those cases in which "reweighting" of each jackknife replicate is

not feasible, the original weights may be used, but this may result in some estimation **bias**. In practice, the magnitude of this bias is often negligibly small.)

There are two jackknife repeated replication estimates that are used to estimate the variance of $g(S)$ and corresponding standard error $g(S)$. These are defined as follows:

$$\text{var}_{\text{JRR-S}}[g(S)] = \frac{1-f}{2}\sum_{h=1}^{H}[g(J_h) - g(S)]^2 + \frac{1-f}{2}\sum_{h=1}^{H}[g(CJ_h) - g(S)]^2, \tag{3}$$

with

$$\text{se}_{\text{JRR-S}}[g(S)] = \{\text{var}J_{\text{BRR-S}}[g(S)]\}^{1/2}; \tag{4}$$

and

$$\text{var}_{\text{JRR-D}}[g(S)] = \frac{1-f}{4}\sum_{h=1}^{H}[g(J_h) - g(CJ_h)]^2, \tag{5}$$

with

$$\text{se}_{\text{JRR-D}}[g(S)] = \{\text{var}_{\text{JRR-D}}[g(S)]\}. \tag{6}$$

Confidence intervals based on these Jackknife Repeated Replication estimates of standard error generally use the Student's t distribution with H "degrees of freedom". The form $\text{se}_{\text{JRR}-\text{D}}[g(S)]$ given in (6) provides a more conservative estimate of standard error and is generally preferred [5].

Balanced Repeated Replication

Balanced Repeated Replication (BRR) estimates of sampling variance and standard error are constructed as follows: we assume $H = a/2$ strata, each consisting of two primary selections units.

Let S denote the entire sample along with any weights that have been applied to the sample observations (including **poststratification**) associated with the full set of a primary selections.

Let HS_i denote the ith half-sample formed by including all of the observations associated with one of the two primary selections from each of the strata; and let CHS_i denote the ith complement half-sample formed by all of the observations associated with the primary selections in S not in HS_i. The method used for choosing the pattern of primary units that form the half-samples HS_i and complement half-samples CHS_i is known as "full-orthogonal balance". In general, to achieve full-orthogonal balance it is necessary to form K half and complement half samples, where K is the smallest multiple of 4 that is equal to or greater than H. Given the K half- and complement half-samples, the two forms for BRR estimates of sampling variance and standard error are [4, 7]:

$$\text{var}_{\text{BRR-S}}[g(S)] = \frac{1-f}{2K}\sum_{i=1}^{K}[g(HS_i) - g(S)]^2 + \frac{1-f}{2K}\sum_{i=1}^{K}[g(CHS_i) - g(S)]^2, \tag{7}$$

with

$$\text{se}_{\text{BRR-S}}[g(S)] = \{\text{var}_{\text{BRR-S}}[g(S)]\}^{1/2}; \tag{8}$$

and

$$\text{var}_{\text{BRR-D}}[g(S)] = \frac{1-f}{4K}\sum_{i=1}^{K}[g(HS_i) - g(CHS_i)]^2, \tag{9}$$

with

$$\text{se}_{\text{BRR-D}}[g(S)] = \{\text{var}_{\text{BRR-D}}[g(S)]\}^{1/2}. \tag{10}$$

Confidence intervals based on these balanced repeated replication estimates of standard error generally use the Student's t distribution with H "degrees of freedom". The form $\text{se}_{\text{BRR-D}}[g(S)]$ given by (6) provides a more conservative estimate of standard error and is generally preferred [5]. For a more complete discussion of variance estimation in survey samples, readers should consult [9].

Residuals for Survival Analysis

The standard definition of a **residual** is the observed datum minus its expected value estimated from a model. Right-censoring precludes its direct application to survival data; a **censored** observation provides incomplete information on the failure time. Alternative definitions of residuals are needed. Three major ones are the generalized residuals of Cox & Snell [13], residuals based on **counting process** martingales and their transforms, and residuals from the **generalized linear regression model** [27] for loglinear **Poisson regression**. The first two are general, while the third is specific to the loglinear **proportional hazards** model of Cox [12] (*see* **Cox Regression Model**). In each case, there are interesting analogies between survival residuals and residuals for normal theory **linear regression**.

The proportional hazards (Cox regression) model is the most frequently used model for survival data, and we emphasize it. The notation and setup are as follows. On each of n independent individuals, one has observed a p-dimensional vector, $\mathbf{X}_i, i = 1, \ldots, n$, of predictor values (or **explanatory variables**), a non-negative random variable, T_i, the duration of follow-up time, and a binary indicator, δ_i, taking the value 1 if the follow-up terminates in the failure event of interest (e.g. death) and 0 if not. Underlying the variables T_i and δ_i is a pair of latent random variables: D_i, the time to failure of person i, and C_i, the time to censoring, where D_i and C_i are conditionally independent given $\mathbf{X}_i$; $T_i = \min(D_i, C_i)$ and $\delta_i = I(D_i \leq C_i)$, with $I(A)$ as the indicator function for event A. Also D_i is assumed to be an absolutely continuous random variable with probability density function $f_D(t)$ and survivor function $S_D(t) = \Pr(D > t)$. Interest centers on modeling the **hazard** function $\lambda_i(t) = f_{Di}(t)/S_{Di}(t)$. Under the Cox model, we have

$$\lambda_i(t) = \lambda_0(t) \exp(\boldsymbol{\beta}' \mathbf{X}_i). \tag{1}$$

The model is parametric if $\lambda_0(t)$ is a specified function of time or **semiparametric** if $\lambda_0(t)$ is unspecified. The covariate vectors may be functions of time; for simplicity, we initially assume that they do not vary over time.

Generalized Residuals

Suppose for the ith individual there exists a function h_i of data $\mathbf{Z}_i$ and parameter vector $\boldsymbol{\theta}$ such that $h_i(\mathbf{Z}_i, \boldsymbol{\theta}) = e_i$, where the e_is are independent and identically distributed of known distribution. Then the Cox & Snell *generalized residual* is $R_i = h_i(\mathbf{Z}_i, \hat{\boldsymbol{\theta}})$, where $\hat{\boldsymbol{\theta}}$ is the **maximum likelihood** estimator of $\boldsymbol{\theta}$.

Crowley & Hu [14] and Kay [22] were the first to apply this definition to censored survival data regression. The cumulative hazards $\Lambda_i(T_i)[= -\ln S_i(T_i)], i = 1, \ldots, n$, are distributed as a censored sample of independent unit **exponentials**, with $1 - \delta_i$ serving as a censoring indicator. Under the Cox model, $\Lambda_i(T_i) = \exp(\boldsymbol{\beta}' \mathbf{X}_i) \int_0^{T_i} \lambda_0(s)\, \mathrm{d}s$, and the Cox–Snell generalized residual is $\hat{\Lambda}_i(T_i) = \exp(\hat{\boldsymbol{\beta}}' \mathbf{X}_i) \hat{\Lambda}_0(T_i)$. Many investigators have proposed standard **hypothesis tests** and plots for assessing the exponentiality of these residuals as global checks for model **goodness of fit** [18]. A common plot is a graph of the ordered residuals on the abscissa with their **Nelson–Aalen** cumulative hazard estimator [5, pp. 445, 556] on the ordinate. If failure times are completely observed, it is just a graph of the ordered residuals against the expected values of exponential **order statistics**. Thus, this plot is the exponential analogue of the normal Q–Q plot for residuals from linear regression (*see* **Normal Scores**).

Unfortunately, the validity of these techniques is highly questionable for semiparametric models [7]. An illustrative extreme case occurs when there are no **covariates**. If the failure times are completely observed, the generalized residuals are *precisely* the expected order statistics of a unit exponential sample [15], and the Nelson–Aalen plot is exactly a 45° line through the origin. **Monte Carlo** simulations show that when there is censoring and one covariate, the appearance of the Nelson–Aalen plot depends on the variance of $|\boldsymbol{\beta}' \mathbf{X}_i|$, with the deviation from the 45° line increasing with the variance [7]. Thus, a model containing covariates may appear to fit less well than one with no covariates, even when the covariates have a substantial impact on the hazard. For parametric models, on the other hand, the generalized residuals behave like standardized residuals from **least squares** regression. The ordered residuals have the correct means but substantially smaller variances than the order statistics from the reference distribution, a unit exponential sample for survival data [7], and a standard Gaussian sample for least squares. The

assessment of exponentiality of generalized survival residuals provides a valid indicator of model appropriateness only for parametric models.

Generalized Linear Model Residuals

The formal similarity between likelihoods for proportional hazards models for survival data and **loglinear models** for **Poisson** data [4, 23, 33] has inspired the use of residuals developed for the generalized linear model which has Poisson regression as an important special case. Let $Z_i, i = 1, \ldots, n$, be independent Poisson variates with means $\mu_i = \exp(\boldsymbol{\beta}'\mathbf{X}_i)$, where $\mathbf{X}_i$ is a p-dimensional covariate vector. The basic "observed minus expected" residual is $z_i - \hat{\mu}_i$, but transformed residuals have proved more useful for model checking. Three of these, the Pearson, deviance, and partial residual have been adapted to the semiparametric Cox model. The Pearson residual is $(z_i - \hat{\mu}_i)/\hat{\mu}_i^{1/2}$, the deviance residual is $\text{sgn}(z_i - \hat{\mu}_i)\{2z_i ln(z_i/\hat{\mu}_i) - z_i + \hat{\mu}_i\}^{1/2}$ [27, p. 39], and the partial residual for the jth covariate is $(z_i - \hat{\mu}_i)/\hat{\mu}_i + \hat{\beta}_j x_{ij}$ [27, p. 402], $j = 1, \ldots, p$.

In the Cox model, the unit of analysis can be either each individual or, more finely, each individual at each death time. The residual definition depends on the choice of unit. For the finer level of analysis, let $T_1 < T_2 < \cdots < T_Q$ denote the ordered death times. Suppose r_q individuals are at risk of death at T_q^-. Let $\delta_{kq} = 1$ if individual $k, k = 1, \ldots, r_q$, at risk at T_q^-, died at T_q and 0 otherwise, for $q = 1, \ldots, Q$. Then, using the Whitehead [33] Poisson formulation, δ_{kq} is the analog of z_i. Conditioning on the **risk set** and assuming no **tied survival times**, the probability of death at time t_q for an individual at risk with covariate $\mathbf{X}_i$ is $p_q(\mathbf{X}_i) = \exp(\boldsymbol{\beta}'\mathbf{X}_i)/\sum_{k=1}^{r_q}\exp(\boldsymbol{\beta}'\mathbf{X}_k)$. The analog of μ_i is $p_q(\mathbf{X}_i)$, a conditional mean. Hall et al. [21] extend to Cox regression the adjusted variable plot from **multiple linear regression**. Their plot for the jth covariate contains $\sum_{q=1}^{Q} r_q$ points (one for each individual at each death time) whose coordinates have complicated formulas but can be interpreted as "adjusted z" versus "adjusted x_j", where the adjustment is for the other covariates, the Poisson weights, and the loglink function. A least squares line through the origin has slope $\hat{\beta}_j$, the maximum partial likelihood estimate from the Cox regression, and residuals equal to the Pearson residuals, $\{\delta_{jk} - \hat{p}_q(\mathbf{X}_k)\}\big/\hat{p}_q(\mathbf{X}_k)^{1/2}$, where $\hat{p}_q(\mathbf{X}_k) = \exp(\hat{\boldsymbol{\beta}}'\mathbf{X}_k)\big/\sum_{j=1}^{r}\exp(\hat{\boldsymbol{\beta}}'\mathbf{X}_j)$. As in linear regression, these plots show the partial leverage and influence of each unit on each β coefficient.

At the level of analysis where each individual is the unit, δ_i is analogous to z_i and $\hat{\Lambda}_0(T_i)\exp(\hat{\boldsymbol{\beta}}'\mathbf{X}_i)$ is analogous to $\hat{\mu}_i$. The analogy is purely formal because $\Lambda_0(T_i)\exp(\boldsymbol{\beta}'\mathbf{X}_i)$, itself a random variable, cannot be the expected value of δ_i nor can it be a conditional mean, since the correct conditional mean is given by

$$\mathrm{E}(\delta|T, \mathbf{X}) = \frac{f_{D|\mathbf{X}}(T)S_{C|\mathbf{X}}(T)}{f_{D|\mathbf{X}}(T)S_{C|\mathbf{X}}(T) + S_{D|\mathbf{X}}(T)f_{C|\mathbf{X}}(T)}.$$

The counting process martingale approach (below) gives a more probabilistic justification for the Poisson residual $\delta_i - \hat{\Lambda}_0(T_i)\exp(\hat{\boldsymbol{\beta}}'\mathbf{X}_i)$. The deviance transformation symmetrizes the distribution of the Poisson residuals and therefore the deviance residual can offer improvement for detecting **outliers** in some cases [31]. A plot of the partial residuals for the jth covariate against X_{ij} (see Figure 1) suggests

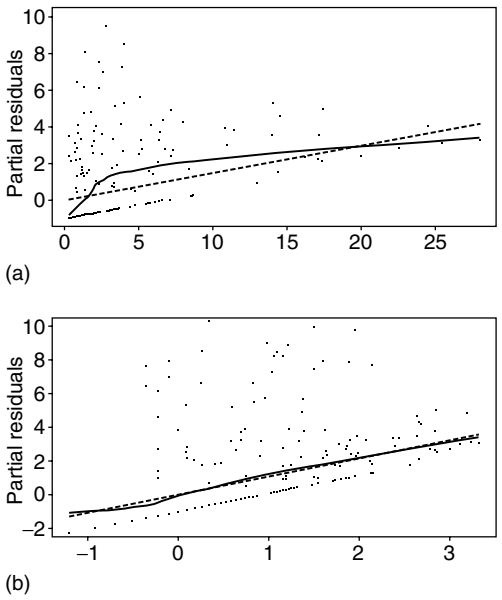

Figure 1 Partial residual plots for primary biliary cirrhosis data, comparing a model with bilirubin (a) to one with log bilirubin (b). The solid line is a weighted smooth, quadratic loess with span of 60% [10] and the dotted line is the fitted functional form from the model. Roughly 10% of the partial residuals are too large to fit on these plots; the vertical scale was chosen to enhance clarity

the correct functional form for the covariates in the linear predictor. As with Poisson regression, a scatterplot smooth superimposed on the residual plot is a useful guide; the smooth should weight each point proportional to $\hat{\mu}_i$ to stabilize variance and reduce bias. If the model is correct, then the smooth will give roughly a straight line with slope $\hat{\beta}_j$. If incorrect, the smooth will suggest the correct functional form. For example, a concave curve would suggest using $\log X_{ij}$ rather than X_{ij}. The primary biliary cirrhosis data [17, Appendix D] provides an illustrative example. Primary biliary cirrhosis (PBC) is a fatal liver disease. A survival model for PBC patients ($n = 312$) was developed and the bilirubin level in the blood was found to be the most important risk factor. The Figure shows the partial residuals from a Cox model with bilirubin as the sole predictor. The weighted smooth in Figure 1(a) is a concave curve, suggesting lack of fit for bilirubin with no transformation. When log bilirubin is used instead (Figure 1(b)), the weighted smooth approximates the line $\hat{\beta}$ log bilirubin quite closely, indicating a good fit for the log transformation. Analogous plots for more extensive models with multiple predictors have a similar appearance [20] and concur in supporting the log transformation as the appropriate functional form for bilirubin. If the covariates are highly correlated, an incorrect functional form for one covariate may influence the appearance of partial residual plots for other covariates. However, the augmented partial residual plot [26] for highly correlated predictors in linear regression works for Cox regression as well. In this technique, the regressors are quadratic polynomials instead of linear terms, and the partial residual is $[(\delta_i - \hat{\mu}_i)/\hat{\mu}_i] + \hat{\beta}_j x_{ij} + \hat{\gamma} x_{ij}^2$ plotted against x_{ij} [20].

Counting Process Martingale Residuals

A counting process $N(t)$ is a **stochastic process** with $N(0) = 0$, and with sample paths that are right-continuous step functions having jumps of size one. Typically $N(t)$ counts the number of events in $[0, t], t \leq \tau$, where τ is the prespecified time for the end of the study. Given a filtration, a sequence of increasing sigma-fields $\{\mathcal{F}_t, t \leq \tau\}$ to which $\{N(t), t \leq \tau\}$ is adapted, the Doob–Meyer decomposition gives

$$N(t) = A(t) + M(t),$$

where $A(t)$ is an increasing, predictable process called the compensator, and $M(t)$ is a mean-zero martingale. Usually $\mathcal{F}_t$ contains all available information on the counting process and any covariates through time t. Heuristically, $\mathrm{E}[\,\mathrm{d}N(t)|\mathcal{F}_{t^-}] = \mathrm{d}A(t)$, so the differential of the compensator gives the conditional probability of an event in the next instant of time, given the preceding history. Because $\mathrm{E}[M(t+s)|\mathcal{F}_t] = M(t)$, the martingale is a process without drift. It has uncorrelated increments and is a natural generalization of a white noise process. Thus, the Doob–Meyer theorem decomposes the counting process into two stochastic processes – a statistical model and a residual process.

Barlow & Prentice [8] laid down the framework for martingale residuals in survival analysis. Allowing for time-varying covariate processes, the data consist of independent triples $\{N_i(t), Y_i(t), \mathbf{X}_i(t); t \leq \tau, i = 1, \ldots, n\}$ and a filtration specified by

$$\mathcal{F}_t = \sigma\{N_i(u), Y_i(u^+), \mathbf{X}_i(u^+); \\ 0 \leq u \leq t, i = 1, \ldots, n\}.$$

In the single-event setting, emphasized here, $N_i(t)$ is 0 prior to the observed death of individual i and 1 at and after the death. For recurrent event data, $N_i(t)$ counts the events in $[0, t]$ occurring for individual i; $Y_i(t)$ is an adapted left-continuous at risk process, which takes the value 1 when individual i is at risk for an observed event and 0 otherwise. $\mathbf{X}_i(t)$ is a vector process, giving the value of p covariates over time for individual i. Suppose that time to death is independent of censoring, and the covariate processes are adapted and have sample paths that are left-continuous step functions with right-hand limits [17, Lemmas 1.4.1 and 2.3.1 and Theorem 4.2.3]. Then, the compensator for N_i is $A_i(t) = \int_0^t Y_i(u)\lambda_i(u)\,\mathrm{d}u$, where $\lambda_i(u)$ is the hazard function for individual i. The subject-specific martingale process is $M_i(t) = \int_0^t \mathrm{d}N_i(u) - \int_0^t Y_i(u)\lambda_i(u)\,\mathrm{d}u$. Transforms of these martingales provide a family of residual processes. Consider a predictable, locally bounded, possibly vector-valued process $H_i(t)$, defined in terms of data on the ith and possibly other subjects prior to t. The martingale transform $R_i(t) = \int_0^t H_i(u)\,\mathrm{d}M_i(u)$ is itself a mean-zero martingale. Furthermore, $\mathrm{cov}[R_i(s), R_j(t)] = 0$ for $i \neq j$, although R_i and R_j are not independent unless H_i and H_j are independent; $\mathrm{var}[R_i(t)] = \mathrm{E}\int_0^t Y_i(u)H_i(u)^{\otimes^2}\lambda_i(u)\,\mathrm{d}u$, where $a^{\otimes^2}$ is the outer

product of vector **a** and has (j, k) element = $a_j a_k$. Having fitted a model, one has estimates $\hat{\beta}$ and $\hat{\Lambda}_0(\cdot)$ and residual processes $\hat{R}_i(\cdot)$. The residual processes evaluated at $t = \tau$ have properties similar to the residuals from multiple linear regression. They sum to zero and are negatively correlated with asymptotic **correlation** $-1/n$. If the correct model has been fitted, then the residual processes have the patternless structure of martingales. Various choices of H_i can be used to detect different aspects of model inadequacy.

In the semiparametric Cox model, two choices of H have proved useful. $H = 1$ gives the estimated subject-specific martingale, $\widehat{M}_i(\cdot)$, which estimates the difference between the number of events observed up to t and the integrated conditional expectation under an assumed model. In the case of time-fixed covariates, $\widehat{M}_i(\tau) = \delta_i - \hat{\Lambda}_0(T_i)\exp(\hat{\boldsymbol{\beta}}' X_i)$, the Poisson residual discussed above. For the second choice, let $H_i(t, \boldsymbol{\beta}) = \mathbf{X}_i(t) - \mathrm{E}\mathbf{X}(t, \boldsymbol{\beta})$, where $\mathrm{E}\mathbf{X}(t, \boldsymbol{\beta}) = \sum_{i=1}^n \mathbf{X}_i(t) Y_i(t) \exp[\boldsymbol{\beta}'\mathbf{X}_i(t)] / \sum_{i=1}^n Y_i(t) \exp[\boldsymbol{\beta}'\mathbf{X}_i(t)]$, the weighted mean covariate vector of those at risk at time t. The score statistic (first partial derivative of the log likelihood) for the Cox partial likelihood can be written as $\sum_{i=1}^n \int_0^\tau H_i(t, \beta)\, \mathrm{d}M_i(t, \beta)$, and $\int_0^\tau \hat{H}_i(t)\, \mathrm{d}\widehat{M}_i(t)$ is the ith score residual. Let $\mathcal{I}(t, \beta)$, a $p \times p$ matrix, denote the negative Hessian of the Cox partial log likelihood; $\mathcal{I}(\tau, \hat{\beta})$ is the observed Fisher **information matrix**. The scaled score residuals, $\mathcal{I}(\tau, \hat{\beta})^{-1} \int_0^\tau [\mathbf{X}_i(t) - \mathrm{E}\mathbf{X}(t, \hat{\beta})]\, \mathrm{d}\widehat{M}_i(t)$, are infinitesimal **jackknife** measures of influence and approximate the change in $\hat{\beta}$ that would occur if the ith individual were deleted. They are the analogs of the dfbeta residuals from linear regression, which have a very similar formula, being proportional to $(\mathbf{X}^{\mathrm{t}}\mathbf{X})^{-1}\mathbf{X}_i\hat{r}_i$, where $\mathbf{X}^{\mathrm{t}}\mathbf{X}$ is the information matrix [9, p. 13]. The sum of the outer products of the dfbeta residuals gives the famous sandwich estimator for the variance of $\boldsymbol{\beta}$ [25].

Suppose the individuals are not independent but come in independent clusters. Examples include time to blindness, where the cluster is the pair of eyes, and studies of households, where the individual lifetimes are clustered into families. A simple approach is to fit a model assuming independence of individuals and then correct the estimated variance of $\hat{\boldsymbol{\beta}}$ for within-cluster covariance. The sum of the dfbeta residuals within each cluster measures the influence of the cluster on β. The sum of the outer products of these summed cluster dfbeta residuals provides a consistent variance estimator which takes into account the within-cluster correlation. This approach provides a simple computational method for the marginal models of Wei et al. [32] as one example.

The integrands of the score residuals are themselves useful residuals. Suppose we have time-fixed covariates and let $\mathbf{X}_{(k)}$ denote the covariate vector of the individual with the event at t_k. Then $\mathbf{X}_{(k)} - \mathrm{E}\mathbf{X}(t_k, \hat{\beta})$ is the Schoenfeld residual [30], useful for detecting nonproportional hazards. An alternative to proportional hazards is time-varying coefficients. Suppose the hazard function is

$$\lambda_i(t) = \lambda_0(t) \exp\left[\sum_{j=1}^p \beta_j(t) X_{ij}\right],$$

where $\beta_j(t) = \beta_j + \theta_j g_j(t)$, with $g_j(t)$ a predictable process for $j = 1, \ldots, p$. Proportional hazards holds if $\theta_j = 0$ for all j. Let

$$\mathbf{V}(t, \boldsymbol{\beta}) = \left[\sum Y_i(t) \exp(\boldsymbol{\beta}'\mathbf{X}_i)\mathbf{X}_i^{\otimes^2} \Big/ \sum Y_i(t) \times \exp \boldsymbol{\beta}'\mathbf{X}_i\right] - \mathrm{E}\mathbf{X}(t, \boldsymbol{\beta})^{\otimes^2},$$

the weighted covariate variance at t, where summation is over the n individuals. Then a Taylor's series expansion shows that

$$\mathrm{E}[\mathbf{X}_{(k)} - \mathrm{E}\mathbf{X}(t_k, \boldsymbol{\beta})] \simeq \mathbf{V}(t_k, \boldsymbol{\beta})\ \mathrm{diag}\ [\theta_j g_j(t_k)].$$

[19, 29, 30,] and a plot of the jth component of the scaled Schoenfeld residuals, $\mathbf{V}(t_k, \hat{\boldsymbol{\beta}})^{-1}[\mathbf{X}_{(k)} - \mathrm{E}\mathbf{X}(t_k, \hat{\boldsymbol{\beta}})] + \hat{\boldsymbol{\beta}}$, against event times suggest the functional form of $\beta_j(t)$, particularly when enhanced by a superimposed scatterplot smooth. A horizontal line is indicative of proportional hazards.

Extensions

Of the three survival residual definitions, the counting process martingale transformations have proved the most successful and have recently been extended to other survival models, beyond the semiparametric Cox model where they were originally developed. Lin & Spiekerman [24] consider a broad class of parametric regression models including proportional hazards and **accelerated failure time**. They suggest plotting martingale residuals against each covariate as an informal check on the correctness of functional

form for the covariate and plotting cumulative sums of martingale residuals, with several realizations simulated from the asymptotic distribution assuming correct functional form superimposed, to assess visually how unusual the observed residual pattern is. They suggest another cumulative residual plot for assessing goodness of link.

As discussed earlier, martingale residual transforms are also useful in assessing leverage and influence. Suppose the hazard has a general form as a parametric function of time and covariate vector, $\lambda_i(t) = \lambda(t, \mathbf{X}_i, \boldsymbol{\theta})$. The contribution of the ith individual to the score statistic is

$$\int_0^\tau \frac{\partial \ln \lambda(s, X_i, \hat{\boldsymbol{\theta}})}{\partial \boldsymbol{\theta}} \, \mathrm{d}\widehat{M}_i(s),$$

where $\widehat{M}_i(t) = N_i(t) - \int_0^t Y_i(s)\lambda(s, \mathbf{X}_i, \hat{\boldsymbol{\theta}}) \, \mathrm{d}s$. This is proportional to the infinitesimal jackknife measure of influence. Escobar & Meeker [16] suggest a quadratic form in these martingale transform residuals as a local influence statistic [11], an approximation to case deletion influence statistics, for parametric accelerated failure time models.

Martingale residuals are also useful in assessing goodness of fit in the linear regression model [1, 2]. The hazard is

$$\lambda_i(t) = \beta_0(t) + \boldsymbol{\beta}'(t)\mathbf{X}_i(t), \tag{2}$$

a linear function of the covariates with time-varying regression coefficients. Because the hazard model is linear, the estimated martingale residual processes $\widehat{M}_i(\cdot)$ are martingales rather than approximations to martingales, as with the loglinear Cox model [3]. Aalen [3] recommends two residual plots. The individuals in the data set are grouped, usually on the basis of similar covariate values, and an overall counting process, compensator, and martingale residual process are computed for each group, by summing the individual processes. The martingale residual process plot graphs each group's martingale residual against time. If the model fits well, then the plot fluctuates around the zero line and thus can identify groups or time intervals for which the model fits poorly, as shown by large deviations from zero. The Arjas plot [6] graphs the overall counting process against the estimated compensator for the group at each event time, thus comparing the "observed" and "expected" number of events (*see* **Real Time Approach in Survival Analysis**). The null configuration is the 45° line. Because the model is linear, the martingale residuals, $\widehat{M}_i(\tau)$, are directly useful in evaluating the correct functional form of covariates, unlike the Cox model, where the transformed residual $\widehat{M}_i(\tau)/\hat{\mu}_i$ is helpful for the partial residual plot. Aalen [3] recommends linear regression of the martingale residuals on curvilinear transformations of the covariates, such as low-order polynomials, to detect nonlinear covariate effects. Martingale transforms are useful for assessing influence. McKeague & Sasieni [28] consider a partially parametric linear hazard model with time-fixed covariates and hazard function

$$\lambda_i(t) = \boldsymbol{\beta}_1(t)'\mathbf{X}_{1i} + \boldsymbol{\beta}_2'\mathbf{X}_{2i},$$

where $\mathbf{X}_{1j}$ and $\mathbf{X}_{2i}$ are q- and p-dimensional covariates. They show that the infinitesimal jackknife influence measure for person i on $\hat{\boldsymbol{\beta}}_2$ is $\mathrm{var}(\hat{\boldsymbol{\beta}}_2) \int \{X_{2i} - \mathrm{E}[X_{2i}|X_{1i}(t)]\} W_{ii} \, \mathrm{d}\widehat{M}_i(t)$, where W_{ii} is the ith diagonal element of a user-defined weight matrix.

It is clear that martingale transform residuals provide a wide variety of diagnostic techniques for a broad class of survival models. As with linear regression, there is no single "one-size-fits-all" general-purpose residual.

Residuals

For the linear **regression** model with response $\boldsymbol{y}$ and fitted values $\hat{\boldsymbol{y}} = \boldsymbol{X}\hat{\boldsymbol{\beta}}$, the residuals are the vector of differences $\boldsymbol{y} - \hat{\boldsymbol{y}}$. Their great importance in the analysis of data lies in their use for checking agreement between the fitted model and the data. With a few exceptions, any pattern in the residuals is evidence either of an inadequate model or of irregularities in the data, such as **outliers**. The pattern suggests how the model may be improved.

In the next section, we describe some general purpose plots for regression residuals, which are helpful in detecting systematic differences between the fitted model and the data. Normal probability plots and simulation envelopes for their interpretation are described in the following section, before a discussion of deletion residuals. The succeeding two sections demonstrate two useful **graphical** procedures involving residuals: added variable plots for the inclusion of a new **explanatory variable** and the related constructed variable plots, demonstrated for a **power transformation** of the response. Residuals for **generalized linear models** and the constructed variable plot for examining the goodness of the link function conclude the entry.

Attention throughout is on the patterns made by residuals in suitable plots. Related material on influence of individual observations is in **Diagnostics**. The extension to the effect of groups of observations is described in the article on the **Forward Search**. Statistics based on aggregations of the residuals over the data are discussed in **Goodness of Fit**.

Least-Squares Residuals

In the **multiple regression** model

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{1}$$

$\boldsymbol{y}$ is the $n \times 1$ vector of responses, $\boldsymbol{\beta}$ is the $p \times 1$ vector of parameters and it is assumed that the additive errors of observation ε are independently distributed with constant variance σ^2. Also in (1) $\boldsymbol{X}$ is the $n \times p$ **matrix** of carriers, that is of explanatory variables and perhaps functions of them, such as quadratics (*see* **Polynomial Regression**) and interaction terms. The observation y_i together with $\boldsymbol{x}_i^T$, the ith row of $\boldsymbol{X}$, form the ith case. The **least-squares** estimate of $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y}. \tag{2}$$

The least-squares residuals are given by

$$\begin{aligned}\boldsymbol{e} &= \boldsymbol{y} - \hat{\boldsymbol{y}} = \boldsymbol{y} - \boldsymbol{X}\hat{\boldsymbol{\beta}} = \boldsymbol{y} - \boldsymbol{X}(\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y} \\ &= (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{y} = \boldsymbol{A}\boldsymbol{y}. \end{aligned} \tag{3}$$

In (3) $\boldsymbol{I}$ is the $n \times n$ identity matrix and $\boldsymbol{H}$ is the "hat" matrix, so called because $\hat{\boldsymbol{y}} = \boldsymbol{H}\boldsymbol{y}$.

Before fitting any model, the data should be plotted to reveal the structure and suggest appropriate models. Once a multiple regression model has been fitted useful plots of residuals include the following:

- Residuals against fitted values $\hat{\boldsymbol{y}}$, to check for constancy of variance. If the variance of the residuals seems to increase with $\hat{\boldsymbol{y}}$, either weighted regression or a transformation of the data may be appropriate.
- Residuals against a variable $\mathbf{x}_{\text{out}}$ not currently included in the model. Any relationship between the two suggests including x_{out} in the model.
- Similarly, the residuals can be plotted against the variables $\boldsymbol{x}_{\text{in}}$ already in the equation. Any structure suggests that either a higher-order term should be included in the model, for example, $\boldsymbol{x}_{\text{in}}^2$ if $\boldsymbol{x}_{\text{in}}$ appears linearly in the model, or that $\boldsymbol{x}_{\text{in}}$ be replaced by a function $f(\boldsymbol{x}_{\text{in}})$, for example, $\log(\boldsymbol{x}_{\text{in}})$.
- Residuals e_i against lagged residuals e_{i-1}. If the observations are in time (or space) order, any pattern in this plot would suggest correlation between the observations, when ordinary least squares is no longer applicable. **Time series** methods should be used, for example the **structural time series** models described by Harvey [11].

Often, it does not make much difference whether the residuals used in plotting are the least-squares residuals $\boldsymbol{e}$ or the studentized or deletion residuals defined in the next two sections.

As a first example of the usefulness of these plots, we take the data from Royston and Altman [13] on mandible length as a function of gestational age in 167 fetuses with ages from 12 weeks. The data, plotted in Figure 2 of **Goodness of Fit**, show a clear

linear relationship, which is statistically highly significant. The plot of the residuals $\boldsymbol{e}$ from the regression of length on age against $\hat{y}$ m, given in Figure 1, shows that the variance of the observations is not constant and partly increases with fitted value. This is not surprising with nonnegative observations ranging from 8 to 45. If the percentage accuracy of the measurements is constant, a logarithmic **transformation** of the response $\boldsymbol{y}$ would yield a response with errors of constant variance. An analysis of these data with $\log(\boldsymbol{y})$ as response is in **Diagnostics**.

The second example is of data on the volume $\boldsymbol{y}$ of 70 shortleaf pine as a function of tree diameter x_1 and of height x_2. The data are tabulated by Atkinson [2] who discusses appropriate models. As a first analysis $\boldsymbol{y}$ was regressed on x_1 and x_2. Comparison of the geometry of the trunk of a pine tree with that of a cone suggests that a term in x_1^2 might also have to be included in the model. To help investigate this suggestion Figure 2 shows the plot of $\boldsymbol{e}$ against x_1. This interesting plot shows strong curvature, suggesting indeed that a term in x_1^2 should be included. The increasing scatter in the plot also suggests that the data may need transformation – the volumes range from 2.0 to 163.5 cubic feet, so measurement errors of constant variance are implausible.

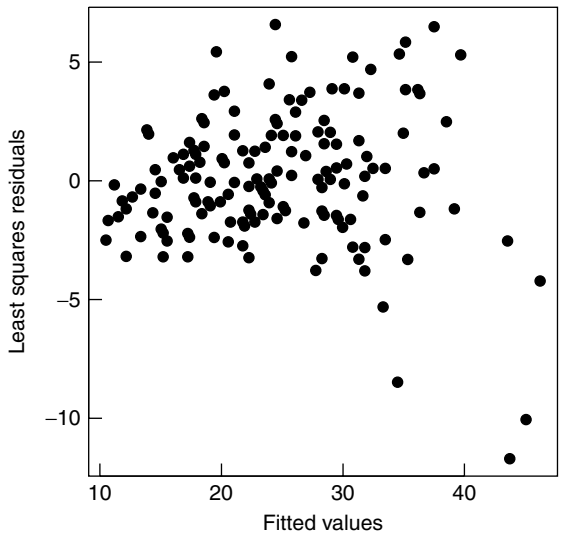

Figure 1 Mandible length data. Residuals $\boldsymbol{e}$ and fitted values $\hat{\boldsymbol{y}}$ from regression of length on gestational age. The increasing variance with $\hat{\boldsymbol{y}}$ suggests a transformation of the response

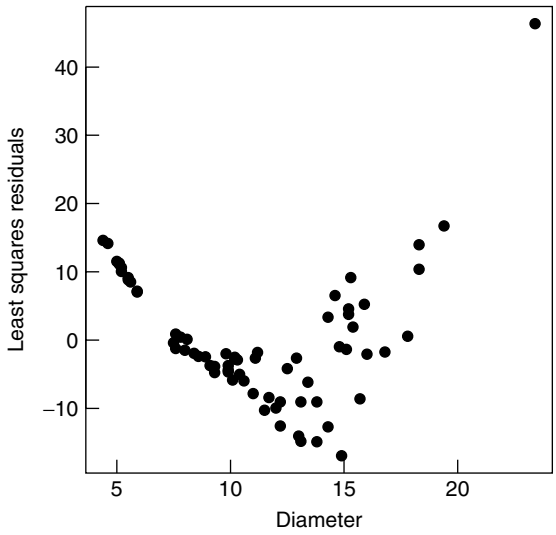

Figure 2 Pine data. Residuals $\boldsymbol{e}$ from regression of volume on diameter and height against diameter, x_1. The curvature in the plot suggests inclusion of a term in x_1^2. The heteroscedasticity again suggests a transformation of the response

Studentized Residuals and Envelope Plots

The plots of the preceding section indicate in a general way which, if any, departures are present from a model. In this and the following sections, descriptions are given of methods involving residuals, which are specific for particular problems, sometimes being derived from score tests. But we start with further consideration of residuals for the regression model.

The residuals $\boldsymbol{e}$ are not independent, nor do they have the same variance. It follows from (2) that they have covariance matrix $(\boldsymbol{I} - \boldsymbol{H})\sigma^2$, so that $\text{var}(e_i) = \sigma^2(1 - h_i)$, with h_i the ith diagonal element of $\boldsymbol{H}$. The *studentized residuals* r_i are given by

$$r_i = \frac{e_i}{s\sqrt{1 - h_i}}, \tag{4}$$

where $s^2 = \sum e_i^2/(n - p)$ is used to estimate σ^2. Although they are not uncorrelated, the r_i all do have variance one. Unfortunately, the nomenclature for residuals is not standard. The r_i are sometimes known as standardized residuals as well as *(internally) studentized residuals*.

The **normality** of the errors ε_i can be checked by a normal probability, or Q–Q, plot of the residuals e_i or

of the studentized residuals r_i. Figure 3 of **Goodness of Fit** gives a normal probability plot of the residuals e_i for the data on mandible length used in Figure 1. This plot is curved and suggests that the residuals are far from normal. However, the plot of the residuals from a fit of a quadratic in age to $\log(\boldsymbol{y})$ in Figure 1 of **Diagnostics** is much straighter, indicating that the transformation helps achieve normality.

The interpretation of residual plots is aided by an indication of how straight the plot can be expected to be. This guidance can be provided by **simulation**. One way is to simulate m sets of data using the fitted model, to calculate the n values of r_i for each simulation and then to produce m Q–Q plots, one per simulation. A comparison is made by eye to see whether the plot of the observed r_i differs in any systematic way from the m simulated plots. A more objective comparison, following Atkinson [1], is to use a simulation envelope. An envelope with 95% content can be constructed by taking the maximum and minimum, at each of the n observational points, of $m = 39$ simulated probability plots. The probability is then 1/40 that the observed value is the largest of itself and the 39 simulated values and 1/40 that it is the smallest, making the probability 5% in all that the observed value lies outside the envelope at each of the n plotting positions. The probability that, for example, at least one point lies outside the envelope is larger. However, the envelopes provide a useful calibration of probability plots, even if the exact probability of the observed plot lying in part outside the envelope is not known.

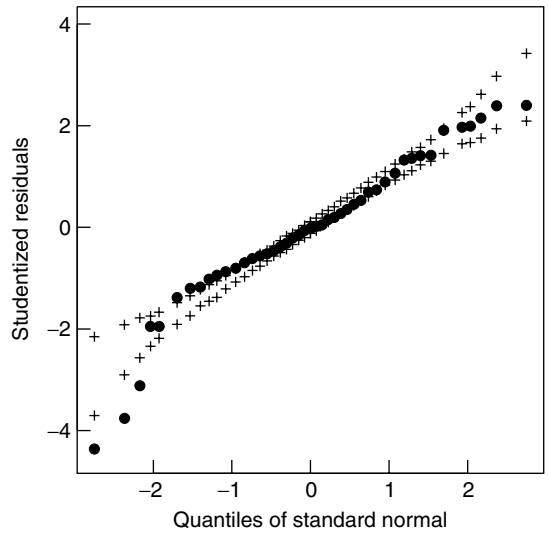

Figure 3 Mandible length data. Normal Q–Q plot of studentized residuals r_i from regression on age: •, residuals; +, simulation envelope. There is clear evidence of departure from normality

For many models, the simulations require estimation of the parameters of the model, in order to generate the simulated values of the data. However, the parameter estimates $\hat{\boldsymbol{\beta}}$ and s^2 are not required for the studentized residuals r_i from linear regression, as their distribution does not depend on the mean and variance of the y_i, but only on the **correlation** induced in the fitting process. The studentized residuals from fitting the linear model with the same matrix of carriers $\boldsymbol{X}$ as the data to a random normal sample therefore have the required distribution.

Figure 3 shows a normal Q–Q plot of the studentized residuals for the mandible length data. The residuals clearly show signs of nonnormality, both in the lower tail of the distribution and in the more moderate values where both positive and negative residuals fall outside the envelope. A smooth envelope was obtained by increasing the number of simulations to 119 and taking the third largest and third smallest values, again giving an envelope with pointwise 95% content. Because of the number of observations, 167, the central part of the plot is congested unless some points are omitted. Here, away from the tails of the distribution, every third or fifth point has been plotted.

Although this example is for studentized residuals from the **normal distribution**, the procedure can be used for other quantities, such as the Cook statistic for influence described in **Diagnostics**. Nonnormal data can also be simulated, for example, for generalized linear models, although, as was mentioned above, the parameters of the model fitted to the data may have to be used in the simulation. Examples for regression models are given by Atkinson [1] and by Venables and Ripley [18].

Deletion Residuals

Even if the errors ε_i have a normal distribution, the distribution of the studentized residuals is not normal, the distribution of r_i^2 being a scaled **beta**. In this section, we discuss the *deletion* or *(externally) studentized residual* r_i^*, which has a **Student's *t* distribution**. This is obtained from (4) on replacing

s^2 as an estimate of σ^2 by the deletion estimate $s^2_{(i)}$, that is, the mean square estimate from the $n-1$ observations excluding case i.Then

$$r_i^* = \frac{e_i}{\sqrt{s^2_{(i)}(1-h_i)}}, \tag{5}$$

has a t distribution on $n-p-1$ **degrees of freedom**.

In common with other deletion quantities for linear regression, the value of $s^2_{(i)}$ can be found exactly from the fit to all the data, the e_i and the leverage measures h_i. If $S(\hat{\beta})$ is the residual sum of squares for all n cases and $S(\hat{\beta}_{(i)})$ is the same without case i, the two estimates of σ^2 are

$$s^2 = \frac{S(\hat{\beta})}{n-p} \quad \text{and} \quad s^2_{(i)} = \frac{S(\hat{\beta}_{(i)})}{n-p-1}. \tag{6}$$

The relationship

$$S(\hat{\beta}_{(i)}) = S(\hat{\beta}) - \frac{e_i^2}{1-h_i} \tag{7}$$

provides a means of calculating $s^2_{(i)}$ and so r_i^*.

A discussion of deletion quantities such as r_i^* is given in **diagnostics**. If there is some systematic departure from normality, as is indicated by Figure 3, there is little to choose between plotting the studentized residuals r_i and the deletion residuals r_i^*, particularly if a simulation envelope is used to aid interpretation of the plot. However, if an outlier is present, particularly, at a leverage point, that is with a value of h_i close to one, the outlier will be revealed by the deletion residuals: the value of $s^2_{(i)}$ will be small, due to deletion of the outlier and so the value of the deletion residual will be large. An informative alternative derivation of $r^*_{(i)}$ is as the t statistic for the presence of an outlier, that is

$$r_i^* = \frac{y_i - \hat{y}_{(i)}}{\text{s.e. } (y_i - \hat{y}_{(i)})} = \frac{y_i - x_i^T \hat{\boldsymbol{\beta}}_{(i)}}{\text{s.e. } (y_i - \hat{y}_{(i)})}. \tag{8}$$

Q–Q plots, with envelopes, of deletion residuals are given by Atkinson [1]. Discussions of deletion diagnostics are also given by Belsley et al. [4], by Cook and Weisberg [7] and by Ryan [14].

Added Variable Plots

Figure 2 is a plot, for the pine data, of the residuals from the regression of volume on x_1 (diameter) and x_2 (height). One implication is that a term in x_1^2 should be considered for addition to the model. This implication can, of course, be examined by fitting the augmented model including x_1^2 and testing the extra term. To find out how the result of this test depends on individual observations an added variable plot can be used, which is a plot of two sets of residuals.

In general, the model $E(\boldsymbol{Y}) = \boldsymbol{X\beta}$ has been fitted and we are interested in the augmented model

$$E(\boldsymbol{Y}) = \boldsymbol{X\beta} + \boldsymbol{w}\gamma, \tag{9}$$

where $\boldsymbol{w}$ is $n \times 1$ and γ is scalar. The least-squares estimate $\hat{\gamma}$ can be found in the usual way by fitting (9) or by using the formulation of multiple regression as a series of linear regressions. For this, it is helpful to extend the notation for the least-squares residuals, (3) and let

$$\boldsymbol{e}(y) = \boldsymbol{e} = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{y} = \boldsymbol{A}\boldsymbol{y}. \tag{10}$$

Similarly, the residuals from regression of $\boldsymbol{w}$ on $\boldsymbol{X}$ are

$$\boldsymbol{e}(w) = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{w} = \boldsymbol{A}\boldsymbol{w}. \tag{11}$$

Then $\hat{\gamma}$ is found by the regression, through the origin, of $\boldsymbol{e}(y)$ on $\boldsymbol{e}(w)$, that is

$$\hat{\gamma} = \frac{\boldsymbol{e}^T(w)\boldsymbol{e}(y)}{\boldsymbol{e}^T(w)\boldsymbol{e}(w)}. \tag{12}$$

Further, the t test for γ when (9) is fitted is exactly that from (12), where the estimate of σ^2 is on $n-p-1$ degrees of freedom, rather than the apparent $n-1$. The output of statistical **software** may need adjustment on this point.

The added variable plot is the residual plot of $\boldsymbol{e}(y)$ against $\boldsymbol{e}(w)$. An advantage of the plot over that of $\boldsymbol{e}(y)$ against $\boldsymbol{w}$ itself is that the use of residuals allows for the effect of other variables in the model, with which $\boldsymbol{w}$ might be highly correlated. Since the plot has a direct regression interpretation, it can provide insight into the effect of individual cases on the evidence for including $\boldsymbol{w}$.

As an example, we return to the pine data. When volume is regressed on x_1 and x_2, the regression on x_2 is not significant. If x_2 is dropped and, following the indication of Figure 2, x_1^2 is included, the new variable is highly significant, with a t value of 13.49. It is then sensible, since much of the variability in the data has been accounted for, to check whether x_2 should now be included. The added variable plot

of Figure 4 accordingly shows the residuals from regressions on x_1 and x_1^2. There is a clear trend in the plot, suggesting the inclusion of x_2 and, in fact, the t value is 9.54. The scatter of points in the plot suggests that evidence for this regression is not confined to a few points, but is supported by all the data.

Further analysis of the pine data is given by Atkinson [2], including comparison with models for the Minitab tree data described by Ryan et al. [15]. Further examples are given by Cook and Weisberg [7] and by Atkinson [1]. In addition, both describe the use of *partial residuals* to provide a complement to the added variable plot, the partial residual plot which again has slope $\hat{\gamma}$. The procedure can be useful for suggesting functional forms $f(\boldsymbol{x})$ to replace regression on $\boldsymbol{x}$.

Constructed Variable Plots

The constructed variable plot extends the idea of the added variable plot to tests of nonlinear aspects of model specification, often through a Taylor series expansion. As an example, we take the Box–Cox power transformation of the response in a regression model.

The analysis of the data on mandible length shows appreciable evidence not only of the nonnormality

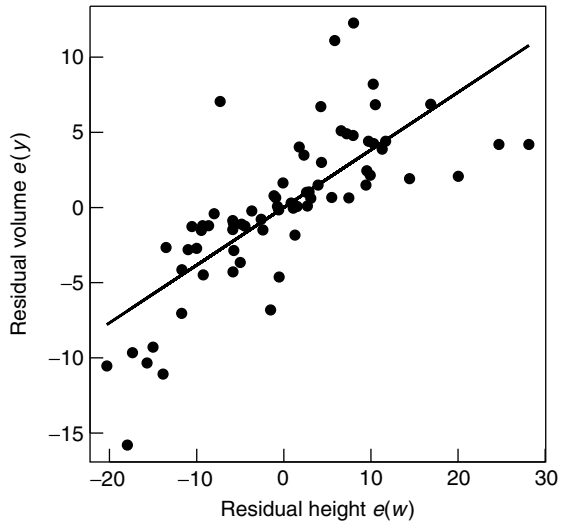

Figure 4 Pine data. Added variable plot. Residuals of $\boldsymbol{y}$ (volume) and height $\boldsymbol{w}$ after regression on diameter, x_1, and on x_1^2. Evidence that height should be included in the regression

of the residuals, Figure 3, but also of increasing variance with fitted value, Figure 1. Often, normality and constant variance can be achieved by fitting the regression model not to $\boldsymbol{y}$ but to a function of $\boldsymbol{y}$, many times $\log(\boldsymbol{y})$. The appropriate transformation frequently also leads to a simple linear model, without quadratic or interaction terms.

The logarithmic transformation is one special case of the normalized power transformation (Box and Cox [6])

$$z(\lambda) = \begin{cases} (\boldsymbol{y}^\lambda - 1)/\lambda \dot{y}^{\lambda-1} & \lambda \neq 0 \\ \dot{y} \log \boldsymbol{y} & \lambda = 0, \end{cases} \tag{13}$$

where the geometric mean of the observations is written as $\dot{y} = \exp(\Sigma \log y_i / n)$. If the residual sum of squares of the $z(\lambda)$ is $R(\lambda)$, the **profile** loglikelihood of the observations, maximized over $\boldsymbol{\beta}$ and λ, is

$$L_{\max}(\lambda) = -\left(\frac{n}{2}\right) \log \left\{ \frac{R(\lambda)}{n-p} \right\} \tag{14}$$

so that $\hat{\lambda}$ minimizes $R(\lambda)$.

For inference about the transformation parameter λ, Box and Cox suggest likelihood ratio tests using (14). A disadvantage of this likelihood ratio test is that a numerical maximization is required to find the value of $\hat{\lambda}$. For regression models, a computationally simpler alternative test is the approximate score statistic derived by Taylor series expansion of (13) as

$$\begin{aligned} z(\lambda) &\doteq z(\lambda_0) + (\lambda - \lambda_0) \frac{\partial z(\lambda)}{\partial \lambda}|_{\lambda=\lambda_0} \\ &= z(\lambda_0) + (\lambda - \lambda_0) \boldsymbol{w}(\lambda_0). \end{aligned} \tag{15}$$

In (15) $\boldsymbol{w}(\lambda_0)$ is the "constructed variable" for the transformation and can be treated as is the extra explanatory variable in (9). The approximate score statistic (*see* **Likelihood**) for testing the transformation, $T_p(\lambda_0)$, is then the t statistic for regression on $\boldsymbol{w}(\lambda_0)$ in (9). For the power transformation (13), the constructed variable is

$$\boldsymbol{w}(\lambda) = \frac{\boldsymbol{y}^\lambda \log \boldsymbol{y}}{\lambda \dot{y}^{\lambda-1}} - z(\lambda) \left(\frac{1}{\lambda +} \right) \log \dot{y}. \tag{16}$$

Provided the model for $z(\lambda)$ contains a constant, regression on (16) is equivalent, in the special cases of $\lambda = 1$ and 0, to regression on

$$\boldsymbol{w}(1) = \boldsymbol{y} \left\{ \log \left(\frac{\boldsymbol{y}}{\dot{y}} \right) - 1 \right\} \quad (\lambda = 1) \tag{17}$$

and

$$\boldsymbol{w}(0) = \dot{y} \log \boldsymbol{y} \left(\frac{\log \boldsymbol{y}}{0.5 \log y - \log \dot{y}} \right) \quad (\lambda = 0). \tag{18}$$

Box and Cox analyze a set of 48 observations on the survival times of animals in a 3×4 factorial experiment and show that a simple additive model is obtained for the reciprocal transformation, that is, for $\lambda = -1$. Rate of death, rather than survival time, is the quantity with a simple structure. If one of the observations for poison II, treatment A is changed from 0.23 to 0.13, the log transformation is indicated, rather than the reciprocal. Figure 5 shows the constructed variable plot for the altered data and the log transformation. The t value for regression on $\boldsymbol{w}$ is 1.15, so that there is no evidence, from this aggregate statistic, that the log transformation is not satisfactory. But, as the figure shows, the evidence for regression provided by the majority of the data is being annulled by the altered observation. When the observation is corrected, further transformation is indicated by the slope of the plot. The constructed variable plot for $\lambda = -1$ then shows no significant patterns.

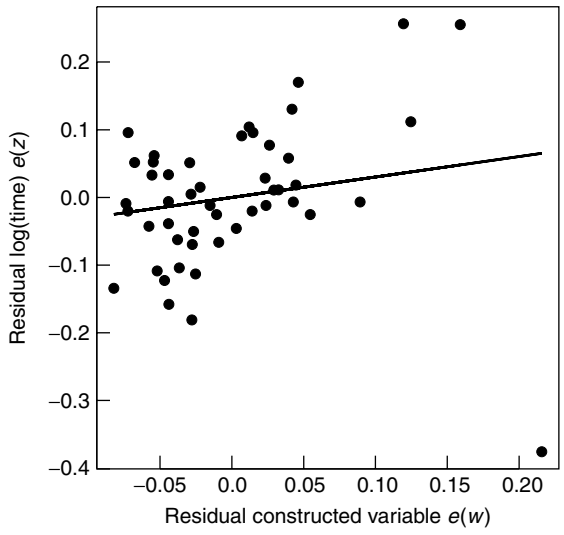

Figure 5 Poison data. Constructed variable plot for the log transformation of the altered data. The line is the regression of $\boldsymbol{e}(y)$ on $\boldsymbol{e}(w)$, which is rendered not significant by the one altered case

This example illustrates the use of the constructed variable plot of residuals against residuals in pinpointing the effect of this one observation on inference about the transformation parameter. Other plots, such as those of $\boldsymbol{e}(y)$ against $\hat{\boldsymbol{y}}$ also suggest that a transformation might be beneficial, but do not indicate the effect of individual cases on the estimated value of λ. An analysis of the poison data, including the altered data, is given by Atkinson [1] with a more complete analysis using the **forward search** in Atkinson and Riani [3]. Cook and Weisberg [8] and [9] describe the use of graphical methods in which λ can be varied interactively: the effects of the value of λ on the straightness of the Q–Q plot of residuals, or on the constructed variable plot, amongst others, can be assessed visually as a complement to the numerical choice of $\hat{\lambda}$. Similar methods can be applied to transformations of the explanatory variables or of both sides of the model mentioned in **Power Transformations**.

Generalized Linear Models

For the generalized linear model there are several definitions of residuals, with slightly different properties, which all reduce to the same quantity for linear regression. In the nomenclature of McCullagh and Nelder [12] the response y_i has expectation $E(Y_i) = \mu_i$, where μ_i is related to the linear predictor $\eta_i = \boldsymbol{x}_i^T \boldsymbol{\beta}$ by the link function $g(\mu_i) = \eta_i$. The variance of Y_i is given by $\text{var}(Y_i) = \phi V(\mu_i)$, where ϕ is the scale factor and $V(\mu_i)$ is the variance function. The **likelihood ratio** statistics for testing hypotheses about the parameters of the linear predictor are based on the differences of the scaled deviances $D(\beta)/\phi$. For the normal theory regression model of earlier sections, the link is the identity, $g(\mu_i) = \mu_i$, $\phi = \sigma^2$ and the deviance $D(\hat{\beta}) = R(\hat{\beta})$, the residual sum of squares. A slightly fuller description is given in **Goodness of Fit**. Three residuals are as follows:

- **Pearson Residual.**

$$r_{Pi} = \frac{y_i - \hat{\mu}_i}{\sqrt{V}(\hat{\mu})}, \tag{19}$$

so named since

$$\sum r_{Pi}^2 = \phi X^2, \tag{20}$$

where X^2 is Pearson's Goodness-of-Fit test (*see* **Chi-square Tests**).

- **Deviance Residual.** Since the observations are independent, the deviance D can be written as

$$D = \sum_{i=1}^{n} d_i^2. \tag{21}$$

The deviance residual is then

$$r_{Di} = d_i \text{sign } (y_i - \hat{\mu}_i), \tag{22}$$

so that r_{Di} and r_{Pi} have the same sign. The distribution of r_{Di} is closer to normal than that of r_{Pi}, although neither will be at all normal for small counts.

- **Deletion Residual.** For least-squares regression, the change in the residual sum of squares on the deletion of the ith case is given by (7), which is the square of the unscaled version of the deletion residual r_i^* (5). Taylor expansion of the change in deviance yields the deletion residual

$$r_{Gi} = \left\{ r_{Di}^2 + \frac{h_i}{1 - h_i} r_{Pi}^2 \right\}^{1/2} \text{sign } (y_i - \hat{\mu}_i), \tag{23}$$

which reduces to $e_i / \sqrt{(1 - h_i)}$ for linear regression. Unless points of high leverage are present (that is some h_i are near one), the deletion residual is close to the deviance residual.

The Pearson and deviance residuals can be studentized by division by $\sqrt{\{\hat{\phi}(1 - h_i)\}}$. The deletion residual can be scaled by the deletion estimate $\hat{\phi}_{(i)}$. In addition, the *working residuals* come from the last stage of the iteratively reweighted least-squares fitting algorithm used for generalized linear models.

Although residuals for generalized linear models can be informative, they are not so helpful as those for normal regression models. One problem is that the discreteness of the data, for **Poisson** and **binomial** models, can induce patterns that have nothing to do with good or bad fit. For example, Pearson residuals for binary data can only take two values, being proportional to either $1 - \hat{\mu}_i$ or $-\hat{\mu}_i$.

As an example where residuals are informative for binomial data with large n_i we turn to the data on the mortality of beetles from Bliss [5], analyzed in **Goodness of Fit**. There are readings at eight dose levels. When a **logistic model** is fitted with linear predictor $\eta_i = \beta_o + \beta_1 x_i$, the residual deviance is 11.23. Since $\phi = 1$ for the binomial distribution, the value is large although not significant at the 5% level when compared with χ_6^2. Figure 6 is a plot, against dose, of the observed and fitted proportions of insects killed. The figure suggests some systematic difference between the two sets of values, which is revealed in Figure 7. This shows the deviance residuals r_{Di} against x_i. There appears to be a U-shaped relationship between residuals and dose, suggesting perhaps that a quadratic term in x should be included. Inclusion of x^2 in the logistic model reduces the residual deviance to 3.19, a clear improvement in the model.

Goodness of Link Plot

In **Goodness of Fit**, a goodness of link test was derived for Bliss's beetle data using the constructed variable $\hat{\boldsymbol{\eta}}^2$. This, like the addition of x^2 in the logistic model, was significant, with a t value of 2.70. It is however possible that this aggregate value is being caused by one or a few cases, as happened in the analysis of the altered survival data. We therefore prepare a constructed variable plot for this test.

The plot is of the Pearson residuals from the fit of the logistic model against the residuals of $\hat{\boldsymbol{\eta}}^2$

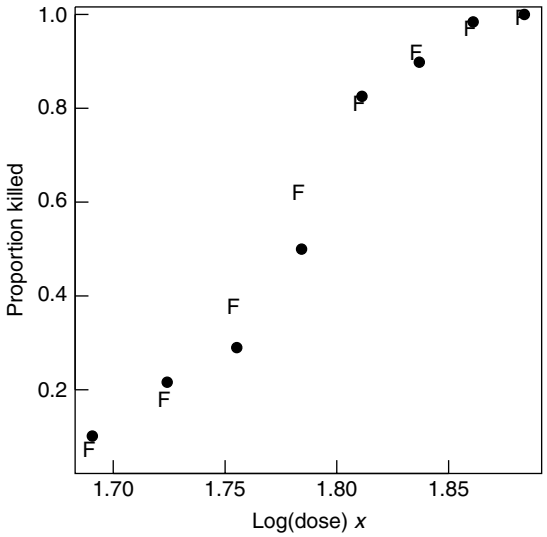

Figure 6 Beetle data. Observed and fitted values for a logistic model in logdose: ●, observed proportions; *F*, fitted. There seems to be a systematic difference between the two

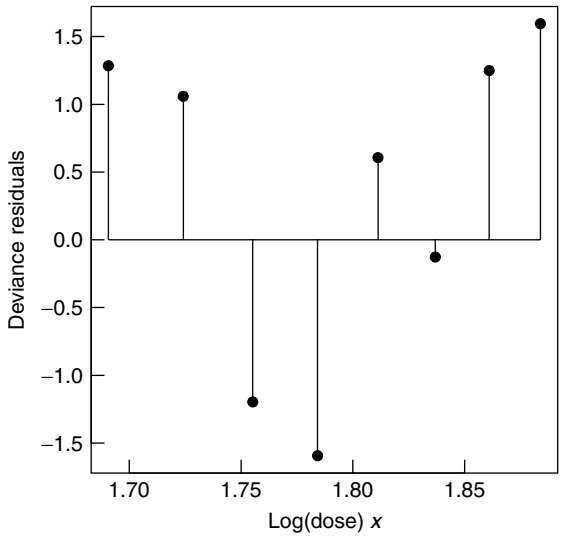

Figure 7 Beetle data. Deviance residuals against x. The curved pattern suggests including a term in x^2 in the model

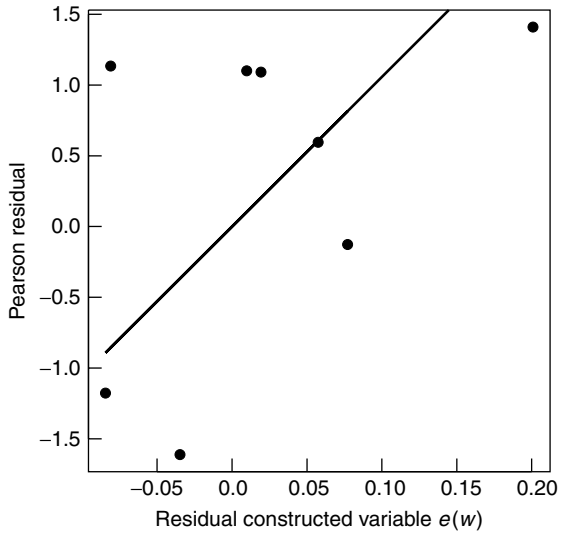

Figure 8 Beetle data. Goodness of link plot for the logistic model in $\boldsymbol{x}$, suggesting that the link is unsatisfactory

from weighted regression on x, the weights being those from fitting the generalized linear model. The plot in Figure 8 shows a trend shared by nearly all points, supporting the conclusion that the logistic link is generally unsatisfactory when combined with a simple linear model. If the complementary log–log model (*see* **Generalized Linear Model**) is used, the residual deviance is 3.45, close to the 3.19 of the quadratic model with the logistic link, but with one less parameter. In this case, the complementary log–log model appears preferable.

Discussion

A fuller discussion of residuals, especially for generalized linear models, is given by Davison and Snell [10]. Seber and Nyangoma [16] present more recent results on residuals for **multinomial** models. Therneau and Grambsch [17] is a book-length treatment of modeling **survival data** when **censoring** is present, including a chapter on residuals with SAS and **S-Plus** code. Other examples of the computation of residuals are given by Venables and Ripley [18]. Like the residuals described in this entry, these residuals are all based on least-squares or maximum likelihood estimation. Often, information on the adequacy of a model can be obtained by comparing such residuals with those from a very **robust** fit such as least **trimmed** squares or least **median** of squares. An example is given in **Diagnostics**.

The successful extraction of the information contained in residuals is aided by good graphical procedures. The flexible environment for data analysis provided by S-Plus permits the calculation and plotting of many kinds of residual (Venables and Ripley [18]). Cook and Weisberg [8] illustrate incisive graphical procedures, using their *Arc* package based on the *Xlisp-Stat* language. An introduction, with an emphasis on regression, is given by the same authors in [9]. Plots of residuals from robust fits during the **forward search** are described by Atkinson and Riani [3] for regression, response transformations, and generalized linear models.

A.C. ATKINSON

Response Effects in Sample Surveys

Sample surveys are the most widely used method for obtaining information from populations of interest because of their flexibility, but they are, of course, subject to **measurement error**, as are all forms of data collection. Response effects, as distinguished from sample **biases**, are those that are caused by the methodology for obtaining answers from respondents: the questions, the context of the questionnaire, the method of data collection, and the characteristics and behavior of interviewers.

For behavioral questions, where presumably there is a "true" answer, response effects are synonymous with response errors. For attitudinal questions, there is now a general recognition that there is not a single "true" answer, but that answers are context dependent. The differences in responses that depend on the survey context are called response effects.

Respondents' Tasks

In the past decade, a major thrust in understanding response effects has been to understand better the cognitive tasks faced by a respondent in answering a question. In general, there is wide agreement among researchers regarding the substantive nature of these tasks, although different researchers use somewhat different labels (see, for example, Groves [15], Strack & Martin [25], Tourangeau [30–32], and Tourangeau & Rasinski [33]).

As a first step, respondents have to interpret the question to understand what is meant. If the question is an opinion question, they may either retrieve a previously formed opinion from memory, or they may "compute" an opinion on the spot. To do so, they need to retrieve relevant information from memory to form a mental representation of the target that they are to evaluate. In most cases, they will also need to retrieve or construct some standard against which the target is evaluated. Once a "private" judgment is formed in their mind, respondents have to communicate it to the researcher. To do so, they may need to format their judgment to fit the response alternatives provided as part of the question. Moreover, respondents may wish to edit their response before they communicate it, due to influences of social desirability and situational adequacy.

Similar considerations apply to behavioral questions. Again, respondents first need to understand what the question refers to, and which behavior they are supposed to report. Next, they have to recall or reconstruct relevant instances of this behavior from memory. If the question specifies a reference period, then they must also determine if these instances occurred during this reference period or not. Similarly, if the question refers to their "usual" behavior, then respondents have to determine if the recalled or reconstructed instances are reasonably representative or if they reflect a deviation from their usual behavior. If they cannot recall or reconstruct specific instances of the behavior, or are not sufficiently motivated to engage in this effort, then respondents may rely on their general knowledge or other salient information that may bear on their task to compute an estimate. Finally, respondents have to provide their estimate to the researcher. They may need to map their estimate on to a response scale provided to them, and they may want to edit it for reasons of social desirability.

Accordingly, interpreting the question, generating an opinion or a representation of the relevant behavior, formatting the response, and editing the answer are the main components of a process that starts with respondents' exposure to a survey question and ends with their overt report. Each of these steps may influence the direction and magnitude of response effects.

Question Comprehension

The key issue at the question comprehension stage is whether or not the respondent's understanding of the question matches what the researcher had in mind: Is the attitude object, or the behavior, that the respondent identifies as the target of the question the one that the researcher intended? Does the respondent's understanding tap the same facet of the issue and the same evaluative dimension?

Belson [1–4] asked respondents after the interview to define what the question meant and clearly demonstrated that many respondents defined terms differently than the researcher intended. In addition, many of the terms used in public opinion research do not have clearly defined lexical meanings to begin with [6, 13, 14], and respondents who ask the interviewer to provide a definition are usually instructed

to define the concept for themselves. As a result, it remains often unclear what a term meant to a respondent. In a study by Fee [12] it was observed that there were at least nine different meanings for the term "energy crisis". Similarly, the term "big government" elicited at least four distinct representations: one referred to "big government" in terms of welfare and overspending; one in terms of big business and government for the wealthy; another one in terms of a combination of federal control and diminished states' rights: and a fourth in terms of bureaucracy and a lack of democratic process. Needless to say, it is nearly impossible to interpret the responses to a question without knowing which interpretation respondents chose.

Aside from the different meanings that individual respondents attach to questions, there are cultural differences as well. This means that cross-cultural comparisons between ethnic groups, whether in the same or different countries, are always subject to differences in interpretation. Finally, the meaning of a term may change over time, posing considerable problems for trend analyses.

Recalling or Computing a Judgment

Once respondents determine what the researcher is interested in, they need to recall relevant information from memory. In some cases, respondents may have direct access to a previously formed relevant judgment that they can offer as an answer. In most cases, however, they will not find an appropriate answer readily stored in memory and will need to compute a judgment on the spot.

Whether respondents can recall a previously formed relevant judgment from memory depends on whether such a judgment has been formed in the first place, and on whether it is accessible at the time of the interview. In the case of *attitude questions*, one of the key determinants is the personal importance of the issue and the degree of respondents' personal experience with the attitude object. Not surprisingly, issues of personal importance are more likely to elicit spontaneous judgments than less important ones. Moreover, some daily activities, such as major purchasing decisions, require the evaluation of different objects and, if the decision was made recently, the evaluations formed at that point may still be accessible in memory. In addition, the likelihood that a respondent has access to evaluative judgments of an attitude object increases with the degree of the respondent's personal experience with the object [11]. Finally, if respondents have been asked a related question before, the judgment formed at that time may still be accessible in memory, provided that little interfering information has been activated in the meantime.

In the case of *behavioral questions*, a relevant answer is most likely to be directly accessible if the behavior is of personal importance and has a low frequency of occurrence [8, 22, 26]. If the behavior is a frequent one, respondents are only likely to have direct access to a judgment if the behavior is highly regular, in which case they may remember a rate of occurrence, such as "once a week" [17]. For infrequent, irregular behavior, forgetting is the most serious problem. Forgetting takes two forms: forgetting that an event occurred at all, leading to under-reporting; and remembering that the event occurred, but mis-remembering when the event occurred, called telescoping [7, 27]. Telescoping usually results in over-reporting of events, because respondents recall events as occurring in the reference period whereas they actually occurred in an earlier period. It is possible to reduce omissions by using aided recall and other cueing methods. It is also possible to reduce telescoping by use of bounded recall methods [18, 29].

Most frequently, however, answers to survey questions are not stored in memory, and respondents will need to compute a judgment when asked. In the case of attitude questions, this is because issues are complex whereas survey questions are necessarily simple, as Schuman & Kalton [21] noted. Thus, even under conditions in which respondents can retrieve an opinion on the issue from memory, this opinion may not exactly match the facet tapped in the question. Similarly, respondents are unlikely to have an appropriate answer to most behavioral questions stored in memory. Even if they can recall relevant instances, they will still need to determine if these instances fit the reference period, and so on. As a result, most of the answers that we record in surveys reflect judgments that respondents generate on the spot, in the specific context of the specific interview. They are therefore strongly influenced by the information that is accessible at that time, which is in part a function of the preceding questions.

For behavioral questions, if the behavior is frequent, but irregular, respondents will estimate by computing a rate for a short time period and extrapolating [5]. The computed rate may be too high or too low because of forgetting, telescoping, or arithmetic errors (*see* **Recall Bias**).

Formatting the Response

Once respondents have formed a judgment, they cannot typically report it in their own words. Rather, they are supposed to report their judgment by endorsing one of the response alternatives provided by the researcher. This requires that they format their response in line with the options given. Accordingly, the researcher's choice of response alternatives may strongly affect survey results [23]. Respondents use the response alternatives as reflecting the researcher's knowledge of the population distribution for an item, with the middle response category reflecting the middle of the distribution. Then, they select an answer category based on whether they believe they are above average, below average, or average relative to the population. One obvious way to avoid this problem is to omit the answer categories (*see* **Questionnaire Design**).

Editing the Response

Finally, respondents may want to edit their response before they communicate it, reflecting considerations of social desirability and self-presentation. Not surprisingly, the impact of these considerations is more pronounced in face-to-face interviews, lower in telephone interviews, and lowest in self-administered questionnaires [10, 24].

Socially desirable behavior that has been studied includes voting, donating to charity, reading, and exercising [19]. Record checks generally reveal significant over-reporting for such behavior that is reduced as the method becomes less personal.

On the other hand, reports of illegal or socially undesirable behavior, such as traffic violations, alcohol consumption, and drug use, are substantially under-reported, and this under-reporting is not usually improved by using self-administered questionnaires. Some improvements are possible by making the questions less threatening and using **randomized response** procedures, but no method has been shown to produce accurate reports of highly threatening behavior such as drunken driving [9, 34].

Interviewer Effects

The visible characteristics of interviewers have been shown to impact responses, particularly to attitude questions. The most notable examples of this have been responses to questions about racial attitudes. Questions asked of white respondents by black interviewers result in more positive attitudes toward blacks than do questions of white respondents asked by white interviewers. Similarly, questions of black respondents by black interviewers result in more militant attitudes toward whites than when the interviewers are white [16, 20].

Similar effects are noted for other ethnic groups when the ethnicity of the interviewer is visible or is revealed by the interviewer's name. Also, interviewer effects are observed based on the gender of the interviewer for questions of men and women dealing with women's rights. No effects are observed when the visible characteristics of the interviewer are unrelated to the topic of the questions. Interviewer effects may also be observed if respondents give ambiguous answers to questions. Then, interviewer **variance** may be observed in how the answer is probed and recorded (*see* **Interviewer Bias**; **Interviewing Techniques**).

The Magnitude of Response Effects

We have discussed the causes and direction of response effects, but no attempt has been made here to quantify their magnitude (see Sudman & Bradburn [27]). For specific surveys, it is difficult to predict the magnitude of effects, especially since there will often be multiple effects, sometimes operating in different directions. Generally, however, response effects are often larger than sampling biases and, for reasonable sample sizes, much larger than sampling variance.

It is often possible, using recently developed cognitive methods, to reduce response effects significantly by careful design and testing of survey instruments and methods [28]. If this is possible, then it is almost always a better use of resources to attempt to do so, or at least to measure response effects, than simply to increase sample size to reduce sampling variances.

Response Surface Methodology

The main purpose of this methodology is to model the response based on a group of experimental factors presumed to affect the response, and to determine the optimal setting of the experimental factors that maximize or minimize the response. The factors are all quantitative and the objective is achieved through a series of experiments.

Let $F_1, F_2, \ldots, F_k$ be k factors affecting the response y and let $\mathrm{E}(y) = f(X_1, X_2, \ldots, X_k)$, where $X_1, X_2, \ldots, X_k$ are the levels of $F_1, F_2, \ldots, F_k$, and $\mathrm{E}(y)$ is the expected response. We assume f to be a polynomial of degree d. A k-dimensional design of order d is said to be constituted of n runs of the k factors $(X_{i1}, X_{i2}, \ldots, X_{ik})$, $i = 1, 2, \ldots, n$, if from the responses recorded at the n points all of the coefficients in the dth degree polynomial are estimable.

First-Order Design

Initially a first-order design will be used to fit the model $\mathrm{E}(y) = \beta_0 + \sum_{i=1}^{k} \beta_i X_i$. For this, one usually uses Plackett & Burman designs [15]. A Hadamard matrix $\mathbf{H}_m$ is an $m \times m$ matrix of ± 1 such that $\mathbf{H}_m' \mathbf{H}_m = m\mathbf{I}_m$, where $\mathbf{I}_m$ is the identity matrix of order m. A necessary condition for the existence of $\mathbf{H}_m$ is $m = 2$ or $m \equiv 0 \pmod 4$. If $4t - 5 \le k < 4t - 1$, in an $\mathbf{H}_{4t}$, the first column will be converted to have all ones, and any k columns of the last $4t - 1$ columns of $\mathbf{H}_{4t}$ will be identified with the coded levels of the k factors in $4t$ runs. These $4t$ runs and several central points $(0, 0, \ldots, 0)$ in coded levels constitute the design. If the lack of fit is significant, then one plans a second-order design at that center. Otherwise, one moves away from the center by the method of steepest ascent to determine a new center to plan a second-order design.

Method of Steepest Ascent

One maximizes the estimated response $\hat{y} = \hat{\beta}_0 + \sum_{i=1}^{k} \hat{\beta}_i X_i$ from the initial design on the contours $\sum_{i=1}^{k} X_i^2 = R^2$. The maximum occurs when $X_i \propto \hat{\beta}_i$. One decides desirable increments to proceed for factor F_i, determines the proportionality constant, and determines X_j for $j = 1, 2, \ldots, k$, $j \neq i$. In this way all coordinates in k dimensions are determined, to obtain Δ. Moving the center by incrementing $\Delta, 2\Delta, 3\Delta, \ldots$, one determines the expected $\hat{y}$. If $\hat{y}$ shows a maximum or minimum in the experimental region, then one moves the center to the setting at which $\hat{y}$ is optimum and carries out a second-order experiment. Otherwise, at a reasonable distance away from the original center, one performs another first-order experiment to determine a new path along which a center in the second-order experiment will be determined.

Second-Order Experiment

Let the design consist of F noncentral points and n_0 central points and let $n = F + n_0$. In the coded doses, without loss of generality, one assumes that:

$$\sum X_{i\alpha} = 0, \qquad \sum X_{i\alpha} X_{i\beta} = 0,$$

$$\sum X_{i\alpha} X_{i\beta}^2 = 0, \qquad \sum X_{i\alpha}^3 = 0,$$

$$\sum X_{i\alpha} X_{i\beta}^3 = 0, \qquad \sum X_{i\alpha} X_{i\beta} X_{i\gamma} = 0,$$

$$\sum X_{i\alpha} X_{i\beta} X_{i\gamma}^2 = 0, \tag{1}$$

$$\sum X_{i\alpha} X_{i\beta} X_{i\gamma} X_{i\delta} = 0, \quad \text{for } \alpha \neq \beta \neq \gamma \neq \delta;$$

$$\sum X_{i\alpha}^2 = n; \tag{2}$$

$$\sum X_{i\alpha}^4 = na,$$

$$\sum X_{i\alpha}^2 X_{i\beta}^2 = n\lambda_4, \quad \text{for } \alpha \neq \beta. \tag{3}$$

If $\mathbf{X}$ is the design matrix, then $\mathbf{X}'\mathbf{X}$ cannot be made diagonal in original parameters. However, in orthogonal polynomials of the factors settings, one may obtain **orthogonality** if $\lambda_4 = 1$. A second-order design is called orthogonal when $\sum X_{i\alpha}^2 X_{i\beta}^2 = n$.

A second-order design is said to be rotatable if the **variance** of the estimated response at $(x_1, x_2, \ldots, x_k)$ is a function of $\rho = \sum_{i=1}^{k} x_i^2$. For a rotatable design, we have $a = 3\lambda_4$ and $\lambda_4 > k/(k+2)$. The last inequality is needed to make $\mathbf{X}'\mathbf{X}$ nonsingular. By making $\mathrm{var}(\hat{y})$ the same at the settings at which $\rho = 1$ and $\rho = 0$, we obtain uniformly precise rotatable designs and, for them, λ_4 for different values of k are as shown in Table 1.

Table 1

k	λ_4
2	0.7844
3	0.8385
4	0.8704
5	0.8918

The nonzero central points are usually taken as follows:

1. A 3^n experiment or a fractional replication of a 3^n experiment in which main effects and two-factor interactions are not aliased with each other; with factor levels $-g$, 0, and g (*see* **Fractional Factorial Designs**).
2. A Central Composite Design (CCD), in which the factorial points form a 2^n experiment or a resolution 5 fractional replication with levels g and $-g$ and $2n$ axial points $(\pm\alpha, 0, \ldots, 0)$, $(0, \pm\alpha, \ldots, 0), \ldots (0, 0, \ldots, \pm\alpha)$.
3. A Box–Behnken design [3], in which the $v \times b$ incidence matrix of a **balanced incomplete block design** with parameters v, b, r, k, and λ, where $r = 3\lambda$, is used, in which the ones in each column are replaced by $\pm g$, so that the v factors are experimented in $b(2^k)$ runs.

The factor levels in the runs are determined so that the design is orthogonal, or rotatable, or uniform precision.

Let us illustrate using a CCD, which is orthogonal and rotatable in $k = 3$ factors. The noncentral points are $F = 8 + 6 = 14$ of the form $(\pm g, \pm g, \pm g)$, $(\pm\alpha, 0, 0)$, $(0, \pm\alpha, 0)$, $(0, 0, \pm\alpha)$. Let n_0 be the number of central points and let $n = 14 + n_0$. If one wants the CCD to be orthogonal and rotatable, one must have

$$8g^4 + 2\alpha^4 = 24g^4, \qquad 8g^4 = 14 + n_0.$$

Furthermore, condition (2) implies that

$$8g^2 + 2\alpha^2 = 14 + n_0.$$

An approximate solution is

$$\alpha = 2.197, \qquad g = 1.306, \qquad n_0 = 9.$$

Canonical and Ridge Analysis

Using a second-order design, one conducts an experiment and, using the data, fits a second-degree regression equation,

$$\hat{y} = \hat{\beta}_0 + \mathbf{X}'\hat{\boldsymbol{\beta}} + \mathbf{X}'\hat{B}\mathbf{X},$$

where $\mathbf{X}' = (X_1, X_2, \ldots, X_k)$ is the vector of the k factors settings, $\hat{\boldsymbol{\beta}}' = (\hat{\beta}_1, \hat{\beta}_2, \ldots, \hat{\beta}_k)$, and

$$\hat{B} = \begin{bmatrix} \hat{\beta}_{11} & \frac{1}{2}\hat{\beta}_{12} & \ldots & \frac{1}{2}\hat{\beta}_{1k} \\ \frac{1}{2}\hat{\beta}_{21} & \hat{\beta}_{22} & \ldots & \frac{1}{2}\hat{\beta}_{2k} \\ \frac{1}{2}\hat{\beta}_{k1} & \frac{1}{2}\hat{\beta}_{k2} & \ldots & \hat{\beta}_{kk} \end{bmatrix}.$$

The critical point at which the derivative of $\hat{y}$ with respect to $\mathbf{X}$ is zero is given by $\mathbf{x}_0$, where $2\hat{B}\mathbf{x}_0 = -\hat{\boldsymbol{\beta}}$. Letting $\mathbf{z} = \mathbf{X} - \mathbf{x}_0$, and $\hat{y}_0 = \hat{\beta}_0 + \mathbf{x}_0'\hat{\boldsymbol{\beta}} + \mathbf{x}_0'\hat{B}\mathbf{x}_0'$, the regression equation can be rewritten as $\hat{y} = \hat{y}_0 + \mathbf{z}'\hat{B}\mathbf{z}$.

Let $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_\kappa$ be the **eigenvalues** of $\hat{B}$, and let D be the diagonal matrix with elements $\lambda_1, \lambda_2, \ldots, \lambda_k$. Let M be an orthogonal matrix such that $D = M'\hat{B}M$, and let $\mathbf{w} = M'\mathbf{z}$. Then $\hat{y} = \hat{y}_0 + \sum_{i=1}^{k} \lambda_i w_i^2$, where $\mathbf{w} = (w_1, w_2, \ldots, w_k)$. This implies that at the critical value $\mathbf{x}_0$ local maximum is attained when $\lambda_1 \leq 0$, and a local minimum is attained when $\lambda_k \geq 0$. When the inequalities are strict, $\mathbf{x}_0$ is the unique critical value, whereas when the inequalities are not strict, $\mathbf{x}_0$ is a point at which a local maximum or minimum is attained. When some λ_i are positive and some negative, one may find an absolute maximum (or minimum) of $\hat{y}$ at concentric spheres of varying radii R_i. The estimated regression function $\hat{y} = \hat{\beta}_0 + \mathbf{X}'\hat{\boldsymbol{\beta}} + \mathbf{X}'\hat{B}\mathbf{X}$ is maximized (or minimized) such that $\mathbf{X'X} = \mathbf{R}^2$, and $\mathbf{x}^*$ satisfying $2(\hat{B} - \mu I_n)\mathbf{x}^* = \hat{\boldsymbol{\beta}}$ maximizes (or minimizes) $\hat{y}$ if $\mu > \lambda_k$ (or $\mu < \lambda_1$). For different choices of μ depending on the objective, $\mathbf{x}^*$ and R^2 will be determined. The $\hat{y}$ values at those $\mathbf{x}^*$ values will be determined, and $\hat{y}$ will be plotted against R^2 to find the absolute maximum or minimum in the region of experimentation.

Response Variable

In many data sets, there is a distinction between *response variables* and **explanatory variables**. If so, the primary questions of the analysis relate to how the response variables depend on the explanatory variables. The term *dependent variable* is often used as an alternative name for a response variable. Cox & Snell [1] indicate that response variables are the primary properties of interest and that explanatory variables hopefully explain systematic variation in the response variables.

Response variables are naturally defined when explanatory variables are fixed by an experimenter and the aim is to assess the effect of the explanatory variables on the subsequently measured response. However, it may be simply that the response variable is regarded as dependent on the explanatory variables. Alternatively, the aim of the analysis may be to predict the response on the basis of the explanatory variables. In all such cases, it is generally helpful if the distinction between variables is maintained in the analysis. The most natural example of this arises in the use of **regression** models.

There may be a number of response variables, perhaps regarded as a multivariate response variable. The formation of a single combined response variable or the separate consideration of the **univariate response** variables will often simplify the analysis. Otherwise, techniques of **multivariate analysis** become appropriate.

Cox & Snell [1] also distinguish intermediate response variables which may, for some purposes, also be treated as explanatory variables. For example, in a **clinical trial** in HIV-infected individuals, the primary response may be the time to the development of **AIDS**. The level of CD4 counts at some time after treatment could be used as an intermediate response to determine the effect of treatment on CD4 counts. The effect of treatment on the time to AIDS would also be investigated but, additionally, this could be examined when information on the changes in CD4 counts is used to define an additional explanatory variable. The latter analysis examines how much of the treatment effect on the primary response variable is accounted for by changes in the intermediate variable.

VERN T. FAREWELL

Restricted Maximum Likelihood

Restricted maximum likelihood estimation (REML) is an approach to estimation that maximizes the **likelihood** over a restricted parameter space. While applicable to more general models, it has most often been applied to the estimation of **variance components** in a **general linear model** with a **multivariate normal distribution**. It is an alternative to **maximum likelihood** (ML) estimation which leads to **unbiased** estimators. This method was first proposed by Patterson & Thompson [12] for a simple balanced data setting, and has been developed by Corbeil & Searle [2], Harville [8], and Dempster et al. [4]. Essentially, the procedure "adjusts" for the fact that the fixed effects are unknown when estimating components of variance. In balanced analysis of variance settings, this takes the form of an adjustment in **degrees of freedom**. In these settings, the REML estimators of the variances are the familiar unbiased **least squares** estimators.

In the case of the ordinary univariate **analysis of variance** (ANOVA) or **multiple linear regression** model, we have

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\alpha} + \boldsymbol{\varepsilon}, \tag{1}$$

where $\mathbf{Y}$ is an $N \times 1$ observed data vector, $\boldsymbol{\alpha}$ is a $p \times 1$ vector of fixed-effects parameters with $\mathbf{X}$ as its associated $N \times p$ design matrix, and $\boldsymbol{\varepsilon}$ is an $N \times 1$ vector of error terms. In this simple case we assume that the error terms are independent and distributed as $\mathrm{N}(\mathbf{0}, \sigma^2\mathbf{I})$. The ML estimator of σ^2 is sse/N, where sse is the residual sum of squares. This, however, is a biased estimator of σ^2, since its expectation is $\sigma^2(N-p)/N$. The REML estimator of σ^2 is, instead, sse/$(N-p)$, the usual least squares estimator of the residual variance, which is unbiased.

Now suppose that the $N \times 1$ vector $\mathbf{Y}$ follows a general linear model of the form

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\alpha} + \mathbf{Z}\mathbf{b} + \boldsymbol{\varepsilon}, \tag{2}$$

where $\boldsymbol{\alpha}$ is a $p \times 1$ vector of fixed-effects parameters, $\mathbf{b}$ is a $q \times 1$ vector of **random effects**, $\mathbf{X}$ and $\mathbf{Z}$ are design matrices of dimension $N \times p$ and $N \times q$, respectively, and $\boldsymbol{\varepsilon}$ is an $N \times 1$ error vector. This error term is assumed to have an $\mathrm{N}(\mathbf{0}, \mathbf{R})$ distribution, the random effects $\mathbf{b}$ are assumed to be distributed as $\mathrm{N}(\mathbf{0}, \mathbf{D})$, and $\boldsymbol{\varepsilon}$ and $\mathbf{b}$ are assumed to be independent. The variance of $\mathbf{y}$ is then $\mathbf{V} = \mathbf{Z}\mathbf{D}\mathbf{Z}' + \mathbf{R}$. The elements of $\mathbf{D}$ and $\mathbf{R}$ may be taken to be functions of a $k \times 1$ unobservable parameter vector $\boldsymbol{\theta}$. The variance of the error terms is often assumed to be $\mathbf{R} = \sigma^2\mathbf{I}$, where $\mathbf{I}$ is the identity matrix, although restrictions on $\mathbf{R}$ may be less severe. When the variance matrix $\mathbf{V}$ is known, the maximum likelihood estimator, $\boldsymbol{\alpha}_{\mathrm{M}}$, of the fixed-effects parameters is the least squares estimator with

$$\boldsymbol{\alpha}_{\mathrm{M}} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{Y}. \tag{3}$$

If $\mathbf{V}$ is unknown, then the estimator takes the same form, with maximum likelihood estimates of $\mathbf{D}$ and $\mathbf{R}$ substituted for the unknown parameters. As in the univariate case, however, these variance estimates may be biased, sometimes severely so.

Patterson & Thompson suggested dividing the data into two independent parts, each represented by an appropriate transformation of the $\mathbf{Y}$ vector. One of these is the set of error contrasts; the other is a set of linear functions of the fixed effects. Some candidates for suitable transformations are $\mathbf{SY}$ and $\mathbf{QY}$, where

$$\mathbf{S} = \mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}',$$

$$\mathbf{Q} = \mathbf{X}'(\mathbf{Z}\mathbf{D}\mathbf{Z}' + \mathbf{R})^{-1}.$$

In univariate regression, as in model (1), $\mathbf{SY}$ is the $N \times 1$ vector of residuals using the least squares estimate of $\boldsymbol{\alpha}$, and $\mathbf{QY}$ is the $p \times 1$ vector of sums of cross-products of $\mathbf{X}$ and $\mathbf{Y}$, divided by the residual variance σ^2. The matrices $\mathbf{S}$ and $\mathbf{Q}$ are not restricted to these forms; any full-rank matrix $\mathbf{S}$ with the property that $\mathrm{E}(\mathbf{SY}) = \mathbf{0}$ for all $\boldsymbol{\alpha}$ may be used. The log likelihood of the data, L, is also divided into the two corresponding parts L' and L'', with $L = L' + L''$. Patterson & Thompson use only the log likelihood of $\mathbf{SY}$ to estimate the variances $\mathbf{D}$ and $\mathbf{R}$. They claim that when the $\boldsymbol{\alpha}$ are regarded as fixed and unknown, linear functions of these, as in $\mathbf{QY}$, cannot provide information about variance parameters. By basing the variance estimators on the error **contrasts** only, the loss of degrees of freedom due to estimating the fixed effects is accounted for. Rao [14] also breaks down the data into the same component parts, but does not use this for estimation. He shows instead that the test for adequacy of the model can be performed using the error contrasts only. The next step is to use the likelihood for $\mathbf{QY}$ to estimate $\boldsymbol{\alpha}$, substituting the variance

estimates already found. The REML estimator of $\boldsymbol{\alpha}$ takes the form of (3) above, substituting the REML estimates for the unknown variances.

The REML estimators of $\boldsymbol{\alpha}$ and its variance are, therefore,

$$\boldsymbol{\alpha}_{\mathrm{R}} = (\mathbf{X}'\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{Y} \tag{4}$$

and

$$\mathrm{var}_{\mathrm{R}}(\boldsymbol{\alpha}) = (\mathbf{X}'\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{X}^{-1}),$$

where

$$\mathbf{V}_{\mathrm{R}} = \mathbf{Z}\mathbf{D}_{\mathrm{R}}\mathbf{Z}' + \mathbf{R}_{\mathrm{R}},$$

and $\mathbf{D}_{\mathrm{R}}$ and $\mathbf{R}_{\mathrm{R}}$ are the REML estimates. The ML estimator of $\boldsymbol{\alpha}$ and its variance have the same form as (4) above, except that ML estimates of the variances $\mathbf{D}$ and $\mathbf{R}$ are substituted in place of the REML estimates. In both cases the variance of the estimator of $\boldsymbol{\alpha}$ is underestimated since it does not account for the variability in the estimates of $\mathbf{D}$ and $\mathbf{R}$. Kacker & Harville [10] and Prasad & Rao [13] have proposed alternative forms for the variance which account for this extra variability but are computationally intensive.

The REML estimator of $\boldsymbol{\theta}$, the unknown components of $\mathbf{V}$, can be shown to maximize the log **likelihood** $L'(\boldsymbol{\theta})$, where

$$\begin{aligned} L'(\boldsymbol{\theta}) = &-\tfrac{1}{2}\log|\mathbf{V}| - \tfrac{1}{2}\log|\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}| \\ &- \tfrac{1}{2}(\mathbf{Y} - \mathbf{X}\boldsymbol{\alpha}_{\mathrm{R}})'\mathbf{V}^{-1}(\mathbf{Y} - \mathbf{X}\boldsymbol{\alpha}_{\mathrm{R}}) \end{aligned}$$

and $\boldsymbol{\alpha}_{\mathrm{R}}$ is the REML estimator of $\boldsymbol{\alpha}$. In contrast, the ML estimator of $\boldsymbol{\theta}$ maximizes the log likelihood $L(\boldsymbol{\theta})$, where

$$L(\boldsymbol{\theta}) = -\tfrac{1}{2}\log|\mathbf{V}| - \tfrac{1}{2}(\mathbf{Y} - \mathbf{X}\boldsymbol{\alpha}_{\mathrm{M}})'\mathbf{V}^{-1}(\mathbf{Y} - \mathbf{X}\boldsymbol{\alpha}_{\mathrm{M}})$$

and $\boldsymbol{\alpha}_{\mathrm{M}}$ is the ML estimator of $\boldsymbol{\alpha}$, defined above. The two likelihoods differ by a single term, usually of order p.

The same REML estimators for $\boldsymbol{\alpha}$, $\mathbf{D}$, and $\mathbf{R}$ can be derived in another way, based on **Bayesian** principles. To do this, assume a vague **prior distribution** for $\boldsymbol{\alpha}$. Specifically, let $\boldsymbol{\alpha}$ have the limiting distribution $\mathrm{N}(\mathbf{0}, \boldsymbol{\Gamma})$, where $\boldsymbol{\Gamma}^{-1} \to \mathbf{0}$. We then find the posterior distribution for $\boldsymbol{\alpha}$, and base inference upon this. We may estimate $\boldsymbol{\alpha}$ by the mean of its posterior distribution. When $\mathbf{D}$ and $\mathbf{R}$ are known, this posterior distribution is normal, with mean and variance

$$\mathrm{E}(\boldsymbol{\alpha}|\mathbf{Y}, \mathbf{D}, \mathbf{R}) = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{Y} \tag{5}$$

and

$$\mathrm{var}(\boldsymbol{\alpha}|\mathbf{Y}, \mathbf{D}, \mathbf{R}) = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}.$$

When the variances are unknown, we must substitute estimates of $\mathbf{D}$ and $\mathbf{R}$ for these parameters. We now compute them from the marginal likelihood of $\mathbf{Y}$, or $f(\mathbf{Y}; \mathbf{D}, \mathbf{R})$. The REML estimators are the maximum likelihood estimators of $\mathbf{D}$ and $\mathbf{R}$ based on this marginal likelihood. In contrast, the usual ML estimators are based on the complete likelihood $f(\mathbf{Y}; \boldsymbol{\alpha}, \mathbf{D}, \mathbf{R})$.

Note that in (4) the variance $\mathrm{var}_{\mathrm{R}}(\boldsymbol{\alpha})$ is not really the variance of the estimator $\boldsymbol{\alpha}_{\mathrm{R}}$; it is the variance in the posterior distribution of $\boldsymbol{\alpha}$. In the Bayesian approach we treat $\boldsymbol{\alpha}$ as a random variable, and should base inference on the posterior distribution. Alternatively, for strict sampling theorists, $\mathrm{var}_{\mathrm{R}}(\boldsymbol{\alpha})$ is a proper estimator of the variance if we use $\mathbf{R}_{\mathrm{R}}$ and $\mathbf{D}_{\mathrm{R}}$ to estimate $\mathbf{R}$ and $\mathbf{D}$ and ignore the variation in $\mathbf{R}_{\mathrm{R}}$ and $\mathbf{D}_{\mathrm{R}}$ themselves. This is true since

$$\begin{aligned} \mathrm{var}(\boldsymbol{\alpha}_{\mathrm{R}}) &\approx (\mathbf{X}'\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{V}\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{X}(\mathbf{X}'\mathbf{V}_{\mathrm{R}}^{-1}\mathbf{X})^{-1} \\ &\simeq \mathrm{var}_{\mathrm{R}}(\boldsymbol{\alpha}). \end{aligned}$$

Likelihood ratio tests for $\boldsymbol{\alpha}$, however, are inappropriate, since the likelihood maximized is actually $f(\mathbf{Y}; \mathbf{D}, \mathbf{R})$ and not $f(\mathbf{Y}; \boldsymbol{\alpha}, \mathbf{D}, \mathbf{R})$.

Harville [7] shows the connection between Patterson & Thompson's REML approach to estimating $\mathbf{D}$ and $\mathbf{R}$ based on the error contrasts and the Bayesian approach which gives $\boldsymbol{\alpha}$ a vague prior normal distribution. Harville first shows that the likelihood for the error contrasts is proportional to the marginal likelihood of $\boldsymbol{\theta}$ based on the full data, $\mathbf{Y}$, or

$$f_S(\mathbf{SY}; \boldsymbol{\theta}) \propto \int f_Y(\mathbf{Y}; \boldsymbol{\theta}, \boldsymbol{\alpha})\ \mathrm{d}\boldsymbol{\alpha}, \tag{6}$$

where f_S and f_Y are the probability density functions of $\mathbf{SY}$ and $\mathbf{Y}$, respectively. If we assign an improper prior, $g(\boldsymbol{\alpha})$, to $\boldsymbol{\alpha}$ that is independent of $\boldsymbol{\theta}$, as do Dempster et al. [4], then

$$\begin{aligned} \int f_Y(\mathbf{Y}; \boldsymbol{\theta}, \boldsymbol{\alpha})\ \mathrm{d}\boldsymbol{\alpha} &\approx \int f_Y(\mathbf{Y}; \boldsymbol{\theta}, \boldsymbol{\alpha}) g(\boldsymbol{\alpha})\ \mathrm{d}\boldsymbol{\alpha} \\ &= f_Y(\mathbf{Y}; \boldsymbol{\theta}). \end{aligned}$$

We see from (6) that our inferences about $\boldsymbol{\theta}$ will be the same as in REML. Also, as long as the joint prior density for $\boldsymbol{\alpha}$ and $\boldsymbol{\theta}$ is proportional to the prior for $\boldsymbol{\theta}$ alone, the marginal density for $\boldsymbol{\theta}$ based on $\mathbf{Y}$ is proportional to that based on the error contrasts. We therefore do not lose information by using only the error contrasts.

Secondly, suppose that the joint prior for $\boldsymbol{\theta}$ and $\boldsymbol{\alpha}$ is flat relative to the data's likelihood, so that the posterior density is proportional to the likelihood. Then the ML estimator of $\boldsymbol{\theta}$ is the $\boldsymbol{\theta}$ component of the mode of the joint posterior distribution. Eq. (6) shows that, in contrast, the REML estimator of $\boldsymbol{\theta}$ based on $f_S(\mathbf{SY};\boldsymbol{\theta})$ is the mode of the marginal posterior distribution of $\boldsymbol{\theta}$.

REML estimation for a **random-coefficients model** for longitudinal data has been presented by Laird & Ware [11]. It has been described for arbitrary structural models for the within-person **covariance matrix** by Jennrich & Schluchter [9]. Both of these works use the **EM algorithm** of Dempster et al. [3] to estimate the parameters with REML. Diggle et al. [5] give an overview of REML estimation for longitudinal data. Suppose that m repeated measures are observed on each of N individuals, with Nm total observations. The distinction between REML and ML estimation is particularly important when the number of fixed parameters p is large relative to Nm, and the ML estimators are more severely biased. REML estimators also perform better when the variance matrix is near-singular, as in an example presented by Tunnicliffe-Wilson [15].

Although largely developed for the case of multivariate normality, REML estimation can be applied to other situations in which the parameter space is restricted. The term has been used when particular restrictions, such as order restrictions, are placed on the parameters (e.g. [1]; *see* **Isotonic Inference**). Many of these problems lead to the technique of **isotonic regression**. Dykstra & Madsen [6], for example, discuss some restricted estimators for the **Poisson distribution**.

Retrospective Study

Retrospective study is a term originally used to describe a **case–control study**, in which the previous exposures and other characteristics of cases with the disease of interest are compared with the previous exposures and other characteristics of disease-free **controls**. More generally, the term is applied to studies in which the relevant exposures and/or disease incidences have occurred before the time of the study data collection. For example, a **historical cohort study**, in which historical records of occupational exposures (*see* **Occupational Epidemiology**) and disease occurrence are analyzed just as in a prospective follow-up study, is sometimes called a retrospective study.

MITCHELL H. GAIL

Reverse Arrangement Test

The reverse arrangement test is used for evaluating whether a sequence of ordered data is derived from independent observations of the same random variable by detecting whether a significant trend underlies the observations. It is a **nonparametric** test, making no assumptions about the distribution of the input data and about a model for the possible trend.

Given a sequence of N observed values of a random variable, $x_1, x_2, \ldots, x_N$, the ith reverse arrangement, A_i, is the number of times that $x_i > x_j$ for $i > j$. The total number of reverse arrangements is $\mathbf{A} = \sum_{i=1}^{N-1} A_i$. The number $\mathbf{A}$ may range between 0 and $N \times (N-1)/2$. If $\{x_i\}$ are N independent observations of the same random variable, then A is a random variable with mean value:

$$\mu_A = N\left(\frac{N-1}{4}\right) \tag{1}$$

and variance

$$\sigma_A^2 = N(N-1)\left(\frac{2N+5}{72}\right) \tag{2}$$

If an increasing or a decreasing trend underlies the data, we may expect $\mathbf{A}$ to be respectively greater or lower than μ_A. The distribution of $\mathbf{A}$ is derived in [2] and that for N between 10 and 100 is tabulated in [1]. The values up to $N = 20$ are shown in Table 1. However, the tendency to normality is extremely rapid: when $N \geq 14$, the variable

$$z = \frac{\mathbf{A} - \mu_A}{\sigma_A} \tag{3}$$

approximately follows the standard normal distribution and can be used to reject the null hypothesis with little loss of accuracy.

To clarify the test, consider the following series of diastolic blood pressure values measured daily in a patient during a two-week monitoring period:

$$\{75; 90; 85; 82; 68; 82; 69; 64; 75; 63; 60; 73; 73; 70\}.$$

Table 1 Reverse arrangement distribution. Values of A_α^N such that the probability $(A > A_\alpha^N) = \alpha$, with N = number of observations

	α					
N	0.99	0.975	0.95	0.05	0.025	0.01
10	9	11	13	31	33	35
12	16	18	21	44	47	49
14	24	27	30	60	63	66
16	34	38	41	78	81	85
18	45	50	54	98	102	107
20	59	64	69	120	125	130

Source: [1]. Reproduced with permission of John Wiley & Sons Ltd. 1986 © John Wiley & Sons Ltd

In this sequence of $N = 14$ measures, $x_1 = 75$ is greater than eight of the following values, and thus $A_1 = 8$; $x_2 = 90$ is greater than all the next 12 observations, and $A_2 = 12$. The value of each reverse arrangement, A_i is:

$$\begin{array}{llll} A_1 = 8 & A_5 = 3 & A_8 = 2 & A_{11} = 0; \\ A_2 = 12 & A_6 = 8 & A_9 = 5 & A_{12} = 1; \\ A_3 = 11 & A_7 = 3 & A_{10} = 1 & A_{13} = 1 \\ A_4 = 9 & & & \end{array}$$

and $\mathbf{A} = A_1 + A_2 + \cdots + A_{13} = 64$. As shown in Table 1, we should reject the null hypothesis at the 5% significance level α because $\mathbf{A}$ does not fall within the range from 27 to 63. Alternatively, we could use (1–3), which give $\mu_A = 45.5$, $\sigma_A^2 = 83.417$, and $z = 2.026$. The two-tails significance of z is $p = 0.043$, and also, in this case, we should reject the hypothesis of independence at $\alpha = 5\%$.

Reversibility

Reversibility in the context of **time series** analysis implies that all modeling and statistical analysis can equally be performed on the reversed time-ordered values as on the original sequence. A reversible sequence will have a statistical time symmetry in its appearance, meaning that features of the series will not change after the time series is presented in reversed order. It only makes sense to consider reversibility in respect of stationary series, and not to consider deterministic aspects such as trend and seasonality. Irreversible or directional time series are very common and can often be identified visually, but most standard methods of time series analysis do not react to directionality. Directionality may be considered as an asymmetric assessment of time series dependence, not detected by autocorrelation or other second-order methods. Thus, models based on second-order properties, such as Gaussian linear time series models, are reversible [12]. However, if the standard innovation variables are not Gaussian, then these models exhibit directionality. Likewise, there are various nonlinear time series models that are unavoidably directional. Directionality can be incorporated in the assessment of suitability of a proposed model, and is particularly relevant when predictive use is anticipated. The classical time series of sunspot numbers and Canadian lynx data are often given as examples with directionality. The literature contains scattered references, and there is an assessment of the area by Lawrance [8].

Technical Definitions

A time series in discrete time, modeled by the random variables $[X(t), t = 0, \pm 1, \pm 2, \ldots]$ is said to be *reversible* when, for all $r = 1, 2, \ldots$, and $t = 0, \pm 1, \pm 2, \ldots$, the joint distribution of $[X(t), X(t+1), \ldots, X(t+r)]$ is equal to the joint distribution of $[X(t+r), X(t+r-1), \ldots, X(t)]$. This definition appears to be by Brillinger & Rosenblatt [3], although the first mention of the idea may be due to Daniels [5]. More limited definitions have been given in [8]. For instance, *first-order reversibility* was proposed as the case $r = 1$ of the general definition; it implies marginal **stationarity**. The term *lag reversibility* was used to denote that the joint bivariate distribution of $[X(t), X(t+r)]$ is the same as that of $[X(t+r), X(t)]$ for $r = 1, 2, \ldots$ and $t = 0, \pm 1, \pm 2, \ldots$. A particular aspect of this type of reversibility is that $\text{corr}[X(t)^2, X(t+r)] = \text{corr}[X(t), X(t+r)^2]$. These conditions can very easily be verified with actual data to give a statistical assessment of directionality.

Theoretical Results

Linear Models

A key contribution of Weiss [12] proved the result that linear autoregressive processes, with or without a moving-average component (*see* **ARMA and ARIMA Models**) are reversible if and only if they are Gaussian. For a moving-average linear model component of the form

$$b_0\varepsilon(t) + b_1\varepsilon(t-1) + \cdots + b_q\varepsilon(t-q),$$

where $\varepsilon(t), t = 0, \pm 1, \pm 2, \ldots$, is an independent and identically distributed innovations sequence of random variables, and $b_0, b_1, b_2, \ldots$ is a sequence of constants, a general condition giving reversibility is that $(b_j = b_{q-j}, j = 0, 1, \ldots, q)$; if the innovations sequence is symmetrically distributed $(b_j = -b_{q-j}, j = 0, 1, \ldots, q)$ also gives reversibility. There are direct consequences of this reversibility to the *invertibility* of linear time series models. Box & Jenkins [2] refer to this as being able to express the innovation term $\varepsilon(t)$ as a linear function of the present and past $X(t)$. If this is to be so, roots of the equation

$$1 - b_1x - b_2x^2 - \cdots - b_qx^q = 0,$$

inside or on the complex unit circle, are not allowed. With odd-order moving-average components, there is always at least one root on the unit circle; with even-order components, there is at least one root inside the unit circle. Thus, in both cases, reversibility precludes invertibility. Moving away from reversible models, a number of directional linear models have been studied. For first-order linear autoregressive models, Gaver & Lewis [6] consider exponential and gamma marginal distributions, and Lawrance [7] gives their compound Poisson innovation distribution (*see* **Contagious Distributions**); Rao et al. [11] give results for such models with self-decomposable marginal

distributions. A striking result for first-order linear models with uniform marginals is the connection between reversibility, chaos and congruential random number generators (*see* **Pseudo-random Number Generator**) [1]. The reversed uniform process is the multibranch generalization of the chaotic shift-map process. This is the continuous-valued version of the congruential random number generator.

Nonlinear Models

Most of the available results for nonlinear models concern first-order autoregressions, although in nonstandard forms. Chernick et al. [4] show that the reversed form of the Gaver & Lewis exponential model was a nonlinear model with minimization replacing addition for combining terms. Lewis & McKenzie [9] construct an extended class of processes based on the minimization operation, modeling **uniform distribution**, **Weibull** and **Pareto distribution**, among others. McKenzie [10] also develops nonreversible models in **negative binomial** variables using a thinning operation in place of multiplication. A variety of other nonlinear models have since appeared in the literature and most are irreversible.

A.J. LAWRANCE

Rheumatology

The field of rheumatology deals with clinical disorders which involve the musculoskeletal system. Rheumatology includes inflammatory and noninflammatory diseases of joints, bones, muscles, and connective tissues. The inflammatory disorders are characterized by the features of inflammation, including pain, stiffness, redness, swelling, and reduced function in the affected areas. Generally, these conditions improve with activity and are worsened by rest. The noninflammatory disorders are characterized by pain which is made worse with activity and improves with rest.

The inflammatory disorders include various forms of arthritis and the collagen vascular disorders. The prototype of inflammatory arthritis is rheumatoid arthritis, which presents with joint pain and swelling associated with stiffness, involving the small joints of the hands and feet as well as the larger joints, in a symmetric distribution. The cause of most forms of inflammatory arthritis is unknown, but it is recognized that the main problem is an inflammatory process in the lining of the joint, the synovium. These conditions tend to be chronic, with periods of exacerbation and remission. With time, the chronic persistent inflammation in the synovium leads to joint destruction, deformity, and disability.

Some forms of inflammatory arthritis have known causes. For example, septic arthritis is caused by infective agents, and some viruses are associated with arthritis. Gout, which is a crystal induced arthritis, results from uric acid deposition in the joints, and pseudo-gout, also a crystal induced arthritis, results from calcium pyrophosphate dihydrate deposition in the joints.

The collagen vascular diseases include a number of inflammatory conditions which affect the connective tissues, including the joints. These conditions are usually multisystem, affecting many organs and systems in the body. Systemic lupus erythematosus, the commonest of these conditions, affects young women, with a variable presentation, course, and prognosis. Scleroderma, also known as systemic sclerosis, also affects women, is not as common, and has an important vascular component. The vasculidites are a group of diseases characterized by inflammation in the blood vessels, and the symptoms and signs depend on the blood vessel involved. Polymyositis is a rarer condition which affects primarily the muscles: when the skin is involved it is called dermatomyositis.

The noninflammatory conditions include degenerative arthropathies, which are the most common form of arthritis, nonarticular rheumatism, and traumatic injuries. Osteoporosis is also included in the noninflammatory rheumatological disorders.

Historical Development

The term “rheuma” was introduced in the first century AD, and indicates a substance that flows. Rheumatic diseases such as gout were recognized as early as the fourth century BC, but the concept of systemic rheumatic disease was introduced in the sixteenth century. The term “rheumatologist”, to refer to the physician dealing with rheumatic diseases, is recent [21].

Gout was the first rheumatic condition to be clinically described and urate was found to be the causative factor in the nineteenth century. Until the late 1940s, almost all patients with arthritis were thought to have either gout or rheumatoid arthritis. However, in 1948 rheumatoid factor was discovered, as an antibody present in the sera of more than 80% of patients with rheumatoid arthritis, but not in patients with osteoarthritis. This further resulted in the differentiation of inflammatory forms of arthritis into those which were rheumatoid factor positive (seropositive), such as rheumatoid arthritis, and those which were rheumatoid factor negative (seronegative), which include psoriatic arthritis, which is associated with psoriasis, ankylosing spondylitis, which affects primarily the back, Reiter’s disease, which affects the back, peripheral joints and skin, and the arthritis of inflammatory bowel disease. In addition to being seronegative, the latter group of conditions have other features in common: they affect the back, are associated with skin and mucous membrane lesions, and are associated with certain genetic factors, namely HLA-B27. In the same year, the diagnosis of systemic lupus erythematosus was facilitated by the discovery of the lupus erythematosus cell preparation. Subsequently, the antinuclear factor was described and the relationship of autoantibodies to the collagen vascular diseases became clear. About 140 arthritic conditions are recognized by the **International Classification of Diseases** (ICD) codes.

With the recognition of these various forms of arthritis, it became necessary to develop criteria for

classification and diagnosis [22]. Criteria were established for the diagnosis of rheumatoid arthritis, systemic lupus erythematosus (SLE), the arteridites, and other conditions. These have facilitated research into the mechanisms involved in these conditions, as well as the inclusion of patients into therapeutic trials (*see* **Clinical Trials, Overview**). Comparisons of patients from different centers can now be achieved, and **multicenter trials** are feasible since patients with similar characteristics may be recruited. A consensus on criteria for response to treatment in rheumatoid arthritis has also been developed [10].

Types of Studies

The classical epidemiologic studies, such as **cohort** and **case–control studies** are used in rheumatological research, although the extent of epidemiologic investigation into risk factors is less than for many other diseases. **Genetic epidemiology** has been and should continue to be an area of particular interest. Types of investigations in this area include those based on sibling pairs, family studies, and the search for candidate genes through disequilibrium testing. Multicenter efforts may be needed to provide adequate sample sizes [14]. Similarly, there are many clinical trials in rheumatology which aid in the evaluation and licensing of treatments. Other investigations are based on clinical databases devoted to patients with a particular rheumatological disease, specific investigations on a specially recruited group of patients, and comparisons of different groups of patients (*see* **Administrative Databases**).

A wide variety of clinical and radiological measures in rheumatology derive from expert assessment. **Reliability studies** are therefore of particular importance in rheumatological research. Reliability of measurement within a single center or across multiple centers may be required, depending on the nature of the investigations under consideration. Reliability and validity studies are also of considerable importance for **quality of life** measurements, which are increasingly being used in research activities.

Historically, classification studies have aided in the definition of different rheumatological conditions. The approach of the collection of **"gold standard"** cases and the comparison of these to individuals with other conditions led to some progress. Recursive partitioning methodology [2] (*see* **Tree-structured Statistical Methods**) has been used in the validation of criteria. These studies continue to be useful, but the methodological requirements, such as the definition of a gold standard, become increasingly challenging as disease subgroups are defined on the basis of immunologic abnormalities, genetic factors, and so on. A related area is the evaluation of new **diagnostic tests** which involves the classic considerations of **sensitivity**, **specificity**, and **predictive value**.

Treatment

The therapeutic approach to arthritis is control of **pain** and inflammation. The choice of anti-inflammatory medication depends on the severity of the inflammatory process, and its possible effect on vital organs. Thus, for mild cases of joint inflammation, nonsteroidal anti-inflammatory drugs (NSAIDs) are used. These have been shown effective in controling inflammation in both animal models of inflammation and in the human disease. An increasing number of NSAIDs have become available, primarily because of their side-effects which motivate attempts to develop newer drugs with less toxicity. When NSAIDs are ineffective, disease modifying drugs are used. These include medications such as gold compounds, penicillamine, antimalarials, salazopyrine, methotrexate, azathioprine, cyclophosphamide, and cyclosporin (see [18, Section VI]).

Corticosteroids are used to control inflammation in the more systemic conditions, as well as in the resistant cases of joint inflammation. These drugs appeared so effective when first introduced in the late 1940s that, although there have not been controlled trials to prove their efficacy, new modalities are now measured against corticosteroids.

On the basis of the current understanding of mechanisms of inflammation, new approaches have been developed including agents that interfere with Tumor Necrosis Factor such as the anti-TNF, antibody infliximab, and the TNF receptor fusion protein etanercept. In RCTs, these later agents have been shown effective in RA, PsA, and ankylosing spondylitis and are being tested in vasculitis. Other agents directed against B cells and T cells are at various stages of development and testing.

Methodological Issues

The nature of rheumatological diseases and their medical management creates some particular methodological difficulties. An obvious initial one is consideration of the time of origin for studies of disease. Patient recall is a source for information on the onset of symptoms. But, for example, there are groups of patients with some features of SLE who have not developed full blown disease even after more than 10 years of follow-up. Similarly, referral patterns related to medical care are widely varied influencing both the time of treatment initiation and the type of clinical center within which treatment is sought. Clinical trials and database studies thus must almost inevitably have time origins which are variable and somewhat arbitrary. However, on balance, many investigators support the notion that the time of diagnosis should be used as the baseline for disease origin [19], sometimes taking it to be the time the diagnosis might have been made had an appropriate physician seen the patient.

At the "other end" of the studies, there is wide variation in the **outcome measures** used by different researchers. Short-term outcomes are common in clinical trials related to drug licensing activities (*see* **Drug Approval and Regulation**) but longer-term outcomes are often of more clinical interest. The identification of a single outcome of interest is usually difficult, as evidenced by the selection of a set of outcomes as the consensus requirements for the reporting of clinical trials in rheumatoid arthritis [11]. Other conditions have not yet reached even this stage of standardization but efforts are being made, for example, in psoriatic arthritis [16] and myositis [15, 17].

The evaluation of these multiple outcomes requires careful consideration. Many classical **multiple comparison** procedures are not relevant, based as they are on an experimental false positive error defined as one or more false positives on individual outcomes. It is difficult to provide a mathematical characterization of the "clinical insight" which jointly evaluates disease progression in terms of these multiple outcomes [4, 5].

As mentioned earlier, there is a subjective evaluative component to many of these outcomes, some evaluated by the patient, some by physicians. In addition to the reliability issue already discussed, it is also important to consider expectation bias which can arise in randomized, but unblinded, clinical trials. Epstein [8] illustrates the dramatic differences which can result when evaluation of a "promising" new treatment is done in a blinded versus unblinded manner.

The classic assumption in most statistical methods to deal with time to event data is that censoring is independent of the outcome (*see* **Censored Data**). Thus, individuals who are lost to follow-up are assumed to be no different, in terms of subsequent outcomes, to individuals who remain under follow-up. Because of the long course of most rheumatic diseases, follow-up is particularly problematic. Specific attention should be paid to the nature of lost-to-follow-up patients before undertaking studies which involve long-term outcomes. There is recent interest in mortality studies which consider the survival of arthritis patients compared with the general population, motivated partly by the **burden of disease** hypothesis. Loss-to-follow-up information is critical in these studies, which must be based on databases accrued over a considerable period of time [9].

The course of rheumatic diseases means that not only are there multiple types of outcomes (*see* **Multiple Endpoints, *P* Level Procedures**) but also multiple measurements of outcomes over time (*see* **Longitudinal Data Analysis, Overview**). A simple example is the number of inflamed joints in a patient with rheumatoid arthritis which could be measured at each clinic visit. Statistical methods for the analysis of times to a single event are therefore not appropriate in many cases. Fortunately, there is increasing methodological interest in models for longitudinal data, and much of this work is relevant to studies in rheumatology.

A particular approach which may be useful is to model disease progression as a Markov multistate model (*see* **Marker Processes**). Not only will this make use of repeated measurements on outcome variables, but it will also allow individuals to enter follow-up at different states and may help to deal with the lack of a well characterized time of disease onset. This approach has been used to study disease progression in psoriatic arthritis [13]. Other approaches should be explored [6, 14] and, of course, **goodness of fit** investigations will be required [1].

In these long-term studies of disease progression, prognostic markers of interest may also be measured at several points in time. Thus the ability to incorporate time-dependent explanatory variables would be a

useful feature of any method of analysis. The incorporation of such variables will reflect what occurs in the clinical monitoring of patients. There are, of course, other time-independent variables such as demographics and genetic factors which must also be considered.

Landmark Studies

Prognosis

The study of survival in SLE performed by Merrell & Shulman [19] provided a framework for subsequent studies of prognosis in SLE and other rheumatic diseases. They defined the onset of the disease as the time of diagnosis, and provide a rationale for its use. They also took appropriate account of patients lost to follow-up who were regarded as censored at the time at which they were last observed.

Treatment

Gold was the first antirheumatic drug to be investigated through a controlled clinical trial in RA [12], although a high placebo effect was noted. A subsequent trial by the Empire Rheumatism Council is considered the landmark article both for the efficacy of gold, and for the standard of clinical trials in rheumatology [7]. This was a multicenter trial involving 24 centers.

Disease Associations

The HLA region of chromosome 6 in man is the major histocompatibility locus. Because of its role in the immune response, it was thought to be related to the susceptibility and/or resistance to disease. It was not until landmark articles from the UK [3] and US [20] that the role of this region in disease susceptibility was confirmed. These studies provided the framework for subsequent studies of **HLA** and disease associations.

Ridge Regression

Ridge regression was initially promoted by Hoerl & Kennard [8, 9] within the multiple regression model:

$$\mathbf{Y} = \mathbf{1}\beta_0 + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{1}$$

where $\mathbf{X}$ is an $(n \times p)$ matrix of n observations on p explanatory variables, the columns of $\mathbf{X}$ have mean zero (i.e. centered), $\mathbf{1}$ is an $(n \times 1)$ vector of ones allied to the mean coefficient β_0; $\mathbf{Y}$ is the n-vector of responses, and $\boldsymbol{\varepsilon}$ the n-vector of random errors with constant variance σ^2. The class of ridge estimators of the p-vector $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}}(k) = (\mathbf{X}'\mathbf{X} + k\mathbf{I})^{-1}\mathbf{X}'\mathbf{y}, \tag{2}$$

with the class indexed by the hyperparameter k. The mean coefficient β_0 is usually estimated by $\bar{y}$, the sample mean of the observed n-vector $\mathbf{y}$; see [3] for alternative forms. The idea of regularization by adding a small constant to the diagonal of $\mathbf{X}'\mathbf{X}$ in (2) had appeared earlier in the context of function minimization, the Levenberg–Marquardt modification of Newton–Raphson, as described, for example, in [14] (*see* **Optimization and Nonlinear Equations**).

Hoerl & Kennard suggested plotting the p-coefficients, $\hat{\beta}_i(k)$, from (2) as functions of k, ranging from $k = 0$ (**least squares**) to $k = \infty[\hat{\beta}_i(\infty) = 0, i = 1, \ldots, p]$. This *ridge trace* typically shows large changes in at least some of the coefficient estimates as k increases from zero. The squared length of the vector, $\hat{\boldsymbol{\beta}}(k)'\hat{\boldsymbol{\beta}}(k)$, monotonically decreases as k increases. At the same time the residual sum of squares may only show a modest increase from the least squares value at $k = 0$. One argument of Hoerl & Kennard was that the least squares estimator of $\boldsymbol{\beta}$ is unnaturally long, especially when the $\mathbf{X}$-matrix is nearly collinear (*see* **Collinearity**), and dramatic reductions in length are possible with small increases in k from zero.

From a slightly different perspective, the effect of the estimator may be judged from the amalgamated **mean squared error** of estimation,

$$\mathrm{E}(\hat{\boldsymbol{\beta}}(k) - \boldsymbol{\beta})'(\hat{\boldsymbol{\beta}}(k) - \boldsymbol{\beta}).$$

This can be decomposed as the sum of variance and a squared bias term. Initially at $k = 0$ the bias is zero, but the variance may be large, especially if $\boldsymbol{X}$ is near collinear. The variance of the ridge estimator reduces as k increases from zero monotonically, the squared bias term increases, and typically the mean squared error, the sum of the two terms, decreases initially and then starts to increase as bias takes over for larger values of k. Hoerl & Kennard provided a theorem proving the existence of $k > 0$ for which the mean squared error was less than that of least squares. Unfortunately this does not provide guidance on the choice of k, which was left to the "elbowing" out of the ridge trace.

Nowadays the ridge trace has been largely abandoned in favor of explicit choices of estimator $\hat{k}$. Whatever value is chosen the improvement in mean squared error of estimation cannot be realized at all values in the parameter space of $\boldsymbol{\beta}$, when near-collinearity is present; see [4, Chapter 4]. The situation is not so critical for prediction squared error loss at the design points, where ill-estimated directions are down-weighted.

Estimators of k are often motivated by **Bayesian** roots. If a priori $\beta_i, i = 1, \ldots, p$, are independent normal with mean zero and variance τ^2 and a vague prior is taken for β_0, then, with normality of the errors in the model in (1), (2) is the Bayes estimate of $\boldsymbol{\beta}$ (mean of the posterior distribution), where $k = \sigma^2/\tau^2$. Such estimators range from simple **empirical Bayes** plug-in values for the hyperparameter τ^2 as in [10], to maximum **marginal likelihood** [1].

Ridge regression may be viewed as a continuous version of **variable selection**, where unimportant variables have their coefficients shrunken towards zero. **Shrinkage** to zero is evident from both the Bayesian roots and the form of the the ridge estimator. In canonical form (2) becomes $[\lambda_i/(\lambda_i + k)]\hat{\alpha}_i$, where $\boldsymbol{\theta}$ is the orthogonally transformed $\boldsymbol{\beta}$, $\hat{\boldsymbol{\theta}}$ its least squares estimate, and $\lambda_1, \ldots, \lambda_p$ the eigenvalues of $\mathbf{X}'\mathbf{X}$ (*see* **Eigenvalue**). Thus, the shrinkage is more pronounced for directions of small eigenvalues of $\mathbf{X}'\mathbf{X}$, corresponding to a large variance of the least squares estimator. Shrinkage to zero is also evident from the augmented form given in [12]. This form is also useful for computation. If the n-vector $\mathbf{Y}$ is augmented by p zeros, to form an $(n + p) \times 1$ vector $\mathbf{Y}^*$, and $\mathbf{X}^*$ is the $(n + p) \times p$ matrix $\mathbf{X}$ augmented by $\sqrt{k}$ times a $p \times p$ identity matrix, then least squares applied to $\mathbf{X}^*$ and $\mathbf{Y}^*$ gives the ridge regression estimator, (2).

For any $k > 0$, the estimator in (2) is not invariant to changes in scale. The Bayesian roots also attest

to the importance of the relative scales of the p explanatory variables, since changing from, say, days to weeks will increase x by a factor of 7 and consequently decrease the corresponding β-coefficient by a factor of 7. The required **exchangeability** of coefficients underpinning ridge regression will not necessarily match the common approach of standardization of explanatory variables to all have variance 1 (autoscaling). This would also imply that it is not necessarily sensible to rescale the explanatory variables each time an observation or observations are left out in **cross-validation** or **bootstrap** approaches to estimation of k.

For reviews of ridge regression and other shrinkage estimators in the context of multiple regression see [7] and [4, Chapter 4]. The simple ridge form of regularization of statistical problems involving many parameters has become commonplace. In the **neural network** literature it comes in the form of a quadratic penalization, a particular example of "weight decay"; see, for example, [13]. The Bayesian form of the technique may motivate adaptations to nonnormal models, as in [2]. Le Cessie & Van Houwelingen [11] adapt ridge to **logistic regression** and apply it to the diagnosis of ovarian cancer using the groups in a histogram of DNA content as explanatory variables. Multivariate forms of ridge regression have been developed by Brown & Zidek [5, 6] (*see* **Multivariate Multiple Regression**).

Risk Adjustment

Some cases are more difficult than others. For example, an 80-year-old hospital patient with a heart attack is more likely to die than one aged 50, while almost anyone admitted for cataract surgery is substantially less likely to die than either of these two. Clearly, when comparing hospitals on patient outcomes (such as mortality) or system outcomes (such as how much of what services are used), comparisons should be adjusted for intrinsic differences in patient risk (see **Case Mix**).

When calculating and adjusting for "risk", it is important to stay focused on "risk of what". For example, patients at a moderate risk of death from coronary artery disease may have the highest risk for receiving coronary artery bypass graft (CABG) surgery, since those who are less sick may not need this aggressive therapy, while the very sickest patients may be deemed too frail to survive it.

Raw comparisons of outcomes can be misleading. For example, in the mid-1980s, reporters used the Freedom of Information Act to force the Health Care Financing Administration (HCFA, called CMS) to release its data on hospital mortality for Medicare patients. Ominously, the "worst" facility had 87.6% of its Medicare patients die; however, this rate seemed less strange when the facility was revealed to be a hospice program. Over the years, HCFA made great strides in the sophistication of the risk-adjustment methods used to produce its annual hospital mortality reports. However, the HCFA administrator's stated reason for abandoning these annual reports in 1993 was that the methodology appeared to unfairly penalize inner city public facilities, whose patients may well be at greater risk of dying than is captured in the data available for modeling.

Thus, differences in patient risk often do not "average out" and failure to adequately adjust for differences between the patients seen by different health care providers can produce seriously misleading comparisons. Much research supports this concern, and supports the use of risk adjustment (*see* **Adverse Selection**).

Thus, for example, instead of reporting an observed rate, O, of mortality following CABG surgery, for a surgeon or a hospital, E, an expected rate based on patient characteristics, is also computed, and some measure of the discrepancy is reported (e.g. the risk difference, O minus E, or the risk ratio, O divided by E). Typically, the expected rate is produced using standard **multivariable modeling** techniques applied to large databases, and all caveats for the care required in developing and using such models apply.

One way to produce a "risk-adjusted" rate for a particular facility is to multiply its risk ratio by a broadly defined average rate. For example, if nationally, 2% of nursing home patients develop bedsores in a six-month period, a facility with O/E equal to 1.10 would have its risk-adjusted problem development rate equal to 2.2%. If either the number of cases seen or the number of expected events at a facility is small, the risk ratio calculation becomes unstable; **empirical Bayes** modeling is one way to produce more stable estimates. For further information, see [1].

Risk Assessment for Environmental Chemicals

In 1983, the National Academy of Sciences (NAS) published a seminal report, *Risk Assessment in the Federal Government: Managing the Process* [8], on the theory and practice of human health risk assessment for chemicals in the environment.

Even though dictionaries define risk in terms of the *probability* of injury, damage, or loss [19], and even though other professions have long since adopted probabilistic frameworks using the **Monte Carlo method** developed in 1946, most human health risk assessments for chemicals in the environment still use deterministic methods that employ point values for all variables. Probabilistic methods have three key advantages over the deterministic ones that they replace. First, probabilistic methods use all the information available about the variability and the uncertainty inherent in the assessment, while deterministic assessments discard most of the information. Secondly, by using probability distributions to represent the range of exposure and/or toxicity, probabilistic methods reveal the compounded conservatisms inherent in deterministic methods. Thirdly, probabilistic methods – relying as they do on the full range of values that a variable may assume – reestablish the now blurred boundary between **risk assessment** and risk management.

We note that risk assessment and *epidemiology* have some goals in common, but that risk assessment differs from epidemiology by its central focus on the prediction of future events.

Risk Assessment vs. Risk Management

The NAS report defined two roles for individuals and stressed the need to keep these roles and associated activities well separated from each other:

1. A *risk assessor* is an analyst – perhaps an engineer or scientist – who uses facts and quantitative reasoning to estimate or bound the exposures and health effects, if any, to a person exposed to chemicals in the environment. The risk assessor may also analyze different technical options for remediation of the property.
2. A *risk manager* is a different person – perhaps a legislator, judge, member of a jury, a regulator, or the public itself – who then weighs the health risks in light of other social, political, and economic factors. The risk manager(s) then decide(s) the actions necessary or appropriate for a given situation. The actions may range from continuing the "do nothing" or "no action" alternative, to restrictions on land use, to complete excavation and removal. Risk management is the process of weighing policy alternatives and selecting the most appropriate regulatory action by integrating the results of risk assessment with engineering data and with social, economic, and political concerns to reach a decision.

Considering a contaminated property as an example, a risk assessor usually (i) performs a "baseline risk assessment", i.e. she or he analyzes the health risks to people who use the property under both the current and reasonable foreseeable use for reducing the risk and then (ii) estimates cleanup targets, as appropriate. A risk assessor may also complete a "verification risk assessment" *ex post* remediation. A risk assessor may perform the same general types of studies to assess or compare the effects of pesticide residues in foods, the operation of a proposed incinerator, new methods to disinfect public water supplies, the reliability of a manufacturing plant, or even the transportation of hazardous materials.

Risk Assessment: The Five-Step Process

Risk assessors usually follow a five-step process when completing a risk assessment. The typical five-step process used today is shown in Figure 1.

In what follows we use the assessment of a contaminated property as an example.

Hazard Identification

In this first step, the risk assessor reviews information about the property, such as location, land use, and abutting land use, and plans for future development. For a hazardous waste site, the risk assessor would review and analyze all of the monitoring data, including, for example, (i) chemical measurements in soils, ground water, sediments, surface water and/or air, and (ii) physical measurements, such as wind speed,

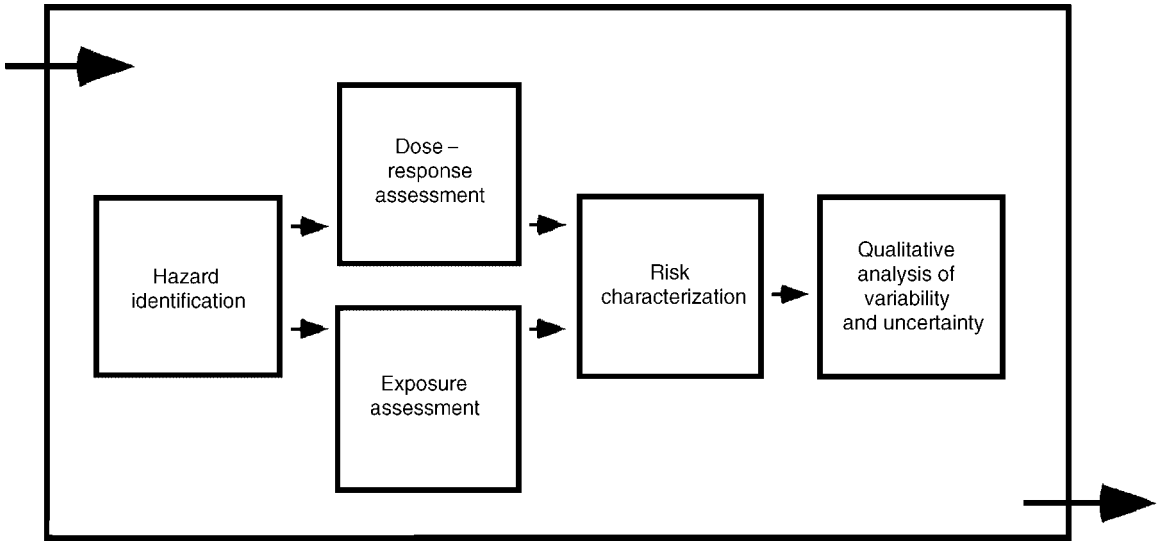

Figure 1 The five-step process for a risk assessment

temperature, hydraulic gradients, and turbulence. In the hazard identification step, the risk assessor must define the nature and extent of the problem, especially the lateral and vertical extent of the contamination. The resulting "study area" need not conform to property boundaries of ownership or even to state lines.

In hazard identification, the risk assessor must also select a list of "study chemicals" or "chemicals of concern", a subset of organic and/or inorganic compounds reported at the site that entails the highest exposure and the highest risk. The risk assessor usually selects the study chemicals for consideration according to these (sometimes competing) factors:

1. high average and/or maximum concentrations;
2. long persistence in the environment;
3. high toxicity, especially carcinogenicity, teratogenicity, or reproductive toxicity;
4. high frequency of detection;
5. great mobility in the environment; and/or
6. high public concern or awareness.

The risk assessor may also consider other factors as well, including whether the chemical is related to human activities or naturally occurring, whether the chemical is reported in concentrations above either natural or anthropogenic background concentrations, and whether the chemical is an essential nutrient for plants or animals.

Dose–Response Assessment

The risk assessor assembles information on the acute, subchronic, and chronic toxicities of the study chemicals selected in the previous step. Toxicologists distinguish between (i) potential carcinogens, which are chemicals that may initiate or promote the development of cancer, and (ii) noncarcinogens, which are chemicals that cause damage other than cancer to cells, tissues, organs, or organ systems in the exposed individual (*see* **Dose–Response Models in Risk Analysis**). More often now, toxicologists also identify neurotoxins, mutagens (agents that may cause somatic or genetic mutations; *see* **Mutagenicity Study**), and teratogens (agents that may cause birth defects in newborns; *see* **Teratology**). Of course, some chemicals may cause multiple effects at different times and doses. For example, in high doses, a particular dioxin called 2,3,7,8-TCDD may cause immediate tissue damage and a skin disease (effects of acute exposure); in lower doses, and over time, it may increase the probability that a few different types of cancer will develop (an effect of low-dose chronic exposure). (For general references, see [7] and [9].)

Developing Reference Doses (RfDs). Studies have shown that many people incorrectly believe "No dose of a chemical is safe". In fact, for any chemical,

there is a dose low enough that it does not cause significant clinical effects and a dose high enough that it probably does. We safely eat small amounts of cyanide in almonds, accidentally swallow apple seeds, and other foods; on the other hand, ingestion of less than a half pound of salt all at once will likely kill an adult. Mammals (including humans) have evolved to eat safely a multitude of naturally occurring toxic chemicals in foods, and, as a result, mammals have excellent defenses against many types of chemicals (including many industrial chemicals) and can readily detoxify and excrete them.

Identifying a dose of a chemical that is unlikely to cause effects is challenging. Experience has taught us that humans do not respond the same way as any particular experimental animal species. Sometimes humans are more sensitive to a certain chemical than rats are but less sensitive than, say, guinea pigs. Different animals (including humans) sometimes even respond to a chemical or drug exposure with different types of responses altogether. For example, some tranquilizer drugs used with dogs and horses will make cats more excited instead of depressing them. And humans themselves vary from person to person in their response: one person can drink alcohol seemingly all evening, while another is quite drunk after one glass of wine. Given a new chemical, a toxicologist cannot predict whether humans are more or less sensitive than the test animal, or whether they will respond with the same toxic effect, or how much variability different people will exhibit in their response. If this were not trouble enough, most animal toxicity tests last for six months to two years, while a human exposure might occur over 30–40 years or more.

The solution to these questions has been to apply limits on the uncertainty. Experience over many years with thousands of chemicals has allowed toxicologists to develop rules for estimating a "safe" dose. The US Environmental Protection Agency (EPA) has developed a standardized method for developing "reference doses" (RfDs) for several hundred of the solvents, pesticides, metals, and other chemicals most commonly encountered in the environment. The method does not identify the highest dose of a chemical that is safe, but it does identify a dose unlikely to cause effects; that is, the highest safe dose is probably not lower than the RfD.

The current EPA method has three main steps (although changes are proposed for the future). First, test animal studies and human observations (if available) are reviewed for study quality and to find the lowest dose at which adverse effects were observed (the "LOAEL" or lowest adverse effect level), and the next lower dose at which these effects are not seen (the "NOAEL," or no observed adverse effect level). Secondly, depending on the quality and findings of the experimental data, several uncertainty factors are applied to the LOAEL (or the NOAEL, if it is available) to estimate the RfD. If good dose information is available from accidental human exposures (as for mercury) one can use a NOAEL directly as an RfD, or one can divide it by a factor of 1–10 to account for variations among humans. For most chemicals we must use animal studies. If we have available only a LOAEL from an animal study, we divide by a factor of 10 to estimate a NOAEL. The factor of 10 accounts for potential differences between humans and experimental animals. The result may be divided by a factor between one and 10 if the experiment lasted less than the animals' lifetime (rats and mice live about two years) to estimate a safe dose for a human lifetime. We can use an additional modifying factor if we have reason for additional concern, such as that the only effects observed in the test are very serious ones. Sometimes we make other modifications in the dose estimate to represent more closely the dose that we expect that humans will receive. This process has been used both for ingested and inhaled doses of chemicals. There is no comparable approach developed for dermal exposure to chemicals; generally we use the oral RfD to evaluate a dermally absorbed dose, in spite of the obvious uncertainties.

The final step in the derivation of an RfD is to identify qualitatively the scientific confidence in it. Good, plentiful, studies with consistent findings result in high confidence, while if the available studies are poor or few, confidence is low. Note that low confidence usually results in a lower RfD because the greater uncertainty is reflected in higher uncertainty factors. So the RfD is no less "safe" if confidence is low; in fact, the true highest safe dose may be 1000 or more times higher.

Most scientists recognize that this approach is not optimal; it may result in overprotection at unnecessary expense. The current approach produces some odd results, such as an RfD for phenol that is below the dose received when one uses a common over-the-counter sore throat medication as directed (phenol is its active ingredient). The EPA and other groups

are working on more effective approaches, using **pharmacokinetics,** modeling, sophisticated statistics, quantitative analysis of variability and uncertainty, and other methods. One such approach is used for lead and is being developed for other metals such as arsenic and mercury. The approach is to use a model to evaluate several sources of exposure to lead and to predict the expected values in a population of a particular biomarker, in this case blood concentrations. (This approach has had only limited success so far.) Meanwhile, risk managers need to be mindful of how RfDs are developed and understand that if a risk assessment shows that a certain chemical concentration "exceeds a level of concern", that this does not mean we shall see toxic effects in exposed people. For most chemicals, there is a large margin of safety built into the toxicity value used in the risk calculation. Also, the target concentrations of concern are so low that the effects cannot be detected in small or medium sized populations.

Developing Cancer Slope Factors (CSFs). Toxicologists agree that there is a safe dose with respect to toxic effects other than cancer. The EPA has assumed that there is not a safe dose for carcinogens; there is, however, a dose that poses an acceptably low risk. Cancer is considered a dose-related example of a **stochastic process**; that is, there is always a chance of acquiring cancer from exposure to a carcinogen, no matter how small the dose; however, the smaller the dose, the smaller the chance. For some cancer causing agents, such as **radiation**, this appears to be true. Cancer (really a group of diseases) differs fundamentally from other toxic effects such as liver damage, in which a certain threshold of damage is necessary before the damage makes any practical difference, since the body can live with or replace many damaged cells. It is thought that cancer can result from a single mutation in DNA. This mutation can theoretically be caused by a single molecule of a carcinogenic chemical [1]. Therefore, there is theoretically always a possibility that a single molecule could cause the damage that leads to cancer. In reality, this is probably not true for most chemicals, but the EPA currently regulates carcinogens on this basis.

There are only about 30 known chemicals or industrial processes that cause cancer in humans. All other chemicals considered carcinogenic are only suspected to cause cancer in humans, perhaps because of weak evidence from human studies, or because the chemical tested positive in an animal test system. Groups of test animals (usually rats, mice, or dogs) receive the highest dose or half the highest dose of the test chemical that one expects they can tolerate for their lifetime without significant toxic effects other than cancer, and at the end of that time (about two years for rats and mice) the test animals are necropsied and examined for tumors. If the test groups have more tumors than the control group, then one can employ tumor data in a model to predict possible cancer rates in humans exposed over a much longer lifetime to much lower doses. The model most commonly used by the EPA produces a "cancer slope factor" (CSF) that one can use to estimate cancer risk in exposed humans. The CSF assumes a linear relationship between exposure dose and carcinogenic response. For example, with a person exposed to 0.02 mg alachlor per kg body weight every day for a lifetime and where the CSF is 0.08 mg/(kg d), an estimate of the cancer risk is $(0.02 \times 0.08) = 0.0016 = 1.6$ in 1000.

Often, results from the animal studies fail to show a clear effect. In any case, toxicologists must evaluate all available evidence for a chemical, including studies among different animal species, and epidemiologic studies in humans, to determine whether the weight of evidence indicates whether a chemical may be a human carcinogen. Under the pre-1996 guidelines [10], the EPA classified carcinogens according to the weight of evidence into one of five groups that ranged from "Known human carcinogen" to "No evidence of carcinogenicity". All but perhaps 35–40 chemicals ever studied fall somewhere between these two categories; their carcinogenicity in humans is uncertain. Guidelines published for review in 1996 replace the five groups with three categories and a narrative to describe the weight of evidence [18].

Much of this uncertainty concerning carcinogenicity comes from the process of identifying and evaluating potential carcinogens. Toxicologists know that there are serious questions about the validity of animal carcinogenicity studies. Some scientists believe cancer in test animals is actually a byproduct of the cell damage and subsequent cell reproduction and tissue repair induced in the experimental animals due to the toxic dose levels typically used in the tests. With humans exposed to extremely low doses of the same chemical in the environment, the cell damage

is too minor to induce tissue repair, and the chemical probably does not cause cancer. On this basis, many people believe that the true risk from such low exposures may be as low as zero. A second argument applies to chemicals that only cause tumors in specific situations. For example, many chemicals appear to cause tumors only in mice – not in other experimental animals – and only in the livers of those mice, rather than in other organs. Chlordane is such a chemical. We would not expect these chemicals to cause cancer in humans: experts disagree, however, so the cancer risk is uncertain. The same issues discussed for noncancer reference doses apply here, as well; toxicologists must extrapolate from high doses to low, short-term experiments to long-term environmental exposure, and animals to humans. Finally, uncertainty about the models used to develop the CSF is large. While the true cancer slope factor is not likely higher than the published CSF, it may be much lower, and perhaps as low as zero (*see* **Extrapolation, Low Dose**).

Sources of Chemical Toxicity Information. The EPA has already established and published the physical, chemical, and toxicological properties of many chemicals found at hazardous waste sites. These evaluations, based on the results from studies conducted by the National Cancer Institute (NCI) and from articles in refereed journals, are often reduced to either "chemical profiles" or simply a handful of numbers that represent toxic potencies. Published by the EPA, the findings and opinions on these chemicals are usually listed in two widely available resources: (i) the Integrated Risk Information System (known as IRIS [17]), a database updated monthly and available over several wide-area computer networks and (ii) the Health Effects Assessment Summary Tables (known as HEAST [16]), a database updated quarterly or semiannually and available in print from the National Technical Information Service (NTIS) in Springfield, Virginia. These two databases typically give several toxicity values for a single chemical, depending whether the exposure occurs via ingestion (e.g. via food or water) or via inhalation (e.g. via gases or particulates). Neither of these databases currently includes toxicity values for dermal exposures.

For use in a numerical example later in this article, we note that EPA's IRIS database recently listed the CSF for the ingestion of benzene as 2.9×10^{-2} mg/(kg d).

Exposure Assessment

The risk assessor first determines if complete "exposure pathways" exist and then estimates the doses delivered along those pathways [11].

Exposure Pathways. An exposure pathway is any route that a chemical may travel from an environmental source (e.g. an abandoned dry sludge lagoon) to a receptor (also called the exposed individual), such as a child living nearby. An exposure pathway has five main parts:

1. a chemical source;
2. a release mechanism (e.g. leaking, leaching, wind erosion);
3. a transport and/or exposure medium (e.g. air, water, soil, sediment, food);
4. an exposure point with receptors present or potentially present (actual location where exposure is possible); and
5. a route of entry (inhalation, ingestion, dermal contact).

A complete exposure pathway is one that has no functional barrier that prevents an exposure. The pathway may be completed (i) by the chemical moving from the source to the receptor or (ii) by the receptor moving to the source. In this example, fugitive dust that carries the chemicals may blow from the lagoon to the child's house, or the child may play in or near the old lagoon. Either way, with a completed pathway, the receptor comes into contact with some of the chemical from the source. If no exposure pathway is complete, there is no exposure and subsequently no risk.

In exposure assessment, the risk assessor usually considers three different exposure routes into the body: inhalation, ingestion, and dermal contact. With ingestion, the risk assessor considers whether a person may deliberately or inadvertently swallow some liquid or solid, including food, beverages, or soils (say, by hand-to-mouth movement). With inhalation, the risk assessor considers whether a person breathes toxic materials as gases, vapors, aerosols, or particles. With dermal contact, a risk assessor considers whether a person may touch gases, liquids, or solids that contain toxic materials and possibly absorb the chemical through the skin. Of course, in some situations, all three exposure routes may convey meaningful amounts of a chemical.

Exposure pathways are often categorized as "direct" or "indirect" pathways. Although no strict definitions exist, a direct pathway exists when the exposed person experiences the chemical in the same medium as that in which it is present in the source. In our example, the child may inadvertently ingest contaminated soil near the abandoned lagoon and thus experience a direct pathway. Alternately, an indirect pathway exists when the exposed person experiences the contaminants in a different medium, often at a distance from the source. In a different example, the child may drink cow's milk containing dioxin that traveled from an incinerator via this complicated route: formation in the incinerator, emission into the atmosphere as a gas, adsorption on to a particle in the atmosphere, wet or dry deposition on to grass in a pasture, ingestion by the cow, secretion in the cow's milk, and ingestion by the child drinking milk. For some types of facilities – for example, some incinerators – risk assessments show that these indirect pathways, although challenging and difficult to measure or analyze, may cause greater exposures than do direct exposures for some chemicals. In some areas of the US and in many other countries, homegrown vegetables may be an important part of the diet, and transfer of chemicals from soil, water, or air to vegetables may be highly important. In other cases, high exposure estimates for indirect pathways may result from compounding many conservative assumptions.

Estimation of Dose. When reading a risk assessment or a research publication, one should always check the definition of dose used by the authors, because different concepts and different units of measurement are common in the literature [1].

Here we distinguish three primary concepts of dose, noting that the first is most commonly used in risk assessments at hazardous waste sites.

1. *Exposure dose* is the mass of chemical that enters a person's body via ingestion, inhalation, or dermal contact. No allowance is made for excretion or exhalation of the chemical before absorption or metabolism. The conventional measure of exposure dose in units of milligrams of chemical per kilogram of body weight per day, mg/(kg d), explicitly scales by body weight, because a larger person needs greater exposure than does a smaller person to have a comparable effect. A milligram of chemical theoretically causes more harm to a child than to an adult.
2. *Absorbed dose* is the mass of chemical absorbed or metabolized by the receptor's body. Although measured in the same units, mg/(kg d), absorbed dose is always smaller than exposure dose, because some of the chemical is excreted or exhaled from the body before absorption in the lungs or gastrointestinal tract. On scientific merit, absorbed dose is always preferable to exposure dose, but it is also more difficult to measure or estimate because the (relative) absorption of the chemical may depend on many factors, including the age, health, and health status of the exposed person. With some chemicals, such as lead and other metals found in soils, identification of the absorbed dose may be very important in estimating risk. It may also be used in extrapolating from one exposure route to another, such as from an ingestion to a dermal dose.
3. The third concept of dose – *biologically effective dose* (BED) – is rarely used today directly in practical risk assessments for hazardous waste sites. BED is the mass of chemical (or sometimes the concentration of chemical) that reaches the target organ or tissue and causes the physiological or genetic damage. Of central importance in laboratory studies, BED is rarely used in practical risk assessments, because it is so difficult to determine even the identity of the chemical or the metabolite that causes the damage at the molecular level in the body. Usually, laboratory scientists study BED using radio-labeled compounds or other chemical measurement and pharmacokinetic models of absorption, metabolism, and excretion. This type of information can be helpful in extrapolating from animal studies to predicted human effects, or from one exposure situation to another. The toxicity values used in risk assessments may be refined as a result of such studies.

The duration of exposure clearly plays a central role in toxicology. Sometimes a brief, relatively large dose may cause less damage to an organism than does a much lower total dose sustained over a longer period of time, and sometimes the opposite is true. While occupational hygienists, police, or fire officials focus on exposures that occur over minutes or hours, risk assessors usually focus on exposures that range

in duration from a year or so to a full lifetime (usually assumed to be 70 years). Thus, risk assessors rarely consider acute health effects (from exposures of a few seconds to a few weeks) and instead tend to focus on subchronic, chronic, or lifetime exposures (here taken to mean, respectively, a few months, a few to many years, or a full lifetime). The exception to this is if very high exposures over a short time are possible, such as during site remediation. When reading an article or report, it is important to understand what time frames are included and what are excluded from the analyses.

We estimate exposure dose from the measurements or models of the exposure point concentration (e.g. the concentration in soil in a residential yard) and the contact rate (e.g. the amount of soil ingested from the yard). The exposure point concentration is the steady or time-varying concentration of the chemical in the medium to which a person has been exposed. In a particular situation, a single exposed person may have several exposures to a single compound. For example, at work, a person may breathe air that contains a chlorinated solvent, while at home the person may ingest water that contains the same compound. If the contaminant comes from a single source, the analysis is usually much easier than if the compound comes from multiple sources. A risk assessor may rely upon measurements or models to estimate the exposure point concentration. In most instances, concentration measurements are more reliable than modeled concentrations. However, models are frequently used if there are no cost-effective or realistic ways to measure the exposure point concentrations directly. Also, models are often used to predict the fate and transport of chemicals in air or ground water.

When using a model to estimate the exposure point concentrations of a chemical, especially a multimedia model, a risk assessor should remember the words of George Box, "All models are wrong but some are useful" [2]. Although originally penned for another purpose, these words suggest the need for great caution in using models to estimate exposure point concentrations and movement of chemicals in the environment. Before one can rely upon any concentrations modeled by oneself or others, we urge that one attempts to understand all of the limitations of the model(s) and to make a reality check for the values before proceeding.

When estimating the contact rate, a risk assessor is really estimating 'in the order of' intensity, frequency, and duration of exposure. A typical adult may drink daily $\sim 1-3$ liters of water, some at home and some at work. Those exposures may last five, 20, or more years, depending on changes in residence, employment, or occupation. The same person may have other exposures also via ingestion, inhalation, or dermal contact. Some exposures happen intermittently in time or space; for example, recreational use of a park.

The EPA has published numerous guidance manuals on the selection of the exposure factors needed to estimate contact rate [15]. For example, the Agency's *Exposure Factors Handbook* [12] lists point values for many physiological or behavioral variables for children and adults. The Agency's *Exposure Factors Handbook* does contain many of the standard values widely quoted and mandated in risk assessments. According to the EPA, each adult is assumed to weigh 70 kg, to ingest 2 l/d of drinking water, to breath $20-24\,m^3$/d of air, and to live in the same residence for 30 years. The Agency chose some of the values as "conservative" or upper bound values (e.g. 2 l/d of drinking water for each adult) and chose others as typical or average values (e.g. 70 kg as the average weight of an adult).

While these numbers are simple to memorize and easy to apply, it is important to realize that they misrepresent conditions that most people experience. People vary in many attributes. Not everyone weighs the same amount, or has the same diet, or lives in a home as long as 30 years. Furthermore, the actual values for some assumptions such as soil ingestion rates are simply unknown. Each of these exposure factors is better represented by a range or distribution of values – a topic discussed later.

As a practical matter, we recommend that risk assessors first estimate the exposure dose to a person on a day during which exposure is known to occur. For example, if a child has exposure to a toxic chemical when trespassing on an industrial property, the risk assessor should first estimate the dose on that particular day of trespass. If the behavior occurs every day of a year, then the average daily dose on a day of exposure equals the average daily dose during that year of exposure. However, if the exposure does not happen every day, then the average daily dose for the year is less than the average daily dose on the day of exposure. All doses need evaluation against

an appropriate measure of toxicity. For example, an adult could drink one Martini every night for two weeks without serious adverse effect, but drinking 14 Martinis in one night would have dangerous health effects, even though the average daily dose over two weeks is the same. The risk assessor must account for high-dose, short-term exposure potential, even during one year or less.

As a numerical example, we estimate the average daily dose (*ADD*) averaged over a lifetime of exposure for an adult who (unwittingly) drank water from a contaminated well at a vacation home. To make the calculation, we estimate the exposure dose to this person who weighed 70 kg, drank 2 l/d of water, and visited the vacation home two days per week (the weekend) for 10 weeks per year (the summer). This person owned the house for 20 years. The well water contained 115 μg/l of benzene (a known human carcinogen). We use this formula:

$$\langle ADD \rangle_{\text{life}} = \frac{Conc \times IngR \times CF}{BW} \frac{D}{7} \frac{W}{52} \frac{Y}{70},$$

where $\langle ADD \rangle_{\text{life}}$ is the average daily dose, averaged over a lifetime (mg/(kg d)), $Conc$ is the concentration in drinking water (μg/l), $IngR$ is the ingestion rate (l/d), CF is the conversion factor (mg/μg), BW is the body weight (kg) D is the number of days of exposure per week, W is the number of weeks of exposure per year, and Y is the number of years of exposure in a lifetime of 70 years.

Substituting the values with $CF = 10^{-3}$, we find $\langle ADD \rangle_{\text{life}} \sim 5.16 \times 10^{-5}$ mg/(kg d).

While doses of carcinogens may be averaged over a lifetime, doses of noncarcinogens are averaged over a shorter time (usually the duration of exposure). In the example above, it is appropriate to average exposure to a noncarcinogen over 20 years.

Risk Characterization

The risk assessor combines all the information gathered in the preceding three steps to estimate quantitatively the health risk. In practice, this step usually culminates (i) in a numerical estimate of noncarcinogenic health effects as measured by a summary statistic called the total *hazard index* (*HI*) and also (ii) in a numerical estimate of the carcinogenic potential as measured by a summary statistic called the total *incremental lifetime cancer risk* (*ILCR*) (see, for example, [13]).

For exposure to a single noncarcinogenic chemical via a single exposure pathway, the hazard index is usually defined as the average daily dose averaged over one year of exposure divided by the reference dose for that chemical via that exposure pathway.

$$HQ_{ij} = \frac{\langle ADD \rangle_{\text{year}}}{RfD},$$

where HQ_{ij} denotes the *hazard quotient* for that combination of chemical and, exposure pathway (as a ratio, it has no units); $\langle ADD \rangle_{\text{year}}$ denotes the average daily dose averaged over one year, expressed in mg of chemical per kg of body weight per day; and RfD denotes the reference dose for that chemical and route of exposure (e.g. inhalation), also expressed in mg of chemical per kg of body weight per day.

In a full study, the risk assessor estimates the hazard index (HI) by summing the hazard quotients over all chemicals and exposure pathways [14]:

$$HI = \sum_i \sum_j HQ_{ij}.$$

Given its definition as a ratio of positive numbers, the HI may range from zero to infinity. If the $HI > 1$, then the risk assessor may disaggregate it into those components that act on a common organ system or by a single molecular mechanism. The reasoning behind this is that the body can handle multiple chemical stresses through multiple defenses. For example, at a mining site, people may be exposed to lead, zinc, arsenic, manganese, and copper. For practical purposes, at low doses, these metals act independently on different organ systems, and regulatory agencies often treat the risks from these metals separately instead of adding them together. The risk manager may become increasingly concerned as the HI disaggregated by organ system or molecular mechanism exceeds unity.

For exposure to a single carcinogenic chemical via a single exposure pathway, the incremental lifetime cancer risk is usually defined as the average daily dose averaged over a lifetime multiplied by the cancer slope factor [10]:

$$ILCR_{ij} = \langle ADD \rangle_{\text{life}} \times CSF,$$

where $ILCR_{ij}$ denotes the incremental lifetime cancer risk for that combination of chemical and exposure pathway (as a probability, it has no units);

$\langle ADD \rangle_{\text{life}}$ denotes the average daily dose averaged over a full life, usually taken as 70 years, expressed in mg of chemical per kg of body weight per day; and CSF denotes the cancer slope factor for that chemical and route of exposure, expressed in the inverse of (mg of chemical per kg of body weight per day).

Continuing the numerical example from above, the adult who drank the water contaminated with benzene ($CSF = 2.9 \times 10^{-2}$ mg/(kg d)) while staying at a vacation home has an estimated $ILCR \sim 1.5 \times 10^{-6}$.

In a full study, the risk assessor estimates the total incremental lifetime cancer risk by summing over all chemicals and exposure pathways [13]:

$$\text{Total } ILCR = \sum_i \sum_j ILCR_{ij}.$$

Before estimating the total incremental lifetime cancer risk, the risk assessor may estimate subtotals by chemical source and by route of exposure to help clarify which exposure pathways cause the greatest risk. Of course, for a contaminated site, the risk assessor must take care to add risks from exposures related to the site.

Because the incremental lifetime cancer risk is formulated and interpreted as a probability of developing cancer at some time during a lifetime, the value (in theory) ranges from zero to one. As a practical matter, the probability of developing cancer is not linear at high doses (as the CSF implies). Even very heavy cigarette smokers are not guaranteed to develop lung cancer. Probabilities that exceed 1 in 100 are usually highly inaccurate.

Analysis of Variability and Uncertainty

The risk assessor names the sources, magnitudes, and likely effects of variability and the uncertainty in the analysis. We define variability and uncertainty as follows:

1. *Variability* represents diversity or heterogeneity in a well characterized population of plants, animals, or people. Fundamentally a property of nature, variability is usually not reducible through further measurement or study. For example, different adults drink different volumes of tap water each day, no matter how carefully or how often we measure their diets.
2. *Uncertainty* represents partial ignorance or lack of perfect information about poorly characterized phenomena or models. Fundamentally a property of the risk analyst, uncertainty is sometimes reducible through further measurement or study. For example, a risk assessor may not now know how much soil each adult ingests per day, but she or he may be able to design experiments to gain additional (but still imperfect) information.

Few risk assessments contain more than a few paragraphs of text acknowledging the variabilities and uncertainties in the methods and results. Some risk assessments go further and include **sensitivity analysis**. For example, a risk assessment may include several calculations of the same result, but each one predicated on a different set of input values chosen within the range of the variability or the uncertainty inherent in the analysis. A sensitivity analysis might indicate that the risk estimate is sensitive to the rate of fish ingestion, and may suggest that a survey of the affected population might tighten the upper and lower bounds on the risk estimate.

Risk assessments may include information on model uncertainty; in other words, the uncertainty inherent in the mathematical formulation of the models used in exposure assessment, dose–response assessment, or risk characterization.

New Directions in Human Health Risk Assessment

The practice of human health risk assessment for exposure to chemicals in the environment is shifting from a deterministic to a probabilistic paradigm. Two features distinguish the two paradigms. In the probabilistic paradigm we consider (i) all variables as **random variables** instead of point values, and (ii) quantitative analyses of variability and uncertainty now become an integral part of risk characterization.

Most people understand intuitively that exposure variables such as body weight, the daily ingestion rate of drinking water, and the number of days a person visits a park are random variables. Similarly, most people understand intuitively that toxicity values, such as the RfD or the CSF, are also random variables (by exhibiting inter-individual variability).

However, some people are uncomfortable with the logical consequence from these facts; namely, if all of the input variables in a risk assessment are random variables, then the output variable – the estimated incremental lifetime cancer risk – is also a random variable. In other words, the estimated risk for a situation is not a point value but a range of values (see, for example, [6] and [3]).

When establishing the probability distributions for the input variables for a risk assessment, it is instructive to distinguish two driving forces behind the need for probability distributions – variability and uncertainty – as defined earlier. For example, with body weight, the random variable captures mostly the known and well measured inter-individual variability in a population. As a second example, for the number of days a person swims in a local pond, the random variable may capture mostly the unknown or poorly measured inter-individual behavior in a population. So in a risk assessment, the random variables inevitably capture different combinations of variability and uncertainty for each different input variable [4].

For the probabilistic risk assessment paradigm, in any given situation, the risk assessor should focus on choice of (i) accurate input distributions and (ii) accurate exposure, toxicity, and risk characterization formulas. In probabilistic risk assessment, the analyst has to select input distributions based on the facts of the situation.

In the probabilistic paradigm, the risk manager receives more information than in the deterministic paradigm; namely, she or he receives distributions for exposure and risk instead of merely point values. While risk management in the deterministic paradigm consists of comparison of point values for estimated and acceptable risks as a so-called "bright line test", risk management in the probabilistic paradigm consists of comparison of estimated and acceptable distributions of risk.

To continue the numerical example from above, we learn that the fixed values used earlier oversimplified the history. After discussion with the exposed individual and with further field testing, we find that we can better represent some of the variables in the equations as probability distributions than as point values, precisely because variability was an intrinsic part of the person's behavior and also of the aquifer from which the person consumed ground water. With this new information, we find that these probability distributions better describe the situation than do the point values that they replace:

1. The variability in *Conc* (concentration) is well described by a triangular probability distribution with a minimum of 80, a mode of 85, and a maximum of 120, in units of μg/l.
2. The variability in *IngR* (ingestion rate) is well described by a **normal** or Gaussian probability distribution with a **mean** of 1.60 and a **standard deviation** of 0.20, in units of l/d.
3. The variability in *BW* (body weight) is well described by a normal or Gaussian probability distribution with a mean of 70 and a standard deviation of 10 in units of kg.
4. The variability in *D* (days per week) is well described by a **uniform distribution** with a minimum of 1.0 and a maximum of 2.5.
5. The variability of *W* (weeks per year) is well described by a uniform distribution with a minimum of 7 and a maximum of 11.

All the other variables and conversions in the equation have the same point values as before.

With this new information, we use a commercial software package named Crystal Ball® [5] to convolve (an operation analogous to ordinary multiplication) the probability distributions and the point values in the equations for estimating $\langle ADD \rangle_{\text{life}}$ and *ILCR*. The results of the convolution (as done by 5000 repetitions of a Monte Carlo simulation in the software package) are shown in Figure 2. Figure 2 now more fully expresses the variability inherent in the situation as a range of values from $\sim 5.0 \times 10^{-7}$ to $\sim 2.0 \times 10^{-6}$. The point estimate calculated earlier ($\sim 1.5 \times 10^{-6}$) occurs well above

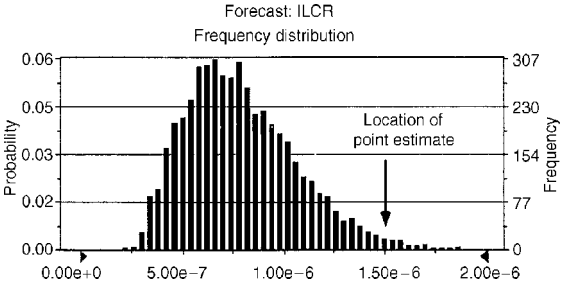

Figure 2 Estimated distribution of risk based on estimated distribution of exposure

the 95th percentile of the estimated distribution. This graph conveys considerably more information than did the point value calculated earlier in this article.

Given an estimated distribution for risk, the risk manager might use decision rules along these lines to render an opinion on the acceptability of the estimated risk: (i) Is the **median** of the risk distribution less than 1 in a million? (ii) Is the average of the distribution less than 1 in 100 000? (iii) Is the 95th percentile of the risk distribution less than 1 in 10 000? If the answer to *all* three questions is "yes", then the risk manager might decide that the risk is acceptable. In other words, the risk manager may only look at selected percentiles or summary statistics when deciding if a risk is acceptable for a population.

The new paradigm does require more effort to specify the input variables and more computation to estimate the distribution of the output variable, namely risk. The probabilistic paradigm still contains unquantified uncertainty. Entire exposure pathways may have been overlooked. Laboratory analyses may have been **biased**. Statistical data analysis may have been inappropriate. Conservative assumptions may have been incorporated in the risk assessment unnoticed. The risk paradigm itself may over- or underestimate risk due to the averaging of exposure, the interactions of chemicals, or other reasons. Overall, the uncertainties for some exposure variables such as soil ingestion rates or toxicity values may have been underestimated in the past due to a focus on specific studies without consideration of fundamental biological principles or other information. One should acknowledge these and other uncertainties to allow for proper interpretation of the distribution of risk. Even considering these remaining uncertainties, the output distribution conveys much more fully the full range and probabilities of plausible health risks – and provides enormous benefit over the simple point estimates that result from a deterministic calculation.

The probabilistic paradigm builds on the fundamental definition of risk as the probability of adverse outcome. It reestablishes the now blurred lines between risk management and risk assessment.

Risk Assessment in Clinical Decision Making

Risk has been defined technically as "the probability that a particular adverse event occurs during a stated period of time, or results from a particular challenge" [5, 21]. In popular usage, the term is usually broader, and can refer simply to exposures that may cause or lead to adverse events, but without reference to probability. For example, the *Oxford English Dictionary* gives as its primary definition: "hazard, danger; exposure to mischance or peril".

In this article, we will use the technical definition of risk and will focus on risks to patients in the clinical setting, particularly of events incurring physical harm due to therapeutic interventions. There are also possible risks to caregivers, e.g. loss of professional reputation or being sued following a poor decision – or even to a health care system or insurance company responsible for paying the costs of decisions made by caregivers and their patients. Similar general principles can be applied to other types of risk, but the issues discussed in this article will relate directly to clinicians and patients, and to the statisticians who provide them with the estimates of risk.

Factors that Modulate Risk Assessment and Clinical Decisions

Clinical decisions are made because it is believed that the actions that follow them will do more good than harm. **Risk assessment**, therefore, is one important component of such decisions. The assessment of risk (like clinical decisions in general) can be modulated by the circumstances or context in which they are made, the values and preferences of the decision makers, and the information available [7, 12]. While some values are already held by each of the decision makers, their ability to assess risk efficiently in different circumstances (in conjunction with their values) depends on whether they are aware of the relevant information needed to make the decisions; they have access to such information; the information is available to them in a manner that is intellectually accessible, unbiased and appealing; they are able to interpret the information; and they have the skills to incorporate the information into their decisions. Information to guide clinical decisions can come from multiple sources, some of which are more reliable than others (*see* **Utility in Health Studies**; **Decision Analysis in Diagnosis and Treatment Choice**).

Ultimately, clinical decisions should take account of both risks and benefits, and should consider alternative actions (including doing nothing). A fully informed decision, therefore, requires knowledge of both the benefits and the risks of the available options. While the beneficial effects of an intervention may be known from randomized controlled trials (RCTs) (*see* **Clinical Trials, Overview**), however, frequently RCTs are not appropriate or have paid less attention to the harm that may result from the same intervention. For example, RCTs (usually of short duration) may be unable to capture all the relevant information on risks associated with drugs that may have long-term side-effects. On those occasions, decision makers are forced to look at other types of study (such as **cohort** or **case–control studies**) or other sources of information (usually less valid, such as anecdotes or **case series**) to guide their decisions.

Components of Risk Assessment

Several aspects make up risk assessment. These aspects include risk estimation, risk communication, risk perception, and risk acceptance.

Risk Estimation

Risk estimation involves the use of statistical techniques to obtain a numerical value of risk. Since this is dealt with in detail elsewhere, we will give here only a brief overview.

Several measures of risk are available: **absolute risk** (and absolute risk difference); **relative risk**; and the **number needed to treat** (NNT) or the number of treatment-years to produce a single adverse outcome. The value of these measures to decision makers depends on their precision, validity (**unbiasedness**), and reliability. A precise estimate may be difficult to achieve if the study generating the measure has small sample size. This is particularly relevant when evaluating interventions with rare outcomes. For example, Miller et al. [15] estimated the risk of neurologic sequelae in previously normal children persisting 1 year after pertussis vaccination to be one in 310 000. In such circumstances, the **confidence interval** might be used to estimate an upper bound on

the risk involved. (In this case, the upper 95% limit was one in 54 000.) (*See* **Pharmacoepidemiology, Adverse and Beneficial Effects**.)

In addition, the validity of the estimate may be threatened if the design of the study that has generated the estimates is **biased**. An unbiased estimate may be difficult to achieve, particularly if the outcome is recorded using subjective measures, the intervention cannot be studied under double-blind conditions (*see* **Blinding or Masking**) or the allocation to study groups is neither concealed nor randomized [1, 2, 22] (*see* **Randomization**). Reliability, in turn, can be affected by limitations in the definition, attribution, recording, identification, classification, reporting, measurement, and analysis of information related to adverse effects of treatments [3, 8, 11]. On occasions, a further complication may be introduced by the need to obtain an exposure–response relationship. Different formulations of a given drug, for example, may contain different amounts of the drug, leading to different risk estimates. (*See* **Dose–Response Models in Risk Analysis**; **Dose-response in Pharmacoepidemiology**.)

Risk Communication

Even when the risk estimates are accurate (precise and unbiased), it would be unrealistic to expect that such estimates will lead automatically to risk assessment. It has been shown, for instance, that the type of risk estimate presented to decision makers (i.e. absolute event data versus **relative risk** reductions) can affect their assessments of risk [16]. The way in which risk estimates are described (or "framed") can also influence the reaction of those given the information. It has been shown repeatedly, for instance, that if the information is worded in a way that emphasizes the negative rather than the positive aspects of the same outcome (e.g. when describing the effects of an anticancer drug in terms of deaths rather than survivors), decision makers may alter their perception of risk and their preferences [18, 23].

In addition to the selection of the outcomes and the way in which the information is framed, the format in which the risk estimates are shown to decision makers can also affect their reactions. **Graphical displays**, for instance, are used frequently to represent risk with the hope that they will facilitate data interpretation. There is little empirical evidence, however, that could be used to guide the selection of graphical displays to communicate risk information. Some of the existing evidence suggests that patients and clinicians may interpret information from the same displays differently. When results of clinical trials are presented as survival curves, for instance, patients appear to focus more on the endpoints, while clinicians pay more attention to intermediate points [14]. Different shading and plotting symbols can also have strong effects on the visual perception of data [24]. More research is required to assess the impact of different visual displays on decision makers. A recent review, for instance, identified 13 methods to display the results of **meta-analyses** graphically, but did not find a single study on the effects of such displays on decisions [9]. Other aspects of risk communication also require more research. Little is known, for instance, on the effect of risk perception of different media to communicate risk (e.g. face-to-face contact, paper, videotapes, audiotapes, CD-ROM, Internet).

In summary, there appears to be no simple best method of presenting information to decision makers. One approach is to provide data to decision makers in several different forms, trying to explain any differences that may arise in the interpretation of the information across the methods.

Risk Perception

Risk estimation and communication play an important role in the way in which risk is perceived. However, they are not the only factors that determine risk perception. Even if decision makers are presented with accurate estimates in multiple forms, their perception of risk could be affected by factors such as: the probability value associated with the particular events and the nonlinearity of decision weights; their prior beliefs and experience; their ability to interpret probabilistic information; their intuitive rules of thumb (heuristics); and the suspicion of vested interest in those generating risk estimates (risks evaluated by those who might have a vested interest in the results may be viewed as understated compared with risks evaluated by independent sources). We consider each of these in turn.

Probability Value. It has been shown that patients and healthy volunteers can be strongly influenced

by different levels of probability of adverse events [18]. When the probability of survival given to cancer patients in that study dropped below 0.5, patients adopted a "dying mode" in which **quality of life** became more salient than quantity of life in decision making [18]. In addition, it has been suggested that decision makers weight different levels of probability in a nonlinear fashion. Moderate and high probabilities, for instance, tend to be underweighted relative to outcomes that are certain, low probabilities tend to be overweighted, and very low probabilities are either severely overweighted or neglected altogether [10]. This has important implications for risk acceptance (see below).

Prior Beliefs and Experience. Prior beliefs of decision makers can also affect their perception of risk. Clinical decision makers, like "lay" people, tend to form opinions rather quickly, usually in the absence of strong supporting evidence. These opinions, once formed, are slow to change in response to new evidence. New evidence is usually handled in a very asymmetric way by decision makers: supportive evidence tends to be considered more convincing than opposing evidence, regardless of the rigor with which it has been gathered [17]. One important factor that can influence dramatically the prior beliefs of decision makers is a vivid experience [17]. A tragic outcome with the last patient can change the way in which a clinician will perceive the risk that the same outcome will occur in the next patient. Similarly, a patient's perception of risk may be influenced more by the experience of a close friend than by evidence collected from thousands of patients in well-controlled clinical trials, leading the patient to reject such evidence – especially if it contradicts the patient's preconceived theories or challenges his/her hopes [20]. Alternatively, if an intervention has been used by clinicians or patients for a long time, the hazards associated with a "new" or unfamiliar intervention may be perceived as worse than those which are more familiar to them [5, 21].

Ability to Interpret Probabilistic Information. The ability of decision makers to interpret probabilistic information can also influence their perception of risk. In part because of their exaggerated reliance on vivid experiences or anecdotes, but also because of their lack of formal training in statistics, patients (and other lay members of the public) have a limited ability to interpret probabilistic information or any other type of scientific evidence that could help them assess risk. This "lack of training" limits their ability to build hypotheses, to assess covariation and **causation** and to predict events [17]. There is little research in relation to the understanding of statistical principles by clinicians. In a recent study, however, doctors who said that they were confident about their ability to evaluate risk of coronary heart disease consistently overestimated such risks in individual patients as well as the absolute benefits of modification of coronary risk factors [6]. In another study, the same tendency of physicians to overestimate risk was identified [19]. Furthermore, the investigators taught the physicians to make better judgments of disease probability, but such an improvement in risk assessment did not result in changes in their treatment decisions [19].

Heuristics. Even if clinicians and patients were equipped with the skills required to evaluate probabilistic information on risks, there are few choices in the clinical setting that could be informed fully with evidence generated in RCTs or **observational studies**. Despite this lack of evidence, most clinicians do make decisions. The way in which they do so in the absence of evidence has been explained by the use of intuitive *ad hoc* rules of thumb, also called "heuristics", to guide their choices [13]. Patients also use heuristics, particularly to reduce complex inferential tasks to simple judgmental operations during the evaluation of event frequency, probability and causality [17]. Many of these strategies are poorly understood and potentially problematic. There have been recent calls for the systematic study of the heuristics of medicine, hoping that the more uniform use of explicit, refined and better heuristics could lead to more efficient medical care [13]. Similar efforts should be made to understand and refine patient heuristics.

Risk Acceptance

Whether a particular risk is accepted or not depends, at least in part, on each of the factors described so far. In addition, there are other elements that could also affect risk acceptance:

Implications of the Decision. A risk may be more acceptable when the adverse event, if it occurs, has

a minor impact on the person making the decision than if it has a major impact. For instance, in cases of mental depression, the risk of experiencing the relatively minor adverse effects associated with tricyclic antidepressants or lithium may be more acceptable than the risks of suicide if the depressive disorder is left untreated.

Type of Outcome. An increase in resource utilization might be regarded as more acceptable to a patient with cancer, particularly if the costs of care are covered by an insurance company, than a reduction in the likelihood of survival.

Timing Between Decision and Outcome. Surgical mortality, an immediate hazard, may be considered worse than later death caused by the toxic effects of a drug, a deferred hazard [5].

Circumstances. Risks imposed for the benefit of others may be less acceptable than risks undertaken for self-protection. For example, compulsory whooping cough vaccinations may be imposed on older children primarily for the benefit of younger age groups [5, 20, 21].

Role. A hypothetical risk is likely to be accepted more easily by a healthy volunteer than a real risk by a patient [4].

Formal Decision Making Procedures

There exist a number of procedures for helping a patient reach a decision which attempt to incorporate the values and preferences of the patient. These include: the **standard gamble**, **time tradeoff**, **utilities**, and **willingness to pay**.

Conclusion

Biostatistics is primarily concerned with providing accurate estimates of risk in clinical situations. What we have shown in this article is that decision making following the estimation of risk depends on more than just the risks (and benefits) involved. Risk communication, perception and acceptance have subtle characteristics that play important roles. Statisticians, health care practitioners and others must be aware of these to help patients reach decisions in the clinical setting.

Risk Assessment

The various usages of the term *risk* all concern the possible occurrence of events or situations, called *hazards*, the consequences of which are uncertain, but may be harmful. Informal usages of **risk** may indicate the nature, or merely the existence, of the possible danger ("There is a risk of post-operative infection"; "I never take risks"). In technical discussions the term is used quantitatively, but even there the usage is not standard.

There are two principal, and mutually incompatible, interpretations:

1. The probability, or chance, of an adverse event. Clearly, this must be put in context: it should refer to a defined set of circumstances, and, for hazards continuing over time, the rate per time unit, or for a unit of exposure, is normally used.
2. A combination of the chance of an adverse effect and its severity. There are obvious difficulties with this type of definition: How is severity measured, and how are the two components combined?

The extensive literature on risk covers many aspects, which are commonly collectively termed *risk assessment* or *risk analysis*. The first of these terms is sometimes used more restrictively, to include the concepts of *risk estimation, risk evaluation*, and *risk perception*, as defined below. The study of risk brings together engineers, behavioral and social scientists, statisticians, and others, and to some extent usage of terms varies amongst these groups. For example, engineers and other technologists tend to favor approach 2, statisticians and biologists tend to favor 1, and behavioral and social scientists tend often to use a mutifaceted approach. Reference [6] contains chapters by groups of writers from different backgrounds, and has extensive bibliographies. See also [1] for a popular exposition.

Risk theory has a specialized meaning, being concerned with the financial integrity of an insurance company in the light of random fluctuations in claims. It forms an application of the theory of **stochastic processes** [7].

Statisticians will note that usage 2 above is closely related to the concept of a *risk function* in **decision theory**. There, uncertain events, the distribution of which depends on an unknown scenario, have consequences measured by a **loss function**; a particular decision function, defining the action to be taken when the event is observed, has an average loss for any given scenario; and the *risk* (or *integrated risk*) is the mean of the average loss when taken over the **prior distribution** of the scenarios. Application of this approach is hampered by the difficulty of determining losses in financial terms, and of defining the various probability distributions.

Attention has been focused on various interrelated aspects of risk, including the following:

1. *Risk estimation*: the estimation of the probabilities of the adverse outcomes, and of the nature and magnitude of their consequences.
2. *Risk evaluation*: determination of the significance of the hazards for individuals and communities. This depends importantly on the next aspect.
3. *Risk perception*: the extent to which individuals assess risks and the severity of possible outcomes, assessments that may differ from those made by "experts".
4. *Risk management*: the measures taken by individuals and societies to prevent the adverse effects of hazards and to ameliorate their consequences.

We deal briefly with these topics in turn. The articles in [6], and their bibliographies, provide a much broader picture. Many of these topics are discussed fully elsewhere, in relation to **risk assessment for environmental chemicals** (also, *see* **Risk Assessment in Clinical Decision Making**).

Health Hazards

There are several clearly distinct categories of hazards that give rise to health risks.

First, there are hazards that arise from the physical and biological environment. Many of the hazards in the physical environment are man-made. It is our own choice, collectively, to pollute the atmosphere with emissions from domestic fires, power stations, or burning oil wells, and to treat water supplies with disrespect. These are examples of damage *to* the environment, and damage to ourselves *from* the environment. The biological environment presents a hazard to us mainly in the form of microorganisms causing infectious disease.

Other hazards arise from personal, rather than societal, choice. These include habits with adverse consequences, such as the consumption of tobacco, alcohol, and narcotic drugs. The category includes also indulgence in sport and travel; and our often unwise dietary choices. We tend to shrug off the hazards that we ourselves incur, by understating the risks or overstating the benefits, while deprecating the folly of others.

Finally, there are hazards that cannot be prevented by personal decisions. They follow inexorably from our innate or ingrained characteristics – our genetic makeup or our experiences in early life. In some instances, medical science can reduce the risk to which susceptible individuals are subject: in others, the burden has to be endured.

Risk Estimation

The risks from many prominent health hazards can be estimated reliably from objective statistical information. In other instances, in which numeric information is lacking, risks may be guessed by informed experts (as in the setting of insurance premiums for nonstandard risks; *see* **Actuarial Methods**). There are, for instance, no reliable data on the frequency of explosions at nuclear power installations, and estimates of risk would have to rely on expert judgments, or on careful estimation of risks of failure at individual links in the chain of connected events.

Even when statistical information is available, an individual may argue that his or her risk is not properly represented by the population estimate. There is a long-standing debate as to whether medical statistical information necessarily applies to an individual in the population concerned; in the nineteenth century, for instance, opposite views were held by **P.C.A. Louis** and by **C. Bernard**. Clearly, if the individual has known characteristics that can be shown to affect the risk, they should be taken into account. If no such characteristics can be identified, it seems reasonable to apply the population estimate to the individual. The point is important, in emphasizing that risk estimation is far from being an objective matter.

Statistical information on the risk of mortality from different diseases is widely available, for individuals of each sex at different ages, in different occupational (*see* **Occupational Epidemiology**) and social groups and for different countries (*see* **Mortality, International Comparisons**). Information on the risks of morbidity is less comprehensive. Such information, based on data for large populations, is of some value for the estimation of risks for random members of the populations, but gives little or no indication of risks for individuals exposed to certain specified hazards; such as environmental pollution (*see* **Environmental Epidemiology**), social habits, or the onset of disease.

For questions of this type, special investigations are required. The whole range of types of epidemiologic study is available, including **case–control studies**, **cohort studies**, and **case–cohort studies**. The risks of adverse progression of disease may be estimated by a study of **prognosis**. See [3] for an example of various investigatory methods employed in a study of the apparent excess risks of childhood leukemia (*see* **Leukemia Clusters**) due to contamination of water supplies in a town.

In many "high-profile" public health problems, it is not possible to mount epidemiologic studies to give unambiguous estimates of risk. The mechanism giving rise to the risk may not be fully understood, or the dangers may arise from a complex chain, the risks for which are difficult to measure. In such instances, the risks may be estimable only within very broad bands. For instance, in the crisis in the British beef industry, due to the outbreak of bovine spongiform encephalopathy (**BSE**), leading to an apparent risk of Creutzfeldt–Jakob disease (CJD), it was very difficult to estimate precisely the risk of CJD to a person eating beef. Since the cessation of use of suspect cattle feed, and the culling of relevant herds, it is probably reasonable to say that the risk is "extremely low", and perhaps to put some upper bound on it, but such estimates would rely on somewhat shaky data, and on the personal judgments of experts.

Another example is that of prolonged exposure to low levels of possibly carcinogenic chemicals. Carcinogenicity experiments, with the administration of high doses to animals (*see* **Animal Screening Systems**; **Serial-sacrifice Experiments**), may give quite precise estimates of a **median effective dose**. However, risk estimation for low-level exposure to humans involves **extrapolation to low doses** (using models that are not necessarily correct [5]), and from the animal to the human species (*see* **Dose–Response Models in Risk Analysis**). The result of such extrapolation may well be reassuring, but it is unlikely to be quantitatively precise.

Risk Evaluation and Perception

The evaluation of risk, either by individuals or by societies, should in principle involve a balancing of the costs and benefits: the potential occurrence of adverse effects, arising from exposure to a hazard, should be balanced against the potential benefits in physical or psychological rewards. Cost–benefit analysis (*see* **Health Economics**) is, however, a somewhat idealized concept. Apart from the difficulties of risk estimation, outlined above, both the potentially adverse effects and the supposed benefits may be difficult to evaluate on commensurate scales.

The benefits may in part be assessable as direct economic gains to a community. They may also include amenities, such as palatable food or attractive cosmetics, the value of which may be estimable by enquiry as to the prices that people are willing to pay for them.

The costs may be even more elusive. They include direct financial losses; for instance, in productivity. They include also disbenefits of pain and other symptoms. One might enquire how much people would be willing to pay to avoid such discomforts, but this would be a difficult exercise for people who had never experienced the symptoms in question.

Then, there is the crucial question of the value of human life. There are various approaches to this task, such as: (i) calculation of lost earning capacity; (ii) implicit evaluation based on societal practice, such as compensation awards or expenditure on specific safety measures; or (iii) the size of insurance premiums.

None of these possible approaches is likely to be simple, but it seems important to encourage further discussion and research, especially for the evaluation of risks for which community decisions, such as the imposition of government regulations, are required.

Evaluation by individuals of risks incurred by possible individual choices, again in principle involves the balancing of costs and benefits, but these may be very subjective and even more difficult to quantify than those involved in community action. In a sense, the decisions actually taken by individuals, sometimes without appreciable introspection, carry implications about the values attached by those individuals to the various elements in the equation. From this point of view, the relevant estimates of risk may be the subjective perceptions of the individuals themselves, rather than more "objective" estimates provided by experts. These two forms of estimate may be quite disparate. We tend to be more concerned about infrequent but dramatic events, such as major air crashes, than about frequent but less dramatic series of events such as the regular toll of road accident deaths. In one study [4], people thought that accidents caused as many deaths as disease, whereas in fact disease causes 15 times as many. The incidences of death from spectacular causes such as murder, botulism, tornadoes, and floods were all overestimated, whereas those for cancer, stroke, and heart disease were underestimated.

The importance of the "benefit" side of the equation is illustrated by the varying acceptability of activities with comparable risks. People are generally prepared to accept much higher risks of death from activities in which they participate voluntarily, such as sports, than from those encountered involuntarily.

Risk Management

This term covers the decisions, taken by individuals and communities, to accept or forego hazardous situations after assessment of risks, or to reduce exposure to the hazards and/or their adverse consequences.

As noted above, decisions by individuals are highly personal, and to a detached observer they may often seem irrational. A rational study of teenage smoking may conclude that the hazardous practice should be avoided, but its conclusions may carry little weight with a young person who is ill-informed about risks, and whose "benefits" include the pleasures of conformity with peer practice. Nevertheless, in such situations, improved information about risks and adverse consequences is highly desirable, and the provision of risk information forms one of the major roles of government and other public bodies concerned with risks.

Institutions with a role in risk management include international, national, and regional governments, and a variety of public and private organizations. Apart from the provision of information, governments may issue regulations to reduce or control the use of hazardous substances. Their decisions may be guided by advisory committees, perhaps internationally based. For instance, in the assessment of evidence of carcinogenicity of chemicals, authoritative advice is provided by the program of the International Agency

for Research on Cancer (IARC) Monographs on the Evaluation of the Carcinogenic Risk of Chemicals to Humans [2].

Institutions concerned with mitigation of the adverse effects of hazards include the judiciary (through compensation awarded in the law courts), insurance companies, and a variety of community bodies concerned with social welfare.

Conclusions

The interdisciplinary nature of all the aspects of risk assessment discussed here has encouraged lively discussion and research. Biostatistics forms only one component in the mixture, but it is an essential ingredient. Publications are spread widely in the technical press, but special note should be taken of the journal *Risk Analysis*.

PETER ARMITAGE

Risk Factor

A factor whose presence is associated with an increase in the probability of developing a disease is called a risk factor for that disease. It is a generic term widely used in epidemiology (*see* **Epidemiology, Overview**) that can stand for genetic traits, sociodemographic characteristics as well as occupational, environmental, or any other types of exposures. This definition implies that a risk factor for a given disease must be present before disease occurrence. By analogy to risk factors that refer to the development of a disease, prognostic factors are defined as factors whose presence is associated with an increase in the probability of patients developing a certain outcome (e.g. recurrence or death) during the course of disease (*see* **Clinical Epidemiology**; **Prognosis**). An association between a risk factor and a disease can be quantified by various measures such as the **relative risk**, **hazard ratio**, **odds ratio**, or risk difference. Risk factors are usually identified from **observational** epidemiologic studies so that the association between a risk factor and a disease is not necessarily of a causal nature (*see* **Causation**; **Hill's Criteria for Causality**), which is why Miettinen [1] recommended the use of the term *risk indicator* rather than risk factor. In contrast with risk factors, factors whose presence is associated with a decrease in the probability of developing a disease are usually called *protective factors*.

JACQUES BENICHOU

Risk Set

In survival analysis, one of the most frequently used methods is the **Kaplan–Meier** estimator for nonparametric estimation of the survival distribution function $S(t)$ based on right-**censored** data. Thus, let $X_1, \ldots, X_n$ be independent identically distributed lifetimes with $S(t) = \Pr(X_i \geq t)$ and assume that $(\tilde{X}_i, D_i)$, $i = 1, \ldots, n$, are observed. Here, $\tilde{X}_i = X_i$ and $D_i = 1$ if individual i is observed to die and $\tilde{X}_i = U_i$, a right-censoring time, and $D_i = 0$ if the lifetime of individual i is censored at time U_i, in which case the only information on X_i is that $X_i > U_i$ ("independent censoring"). Then the Kaplan–Meier estimator is given by

$$\hat{S}(t) = \prod_{\tilde{X}_i \leq t} \left(1 - \frac{D_i}{r(\tilde{X}_i)}\right), \tag{1}$$

where $r(s) = \#R(s)$ and

$$R(s) = \{i : \tilde{X}_i \geq s\} \tag{2}$$

is the *risk set* at time s; that is, the set of individuals alive and uncensored just before time s. Thus, the concept of a risk set is fundamental in nonparametric **survival analysis**.

Also, when the survival times are subject to left-truncation (**delayed entry**) – that is, individual i is followed, not necessarily from time 0, but maybe from a later entry time $V_i \geq 0$ – the survival distribution function may be estimated by (1) by redefining the risk set to be the set

$$R(s) = \{i : V_i < s \leq \tilde{X}_i\} \tag{3}$$

of individuals alive and uncensored just before time s and with entry times before time s.

The **Nelson–Aalen estimator**

$$\hat{A}(t) = \sum_{\tilde{X}_i \leq t} \frac{D_i}{r(\tilde{X}_i)}, \tag{4}$$

of the cumulative **hazard** function $A(t) = -\log S(t)$ also involves the risk set in an explicit way, and since most linear nonparametric test statistics for comparison of survival distributions are based on sums of weighted differences of the Nelson–Aalen estimators, the risk sets, again, play a fundamental role.

The **Cox regression model** states that the hazard function for the conditional distribution of X_i given covariates $\mathbf{Z}_i$ is given by

$$\alpha_i(t|\mathbf{Z}_i) = \alpha_0(t) \exp(\boldsymbol{\beta}'\mathbf{Z}_i),$$

and the unknown regression coefficients β are estimated by maximizing the Cox **partial likelihood**

$$L(\beta) = \prod_{i=1}^{n} \left(\frac{\exp(\boldsymbol{\beta}'\mathbf{Z}_i)}{\sum_{j \in R(\tilde{X}_i)} \exp(\boldsymbol{\beta}'\mathbf{Z}_j)} \right)^{D_i}. \tag{5}$$

Thus, at every failure time, the risk score $\exp(\boldsymbol{\beta}'\mathbf{Z}_i)$ for the individual failing at that time is compared with the sum of the corresponding risk scores $\exp(\boldsymbol{\beta}'\mathbf{Z}_j)$ for all individuals, j, in the risk set (2) or (3) at that time.

If the sample size, n, is large and, in particular, if the Cox regression includes time-dependent covariates, then the calculation of the sum over the risk set in (5) may be time consuming. In such cases, sampling from the risk set may be advantageous. This amounts to replacing $R(\cdot)$ in (5) by a sampled subset, say $\tilde{R}(\cdot)$, of the risk set. This kind of sampling is frequently used in epidemiology in so-called nested case–control designs.

In multistate survival models based on, for example, nonhomogeneous **Markov processes**, the Nelson–Aalen estimator (4) carries over in a rather straightforward manner. Thus, for the intensity of transition $\alpha_{hj}(t)$ from *state* h to *state* j one may estimate the integral $A_{hj}(t) = \int_0^t \alpha_{hj}(s)\,\mathrm{d}s$ by the sum

$$\widehat{A_{hj}}(t) = \sum_{X_{hji} \leq t} \frac{D_{hji}}{r_h(X_{hji})}$$

over all the observed $h \to j$ transition times, $X_{hji} \leq t$. Here, D_{hji} is the number of such transitions at X_{hji} and $r_h(s)$ is the number of individuals *at risk for making an* $h \to j$ *transition* just before time s; that is, the number of individuals in state h at time $s-$ or, stated slightly differently, *the size of the type* h *risk set* at time $s-$. So, also in multistate models, the concept of a risk set is important.

PER KRAGH ANDERSEN

Risk

Risk is the probability that an individual without disease will develop disease over a defined age or time interval. If risk is estimated as the proportion of members of a fixed cohort who develop disease in a defined time period, it corresponds to an average individual-specific risk (*see* **Cumulative Incidence**). This proportion is an estimate of a **crude risk** or **absolute risk** because it is reduced by the chance that subjects will die of other diseases before they develop the disease of interest (*see* **Competing Risks**).

Often the risk for the interval $[0, t)$ is calculated from $1 - \exp(-\int_0^t \lambda(u)\,\mathrm{d}u)$, where $\lambda(u)$ is the cause-specific **hazard rate**. For small hazard rates, this expression is approximately equal to the **cumulative hazard**, $\int_0^t \lambda(u)\,\mathrm{d}u$. These expressions correspond to pure probabilities of disease and estimate the probability of developing disease in the absence of other causes of death under the assumption that the various causes of death act independently.

MITCHELL H. GAIL

Robust Methods in Time Series Analysis

In general, a statistical procedure might be said to be robust if it is not overly sensitive to departures from any assumptions upon which it depends. **Robustness** was introduced by Box [4] when he considered the properties of tests of equality of variances. Robust *estimators*, usually of *location* and *scale* parameters, are not sensitive to the presence of **outliers**. The three main kinds of robust estimator are those defined as L-estimators (linear functions of **order statistics**), R-estimators (based on tests involving **ranks**), and M-estimators (maximization of some function of the data and parameter). There exists an extensive literature concerned with the robust estimation of location and scale parameters in statistical analysis [2, 15, 17, pp. 157–162].

Associated with the notion of robustness, particularly in the context of time series, is the procedure of smoothing – where the purpose is to "remove or suppress", in some way, the possible effects of *contamination* or *spurious* information. This occurs commonly with biomedical time series data. Tiao & Xu [30] bring these ideas together and extend methods first introduced by Cox [12], to produce robust exponential smoothing in multistep forecasts with autoregressive integrated moving average (ARIMA) models (*see* **ARMA and ARIMA Models**).

Many biostatistical investigations use the class of Gaussian ARIMA models to analyze time series data. If $\{Y_t\}$ is a time series, then the standard ARIMA (p, d, q) model is written

$$\Phi(B)\nabla^d Y_t = \Theta(B)a_t, \qquad (1)$$

where B is the backshift operator $B(Y_t) = Y_{t-1}$ (*see* **Backward and Forward Shift Operators**); $\nabla \equiv 1 - B$, the differencing operator; $\Phi(B) \equiv (1 - \phi_1 B - \cdots - \phi_p B^p)$, $\Theta \equiv (\theta_0 - \theta_1 B - \cdots - \theta_q B^q)$ the autoregressive and moving average polynomials in B, respectively; $\{a_t\}$ is an assumed white-noise process (*see* **Noise and White Noise**); and, $\phi_1, \ldots, \phi_p$ and $\theta_0, \theta_1, \ldots, \theta_q$, unknown parameters to be estimated. The specification and estimation of p, d, and q also present robustness considerations.

To fit the model, the investigator carries out a sequence of steps: tentatively specifying a model; using maximum likelihood to estimate the parameters; and then, performing various diagnostic tests to check the adequacy of the model. If the model is found to be deficient in some respect, than the sequence is repeated.

This general procedure is an important example where *robustification* [17, pp. 176–181] is often necessary to remove the unwarranted effects of contamination or the breakdown of assumptions, or both. A detailed review and summary of the many different aspects and considerations of robust time series techniques (up to 1987) is provided by Stockinger & Dutter [27].

Time Series Outliers

Outliers in time series are usually classified as either innovation or additive [14]. For a variety of reasons, *gross* values can occur quite "naturally" in sets of biological and medical observations – for example, in the continuous monitoring of heart-rate, sudden and unusual measurements can often be observed, attributable to well-known characteristics of the body system. In fact, it is the nature of many feed-back mechanisms in the human body to allow and adjust for such events.

In general, there are two main ways of handling time series outliers. Detection followed by removal, or robust modeling and estimation. Details of the detection approach can be found in [8], in which outliers are identified on a one-by-one basis and the contaminated series adjusted accordingly.

Any algorithm used to estimate the parameters of a model must be able to protect these estimates from outliers. Because the estimation problem is nonlinear, these *robust algorithms* are almost always *iterative*. Sejling et al. [26] discuss various such algorithms, and, building upon previous work, introduce a general method for obtaining recursive robust parameter estimates in autoregressive (AR) models. Two algorithms derived from this model are compared with the use of a recursive *least squares* estimation algorithm, in which the outliers are treated as *missing*. McDougall [22] extends these ideas and produces methods applicable to general ARIMA models, where both kinds of outliers, innovation and additive, might be present.

With the knowledge that any time series $\{Y_t; t = 0, \ldots, N-1\}$ can be represented as the sum of N sines and cosines at the Fourier frequencies $\{\omega_k =$

$2\pi k/N; k = 0, \ldots, N/2\}$, an approach to the analysis of real data is to produce initially a robust form of the discrete Fourier transform (*see* **Fast Fourier Transform (FFT)**). The coefficients can then be inverse Fourier transformed to produce a *filter* for the data. The filtered time series data can then be used for standard analysis. Tatum & Hurvich [29] give details of a filter that can handle large amounts of contamination and outliers. Details of other non-Gaussian filters that deal with both types of outlier can be found in [1, 16], and [9].

Other methods for robust filtering and smoothing include the use of the robust Kalman filter [10], *M* estimate smoothers, and robustified **splines** [27].

Robust Bayesian Estimation

Bayesian ideas and methods have been used by a number of authors to obtain time series models robust to outliers. Le et al. [18] use the ratio of posterior to prior odds, known as *Bayes factors*, to compare autoregressive models on a pairwise basis. This comparison is made, in the presence of outliers, using a *robust likelihood* procedure following the techniques of Martin [24]; see also [28].

Neural Networks

The application of an artificial **neural network** to nonlinear systems has been a major area of research in recent years. Wu [32] gives details of an economic example, where the performances of ARIMA models and neural networks are compared in terms of their robustness. Connor et al. [11] developed a robust learning algorithm, applied it to *recurrent* neural networks in order to filter outliers from time series data, and assessed the sensitivity of the procedure.

Statistical Tests

A well-known statistic for testing the adequacy of a time series model is the Box–Pierce [5] or so-called *portmanteau statistic*. Li [19], Chan [7], and Wong & Li [31] have produced robust versions of this statistic, and examined their performance in the presence of outliers. Li & Hui [20] have produced a robust multivariate version of the portmanteau statistic for use in multiple time series modeling. Large-sample properties of robust M-estimates used in the testing of hypotheses in autoregressive models can be found, for example, in [3]. Li & Hui [21] have also developed robust tests for lagged relations between two time series.

Examples

A discussion of many of the issues, including that of robustness, associated with autoregressive and **spectral analysis** models in heart rate variability studies is given in [6]. The robust smoothing and filtering of psychophysiological time series data has been considered by Schmitz et al. [25]. Details of methods, originally developed for engineering applications but applicable to many problems in the medical and life sciences, to identify and model time-varying biological systems can be found in [23]. The authors show, in **simulation** studies, that these methods are robust to the presence of general noise in the system, and apply the techniques to a study of ankle stiffness.

An investigator must not lose sight of the fact that what constitutes an outlier, contamination, or spurious information is often a matter of judgment and degree. Understanding of the system (e.g. biological or medical) that has given rise to the data is important in all aspects of the modeling of biostatistical time series data [13].

CLIVE J. LAWRENCE

Robust Regression

The term *robust regression* refers to a collection of procedures and a body of theory associated with the application of robust or resistant procedures to **regression models**.

Robustness and resistance are related properties which differ slightly in their foundations: the definition of robustness is grounded in distributional assumptions while that of resistance is based on the numerical properties of an algorithm. The idea of robustness has many different tight mathematical definitions, all capturing some characteristic of a procedure the properties of which are relatively insensitive to small changes in the assumptions specifying a model. The property of resistance, on the other hand, is the insensitivity of the results of a procedure to changes in a small fraction of the data.

Here, a regression model will denote a statistical model relating a response y to a collection of explanatory variables $\mathbf{x} = (x_1, \ldots, x_p)'$. The regression models most commonly used include: **additive models** of the form

$$y = \mathbf{x}'\boldsymbol{\beta} + \sigma e,$$

where $\boldsymbol{\beta}$ is a vector of regression parameters, σ is a scale parameter, and e denotes an error variable, typically of mean 0; **logistic regression**, where y is assumed to be **binomial** with mean $n\exp(\mathbf{x}'\boldsymbol{\beta})/[1 + \exp(\mathbf{x}'\boldsymbol{\beta})]$; and **loglinear** models, where y is assumed to be **Poisson** with mean $\exp(\mathbf{x}'\boldsymbol{\beta})$.

Regression models are very widely applied. Their structure has implications for the robustness and resistance of any estimation procedure, and has given rise to many different procedures for estimation and testing. This is because the observations, although typically assumed to be independent, are not identically distributed and, as a result, have differing influences on the estimates. The ideas of robustness and resistance are illustrated by the mean and median in a location model (*see* **Location–Scale Family**).

Location Models

Location models are the simplest regression models. These involve only one parameter and have the form $y = \mu + \sigma e$. The parameter may be estimated by the **mean** $\overline{y}$ or by the **median** $\tilde{y}$ (and a great many other estimators). Small changes in the tail length of the distribution can make much greater changes in the variance of the mean than of the median. The median is more robust than the mean. Large changes in only one observation produce much greater changes in the mean than in the median. The median is more resistant.

Least Squares Regression

Least squares estimates are **maximum likelihood** estimates if the errors e are assumed to be independent **normally distributed** or Gaussian random variables with mean 0 and common variance. The Gauss–Markov theorem (*see* **Least Squares**) states that the resulting estimates have minimum variance among the class of linear, unbiased estimates. However, because the estimate is linear, it is not resistant: one observation y can change the estimate by an arbitrarily large amount. And, as in the case of location, the variance of the parameter estimate depends heavily on the assumed tail length of the distribution. The estimates are not robust.

These properties are exacerbated if some observations are potentially highly influential. This arises when the explanatory variables of the observations are very different from the rest. This is easily seen by considering the variances of the **residuals**. If $\mathbf{X}$ denotes the matrix with rows the explanatory variables $\mathbf{x}'$, then the variance matrix of the residuals is proportional to $\mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}' = \mathbf{I} - \mathbf{H}$. The diagonals of this matrix, $1 - h_{ii}$, are the variances of individual residuals. Some of these can be arbitrarily small. If this is the case, then the associated residuals must be small and the fitted values $\mathbf{x}'\hat{\boldsymbol{\beta}}$ very close to the observation. This implies that observations associated with small residual variances will have a determining effect on the estimation. Such points are called leverage points (*see* **Diagnostics**).

L_p Regression Estimation

For the location model, least squares, minimizing the sum of squares of the residuals, $y - \hat{\mu}$, led to the estimate $\hat{\mu} = \overline{y}$. The median may be shown to minimize the sum of absolute residuals. These are special cases of L_p estimates, which are defined to minimize the sum of pth powers of the residuals. The robustness and resistance of the median might

suggest that the same properties would hold for L_p estimates with $p < 2$ and for $p = 1$ in particular. However, this is not the case if points of high leverage exist. An observation with very unusual explanatory variables will have fitted values very dependent on the parameter estimates. These differences will have a large, determining effect on L_p estimates, including L_1 estimates.

M-Estimation for Regression

Maximum likelihood estimates for regression models are defined to maximize $\sum \psi((y - \mathbf{x}'\hat{\boldsymbol{\beta}})/\sigma)$, where $\psi(\cdot)$ is the log density of e. If ψ is differentiable, the estimates may be defined by the system of p equations

$$0 = \sum x_i \phi\left(\frac{y - \mathbf{x}'\hat{\boldsymbol{\beta}}}{\sigma}\right) \quad \text{for } i = 1, \ldots, p, \quad (1)$$

where ϕ is the derivative of the log density.

M-estimates are the generalization of (1) that arises when ϕ is not restricted by a relation to a density function. Different choices of ϕ lead to different estimators with different properties of resistance and robustness.

For example, if ϕ is unbounded, a single observation may contribute an arbitrarily large component to the sum in (1). Bounded functions, ϕ, may be expected to have greater resistance to individual observations. If ϕ is 0 outside of a finite interval, observations outside of this interval will not contribute to the sum defining the estimate. Estimates defined by such functions will be insensitive to the length of the extreme tails of the distribution. Such estimates will be robust to differences in the extreme tails.

Huber [3], studying the location model, used a specific measure of distance between distributions and found the form of ϕ to minimize the maximum variance of the estimate in a neighborhood of the normal or Gaussian distribution. The resulting ϕ was the derivative of the density of the least favorable distribution in the neighborhood. The function ϕ is given by

$$\begin{aligned} \phi(u) &= -c, \quad u < -c, \\ &= u, \quad -c < u < c, \\ &= c, \quad u > c. \end{aligned} \quad (2)$$

The bounded nature of the function leads to resistance of the estimate to single observations.

The estimating equations (1) may be expressed in the form of the equations defining weighted least squares estimates:

$$0 = \sum w\left(\frac{y - \mathbf{x}'\hat{\boldsymbol{\beta}}}{\sigma}\right) x(y - \mathbf{x}'\hat{\boldsymbol{\beta}}),$$

where $w(u) = (1 - u^2)^2$. This is equivalent to (1) with

$$\phi(u) = uw(u). \quad (3)$$

The weights are often called the bi-square weights. The Princeton robustness study [1] presents properties of a large variety of M-estimates for the location model.

The M-estimates described above involve the parameter σ. Estimates are produced by replacing this parameter with an estimate of scale. The median of the absolute residuals,

$$MAD = \text{median}(y - \mathbf{x}'\hat{\boldsymbol{\beta}}) \quad (4)$$

may be rescaled to yield a robust estimate of scale. The regression estimates may then be computed by iteration, successively estimating scale by *MAD* and regression parameters by weighted least squares. Beginning with an initial estimate of the regression parameters, the scale may be estimated. The regression estimates are then updated using weighted least squares with weights given by (3).

Alternatively, a defining estimating equation for σ may be added to (1) and the larger system of equations solved iteratively.

The solution is unique if the system of equations corresponds to the derivatives of a convex function. In other cases, the value of the estimate will depend on the initial values iteration. Huber [4] contains a more detailed discussion of iteration and convergence.

Downweighting Leverage Points

Observations with unusual values of the independent variables may remain highly influential for the M-estimate. For this reason, many authors have proposed the use of iterated weighted least squares, where the weights include a factor that diminishes the influence of such observations. Many of these

proposals are based on the least squares estimate of the variance of residuals: $1 - h_{ii}$. Huber [4] suggests replacing ϕ in (1) with $(1 - h_{ii})^{1/2}\phi$. Observations with high leverage and therefore with small residual variance will have little influence in the equation defining the estimate. Krasker & Welsch [5] review more extensively the handling of leverage points.

R and S Estimators

Two other classes of robust estimators have been proposed. Hettmansperger [2] develops R-estimates based on the **ranks** of **residuals**. Estimates are defined to minimize $\sum a(R_i)r_i$, where r_i denotes a residual and R_i its rank. The function a is bounded and monotonic.

Because the defining equation is linear rather than quadratic in the residuals (as in the case of least squares), the estimates are more resistant and robust.

Least squares estimates may also be considered as those which minimize s^2, an estimate of scale. Any estimate of scale may be used to define an estimate of the regression parameters. Such estimates are called S-estimates [11, 12].

Rousseeuw [10] proposed defining estimates to minimize the *MAD* (4). Although the computational problems involved in this minimization are extremely difficult, the resulting estimate is very resistant.

Robust Logistic Regression

Logistic regression is used to model binomial data. Since such data are bounded, insensitivity to gross outliers is not a concern. However, even in this case, individual observations can greatly influence the maximum likelihood estimates.

The maximum likelihood estimates are found by minimizing the sum of deviances, essentially negative components of the log-**likelihood**. These deviance components are the logistic analogs of squared residuals. Pregibon [7] proposed estimates found by dampening the contribution of large deviances to the minimization. The proposed form corresponds to the function ϕ in (2). The resulting estimates are not unbiased. Kunsch et al. [6] proposed alternative estimators which are conditionally unbiased. Morgenthaler [9] proposed estimates of parameters in **generalized linear models** [8], and for logistic models in particular, based on least absolute deviations of residuals.

DAVID F. ANDREWS

Robustness

Robust procedures are generally considered to be statistical methods which are insensitive to small deviations from the underlying assumptions. In particular, if the optimal procedures require the assumption of normality, then the corresponding robust procedures would not be influenced by departures from normality of the form of slightly longer or shorter tails or slight skewness in the underlying distribution. Such departures from normality could result from the presence of a small proportion of **outliers** or spurious values in the observations. Robust procedures are ones such that these outliers, if they occurred, would have little effect on the analysis of the data.

Historical Development

Huber [17], in his extensive review article, points out that in 1821 **Gauss** [9] specifically introduced the **normal distribution** to suit the sample **mean**, and Huber suggests that a misunderstanding of the Gauss–Markov theorem and the **central limit theorem** by contemporary nineteenth-century researchers, led to the almost exclusive use of the arithmetic mean in practical applications throughout that time (*see* **Least Squares**). These theorems refer to the arithmetic mean as the best linear unbiased estimator of the expected value of a population, and to its distribution being approximately normal. If the observations are independent with a common normal distribution, then the sample mean is the least squares (**maximum likelihood**) estimator, the best unbiased estimator (*see* **Unbiasedness**), the **minimax** estimator, and is asymptotically efficient (*see* **Efficiency and Efficient Estimators**), so it is best in a variety of ways. However, the sample mean is not robust against quite small departures from the assumption of normality; in particular, being seriously affected by outliers or long-tailedness. The occurrence of discordant values or of distributions with longer tails than normal was recognized by researchers in the nineteenth century, but the full significance of the effect of these on the behavior of the sample mean as an estimator was not fully appreciated, except by a few.

Huber's historical review gives details of a few instances of anxieties caused by the problems of dealing with outlying values and long-tailed distributions. He cites, for example, an early case of the routine application of a 5% trimmed mean (*see* **Trimming and Winsorization**) for estimating land yields in France from 20 consecutive years of observations with the highest and lowest values removed, and refers to the development of procedures for detecting and rejecting grossly discordant observations by Peirce [24] and Chauvenet [4]. More details of the heated controversy that Peirce's criterion for rejecting observations generated are given by Stigler [26], who also describes many overlooked contributions to the development of robust estimators between 1885 and 1920. In particular, Stigler discusses Newcomb's [22] use of subjectively weighted astronomical observations and long-tailed distributions, produced from mixtures of normal distributions, to derive a Bayes-type estimator (*see* **Bayesian Methods**) which effectively gives lower weight to the extreme observations. The computational efforts involved in evaluating some of these alternative estimators was a major deterrent to their general acceptance. **Edgeworth** [7] investigated properties of the **median** and later, in 1893, he suggested an estimator based on weighted quartiles. Eddington [6] and **Jeffreys** [19], amongst others, proposed alternative probability models for errors with long-tailed distributions and used robust alternatives to the usual estimators, remarkably similar to some of the procedures rediscovered more recently. Stigler [27] gives an account of an original suggestion, by Smith [25], of a robust estimator of location which is surprisingly similar to a biweighted M-estimator.

The effects of nonnormality on estimates of **variance** and the sensitivity of tests involving sample variances, such as F tests and t tests, were noted by E. S. **Pearson** and by R.A. **Fisher**, but there was little formal development of robust methods during that time. The word "robust" was initially used by Box [3] as a technical term in connection with the comparison of variances problem.

It was not until around 1960 that J.W. Tukey and the Statistical Research Group at Princeton began to investigate seriously the properties of robust estimators of location and scale. Tukey [28, 29] provided a survey of this work. He dramatically illustrated the sensitivity of the mean square deviation (*see* **Standard Deviation**)

$$s_n = \left[\frac{1}{n}\sum (x_i - \overline{x})^2\right]^{1/2},$$

based on a sample of n observations $x_i, i = 1, \ldots, n$, with sample mean $\overline{x} = \sum x_i/n$, to very slight departures from normality. He considered the **asymptotic relative efficiency (ARE)** of this estimator of scale, relative to the **mean** (absolute) **deviation**

$$d_n = \frac{1}{n} \sum |x_i - \overline{x}|,$$

for samples from a contaminated normal distribution with distribution function

$$F(x) = (1 - \varepsilon)\Phi\left(\frac{x - \mu}{\sigma}\right) + \varepsilon\Phi\left(\frac{x - \mu}{3\sigma}\right), \quad (1)$$

where $\Phi(x)$ is the standard normal cumulative distribution and ε is the proportion of contamination of the standard normal by the normal with three times its standard deviation. When ε equals zero (or one), the relative efficiency of d_n to s_n is nearly 88%, so that there is a 12% loss in efficiency if d_n is used instead of s_n with normal samples. However, ε need be only 0.002 for the relative efficiency of d_n to s_n to exceed 100%. Only two observations in 1000 need to come from the wider distribution for the mean absolute deviation to be a better estimate of scale than the mean square deviation. This was quite a surprising result and does not even imply that these two observations are outliers. They need only to have come from the contaminating distribution which produces a population that has slightly longer tails than the normal distribution. This work prompted further investigation into alternative robust estimators for both location and scale, with important early contributions from Huber [16] and Hampel [10].

Criteria of Robustness

One of the major problems in the application of a robust procedure is the consideration of an appropriate set of criteria that the procedure should satisfy. Different criteria have led to the development of different robust methods. The Princeton Robustness Study investigated the behavior of 68 estimators of location over a wide variety of nonnormal distributions. The six authors [1] agreed that many of these alternative estimators were more robust than the sample mean, but they were not able to recommend a specific estimator which would meet the various requirements of robustness, because they did not agree on the criteria to be used.

Huber [17], in his Wald lecture, asks "What is a robust procedure?" and points out that there are several conflicting aims which make it difficult to choose, in a rational manner, between different robust competitors. The assumptions, such as normality, underlying any procedure are required to allow calculation of certain probabilities such as the type I error for tests or the **confidence** levels for estimates, or to show that the method is efficient or has high **power**. These probabilities will change under departures from the assumptions. Procedures which maintain the type I error or the actual confidence levels are regarded as *validity robust* while those that maintain high power or size of confidence interval are regarded as *efficiency robust*. Even within these categories it is possible to consider different kinds of departure from the underlying assumptions and different characteristics of the estimators or test statistics involved. The characteristics used for judging the competing methods could include the asymptotic variance, the absolute efficiency or the relative efficiency. If the distribution function is represented by F, then the range of alternative distributions could include all smooth F, or all F belonging to a selected finite set of F_i such as the normal, **Cauchy**, two-sided **exponential** and rectangular distributions, or all F in the neighborhood of a specific F. Huber [16] considers procedures with a small asymptotic variance over distributions in a neighborhood of the normal distribution, while Hampel [10, 11] considers estimates whose distribution changes little under arbitrary small variations of F. The various objectives of robustness have resulted in the development of a variety of robust estimation methods broadly classified as M-estimators (based on maximum likelihood methods), L-estimators (based on linear functions of order statistics) and R-estimators (based on ranking methods).

M-Estimators

If $f(x - \theta)$ is the density function of a **random variable** x with unknown location parameter θ, then the log **likelihood** function, $l(\theta)$, for a sample $x_i, i = 1, \ldots, n$, is

$$l(\theta) = \sum_{i=1}^{n} \ln f(x_i - \theta) = -\sum_{i=1}^{n} \rho(x_i - \theta), \quad (2)$$

where $\rho(x) = -\ln f(x)$.

If possible, the maximum likelihood estimator of θ is found by differentiation of $l(\theta)$, which gives

$$\frac{\mathrm{d}[l(\theta)]}{\mathrm{d}\theta} = -\sum_{i=1}^{n} \frac{f'(x_i - \theta)}{f(x_i - \theta)} = \sum_{i=1}^{n} \varphi(x_i - \theta), \quad (3)$$

where $\rho'(x) = \varphi(x)$. The solution of

$$\sum_{i=1}^{n} \varphi(x_i - \theta) = 0 \quad (4)$$

that maximizes $l(\theta)$ is called the maximum likelihood estimator, or M-estimator, of θ. The form of the M-estimator depends on the shape of the function ρ, or equivalently the shape of the function φ. For the normal distribution $\rho(x) = x^2/2$ (apart from a constant), from which $\varphi(x) = x$, and the solution to (4) is the sample mean $\overline{x}$. For the two-sided exponential distribution, which has longer tails than the normal distribution, $\varphi(x) = -1$ for $x < 0$ and $\varphi(x) = 1$ for $x > 0$, leading to the median as the M-estimator. Other distributions with long tails have φ functions which are bounded or which "descend" to zero for $|x| > k$, for some k. Huber's [16] robust estimator, proposed to minimize the asymptotic variance over a class of distributions in the neighborhood of the normal, is one of these M-estimators with $\varphi(x) = x$ for $|x| \leq k$, and $\varphi(x) = k \text{ sign}(x)$ for $|x| > k$. Eq. (4) would in this case need to be solved by an iterative method. One feature of this and other estimators based on bounded or redescending φ functions, is that they are not scale invariant. A scale invariant version may be obtained if

$$\sum_{i=1}^{n} \varphi\left[\frac{(x_i - \theta)}{d}\right] = 0 \quad (5)$$

is solved instead, where d is a robust estimate of scale. One possible robust estimate of scale which could be used for d is

$$d = \frac{\text{median}|x_i - \text{median}(x_i)|}{0.6745}. \quad (6)$$

This form of robust scale estimate is known as the mean absolute deviation (from the median), and includes the factor 0.6745 so that d approaches the population standard deviation for large samples. The sample standard deviation is not used for d since it is not robust to outliers. The value of k may be determined so that the asymptotic efficiency of the estimator reaches a satisfactory level under normal assumptions. For instance, when $k = 1.5$ the asymptotic efficiency was shown by Huber [16] to be greater than 95%.

Other forms of M estimators have been proposed, including Hampel's redescending φ function, Andrews' sine wave and Tukey's "biweight". These are respectively defined as follows:

1. Hampel's redescending φ:

$$\begin{aligned} &\varphi(x) = && \text{if} \quad -k_1 < x < k_1, \\ &\varphi(x) = k_1 \text{ sign}(x) && \text{if} \quad k_1 \leq |x| < k_2, \\ &\text{and} \\ &\varphi(x) = k_1 \left(\frac{k_3 - |x|}{k_3 - k_2}\right) \text{sign}(x) \\ &&& \text{if} \quad k_2 \leq |x| < k_3, \end{aligned}$$

   with $k_1 = 1.7$, $k_2 = 3.4$, and $k_3 = 8.5$.
2. Andrews' sine wave: $\varphi(x) = \sin(x/k)$ if $|x| \leq k\pi$, and $\varphi(x) = 0$ if $|x| > k\pi$, with $k = 1.5$.
3. Tukey's biweight: $\varphi(x) = x[1 - (x/k)^2]^2$ if $|x| \leq k$, and $\varphi(x) = 0$ if $|x| > k$, with $k = 5$.

These values of the constants give reasonable performance of the estimators when the distribution is normal, but alternative values may be used instead. Further comments about the convergence properties of the iterative procedures involved in deriving these M-estimators are given in the review article by Hogg [14]. In his article, Hogg also discusses the extension of this approach, using M-estimators based on robust ρ and φ functions, to the estimation of the coefficients in the linear model $\mathbf{y} = \mathbf{X}\boldsymbol{\beta}$. This leads to the concept of **robust regression**.

L-Estimators

An L-estimator is one that is based on a linear combination of the ordered sample values. Examples of such estimators are the median and the α-symmetrically trimmed means, defined as

$$\overline{x}_{\alpha\mathrm{T}} = \frac{\sum_{i=r+1}^{n-r} x_{(i)}}{n - 2r}, \quad (7)$$

where $r = [n\alpha]$ is the largest integer less than or equal to $n\alpha$ and $x_{(i)}$ is the ith ordered observation. A symmetrically Winsorized mean is obtained in a

similar way except that, instead of the r smallest and largest observations being deleted, they are replaced by the values of the smallest and largest untrimmed observations, $x_{(r+1)}$ and $x_{(n-r)}$ respectively, so that the α-symmetrically Winsorized means are defined as

$$\overline{x}_{\alpha\mathrm{W}} = \left(r x_{(r+1)} + \sum_{i=r+1}^{n-r} x_{(i)} + r x_{(n-r)} \right) \Big/ n. \quad (8)$$

For samples from a symmetric population, the symmetrically **trimmed and Winsorized** means are both unbiased estimators of the population mean. For estimating from asymmetrical distributions, it would be natural to define asymmetrically trimmed or Winsorized means in an obvious manner.

This class of robust L-estimators also includes those based on selected percentiles, such as Gastwirth's [8] weighted average of the $33\frac{1}{3}$rd, 50th (median) and $66\frac{2}{3}$rd percentiles, with weights 0.3, 0.4, and 0.3, and the trimean using the 25th, 50th, and 75th percentiles with weights 0.25, 0.5, and 0.25. Patel et al. [23] considered that the "trimmed means, the tri-mean and Gastwirth's estimator are perhaps the simplest among reasonably good robust estimators" of location. David [5] provides a detailed review of linear order-statistic estimators (*see* **Order Statistics**). The link between these estimators and M-estimators through the influence function (*see* **Diagnostics**) is discussed by Hampel [12].

R-Estimators

The development of nonparametric procedures such as the Wilcoxon and Mann–Whitney tests (*see* **Wilcoxon–Mann–Whitney Test**), which are suitable under more general conditions than the corresponding t tests, provided some respite for those worried about nonnormality. For normal populations the one- and two-sample Wilcoxon tests have efficiency of more than 95% compared with the t tests, and can be substantially more powerful if the samples come from long-tailed distributions. Highly efficient Hodges & Lehmann [13] estimates may be developed from the Wilcoxon tests. These are the median of all pairwise averages, med $[(x_i + x_j)/2]$, for the location of a single population, and the median of all between-sample pairwise differences, med $(y_i - x_j)$, for the difference between the locations of the two populations. These estimates may be used to provide suitable confidence intervals in fairly general situations. An extensive introduction to rank statistics is given by Lehmann [20], and further discussion of R-estimates may be found in Huber [18].

Adaptive Procedures

The basic idea of adaptive estimation is that the estimation procedure is selected after observing the data. For example, the form of the estimator is dictated by the sample values themselves or some characteristic of the sample such as **skewness** or **kurtosis**, so that samples with large kurtosis (heavy tailed) could use the median as a location estimator, while those with kurtosis near zero (normal) would use the sample mean. More generally, an adaptive trimmed mean uses some characteristic of the sample, such as a ratio of linear functions of order statistics, to determine the proportion of trimming applied to the ordered sample. Hogg & Lenth [15] give a detailed review of full and partial adaptive procedures used in estimating location and include illustrations involving the extension of these procedures to **regression** analyses and **analysis of variance**.

Resistant Procedures

A statistical procedure is called *resistant* if the estimate or test statistic has a value which is insensitive to small changes in the underlying sample [21]. The underlying distribution does not really come into this definition, but Hampel's theorem, linking continuity of estimators and robustness in a neighborhood of the underlying distribution, suggests that although conceptually different, resistance and robustness are, for practical purposes, the same.

Extension to Other Problems

Over the last 30 years there has been extensive research into robust methods applicable to a variety of statistical problems. The ideas of robust estimation of location using M-, L-, and R-estimators, have been extended to multivariate data and to **robust regression**. There is now an extensive literature on robust estimation in the presence of **outliers**,

robust regression **diagnostics**, robust estimation of **correlation matrices** for use in multivariate techniques, robustness in scientific modeling, in **time series** modeling and in **experimental design**. Barnett & Lewis [2] provide a comprehensive coverage of all aspects of dealing with outliers in statistical data.

PHILIP PRESCOTT

Rotation of Axes

Both **principal components analysis** and **factor analysis** are procedures which transform a set of p correlated variables into a set of k new variables. In the case of principal components analysis, the new variables, the principal components, are uncorrelated (*see* **Correlation**). In the case of factor analysis, the new variables, the factors, are uncorrelated within a reduced space defined by the reduction in total variability due to residual variability associated with each variable, independent of the others. For both procedures, these transformations are generally linear. In most cases, $k < p$, since a principal aim of both procedures is to reduce the dimensionality required to describe a multivariate situation. The coefficients defining these transformations, often referred to as *loadings*, are used to aid in identifying the nature of the new variables. Sometimes, the new variables will be difficult to interpret. At other times, the procedure has been employed chiefly as an intermediate step in determining a reduced *set* of the original variables which satisfactorily account for the variability of the deleted variables. In either case, a second linear transformation may be useful. This latter transformation is generally referred to as a *rotation* of the components or factors.

If there are k components or factors to be rotated, then there will be k new rotated variables. The variables produced by rotation may be correlated. They will account for the same amount of variability of the original variables as the components or factors from which they were derived. Most texts on principal components and/or factor analysis will have some material on rotation. Among those with detailed explanation of the philosophy and general mechanics of rotation are [3] and [4]. Other articles in this Encyclopedia deal extensively with principal components analysis, factor analysis, and specific rotation methods.

Simple Structure

Most of the methods described in this article are designed to attain the properties of what Thurstone [7] called **simple structure**. Its purpose is to produce rotated vectors whose coefficients are either relatively large or close to zero. If the matrix of dimension $p \times k$ of rotated vectors is $\mathbf{B}$, each column defining a transformed variable, then simple structure requires that:

1. each row of $\mathbf{B}$ should contain at least one zero. This means that each of the original variables should be uncorrelated with at least one of the rotated components or factors
2. if there are k components or factors, then each column of $\mathbf{B}$ should have at least k zeros. This specifies a goal; for interpretation, the more zeros the better
3. for each pair of columns of $\mathbf{B}$, there should be several variables that have zeros in one column but not the other and, if $k \geq 4$, a large number of variables with zeros in both columns and a smaller number of variables with nonzero coefficients in both columns. This is an attempt to obtain some independence among the variables produced by the rotated vectors.

The objective of simple structure is to produce a set of new vectors, each involving primarily a subset of the original variables with as little overlap as possible so that the original variables are divided into groups somewhat independent of each other. This is, in essence, a method of clustering the original variables (*see* **Cluster Analysis, Variables**), and some computer packages (*see* **Software, Biostatistical**) employ this method to do it. Most statistical computer packages that include principal components and factor analysis will also have a number of rotation options.

In practice, it is nearly impossible to obtain the number of zeros required for a simple structure, but rotated vectors containing very small coefficients will suffice for most problems of interpretation.

Algebraically, rotations may be described as follows: Let the transformation of the original p variables, $\mathbf{x}$, into k components or factors, $\mathbf{y}$, be $\mathbf{y} = \mathbf{V}\mathbf{x}$, where $\mathbf{V}$ is a matrix of dimension $p \times k$ and consists of a set of vectors relating one set of variables, $\mathbf{x}$, to the other, $\mathbf{y}$ (*see* **Principal Components Analysis** and **Factor Analysis, Overview** for a discussion of the mathematical models underlying these transformations.) Then the rotation of the vectors $\mathbf{V}$ into a new set $\mathbf{B}$ is done by the relationship $\mathbf{B} = \mathbf{V}\boldsymbol{\Theta}$, where $\boldsymbol{\Theta}$ is a matrix of dimension $k \times k$ consisting of angles defining the rotation. This rotation takes place only in the subspace defined by the k retained components or

factors. Because of this, the amount of variability of the original variables accounted for by the variables obtained by this rotation will be exactly the same as that accounted for by the original components or factors. If the number of retained components or factors is changed, then the rotated results will also change. Early rotation procedures were graphical solutions which, while quite sophisticated, could handle only problems of limited size. Present day solutions are generally performed by means of computerized mathematical **algorithms**.

Numerical Example

Table 1 displays a correlation matrix related to some physical measurements on 305 girls [4]. Note that the first set of four variables – measurements of "lankiness" – are highly correlated, as are the second set, representing "stockiness". The intercorrelations among the two sets are smaller. The characteristic vectors defining the first two principal components are displayed in Table 2, where the vectors are normalized to their corresponding characteristic roots. The first principal component, accounting for 58% of the total variability, is a measure of overall size. The second component (22%) represents a contrast between the two types of measurement.

Orthogonal Rotation

An **orthogonal rotation** is a rotation which preserves the **orthogonality** of the transformed component or factor. For the above example, one possible orthogonal rotation has the matrix defining the angle of rotation as

$$\Theta = \begin{bmatrix} 0.771 & 0.636 \\ -0.636 & 0.771 \end{bmatrix}.$$

This particular orthogonal rotation is a **varimax rotation**. The rotated vectors are shown in Table 2. The first four coefficients of the first vector, representing the lankiness measurements, are quite large relative to the remaining four. The situation for the second vector is reversed. The conclusion is that there are two groups of variables: the first four and the second four. While this seems obvious when rotating a pair of vectors, examples requiring higher dimensionality are apt to be more difficult to interpret, particularly if one wishes to cluster variables.

The rotated axes are shown in Figure 1 and are represented by the dashed lines. The points represent the original eight variables in terms of the loadings of the two characteristic vectors. If these same points are projected against the new axes, then the coefficients or loadings of **B** will result. This is an *orthogonal rotation*, in that the new axes are still at right angles to each other.

There are a number of methods for producing orthogonal rotations, each having their strengths and weaknesses. A more detailed description of some of them appears in the article **Orthogonal Rotation**, as well as in separate entries for some specific methods.

Oblique Rotation

It is possible to obtain an even greater differentiation between the two sets of physical measurements by performing an **oblique rotation**, one in which the resultant axes are not at right angles to each other. One such oblique rotation is the **orthoblique** or Harris–Kaiser rotation, which is also shown in Table 2.

This produces greater differences between the two sets of coefficients but at the cost of loss of orthogonality. The amount of variability of the original variables attributed to these rotated variables will be the same as that due to the components or factors. The improvement towards the simple structure is shown in Figure 2. There are now *two* sets of rotated vectors. Those labeled P_1 and P_2 are called *primary* vectors, which pass through the clusters of points. R_1 and R_2 are *reference* vectors, R_i and P_i being orthogonal to each other. It is the projection of the points on the reference vectors that produce the rotated vectors **B**. In orthogonal rotations, this situation does not exist. Note, in Table 2, that the amount of variability attributable to the two orthogonally rotated components equals the amount attributable to the principal components, but those of the oblique rotation do not. These latter quantities must also include the joint contribution of the rotated components pairwise; these, added to that of the rotated components themselves, will add to the total.

There are a number of methods for producing oblique rotations which will appear in the article **Oblique Rotations**, as well as separate entries for some specific methods. A number of both

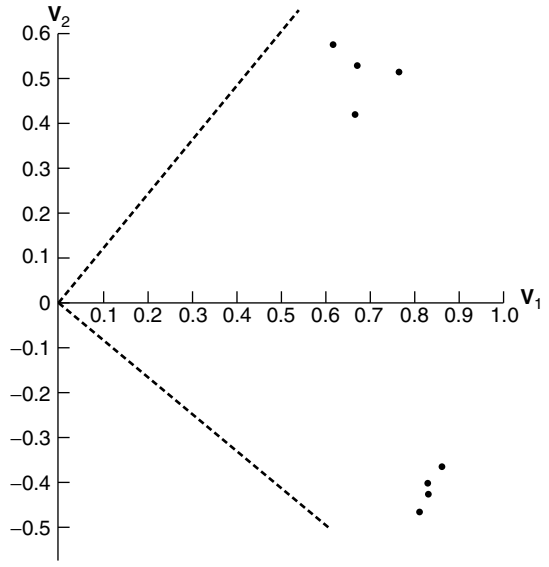

Figure 1 Physical measurements: orthogonal (varimax) rotation

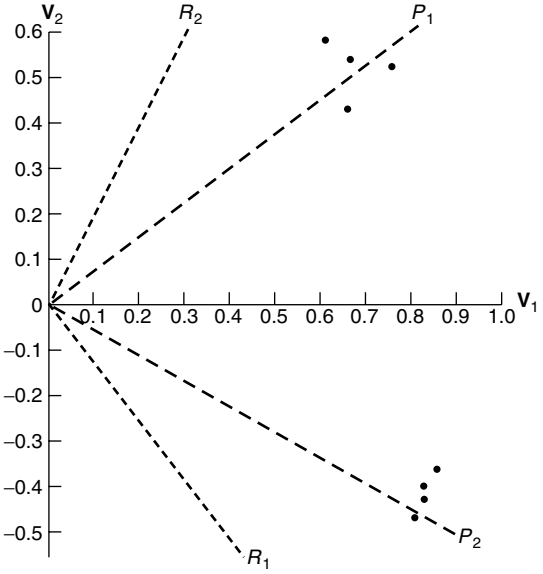

Figure 2 Physical measurements: oblique (orthoblique) rotation

orthogonal and oblique rotations can be expressed in a generalized form known as *quartic* rotation procedures. An overview of these procedures may be found in [2].

Procrustes Rotation

The occasion may arise where one already has two sets of vectors and wishes to find the matrix which will best "rotate" one set into the other. The method which attempts to determine this relationship is called **Procrustes rotation**, and is described in that article.

Applicability

Rotational procedures may be quite useful when one wishes to cluster variables, and as such have found widespread use in such diverse fields as psychology, education, anthropology, biology, and market research. These procedures have somewhat less application in sciences such as chemistry or physics. The physical measurements example of Table 1 is a typical application in the field of multivariate biostatistics.

Numerical Examples

The numerical example above is useful in producing a graphical explanation of rotation but will not be as useful in illustrating the various rotation techniques because only two vectors are being rotated. In the case of $k = 2$, many of these techniques produce the same results. We need $k > 2$ to show the difference. For this reason, two additional examples will be given. One of these will be an example where rotation was appropriate and the other where it was not. These examples will also be employed in some of the separate articles in this Encyclopedia dealing with specific procedures.

The first example deals with Decathlon data for 160 individual records from the first eight Olympics after World War II [6]. Table 3 includes both the characteristic vectors **(eigenvectors)** associated with the four retained principal components of these data and the corresponding varimax rotation. (The correlation matrix is included in the original reference and also in [1].) The other common rotation techniques all showed similar results.

The first rotated vector has high loadings for 100 m run and 400 m run along with somewhat lower loadings for long jump (which requires a short run before execution) and the 110 m hurdles. This would imply a cluster involving short distance running and associated jumping. The second rotated vector has high loadings for shot put, discus, and javelin, all of which are throwing events. The third rotated vector has high loadings for the long jump, high jump, 110 m hurdles, and the pole vault, all events requiring jumping. The final rotated vector has a high loading for the 1500 m run and a lower loading for the 400 m run, indicating a cluster for long distance running. The 1500 m run had a correlation of 0.39 with the 400 m run and very low correlations with anything else. In interpreting rotation results, reference to the original correlation matrix will also be of use. Although most of the results obtained by rotation probably could have been deduced from the characteristic vectors, the rotated results may seem much clearer.

The second example deals with the audiometric examinations of 100 39-year-old men [5]. Table 4 includes both the characteristic vectors associated with the four retained principal components of these data and the corresponding varimax rotation. The variables represent hearing loss from a standard at four different frequencies for both left and right ears.

The first principal component represents an overall shift in hearing for all frequencies in both ears. The second component represents a contrast between high and low frequencies and can be used as an early warning of hearing loss. The third component is another contrast, primarily between the two higher frequencies, and the fourth component represents the difference between left and right ears. The variability unexplained by these four components is a measure of testing and measurement variability. The results from the varimax rotation are not as distinct as those obtained in the other example. One could probably deduce that the 500 Hz and 1000 Hz measurements formed one cluster, the 2000 Hz a second, and the 4000 Hz a third. There is a suggestion of ear differences also, but the results are not very distinct. In this case, the characteristic vectors furnish all the

Table 3 Decathlon data: characteristic and rotated vectors

	Characteristic vectors				Varimax rotation			
	$\mathbf{v}_1$	$\mathbf{v}_2$	$\mathbf{v}_3$	$\mathbf{v}_4$	$\mathbf{b}_1$	$\mathbf{b}_2$	$\mathbf{b}_3$	$\mathbf{b}_4$
100 m run	0.69	0.22	−0.52	−0.21	0.88	0.14	0.16	−0.12

information needed, and no rotation is needed. The frequencies chosen for the audiometric procedure are from a continuum of frequencies that could have been chosen, and, when the original variables are of this form, rotation is less likely to be useful than the decathlon example where the variables are specific events. All of the common rotation procedures had similar problems with these data except for **quartimax**. That exception is dealt with in the article on quartimax.

J. EDWARD JACKSON

Roy's Maximum Root Criteria

To illustrate his **union–intersection principle**, Roy [37, 38] proposed the maximum characteristic root **eigenvalue** test statistic for each of the following problems: (i) testing the equality of k p-variate normal distributions (*see* **Multivariate Normal Distribution**) with the same but unknown **covariance matrix**; (ii) testing the independence between two sets of variates jointly distributed as a normal distribution with unknown mean vector; (iii) testing the equality of covariance matrices of two p-variate normal distributions with unknown mean vectors; and (iv) testing that the covariance matrix of a p-variate normal distribution with unknown mean vector equals a specified matrix $\mathbf{\Sigma}_0$.

For problems (i)–(iii), the test statistic can be expressed as the largest characteristic root b_1 of a random matrix $\mathbf{B} \equiv \mathbf{S}_1(\mathbf{S}_1 + \mathbf{S}_2)^{-1}$. For problem (i), which can be considered as a version of **multivariate analysis of variance** (MANOVA), the matrices $\mathbf{S}_1$ and $\mathbf{S}_2$ denote the sums of squares and cross-products matrices "due to hypothesis" and "due to error" with **degrees of freedom** (df) ν_1 and ν_2, respectively. For problem (ii), $\mathbf{S}_1 = \mathbf{S}_{12}\mathbf{S}_{22}^{-1}\mathbf{S}_{21}$, $\mathbf{S}_2 = \mathbf{S}_{11} - \mathbf{S}_{12}\mathbf{S}_{22}^{-1}\mathbf{S}_{22}$, where $(\mathbf{S}_{ij}; i, j = 1, 2)$ is the partitioned sums of squares and cross-products (SP) matrix corresponding to the two sets. Lastly, $\mathbf{S}_1$ and $\mathbf{S}_2$ denote the SP matrices corresponding to random samples from the two populations for problem (iii). Furthermore, Roy also considered the largest characteristic root t_1 of the matrix $\mathbf{S}$ as a test statistic for problem (iv), $\mathbf{S}/\nu_1$ being the sample covariance matrix with df ν_1.

The null distribution of b_1 takes the same form for each of the problems (i)–(iii). Moreover, the limiting distribution of $\nu_2 b_1$ is the same as the distribution of t_1 defined for (iv) with $\mathbf{\Sigma}_0 = \mathbf{I}$, as $\nu_2 \to \infty$. We shall assume that the number s of nonzero roots of $\mathbf{B}$ equals p, in the sequel; for $s < p$, see [22] for an appropriate change of parameters for (i).

The literature on this topic is rather extensive. We cite only the major references which give information on many other related works. In a pioneering paper, Roy [36] considered the maximum root statistic for problem (i) and derived its null distribution with an explicit expression for $s = 2$, 3, and 4. Later, the null distribution of b_1 has been derived in a series form following the reduction method of Roy, the Pfaffian method of Mehta [21], and through zonal polynomials introduced by Constantine [8] for the distribution of roots. See [1, 18, 19, 28], and [40] for more details.

To make the null distribution of b_1 amenable to evaluation of upper percentage points, Pillai [24] has suggested an approximation. Using this approximation as well as using the exact distribution, tables have been constructed for the upper percentage points of b_1 for various values of the parameters (see [19, 25, 26, 31], and [44].

The nonnull distribution of b_1 in the multivariate analysis of variance problem has been obtained by Khatri & Pillai [16], DeWaal [11], Pillai & Sugiyama [35], Krishnaiah & Chang [20], and Khatri [15], among others. The noncentral distribution of the largest **canonical correlation** coefficient has been derived by Pillai & Sugiyama [41], DeWaal [11], Pillai [27], and Khatri [15], in particular. For problem (iii), the nonnull distribution of b_1 has been obtained by Khatri [14], Pillai & Sugiyama [35], and Chang [5] in the general case. For this problem, Chang [5] has obtained a beta-type asymptotic expansion of the distribution of b_1. For asymptotic distribution of the maximum root for problems (i) and (ii) see [1] and [22]. Also see the review paper by Pillai [29].

8The distribution of the largest characteristic root of a **Wishart** matrix follows from the result in Constantine [8]; it has been obtained also by Sugiyama [41], Krishnaiah & Chang [20], and Khatri [15]; see [22] for its asymptotic distribution. Tables for the upper percentage points of t_1 are given in Clemm et al. [7] and Krishnaiah [19]. The distribution of the maximum root of a noncentral Wishart matrix has been obtained by Hayakawa [13]. For an approximation to the cumulative distribution function of the largest root of the covariance matrix, see [32].

The maximum root test for MANOVA has been shown to be admissible (*see* **Decision Theory**) by Ghosh [12] and Anderson & Takemura [4]. The monotonicity of the **power** function of Roy's maximum root test in terms of the corresponding noncentrality parameters has been shown by Das Gupta et al. [10] for MANOVA, by Anderson & Das Gupta [2] for the test of independence, and by Anderson & Das Gupta [3] for problems (iii) and (iv) with one-sided alternatives.

It has been observed that Roy's maximum root test for (i) and (ii) has relatively (in comparison with

other standard tests) lower power for local alternatives and nonlinear alternatives; see [33, 34], and [39]. Based on a **Monte Carlo** study, Olson [23] has observed that Roy's test for MANOVA is (relatively) most affected by deviations from normality and homoscedasticity; see Korin [17] for a similar study. For testing the equality of covariance matrices, Chu & Pillai [6] have observed that Roy's two-sided test based on the maximum root performed best locally among all standard two-sided tests. Pillai & Hsu [34] have studied robustness of the test of independence based on Roy's maximum root criterion along with three other criteria.

For **simultaneous confidence intervals** based on the maximum root, see Roy [38] and Srivastava & Khatri [40]; properties of such confidence intervals have been studied by Wijsman [42, 43]. The relative efficiency of these confidence intervals has been studied by Cox et al. [9].

SOMESH DASGUPTA

Royal Statistical Society

The Statistical Society of London was established in 1834, with the stated purpose of procuring, arranging, and publishing "Facts calculated to illustrate the Condition and Prospects of Society". Four main classes of study were specified in the founding prospectus: economical statistics, political statistics, medical statistics, and moral and intellectual statistics. Although the term "medical" was then primarily applied to issues of public health, the Royal Statistical Society (as it was to become in 1887), is still strongly associated with what is now known as **"biostatistics"**. This article has a biostatistical perspective; for more general historical articles, see [2, 7, 13, 14, 16].

Early volumes of the *Journal of the Statistical Society* (*see* ***Journal of The Royal Statistical Society***) are full of worthy statistical data on national and international trade and economics, the empire, transport, mortality, and social investigations. The latter strongly reflect the Victorian concern, if not obsession, with insanity, crime, and the ills of the lower classes. Typical examples include: Report upon the Mortality of Lunatics (1841), Sanitary Condition of Borough of Reading (1847), Rate of Mortality among Persons of Intemperate Habits (1851), Duration of Life among the Clergy (1851), Statistics of the Insane, Blind, Deaf and Dumb, and Lepers, of Norway (1852), and Vital and Medical Statistics of Chittagong (1862). Sadly, the content of such papers does not always live up to the interest aroused by their titles; there is a general dullness of presentation, a lack of graphics, and an absence of incisive interpretation. The latter merely puts into practice the strictures expressed in the original prospectus in 1834: "The Statistical Society will consider it to be the first and most essential rule of its conduct to exclude carefully all opinions from its transactions and publications, – to confine its attention rigorously to facts, – and, so far as it may be found possible, to facts which can be stated numerically and arranged in tables."

An exception to this self-imposed role is Florence **Nightingale**, who returned in 1857 from her revolutionary work in the Crimean War, determined to use all possible statistical tools as polemical weapons in her crusade to reform military and civil hospitals. She enlisted the help of William **Farr**, who was then the dominant force in the statistical analysis of public health data; he contributed many articles to the *Journal* and became President of the Society in 1871. Florence Nightingale was elected as the first woman Fellow of the Society in 1858, and embarked in 1859, on a campaign for uniform hospital and surgical statistics, which would "enable us to ascertain the relative mortality of different hospitals. . .". In 1860, the International Statistical Congress in London decided that "Miss Nightingale's Scheme for Uniform Hospital Statistics should be conveyed to all governments represented". The *Journal of the Statistical Society* published summaries of these statistics for London and provincial hospitals for five years, as a series of tables without comment. These were summarized in 1867 by **Guy** [6], who specifically denied that any variability in outcome could be due to **quality of care** given by the staff "chosen, as it is, from among those members of the profession who have already given proofs of sound training, ability, and skill in practice".

The Society, which became the Royal Statistical Society with the award of the Royal Charter in 1887, was slow to embrace the dramatic methodological and applied developments in statistics that began near the end of the nineteenth century; only **Edgeworth** and **Yule** seriously contributed to the methodological content of the *Journal*, beginning with a classic exposition in the 1885 Jubilee issue [4]. Here, Edgeworth discusses the variability of the **mean** of a set of observations, the **central limit theorem**, and introduces the term "insignificant", while Yule [17] displays a remarkable use of modern statistical method: model fitting (*see* **Model, Choice of**), estimates of error, tests of **goodness of fit**, and interpretation of a large data set. There were also mathematical papers by Karl **Pearson** and **Galton**, but these were largely summaries of longer papers given elsewhere; Karl Pearson was never a Fellow of the Society, and the new Biometric school primarily relied on its own new journal ***Biometrika*** as an outlet. The hugely influential work of **Fisher** carried out at Rothamsted Experimental Station was also not reflected in the *Journal* until the 1930s.

The Society began publishing the discussion of its read papers in 1873, but it was not until the 1930s that a notorious series of papers established its continuing reputation for public statistical disputes. **Neyman** presented his development of **confidence intervals** to the Society on June 19, 1934, in which he sought to make **inferences** about parameters without having

to use a **prior distribution** [10]. Arthur Bowley, a strong advocate of **Bayesian methods**, or "inverse probability" as it was then known, was given the task of proposing the vote of thanks. He started by saying "I am not at all sure that the 'confidence' is not a 'confidence trick"', and added "Does that really take us any further? Does it take us beyond Karl Pearson and Edgeworth? Does it really lead us towards what we need – the chance that in the universe which we are sampling the proportion is within certain limits? I think it does not." He finished with "The statement of the theory is not convincing, and until I am convinced I am doubtful of its validity."

R.A. Fisher, however, was generous in his praise of the paper, interpreting it as direct support for his own "**fiducial** theory". This good-natured alliance against the inverse probabilists was soon to break down. Later that year, Fisher was strongly attacked when he presented his work on **likelihood** [5], and in 1935, he rounded on Neyman: ". . .were it not for the persistent efforts which Dr Neyman and Dr [E.S.] **Pearson** had made to treat what they speak of as problems of estimation, by means merely of tests of significance, he had no doubt that Dr Neyman would not have been in any danger of falling into the series of misunderstandings which his paper revealed" [11]. Published continuations of this personal dispute were still appearing 20 years later, and it might be still claimed to be reflected in arguments concerning the focus of regulatory bodies on ***P* values**.

The war focused attention on industrial statistics, but in the 1950s, the Society began to turn its attention to modern biostatistics. Austin Bradford **Hill** became President in 1950, Sir Ronald Fisher in 1952, and in October 1955, the Study Circle on Medical Statistics became a Section. The computer was enthusiastically embraced: Bartlett [1] records early work on "the Manchester computer" in simulating epidemics (*see* **Epidemic Models, Stochastic**), and in the discussion, Norman Bailey generously states that "provided they are not made an excuse for avoiding difficult mathematics, I think there is great scope for such computers in biometrical work". Hollingsworth [8] is the first published example of **"computer-aided diagnosis"**.

The year 1972 turned out to be somewhat of an *annus mirabilis* for methods applicable in biostatistics: Nelder & Wedderburn [9] described the basic algebraic and computational framework for **generalized linear models**, Peto & Peto [12] established the theoretic framework for the **logrank test**, and Cox [3] introduced the **proportional hazards** model with an arbitrary underlying **hazard rate** function, and hence made possible the introduction of multiple **covariates** into **survival analysis**. Consulting the Science Citation Index in April 1997, we find Nelder & Wedderburn [9] had over 600 citations and Peto & Peto [12] over 1100, but these are paltry compared with the 6000 citations of Cox [3].

Biostatistical activity in the Society has continued to grow in line with the increasing importance of the subject in medical research. The 1960 regulations state that the Medical Section may "arrange periodical meetings or conferences of the Section for the reading of papers, discussion or demonstrations. . .. The Section Committee may recommend that any papers read before the Section shall be published by the Society." This has led to special meetings and collected articles on such topics as HIV/**AIDS** (1988), cancer near nuclear installations (1989) (*see* **Leukemia Clusters**), institutional **"league tables"** (1996), **BSE/CJD** (1997) and ethics, integrity, and clinical trials (2002) (*see* **Medical Ethics and Statistics**).

Guy Medals are awarded in gold (since 1892), silver (since 1893), and bronze (since 1936). In 1999, the Guy Gold medal was awarded to Michael Healy for his extensive statistical contributions to agriculture, medicine, and a wide variety of other applications in which he has had a significant influence. Discussion papers cited in awards of the Guy Silver Medal often feature biostatistical themes; they include examples on repeated significance tests (*see* **Sequential Analysis**), multivariate proportional hazards (*see* **Multivariate Survival Analysis**), **DNA sequencing**, Bayesian methods in the **pharmaceutical industry**, medical expert systems (*see* **Artificial Intelligence**), and so on. The Bradford Hill Medal for medical statistics was inaugurated in 1994, with a posthumous award to Martin **Gardner**.

The Institute of Statisticians was for many years the professional body for statisticians in the United Kingdom, but after many years of attempted negotiations, the Society finally merged with the Institute on January 1, 1993. The increased emphasis on professional matters led to the introduction of Chartered Statistician (CStat) status, and the formation of a Professional Affairs Committee. There is a strong relationship with the pharmaceutical industry: the Society was instrumental in bringing full-time

statisticians into the United Kingdom drug regulatory framework [15] (*see* **Drug Approval and Regulation**), and there is continued dialog with statisticians in the pharmaceutical industry (*see* **Statisticians in the Pharmaceutical Industry (PSI)**).

The merger with the Institute of Statisticians raised membership of the Society to over 6000. Sections currently include Medical, Research, General Applications, Social Statistics, Business and Industrial, Quality Improvement, Official Statistics, and Statistical Computing, and there are study groups in Environmental Statistics and Primary Health Care. General conferences are held every two years, alternating with specialist meetings on topics such as Practical Bayesian Statistics and **teaching statistics**. In 2003, the theme of the Society's conference was statistical genetics and **bioinformatics** and in 2005, the Society and PSI will be organizing a joint conference in statistics and health care.

In March 2004, *Significance* was launched as the Society's new quarterly magazine for anyone interested in statistics and the analysis and interpretation of data. Its aim is to communicate and demonstrate in an entertaining and thought-provoking way, the practical use of statistics in all walks of life and to show how statistics benefit society. Articles are largely nontechnical and hence accessible and appealing, not only to members of the profession, but also to all users of statistics. It is intended that the magazine should be relevant to people working, for instance, in central and local government, medicine and health care, administration, economics, business and commerce, industry, social studies, survey research, science, and the environment.

After many years without a base in which general meetings could be held, in 1995, the Society finally moved into excellent premises at 12 Errol Street in London. In the last 10 years, the Society has increasingly sought to raise its own profile and that of statistics. The Society is committed to a policy of outreach – disseminating and promoting the use and understanding of statistics to advance the welfare of society. In line with this policy, it has, for instance, taken a close interest in statistical education at all levels and has established a Centre for Statistical Education, currently based at Nottingham Trent University. The Society has produced a report on the use of performance indicators and is now working with stakeholders in this area to develop good practice not only in target setting, but also in the design, analysis, and reporting of performance indicators. It is similarly working with stakeholders within the legal and associated professions to ensure the appropriate collection and use of forensic statistical evidence (*see* **Medico–Legal Cases and Statistics**; **Statistical Forensics**). Since 1990, the Society has argued that an independent statistical service, free from political interference, is essential to the maintenance of a healthy democracy and has paid close attention to the UK Government's measures to implement National Statistics. Comprehensive information about the Society, its purposes and activities, can be found at `www.rss.org.uk`.

With a thriving Medical Section, the Royal Statistical Society continues to keep its traditional balance between biostatistical methodology and practice. It now stands in a very strong position to further the role of statistics in public life in general, and in the health field in particular.

Saddlepoint Approximation

Saddlepoint approximations are a class of asymptotic approximations to a density or tail probability of a statistic. McCullagh [5], Jensen [8], and Kolassa [6] discuss these methods in detail. Suppose that $T = \sum_{j=1}^{n} Y_j/n$, for Y_j independent and identically distributed. Suppose that the **cumulant generating function** $\mathcal{K}(\beta) = \log \mathrm{E}\left[\exp(\beta Y_j)\right]$ exists for β in an open set about 0. Let $f_T(t)$ represent the density of T. Then $f_T(t)\exp([t\beta - \mathcal{K}(\beta)])$ represents an **exponential family** for T at a potential value t. Note that $\mathrm{E}_\beta[T] = \mathcal{K}'(\beta)$ and $\mathrm{Var}_\beta[T] = \mathcal{K}''(\beta)$. Let $\hat{\beta}$ solve $t = \mathrm{E}_{\hat{\beta}}[T]$, or

$$\mathcal{K}'(\hat{\beta}) = t. \tag{1}$$

Applying the Gaussian approximation (*see* **Normal Distribution**) to $f_T(t)\exp(n[t\hat{\beta} - \mathcal{K}(\hat{\beta})])$, one obtains

$$f_T(t)\exp(n[\hat{\beta}t - \mathcal{K}(\hat{\beta})]) = \frac{(\exp(0)/\sqrt{2\pi})}{\sqrt{\mathcal{K}''(\hat{\beta})}}\left(1 + O\left(\frac{1}{n}\right)\right). \tag{2}$$

The notation $O(1/n)$ indicates a quantity that, when multiplied by n, is bounded as $n \to \infty$, and represents a relative error; that is, it reflects the difference between the density approximation and the true density, divided by the true density. Daniels [2] showed that

$$f_T(t) = \frac{\sqrt{n}\exp(n[\mathcal{K}(\hat{\beta}) - \hat{\beta}t])}{\sqrt{2\pi\mathcal{K}''(\hat{\beta})}}\left(1 + O\left(\frac{1}{n}\right)\right). \tag{3}$$

Approximation (3) is preferred to direct application of the **central limit theorem**, because the bound on the relative error is uniform for t in compact regions in the range of $\mathcal{K}'$; a uniform bound on the relative errors of more direct Gaussian-based approximations generally exist only for $t/\sqrt{n}$ bounded. The other approximations given below share this relative error behavior. Approximations discussed in this article are called saddlepoint approximations, since they might also be derived using complex integration techniques, in which the integrand near $\hat{\beta}$ is shaped like a saddle; $\hat{\beta}$ is known as the saddlepoint.

When $\boldsymbol{T} = (T^1, \ldots, T^d)$ is the mean of independent and identically distributed random vectors, each with d components, the above logic motivates the approximation

$$f_{\boldsymbol{T}}(\mathbf{t}) = \frac{n^{d/2}\exp(n[\mathcal{K}(\hat{\boldsymbol{\beta}}) - \hat{\boldsymbol{\beta}}\mathbf{t}])}{\left[(2\pi)^{d/2}\sqrt{|\mathcal{K}''(\hat{\boldsymbol{\beta}})|}\right]}\left(1 + O\left(\frac{1}{n}\right)\right), \tag{4}$$

where $\hat{\boldsymbol{\beta}}$ satisfies

$$\mathcal{K}'(\hat{\boldsymbol{\beta}}) = \mathbf{t}. \tag{5}$$

Statistical applications typically require approximate tail probabilities rather than approximate densities, since tail probabilities may be used to construct **hypothesis tests**, and hypothesis tests may be inverted to construct confidence intervals; see [3]. When $d = 1$, one might integrate (3) to approximate $\mathrm{P}[T \geq t]$. Typically, one cannot perform these integrations exactly. One might integrate by parts, and demonstrate that an omitted term is sufficiently small. Let $\hat{w} = \sqrt{(2[\hat{\beta}t - \mathcal{K}(\hat{\beta})])}\,\mathrm{sgn}(\hat{\beta})$. Lugannani and Rice [7] show that

$$\mathrm{P}[T \geq t] = 1 - \Phi(\sqrt{n}\hat{w}) + \frac{\phi(\sqrt{n}\hat{w})(1/\hat{w} - 1/\hat{z})}{\sqrt{n}}\left(1 + O\left(\frac{1}{n}\right)\right), \tag{6}$$

where $\hat{z} = \hat{\beta}\sqrt{(K''(\hat{\beta}))}$. [1] derives the r^* form of the approximation

$$\mathrm{P}[T \geq t] = 1 - \Phi(\sqrt{n}\hat{w}^*)\left(1 + O\left(\frac{1}{n}\right)\right) \text{ for } \hat{w}^* = \hat{w} + (n\hat{w})^{-1}\log\left(\frac{\hat{z}}{\hat{w}}\right). \tag{7}$$

Conditional probability densities may be approximated by calculating (4) for both the joint and the marginal densities (*see* **Marginal Probability**), and dividing the results. Applying this technique to the distribution of the last component T^d, conditional on all other components $\boldsymbol{T}_{-d} = (T^1, \ldots, T^{d-1})$, yields

$$f_{T^d|\boldsymbol{T}_{-d}}(t^d|\mathbf{t}_{-d}) = \frac{\sqrt{n}\phi(\sqrt{n}\hat{w})}{\sqrt{|\mathcal{K}''(\hat{\boldsymbol{\beta}})|/|\mathcal{K}''_{-d}(\tilde{\boldsymbol{\beta}})|}} \times \left(1 + O\left(\frac{1}{n}\right)\right). \tag{8}$$

Here $\hat{\boldsymbol{\beta}}$ solves (4) and $\tilde{\boldsymbol{\beta}}$ solves $\tilde{\beta}_d = 0$ and $\mathcal{K}'_{-d}(\tilde{\boldsymbol{\beta}}) = \mathbf{t}_{-d}$, $\mathcal{K}''_{-d}$ is the matrix $\mathcal{K}''$, omitting the row and column corresponding to d, $\mathcal{K}'_{-d}$ represents $\mathcal{K}'$ with component d omitted, and $\hat{w} = \sqrt{(2[\mathcal{K}(\tilde{\boldsymbol{\beta}}) - \mathcal{K}(\hat{\boldsymbol{\beta}}) + [\hat{\boldsymbol{\beta}} - \tilde{\boldsymbol{\beta}}]\mathbf{t}])}$. Again, $\mathrm{P}\left[T^d \geq t^d | \boldsymbol{T}_{-d} = \mathbf{t}_{-d}\right]$ may again be approximated by (6) or (7), for $\hat{z} = \hat{\beta}_d \sqrt{(|\mathcal{K}''(\hat{\boldsymbol{\beta}})|/|\mathcal{K}''_{-d}(\tilde{\boldsymbol{\beta}})|)}$. Skovgaard [9] derived this approximation, using (6). Approximations (6) and (7) are called double saddlepoint approximations, to distinguish them from an application of the univariate saddlepoint distribution function approximation based on the cumulant generating function of the conditional distribution, which might be called a single saddlepoint conditional probability approximation. The single saddlepoint approach is useful when the conditional cumulant generating function is available, or when, like [4], one employs an approximation to the conditional cumulant generating function.

The preceding development is for continuous **random variables**. If possible values of components of $\boldsymbol{T}$ are separated by a constant, say $1/n$, then probability masses for $\boldsymbol{T}$ are approximated by (3) or (4). When $d = 1$, one might add (3) over the tail region to show that (6) and (7) still hold, with $\hat{z} = 2n \sinh(\hat{\beta}/(2n))\sqrt{(\mathcal{K}''(\hat{\beta}))}$, and with $\hat{\beta}$ satisfying $\mathcal{K}'(\hat{\beta}) = t - 1/(2n)$. For $d > 1$, when the possible values of T^d are separated by $1/n$, (6) and (7) hold as approximations to $\mathrm{P}\left[T^d \geq t^d | \boldsymbol{T}_{-d} = t_{-d}\right]$, where $\hat{z} = 2n \sinh(\hat{\beta}_d/(2n))\sqrt{(|\mathcal{K}''(\hat{\boldsymbol{\beta}})|/|\mathcal{K}''_{-d}(\tilde{\boldsymbol{\beta}})|)}$, and t_d is corrected for **continuity** before applying (5).

JOHN E. KOLASSA

Salk Vaccine

The largest and, until the 1980s, the most expensive medical experiment in history was carried out in 1954. Well over a million young children participated, and the immediate direct costs were over 5 million mid-century dollars. The experiment was carried out to assess the effectiveness, if any, of the Salk vaccine as a protection against paralysis or death from poliomyelitis. The study was elaborate in many respects, most prominently in the use of placebo controls (children who were inoculated with simple salt solution) assigned at random (that is, by a carefully applied chance process that gave each volunteer an equal probability of getting vaccine or salt solution) (*see* **Randomization**) and subjected to a double-blind evaluation (that is, an arrangement under which neither the children nor the physicians who evaluated their subsequent state of health knew who had been given the vaccine and who the salt solution; *see* **Blinding or Masking**).

Why was such elaboration necessary? Did it really result in more or better knowledge than could have been obtained from much simpler studies? These are the questions on which this discussion is focused.

Background

Polio was never a common disease, but it certainly was one of the most frightening and, in many ways, one of the most inexplicable in its behavior. It struck hardest at young children, and, although it was responsible for only about 6% of the deaths in the age group 5 to 9 in the early 1950s, it left many helpless cripples, including some who could survive only on a respirator. It appeared in epidemic waves, leading to summer seasons in which some communities felt compelled to close swimming pools and restrict public gatherings as cases increased markedly from week to week; other communities, escaping an epidemic one year, waited in trepidation for the year in which their turn would come.

The determination to mount a major research effort to eradicate polio arose in no small part from the involvement of President Franklin D. Roosevelt, who was struck down by polio when a successful young politician. His determination to overcome his paralytic handicap enabled a great deal of attention, effort, and money to be expended on the care and rehabilitation of polio victims and – in the end, more importantly – on research into the causes and prevention of the disease.

During the course of this research, it was discovered that polio is caused by a virus. Although clinical manifestations of polio are rare, it was discovered that the virus itself was not rare, but common, and that most adults had experienced a polio infection sometime in their lives without ever being aware of it. This finding helped to explain the otherwise peculiar circumstance that polio epidemics seemed to hit hardest those who were better off hygienically (that is, those who had the best nutrition, most favorable housing conditions, and were otherwise apparently most favorably situated). Indeed, the disease seemed to be virtually unknown in those countries with the poorest hygiene. The explanation is that because there was plenty of polio virus in the less-favored populations, almost every infant was exposed to the disease early in life while still protected by the immunity passed on from the mother. As a result, everyone had polio, but under protected circumstances, and, thereby, everyone had developed immunity.

As with many other virus diseases, an individual who has been infected by polio and recovered is usually immune to another attack (at least by a virus strain of the same type). The reason for this is that the body, in order to fight the infection, develops antibodies in response to the presence of the protein part of the polio virus. Once the body has learned how to make antibodies to a particular kind of virus, it is able to make them again very rapidly, if the virus should attack a second time. This ability to make antibodies rapidly to fight against subsequent viral attacks is part of what makes people immune.

Smallpox and influenza illustrate two different approaches to the preparation of an effective vaccine. For smallpox, which has long been controlled by a vaccine, we use for the vaccine a closely related virus, cowpox, which is ordinarily incapable of causing serious disease in humans, but which gives rise to antibodies that also protect against smallpox. (In a very few individuals this vaccine is capable of causing a severe, and occasionally fatal, reaction. The risk is small enough, however, so that before smallpox was conquered we did not hesitate to expose all our school children to it in order to

protect them from smallpox.) In the case of influenza, however, instead of a closely related live virus, the vaccine is a solution of the influenza virus itself, prepared with a virus that has been killed by treatment with formaldehyde. Provided that the treatment is not too prolonged, the dead virus still has enough antigenic activity to produce the required antibodies so that, although it can no longer infect, it is sufficiently like the live virus to be a satisfactory vaccine.

For polio, both of these methods were explored. A live-virus vaccine would have the advantage of reproducing in the vaccinated individual and, hopefully, giving rise to a strong reaction that would produce a high level of long-lasting antibodies. With such a vaccine, however, there might be a risk that a vaccine virus so similar to the virulent polio virus could mutate into a virulent form and itself be the cause of paralytic or fatal disease. A killed-virus vaccine should be safe because it presumably could not infect, but it might fail to give rise to an adequate antibody response. These and other problems stood in the way of the rapid development of a successful vaccine. Some unfortunate prior experience also contributed to the cautious approach of the researchers. In the 1930s, attempts had been made to develop vaccines against polio; two of these were actually in use for a time. Evidence that at least one of these vaccines had been responsible for cases of paralytic polio soon caused both to be promptly withdrawn from use. This experience was very much in the minds of polio researchers, and they had no wish to risk a repetition.

Research to develop both live and killed vaccines was stimulated in the late 1940s by the development of a tissue culture technique for growing polio virus. Those working with live preparations developed harmless strains from virulent ones by growing them for many generations in suitable tissue culture media. There was, of course, considerable worry lest these strains, when used as a vaccine in humans, might revert to virulence and cause paralysis or death. (It is now clear that the strains developed are indeed safe – a live-virus preparation taken orally is the vaccine presently in widespread use throughout the world.) Those working with killed preparations, notably Jonas Salk, had the problem of treating the virus (with formaldehyde) sufficiently to eliminate its infectiousness, but not so long as to destroy its antigenic effect. This was more difficult than expected, and some early lots of the vaccine proved to contain live virus capable of causing paralysis and death. There are statistical issues in the safety story [1], but our concern here is with the evaluation of effectiveness.

Evaluation of Effectiveness

In the early 1950s the Advisory Committee convened by the National Foundation for Infantile Paralysis (NFIP) decided that the killed-virus vaccine developed by Jonas Salk at the University of Pittsburgh had been shown to be both safe and capable of inducing high levels of the antibody in children on whom it had been tested. This made the vaccine a promising candidate for general use, but it remained to prove that the vaccine actually would prevent polio in exposed individuals. It would be unjustified to release such a vaccine for general use without convincing proof of its effectiveness, so it was determined that a large-scale "field trial" should be undertaken (*see* **Vaccine Studies**).

That the trial had to be carried out on a very large scale is clear. For suppose we wanted the trial to be convincing if indeed the vaccine were 50% effective (for various reasons, 100% effectiveness could not be expected). Assume that, during the trial, the rate of occurrence of polio would be about 50 per 100 000 (which was about the average incidence in the US during the 1950s). With 40 000 in the **control** group and 40 000 in the vaccinated group, we would find about 20 control cases and about 10 vaccinated cases, and a difference of this magnitude could fairly easily be attributed to random variation. It would suggest that the vaccine might be effective, but it would not be persuasive. With 100 000 in each group, the expected numbers of polio cases would be 50 and 25, and such a result would be persuasive. In practice, a much larger study was clearly required because it was important to get definitive results as soon as possible, and if there were relatively few cases of polio in the test area, the expected number of cases might be well under 50. It seemed likely, also, for reasons we discuss later, that paralytic polio, rather than all polio, would be a better criterion of disease, and only about half the diagnosed cases are classified "paralytic". Thus the relatively low incidence of the disease, and its great variability from place to place and time to time, required that the trial involve a huge number of subjects – as it turned out,

over a million (*see* **Sample Size Determination for Clinical Trials**).

The Vital Statistics Approach

Many modern therapies and vaccines, including some of the most effective ones such as smallpox vaccine, were introduced because preliminary studies suggested their value. Large-scale use subsequently provided clear evidence of efficacy. A natural and simple approach to the evaluation of the Salk vaccine would have been to distribute it as widely as possible, through the schools, to see whether the rate of reported polio was appreciably less than usual during the subsequent season. Alternately, distribution might be limited to one or a few areas because limitations of supply would preclude effective coverage of the entire country. There is even a fairly good chance that were one to try out an effective vaccine against the common cold, convincing evidence might be obtained in this way.

In the case of polio – and, indeed, in most cases – so simple an approach would almost surely fail to produce clear-cut evidence. First and foremost, we must consider how much polio incidence varies from season to season, even without any attempts to modify it. From Figure 1, which shows the annual reported incidence from 1930 through 1955, we see that, had a trial been conducted in this way in 1931, the drop in incidence from 1931 to 1932 would have been strongly suggestive of a highly effective vaccine because the incidence dropped to less than a third of its previous level. Similar misinterpretation would have been made in 1935, 1937, and 1952. One might suppose that such mistakes could be avoided by using the vaccine in one area, say, New York State, and comparing the rate of incidence there with that of an unvaccinated area, say, Illinois. Unfortunately, an epidemic of polio might well occur in Chicago – as it did in 1956 – during a season in which New York had a very low incidence.

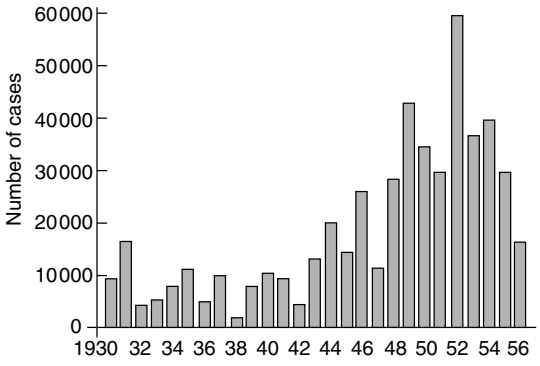

Figure 1 Poliomyelitis in the US, 1930–1956. *Source*: Meier [2]. Estimated. Figures complete through December 8

Another problem, more subtle, but equally burdensome, relates to the vagaries of diagnosis and reporting. There is no difficulty, of course, in diagnosing the classic respirator case of polio, but the overwhelming majority of cases are less clear-cut. Fever and weakness are common symptoms of many illnesses, including polio, and the distinction between weakness and slight transitory paralysis will be made differently by different observers. Thus the decision to diagnose a case as nonparalytic polio instead of some other disease might well be influenced by a physician's general knowledge or feeling about how widespread polio is in his or her community at the time.

These difficulties can be mitigated to some extent by setting down very precise criteria for diagnosis, but it is virtually impossible to obviate them completely when, as would be the case after the widespread introduction of a new vaccine, there is a marked shift in what the physician expects to find (*see* **Outcome Measures in Clinical Trials**).

The Observed Control Approach

The difficulties of the **vital statistics** approach were recognized by all concerned, and the initial study plan, although not judged entirely satisfactory, circumvented many of the problems by introducing a control group similar in characteristics to the vaccinated group. More specifically, the idea was to offer vaccination to all children in the second grade of participating schools and to follow the polio experience not only in these children but in the first- and third-grade children as well. Thus the vaccinated second graders would constitute the treated group, and the first- and third-graders would constitute the control group. This plan follows what we call the observed control approach.

It is clear that this plan avoids many of the difficulties listed above. The three grades all would be drawn from the same geographic location so that an epidemic affecting the second grade in a

given school would certainly affect the first and third grades as well. Of course, all subjects would be observed concurrently in time. The grades, naturally, would be of different ages, and polio incidence does vary with age. Not much variation from grade to grade was expected, however, so it seemed reasonable to assume that the average of first and third grades would provide a good control for the second grade.

Despite the relative attractiveness of this plan and its acceptance by the NFIP advisory committee, serious objections were raised by certain health departments that were expected to participate. In their judgment, the results of such a study were likely to be insufficiently convincing for two important reasons. One is the uncertainty in the diagnostic process mentioned earlier and its liability to be influenced by the physician's expectations, and the other is the selective effect of using volunteers.

Under the proposed study design, physicians in the study areas would have been aware of the fact that only second-graders were offered vaccine, and in making a diagnosis for any such child, they would naturally and properly have inquired whether the child had been vaccinated. Any tendency to decide a difficult diagnosis in favor of nonpolio when the child was known to have been vaccinated would have resulted in a spurious piece of evidence favoring the vaccine. Whether or not such an effect was really operating would have been almost impossible to judge with assurance, and the results, if favorable, would have been forever clouded by uncertainty (*see* **Bias in Observational Studies**).

A less conjectural difficulty lies in the difference between those families who volunteer their children for participation in such a trial and those who do not. Not at all surprisingly, it was later found that those who do volunteer tend to be better educated and, generally, more well-to-do than those who do not participate. There was also evidence that those who agree to participate tend to be absent from school with a noticeably higher frequency than others. The direction of effect of such selection on the incidence of diagnosed polio is by no means clear before the fact, and this important difference between the treated group and the control group also would have clouded the interpretation of the results (*see* **Selection Bias**).

Randomization and the Placebo Control Approach

The position of critics of the NFIP plan was that the issue of vaccine effectiveness was far too important to be studied in a manner that would leave uncertainties in the minds of reasonable observers. No doubt, if the vaccine should appear to have fairly high effectiveness, most public health officials and the general public would accept it, despite the reservations. If, however, the observed control scheme were used, a number of qualified public health scientists would have remained unconvinced, and the value of the vaccine would be uncertain. Therefore, the critics proposed that the study be run as a scientific experiment with the use of appropriate randomization procedures to assign subjects to treatment or to control and with a maximum effort to eliminate observer bias (*see* **Randomized Treatment Assignment**). This plan follows what we call the placebo control approach.

The chief objection to this plan was that parents of school children could not reasonably be expected to permit their children to participate in an experiment in which they might be getting only an ineffective salt solution instead of a probably helpful vaccine. It was argued further that the injection of placebo might not be ethically sound since a placebo injection carries a small risk, especially if the child is unknowingly already infected with polio (*see* **Ethics of Randomized Trials**).

The proponents of the placebo control approach maintained that, if properly approached, parents would consent to their children's participation in such an experiment, and they judged that because the injections would not be given during the polio season, the risk associated with the placebo injection was vanishingly small. Certain health departments took a firm stand: they would participate in the trial only if it were such a well-designed experiment. The consequence was that, in approximately half the areas, the randomized placebo control method was used, and in the remaining areas, the alternating-grade observed control method was used.

A major effort was put forth to eliminate any possibility of the placebo control results being contaminated by subtle observer **biases**. The only firm way to accomplish this was to ensure that neither the subject, nor the parents or the diagnostic personnel could know which children had gotten the

vaccine until all diagnostic decisions had been made. The method for achieving this result was to prepare placebo material that looked just like the vaccine but was without any antigenic activity, so that the controls might be inoculated and otherwise treated in just the same fashion as were the vaccinated.

Each vial of injection fluid was identified only by a code number, so that no one involved in the vaccination or the diagnostic evaluation process could know which children had gotten the vaccine. Because no one knew, no one could be influenced to diagnose differently for vaccinated cases and for controls. An experiment in which both the subject getting the treatment and the diagnosticians who will evaluate the outcome are kept in ignorance of the treatment given each individual is called a double-blind experiment. Experience in clinical research has shown the double-blind experiment to be the only satisfactory way to avoid potentially serious observer bias when the final evaluation is in part a matter of judgment.

For most of us, it is something of a shock to be told that competent and dedicated physicians must be kept in ignorance lest their judgments be colored by knowledge of treatment status. We should keep in mind that it is not deliberate distortion of findings by the physician that concern the medical experimenter. It is rather the extreme difficulty in many cases of making an uncertain decision that, experience has shown, leads the best of investigators to be subtly influenced by information of this kind. For example, in the study of drugs used to relieve postoperative pain, it has been found that it is quite impossible to get an unbiased judgment of the quality of pain relief, even from highly qualified investigators, unless the judge is kept in ignorance of which patients were given the drugs.

The second major feature of the experimental method was the assignment of subjects to treatments by a careful randomization procedure. As we observed earlier, the chance of coming down with a diagnosed case of polio varies with a great many factors, including age, socioeconomic status, etc. If we were to make a deliberate effort to match up the treatment and control groups as closely as possible, we should have to take care to balance these and many other factors, and, even so, we might miss some important ones. Therefore, perhaps surprisingly, we leave the balancing to a carefully applied equivalent of coin tossing: we arrange that each individual has an equal chance of getting vaccine or placebo, but we eliminate our own judgment entirely from the individual decision and leave the matter to chance.

The gain from doing this is twofold. First, a chance mechanism usually will do a good job of evening out all the variables – those we did not recognize in advance as well as those we did recognize. Secondly, if we use a chance mechanism in assigning treatments, we may be confident about the use of the theory of chance (that is, **probability theory**) to judge the results. We can then calculate the probability that so large a difference as that observed could reasonably be due solely to the way in which subjects were assigned to treatments, or whether, on the contrary, it is really an effect due to a true difference in treatments.

To be sure, there are situations in which a skilled experimenter can balance the groups more effectively than a random-selection procedure typically would. When some factors may have a large effect on the outcome of an experiment, it may be desirable, or even necessary, to use a more complex experimental design that takes account of these factors. However, if we intend to use probability theory to guide us in our judgment about the results, we can be confident about the accuracy of our conclusions only if we have used randomization at some appropriate level in the experimental design.

The final determinations of diagnosed polio proceeded along the following lines. All cases of polio-like illness reported by local physicians were subjected to special examination, and a report of history, symptoms, and laboratory findings was made. A special diagnostic group then evaluated each case and classified it as nonpolio, doubtful polio, or definite polio. The last group was subdivided into nonparalytic and paralytic, with paralytic further divided into nonfatal and fatal polio. Only after this process was complete was the code broken and identification made for each case as to whether vaccine or placebo had been administered.

Results of the Trial

The main results are shown in Table 1, which shows the size of the study populations, the number of cases classified as polio, and the disease rates; that is, the number of cases per 100 000 population. For example, the second line shows that in the placebo

Table 1 Summary of study cases by diagnostic class and vaccination status (rates per 100 000)

Study group	Study population	All reported cases		Poliomyelitis cases								Not polio	
				Total		Paralytic		Nonparalytic		Fatal polio			
		No.	Rate	No.	Rate	No.	Rate	No.	Rate	No.	Rate	No.	Rate

[b]First- and third-grade total population.

control area there were 428 reported cases, of which 358 were confirmed as polio, and, among these, 270 were classified as paralytic (including four that were fatal). The third and fourth rows show corresponding entries for those who were vaccinated and those who received placebo, respectively. Beside each of these numbers is the corresponding rate. Using the simplest measure – all reported cases – the rate in the vaccinated group is seen to be half that in the control group (compare the boxed rates in Table 1) for the placebo control areas. This difference is greater than could reasonably be ascribed to chance, according to the appropriate probability calculation (*see* **Hypothesis Testing**). The apparent effectiveness of the vaccine is more marked as we move from reported to paralytic cases to fatal cases, but the numbers are small and it would be unwise to make too much of the apparent very high effectiveness in protecting against fatal cases. The main point is that the vaccine was a success; it demonstrated sufficient effectiveness in preventing serious polio to warrant its introduction as a standard public health procedure.

Not surprisingly, the observed control areas provided results that were, in general, consistent with those found in the placebo control areas. The volunteer effect discussed earlier, however, is clearly evident (note that the rates for those not inoculated differ from the rates for controls in both areas). Were the observed control information alone available, considerable doubt would have remained about the proper interpretation of the results [3].

Although there had been wide differences of opinion about the necessity or desirability of the placebo control design before, there was great satisfaction with the method after the event. The difference between the two groups, although substantial and definite, was not so large as to preclude doubts had there been no placebo controls. Indeed, there were many surprises in the detailed data. It was known, for example, that some lots of vaccine had greater antigenic power than did others, and it might be supposed that they should have shown a greater protective effect. This was not the case; lots judged inferior in potency did just as well as those judged superior. Another surprise was the rather high frequency with which apparently typical cases of paralytic polio were not confirmed by laboratory test. Nonetheless, there were no surprises of a character to cast serious doubt on the main conclusion. The favorable reaction of those most expert in research on polio was expressed soon after the results were reported. By carrying out this kind of study before introducing the vaccine, it was noted, we had facts about the Salk vaccine that we still lack about the typhoid vaccine, and about the tuberculosis vaccine after many decades of use.

Epilogue

It would be pleasant to report an unblemished record of success for the Salk vaccine following so expert and successful an appraisal of its effectiveness, but it is more realistic to recognize that such success is but one step in the continuing development of public health science. The report of the field trial was followed by widespread release of the vaccine for general use, and it was discovered very quickly that a few of these lots had actually caused serious cases of polio. Distribution of the vaccine was then halted while the process for making the vaccine was reevaluated. Distribution was reinitiated a few months later, but the momentum of acceptance had been broken and the prompt disappearance of polio that researchers had hoped for did not come about. Meanwhile, research on a more highly purified killed-virus vaccine and on several live-virus vaccines progressed, and within a few years the Salk vaccine was displaced in the US (but not in Sweden) by live-virus vaccines.

Sample Size Adequacy in Surveys

Introduction

The Cambridge Dictionary of Statistics defines a **sample survey** as "A study that collects planned information from a *sample* of individuals about their history, habits, knowledge, attitudes, or behavior in order to *estimate* particular *population* [Italics ours] characteristics" [5]. While the general concepts involved in the determination of **sample size** adequacy are essentially the same for sample surveys as they are for other designs, the actual process is generally driven by the following three features:

Consideration of Sample Design

In most other study designs, the data are assumed to arise from an unrestricted **random sampling** process (i.e. random sample from an infinite universe). In sample surveys, the sampling process can involve **stratification**, **clustering**, **multistage** selection, and other complications such as **missing data**; and methodology has to take these into consideration. Also, the chances of being selected in the survey may not be the same for each population unit (i.e. unequal selection probability).

Emphasis on Estimation

In sample survey work, the primary objectives generally focus on construction of point and interval estimates of characteristics of the population (*see* **Estimation**; **Estimation, Interval**). Hypothesis testing is often a secondary objective. Thus, sample size assessment is generally stated in terms of the widths of symmetric α **confidence intervals** achievable with a particular n (number of units or number of clusters) rather than the statistical **power** of rejecting a specified **null hypothesis**.

Population

Sample surveys involve samples of n units from a population of N units, where N is some finite number. As noted above, this contrasts with the usual (often implied) assumptions made in statistical **inference**; namely, that the units are selected by random sampling from a universe assumed to be infinite. It also allows estimation of population totals or aggregates, which are not possible if populations are considered infinite.

Objectives

With this in mind, our objective in this entry is to formulate an approach to sample size assessment, which is accessible and can be readily used in a wide variety of situations for point estimation of entities such as means, totals, proportions, and ratios. We are aiming this discussion at researchers who need to assess adequacy of sample size for purposes of a grant or contract application or some similar activity. The methods described below are not "cutting edge" but are widely known, widely used, and applicable to many situations found in practice.

Approach

The approach we are taking is very similar to that used by Thompson in his sampling book [12]. Let us suppose we are assessing the adequacy of a sample survey design based on a **simple random sample** of n enumeration units from a population containing N enumeration units, and we want the resulting half-width of the α confidence interval for the estimated mean to be no wider than ε units on the scale of the variable being estimated. Let us first ignore the fact that we are sampling from a finite population and assume that we are using unrestricted random sampling from an infinite universe and that the variable of interest is **normally distributed** about its mean with **variance** equal to σ^2, where σ^2 is known. Since the **standard error** of an estimated mean under unrestricted random sampling is equal to $\sigma/\sqrt{n}$, the half-width of the α confidence interval for the estimated mean is equal to $z_{1-\alpha/2}\sigma/\sqrt{n}$. Then from classical theory, the sample size, n, satisfies the specifications if the following holds:

$$z_{1-\alpha/2}\left(\frac{\sigma}{\sqrt{n}}\right) \leq \varepsilon$$

or

$$n \geq \frac{z_{1-\alpha/2}^2 \sigma^2}{\varepsilon^2} \tag{1}$$

where

$z_{1-\alpha/2}$ = the $100 \times (1-\alpha/2)$ percentile of the normal distribution

σ^2 = the variance of the variable being analyzed

For finite population sampling, if $\hat{d}$ is an estimate of a parameter, d, then the specifications are that we want n large enough that the half-widths of the resulting $100 \times (1-\alpha/2)\%$ confidence intervals are no wider than ε. However, the variance of $\hat{d}$ is dependent not only on the variance, σ^2, and the sample size, n, but also on the sample design being used (denoted by Ψ) and the population size, N.

Let $\mathrm{Var}(\hat{d}) = f_\Psi(\sigma, n, N)$. Then the specification is satisfied if the following inequality holds:

$$z_{1-\alpha/2}\sqrt{f_\Psi(\sigma, n, N)} \leq \varepsilon \tag{2}$$

Frequently Used Sample Designs

Simple Random Sampling

If the design is simple random sampling of n units from a population of N units, then the inequality (2) is given by

$$z_{1-\alpha/2}\sqrt{\left(\frac{\sigma^2}{n}\right)\left(\frac{N-n}{N-1}\right)} \leq \varepsilon \tag{3}$$

Solving inequality (3) for n, we see that the specification is satisfied if

$$n \geq \frac{N\sigma^2 z_{1-\alpha/2}^2}{\sigma^2 z_{1-\alpha/2}^2 + (N-1)\varepsilon^2} \tag{4}$$

If n is very much smaller than N (for practical purposes, $n \leq 10\%$ of N), then the right hand side of relation (4) reduces numerically to the right hand side of relation (3).

The following example will illustrate the procedures discussed above for determining the adequacy of sample size. Suppose we guess that approximately two-thirds of the clients of a chain of weight loss clinics will lose between 2 and 14 pounds during the first month, and that we wish to take a simple random sample of 25 clients from the 750 registered clients. We wish to be 95% confident of estimating the true mean weight loss to within 3 pounds of its true value. Is the proposed sample of 25 clients large enough to meet this specification?

In this example, $N = 750$, $n = 25$, $\varepsilon = 3$, $\sigma = 8$ (assuming a normal distribution, approximately two-thirds of values encompass 2 standard deviations from the mean), and $z_{1-\alpha/2} = 1.96$. From relation (4), it would require a sample of 26.39 (which rounds to 27) persons to satisfy the specification, so $n = 25$ is too small a sample size.

Stratified Random Sampling

A major rationale for stratification is its potential property as a variance lowering design tool. Thus, if effective, it should yield an estimate that has a lower standard error than that obtained by a simple random sampling design having the same number of observations. Thus, it should require a smaller n to obtain the same specifications of precision.

The variance of an estimate from **stratified random sampling** depends on the strata variances within, denoted $\sigma_h : h = 1, \ldots, L$; the strata population sizes, $N_h : h = 1, \ldots, L$, and the sampling allocations, $\pi_1 = n_1/n, \ldots, \pi_L = n_L/n$ within each stratum (see [9], p. 147 for the specific form of the variance). Using this and solving the resulting expression in relation (2), we would obtain the following approximate expression for the total sample size, n, that satisfies the specifications:

$$n \approx \frac{\left(\frac{z_{1-\alpha/2}^2}{N^2}\right)\left(\sum_{h=1}^{L}\frac{N_h^2\sigma_{hx}^2}{\pi_h}\right)}{\varepsilon^2 + \left(\frac{z_{1-\alpha/2}^2}{N^2}\right)\left(\sum_{h=1}^{L}N_h\sigma_{hx}^2\right)} \tag{5}$$

If estimates of the components of (5) are available from pilot studies, previous or similar surveys, or can be "guesstimated", then (5) can be used to assess the adequacy of the sample size.

Two-stage Cluster Sampling

In many situations, it may not be either feasible or possible to compile **sampling frames** that enumerate all units for the entire population. In such cases, one may be able to construct a sampling frame that identifies groups or *clusters* of enumeration units without listing explicitly all individual units. One can perform sampling from such frames by taking a sample of clusters, obtaining a list of individual

units within each selected cluster, and then selecting a sample of the enumerated units.

While the approach for sample size estimation is similar for two-stage **cluster sampling** designs as for the more simple designs considered above, the variance formulas are often more complex, especially if the clusters vary with respect to the number of sampling units and are selected with unequal probabilities at the first stage of sampling. One approach is to use the following approximate formula for the variance of an estimate from a two-stage cluster sample and substitute it into relation (2):

$$\mathrm{Var}(\overline{\overline{x}}_{\mathrm{clu}}) = \mathrm{Var}(\overline{x}_{\mathrm{srs}}) \times DEFF, \qquad (6)$$

where

$\mathrm{Var}(\overline{\overline{x}}_{\mathrm{clu}})$ = the variance of an estimated mean per unit from a two-stage cluster sample,

$\mathrm{Var}(\overline{x}_{\mathrm{srs}})$ = the variance of an estimated mean per unit from a simple random sample of the same number, n, of observational units,

and

$$DEFF = \frac{\mathrm{Var}(\overline{\overline{x}}_{\mathrm{clu}})}{\mathrm{Var}(\overline{x}_{\mathrm{srs}})}$$

DEFF is a quantity known as the **design effect**, which reflects the inflation in variance (mostly due to the sampling of clusters and the unequal weighting of observations intrinsic in most multistage designs). Sometimes the design effect can be estimated as a product of two factors: one representing the inefficiency of the unequal weighting used in the sample design and the other representing the intraclass correlation coefficient (*see* **Correlation**), which represents, in essence, the inefficiency in sampling more than 1 unit from the same cluster. Specific formulas are shown in [9].

Some Practical Guidelines for Assessing Sample Size Adequacy

The authors highly recommend utilizing the following guidelines to help ensure both appropriateness and accuracy in determining sample size adequacy.

Required Input from Client

1. Specification of key variables (and their approximate value or range of values) on the basis of which sample sizes will be determined.
2. Specification of needed precision of the estimates and "credibility level" of obtaining that level of precision. Note: different clients may request precision in a variety a ways (e.g. standard error of the estimate, half-width of confidence interval, coefficient of variation (CV) (*see* **Standard Deviation**), and effective sample size). Sometimes differences are of interest, so aspects such as power, detectable differences or effect size (*see* **Design Effects**) might be what are specified.
3. Available budget (if applicable) or cost components.
4. Sample Design (sampling plan and estimation procedure).
5. "Guesstimates" of variance of relevant variables, intracluster correlations or a range of possible correlations.
6. Will the survey be designed to satisfy multiple constraints?
7. Response and eligibility definitions and rate assumptions.

Computation of Required Sample Sizes

1. Search for available **algorithms/software** that is appropriate to obtaining the required sample size based on the particular sample design and estimation procedure being used.
2. On the basis of client input (3. above), run appropriate statistical algorithm. Though a theoretical algorithm may exist, an applicable one may not and hence some programming may be necessary.
3. Perform quality control (QC) procedures on the resulting sample size determination.

Items/Procedures for QC Checks

1. Verify with client investigators that determined sample sizes have both "face validity" (*see* **Health Status Instruments, Measurement Properties of**) and are likely to be obtained given the available budget.
2. Verify that the sample size satisfies the study specifications (i.e., using the obtained sample size, compute the precision of the estimate). This should be performed for several key estimates (at least for all on which sample sizes are based), if the survey is required to satisfy multiple constraints.

Appendix

Sample Size Determination for Clinical Trials

A fundamental rule of **sample size determination** is that the method of calculation should be based on the planned method of analysis. For **clinical trials**, the array of analytic methods is large. Rather than produce a catalog of methods, this article will provide the reader with a discussion of the conceptual issues behind sample size determination that arise specifically in clinical trials.

One defining characteristic of a clinical trial is that observations are made on human subjects. This impacts on the sample size calculation of clinical trials in the form of three primary distinguishing features. First, however well-intentioned, patients cannot always be cooperative with the planned conduct of the study. In dealing with plots of land or laboratory animals, one is usually less concerned about the experimental "units" receiving only part of the assigned treatment, or receiving another treatment, or failing to be present for a scheduled measurement. Factors such as these are a significant part of everyday clinical trials, and their impact on sample size can be substantial.

Secondly, because clinical trials deal with the treatment of humans, ethical issues (*see* **Ethics of Randomized Trials**) raise the importance of the sample size calculation. A sample size that is too small can lead to a failure to detect a treatment effect and consequently the abandonment of what may be a very promising treatment. This in turn represents the breach of an implicit contract with the study patients that the trial, as designed, is of sufficient size to detect a useful improvement in treatment. If it is not, then the patients may have needlessly donated their cooperation and needlessly been exposed to an experimental therapy whose **risks** and benefits are as yet not clearly known.

Finally, clinical trials tend to be costly. The Systolic Hypertension in the Elderly Program [1] trial was budgeted at 50 million dollars, and the Women's Health Initiative at about ten times that amount. With such large expenditures involved, one needs to balance carefully the extra cost of requiring a larger sample size with the danger of failing to detect a useful treatment difference. To repeat a very complex or large trial with another of adequate sample size will often be difficult to justify, even if the sponsor's objectives are still worth pursuing.

Clinical trials can be designed in many ways, but the setting most frequently encountered is the comparative trial, in which two or more treatments are compared. It will be assumed here that the primary objective is **hypothesis testing**, and initially, the discussion will be restricted to the two-group case.

Sample size formulas frequently take the form

$$N_{\text{tot}} = \frac{c^2(z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_{\text{A}})^2}{\delta^2}, \qquad (1)$$

where N_{tot} is the total sample size, c is a constant, $z_{1-\alpha}$ is the **standard normal deviate** whose probability of being exceeded is α, σ_0 and σ_{A} are the **standard deviations** under the **null** and **alternative hypotheses**, and δ is the treatment effect. The variables on the right-hand side of this formula are parameters whose values depend on the design of the trial. Values for all parameters must be obtained to determine the sample size. In most cases, however, one cannot be confident of knowing all of these values with precision. Arriving at a chosen sample size often involves calculating sample size for a range of values of the uncertain parameters and choosing a size that seems feasible and reasonably close to meeting the scientific requirements of the study. Sample size calculations usually involve other considerations, such as non **compliance** and **missing data**, which directly impinge on the parameters in (1).

Choice of Outcome Measure

Primary and Secondary Outcomes

Often in clinical trials there are many variables that can be used to assess the success of the treatment. These are called outcome or endpoint variables (*see* **Outcome Measures in Clinical Trials**). Under the **null hypothesis** of no treatment effect, the formal testing of many outcome variables (*see* **Multiplicity in Clinical Trials**) increases the probability of falsely discovering a significant effect for at least one of them. To maintain the desired probability of a type I error in the presence of many outcomes, adjustment for **multiple comparisons** is necessary. One consequence of such adjustment is that the **power** is reduced for demonstrating that a specific one of those

outcomes is significantly altered by the treatment. In order to strike a balance between the desirability of assessing the effect of treatment on many variables, while maintaining adequate power for specific variables, outcomes in clinical trials are often classified as primary or secondary. Usually the primary endpoint is limited to one outcome, although there are exceptions. The efficacy of the treatment is then formally based on statistical significance only with respect to the primary outcome. If more than one primary outcome is chosen, then a multiple comparisons adjustment is usually applied; this is reflected in the sample size calculations through the significance levels assigned to the individual primary outcomes. The sample size is then chosen so that there is adequate power for each primary outcome. Note that multiple comparisons are appropriate only if one will claim success when any of the primary outcomes is significant. If significance is required for all of the primary outcomes, then the type I error becomes much smaller, rather than larger, than the nominal significance level. The usual practice in this case, however, is to use the nominal significance level.

Repeated Measurements

Now assume that a single primary outcome has been chosen, and attention is at first restricted to continuous measurements. For purposes of illustration, consider a trial of hypertensive patients in which blood pressure has been identified as the primary outcome. There are many possible times at which this measurement can be taken. Before **randomization** it can be used to identify patients who are eligible for the trial, i.e. hypertensive patients. In a long trial, blood pressures may be measured frequently to assure that the blood pressure of hypertensive patients is adequately controlled. It also could be measured frequently to study the time course of response. Furthermore, since the variability of the measurement is a crucial factor for sample size, one can use/repeated measurements (*see* **Longitudinal Data Analysis, Overview**) to reduce the variability. For example, one can average all of the postrandomization measurements for an individual. For blood pressure, this is rarely done, because the initial response may wane, owing to biologic changes or diminishing compliance with the treatment regimen. Alternatively, the **variance** can still be reduced by taking multiple measurements near the end of a specified period of interest. In deciding whether to take multiple measurements, many factors must be considered. It is well known that the variability of blood pressure measurements has between-patient and within-patient variability, and within a patient, there are also within-visit and between-visit components of variability. While it is less expensive to measure a patient repeatedly within a single visit, repeating the within-visit measurement beyond two or three times is generally not done because at this point the between-visit variability becomes the dominant source of variation. The cost of increasing the number of visits has to be weighed against the cost of enrolling more patients. Additionally, increasing the number of visits per patient may result in increasing rates of failure to attend some of these visits.

Change from Baseline

Should one use change from baseline or just the follow-up assessment? The choice here hinges on the **correlation** between baseline and follow-up: if the correlation is less than 0.5, then only the follow-up measurement should be used, otherwise the difference is preferred. This correlation is a function of the length of time between baseline and follow-up. The same considerations regarding the **variance components** of the final measurement also apply to the baseline measurement (*see* **Baseline Adjustment in Longitudinal Studies**).

Survival

If the outcome is an "event" that may happen over time, then the trial is frequently called a survival trial (*see* **Survival Analysis, Overview**). Although survival trials bring to mind outcomes such as death or heart attack, for a drug designed to relieve pain the event could be meaningful pain relief. Patients who do not have an "event" during a specified period are said to have **censored** observations. With a survival-type event, an important consideration is whether one is interested in comparing the entire survival curve (i.e. the times to an event) or only the proportions surviving at a specified time. In sepsis trials, patients have virulent infections with high mortality rates within 30 days (*see* **Clinical Trials of Antibacterial Agents**). Suppose, at the end of 30 days, the drug is unable to keep alive more patients than the placebo. While a comparison of survival curves may detect a difference in time to death, this may amount to a

few extra days of life for unwell patients who still succumb within the 30 days. Thus, it is argued, only the proportions surviving at 30 days are important.

When there is censoring, comparing proportions becomes more difficult. In a trial such as the sepsis trial, where each patient is observed for exactly 30 days, and mortality from any cause is the primary outcome, censoring is not expected to be a problem, since the outcome information can presumably be determined for all patients. However, in a trial where the outcome is fatal or nonfatal heart attack, death from a noncardiac disease would censor the data. In long-term trials, where patient entry is staggered over a recruitment period, and each patient is followed until the trial is closed out, censoring is very common. In these situations, each patient has a different length of follow-up. It is difficult to assign meaning to the term "proportion surviving" without specifying a fixed period of observation common to all patients. One can estimate the probability of surviving when patients have differential lengths of follow-up using the **Kaplan–Meier** method. Kaplan–Meier estimates of the probability of surviving to the end of such a trial are usually very unreliable because of heavy censoring towards the end of the trial. Often in these long-term trials, survival curves are compared and the **logrank test**, which compares the entire survival experience, is usually preferred. Sample size methodology for the logrank statistic has been developed by Schoenfeld [12], Freedman [4], and Lakatos [7]. The Kaplan–Meier method and logrank statistic are designed only for noninformative censoring, and the sample size methods just referenced assume noninformative censoring as well (*see* **Sample Size Determination in Survival Analysis**).

Selecting the Parameters

Frequently, identifying a method or formula which is reasonable for determining the appropriate sample size is the easy part of the problem. With every sample size formula, the statistician must choose values for the parameters. Unfortunately, the values of most of the parameters are only poorly known before the trial. In specific applications, the values of some of the parameters may be fairly well agreed upon. Some statisticians rely on the clinicians to provide values for the parameters. However, the statistician is best served by judging his or her own estimates for all parameters, and negotiating these judgments with the clinicians. It should be understood that the ability to negotiate successfully for adequate sample size may be greatly diminished if the statistician does not have a firm position on the clinical background and the choice of parameters.

Type I and Type II Error Rates (Significance and Power)

Type I Error (Corresponding to $z_{1-\alpha}$)

The **null hypothesis**, H_0, is that the experimental therapy has no different effect on the outcome compared with the **control**. Associated with every test is the type I error rate, or significance level, which is the probability of falsely rejecting the null hypothesis. When testing an experimental treatment, it is usually assumed that one has introduced this new treatment because it is thought to be superior to control, and that the trial is being carried out to "prove" this. There is rarely any interest in proving that it is worse; often sponsors will abandon a drug that is not much better than the control (although see the section "Equivalence Trials" below). According to most authors, the standard by which a new treatment is judged a success is whether the equivalent of the **standard normal deviate** value of the primary outcome statistic exceeds 1.96. The implied level of significance corresponding to 1.96 is generally felt to be a reasonable standard against which all trials should be judged. The 1.96 can correspond to a one-sided hypothesis with significance level 0.025 or a two-sided hypothesis of significance level 0.05. If one is truly interested in also knowing whether the treatment is worse than control (a recent trial of digitalis is an example), then 1.96 can also be used as the standard for testing this. A minority opinion is that because the researcher is not interested in testing whether the treatment is worse than control, a reduced standard, such as 1.645, is appropriate for judging whether the experimental therapy is better. However, most biostatisticians consider that the standards by which an experimental therapy is judged better than control should not depend on whether one was interested in proving that it is worse than control.

Type II Error Rate (Corresponding to $z_{1-\beta}$)

The choice of the **alternative hypothesis**, H_a, is an area of frequent contention (see below). The type II

error rate is the probability of failing to reject the null hypothesis, given that the alternative hypothesis is true. The power is one minus the type II error rate. In other words, if the experimental treatment is truly better than control by the amount postulated in the alternative hypothesis, the power is the probability of showing a significant difference. When trials are designed, a good deal of attention may be placed on whether the power is adequate, with 90% power the generally accepted standard for major Phase III trials. However, when a trial is analyzed, there is often little or no attention paid to the power, with the significance level dominating the spotlight. If the trial fails to reach the conventional criterion for statistical significance, then it is often concluded that the experimental treatment was no better than control. Such a conclusion may not be true – the lack of significance may simply be a matter of inadequate power. In the analysis of the trial, lack of power is properly expressed in a wide **confidence interval** for the treatment difference.

A Balance Between Type I and Type II Errors

The error of falsely concluding benefit of an ineffective therapy (type I error) has traditionally been thought of as the more critical of the two types of error. If ineffective therapies were given the stamp of approval, then physicians would end up prescribing ineffective medications, and patients would spend large amounts of money on worthless treatments. More importantly, patients might be denied superior therapies because physicians believed an approved inferior was effective. Furthermore, research in a disease might be impeded because a beneficial therapy appeared to exist.

However, if trials are designed with inadequate power, then there are also important consequences. Some of these were discussed at the beginning of the article. Inadequate power can result in failure to detect a treatment that is truly effective. If the therapy is subsequently abandoned, then patients are denied therapy that could provide relief or even save lives. Alternatively, if there is still hope and conviction that the treatment is sufficiently promising, then trials will have to be rerun, this time with adequate power; this process leads to loss of time and money.

On balance, primary importance is still given to the type I error. Additionally, some trials are felt to be of sufficient importance to warrant very large sample sizes and consequently high power. Even then, the type I error rate is generally chosen to be at least as small as the type II.

The Treatment Effect (δ)

There are a number of different criteria that may be used to arrive at the treatment effect for the calculation, i.e. the alternative hypothesis H_a. Two criteria that are very important are (1) the smallest clinically meaningful difference (SCMD), and (2) the anticipated treatment effect (ATE).

As sample sizes increase, the size of an estimated treatment effect that can be detected as statistically significant decreases towards 0. However, very small treatment effects may not be meaningful clinically, and trials need not be designed to detect such small differences. But if the sample size of a trial is based on a rather large treatment effect which is considerably larger than some meaningful difference then, at the final analysis, statistical significance may very well not be achieved because the treatment effect is smaller than the large assumed treatment effect, but still clinically meaningful. Had the original trial been powered to detect this smaller effect, statistical significance of this clinically meaningful difference would have been achieved. Thus, it is important to consider what is the SCMD, even if its exact value is often elusive (see below).

The decision as to what is a clinically meaningful difference is one that requires the input of the statistician, the clinician and the sponsor. Consider first, mortality. While "clinically meaningful" seems to imply a physician's opinion, one could argue that patients are often in the best position to judge whether a decrease in mortality is meaningful in a specific situation. Some people feel that any decrease in mortality is meaningful. Others might consider a minimum of 10% decrease in the probability of mortality necessary to offset the toxic side effects of a given chemotherapy regimen. A sponsor may consider the **prevalence** of a disease to be so low that if the drug produces only a 10% reduction in mortality, then it would not be worth the cost of development. With so many diverse considerations, it should not be surprising that agreement on an SCMD in mortality is often difficult.

Now suppose the primary endpoint of the trial is diastolic blood pressure. For an individual patient,

a physician might feel that a 10 mmHg decrease is the smallest that is clinically meaningful. The desired decrease might be larger for patients with higher initial blood pressures. In many trials, however, the targeted treatment effect compared with placebo is chosen to be in the range of 3–5 mmHg reduction. Why is there this discrepancy? One reason may be that the anticipated treatment effect (ATE) is much smaller than 10 mmHg. This arises because the observed reduction will be the average of a population of individual changes, with some of the distribution of changes being well below 10 mmHg. One could consider using a drug that achieved a 10 mmHg or larger reduction in only a portion of the patients. Physicians routinely monitor the blood pressure of hypertensive patients, and if a patient's blood pressure remains excessive with the current prescribed medication, the physician will usually change the prescription.

If the ATE is considerably larger than the SCMD, then it is unrealistic to expect the sponsor to support the sample size needed to detect an effect much smaller than is likely to occur. However, it has been common to conduct trials that attempt to detect treatment effects that are far larger than could realistically be anticipated. In summary, the chosen treatment effect should reflect both of these considerations: it must be achievable and it must be meaningful.

Equivalence Trials

Sometimes treatments are introduced which are expected to have no better efficacy, or minimally poorer efficacy, than an already accepted treatment. Some reasons for introducing such a therapy may be because this new treatment may be less toxic, less expensive, or have fewer side effects (*see* **Equivalence Trials**). One of the key differences between testing for superiority and equivalence is that the latter requires the designers to specify the largest acceptable treatment difference as part of the null hypothesis. This factor is critical, because this declared difference plays a large role in the ***P* value** obtained at the end of the trial, and whether or not the nominal significance level is attained. A central issue for equivalence testing is agreeing upon how much one is willing to accept reduced efficacy in exchange for other benefits such as reduced toxicity. If a new therapy offers very visibly reduced side effects as compared with a standard highly toxic chemotherapy, a patient or his physician may be willing to accept up to perhaps a 5% or 10% increase in mortality. With an antihypertensive medication, where the side effects are much less severe, such an increase in mortality may appear less acceptable. If, however, the fact that the patient must take the antihypertensive medication with these side effects for the rest of his life is factored into the picture, then a mortality increase may appear less objectionable. A sample size formula for this situation is

$$N_{\text{tot}} = \frac{c^2(z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_{\text{A}})^2}{(\delta_{\text{a}} - \delta_0)^2}$$

Here, δ_{a} is the difference that one is willing to accept, and δ_0 is the expected or true difference. For equivalence, we usually set $\delta_0 = 0$. Confidence intervals are often the preferred approach for analyzing the results of equivalence trials. The above formula is valid for confidence intervals.

Sample Size Adjustment

There are many factors which influence the sample size which are not considered in the sample size formulas above. These factors should be accounted for in the method of calculation. A few common factors are now discussed.

A Simple Adjustment for Noncompliance

One of the factors that distinguishes clinical trials from other experiments is the difficulty in getting patients to adhere to their assigned treatment regimens. This is particularly true in the longer **prevention trials**, since the motivation of an acute condition is not present. The **intention to treat** paradigm dictates that patients be analyzed with respect to their initial treatment assignment. The usual philosophy in sample size determination is that a treatment difference that is both meaningful and likely to occur is identified. Then, recognizing that many patients may take less than their assigned treatment regimen, the statistician models the impact of noncompliance on the treatment effect and in turn on the probability of rejecting the null hypothesis. Many models have been proposed for accounting for noncompliance in sample size calculation [5, 6, 14]. A simple approach is discussed here that can be applied regardless of the type of outcome

variable. A more complex procedure is discussed later under survival analysis. In some trials, most of the noncompliance is likely to occur near the time of randomization. If there are difficult side effects, then these are likely to occur soon after initiation of therapy, and most patients will not endure these for long periods. Furthermore, those patients who enroll but have little interest in the therapy will stop taking medications soon after randomization. Perhaps the simplest model for noncompliance is for a new treatment vs. placebo trial, in which a proportion of the patients on the new treatment discontinue their medication immediately, while the remainder adhere. In this case, a proportion will receive no benefit of therapy, while the remainder receive full benefit. This model is considered conservative. One approach to account for this is to calculate what is referred to as the "observed treatment effect". If δ is the treatment effect under full compliance, then the observed treatment effect is $d = (1 - p_m)\delta$, where p_m is the proportion of noncompliers. A sample size adjustment factor based on this observed treatment effect d would be $n_{adj} = n/(1 - p_m)^2$, since

$$\frac{n_{adj}}{n} = \frac{4(z_\alpha + z_\beta)^2\sigma^2}{(1 - p_m)^2\delta^2} \Big/ \frac{4(z_\alpha + z_\beta)^2\sigma^2}{\delta^2}$$

Table 1 presents some inflation factors using this model and various proportions of noncompliance.

A Simple Adjustment for Nondifferential Loss to Follow-up

The term "loss to follow-up" refers to a type of censoring applied to any patient whose status with respect to the final endpoint cannot be determined at the time of the analysis. Thus, if the endpoint is stroke, and the patient dies of cancer prior to having a stroke, then this is considered loss to follow-up. If the reason for censoring is not related to the endpoint, then the censoring is referred to as noninformative or nondifferential censoring. If the probability of nondifferential loss to follow-up is l, then a simple adjustment is $n_{adj} = n/(1 - l)$. This is equivalent to assuming that all patients who are lost will be lost at the time of randomization; generally this is conservative.

Table 1 Inflation factors for a simple, conservative noncompliance adjustment

Proportion noncomplying	0.05	0.10	0.20	0.30	0.50
Inflation factor $= 1/(1 - p_m)^2$	1.11	1.23	1.56	2.04	4.00

Adjusting Survival Analyses for Noncompliance and Other Factors

Many models have been proposed for analyzing survival data. The desirability of a comparison of proportions vs. a comparison of survival curves was discussed in the section "Choice of Outcome Measure" earlier in this article. In those situations for which survival curves should be compared, the curves may have a variety of shapes. A common pattern is for events to happen soon after randomization, and then taper off. The pattern is dramatic in congestive heart failure (e.g. Study of Left Ventricular Dysfunction [13] and CONSENSUS [2]), and in angioplasty. In these nonconstant hazard situations, **proportional hazard** models should be used in preference to **exponential** models, since the latter assume that the **hazard rate** will be constant throughout the trial. Additionally, the treatment effect may vary during the trial. In angioplasty, Reopro, which is administered intravenously, is usually given for less than a day. The effects on mortality appear to continue for perhaps 6 months. However, the largest benefit is around the time of administration, with the benefit tapering rapidly over the first 30 days. A similar tapering of benefit occurs on a group basis when there is noncompliance. In these cases, nonproportional hazards models should be used in preference to proportional hazard models. Lakatos [7] provided a general method for calculating sample size for the logrank statistic which allows a great deal of flexibility in simultaneously specifying nonuniform accrual patterns, nonconstant and nonproportional hazard functions, lags in treatment effects, loss to follow-up, noncompliance, and dropout. The Lakatos method employs nonstationary **Markov** models; a simple computer program is needed for implementation. Exponential models are not appropriate if noncompliance, drop-in or treatment lag are to be modeled, and the nonstationarity of the Markov model is essential.

Determining Duration and Treatment Effect for Survival Trials

Increasing the duration of a trial increases the overall failure rate and, in turn, can reduce the required

sample size, especially if failure is a rare event. The relationship between required sample size and duration may be complex in survival trials, particularly if there is noncompliance or nonconstant hazards. Although a parameter for duration does not appear explicitly in the sample size formula, the duration which provides a prespecified power can be determined by fixing all other parameters (including sample size). A simple iterative procedure is then used, in which power is calculated for a series of fixed trial durations which are successively adjusted to bring the power as close as desired to the target power.

Similarly, for survival trials, the treatment effect may be a complex function of other factors. Noncompliance, for example, can cause a diminution of the treatment effect over time. As with duration, an iterative procedure can be used.

Adjusting for Group Sequential Designs

Methods for calculating sample size when group sequential procedures will be used (*see* **Sequential Analysis**) in the presence of trial complexities such as noncompliance, drop-in, loss-to-follow-up and the like have been developed by Lakatos [8]. Here a few issues are discussed. Suppose there is a boundary z_1, $z_2, \ldots, z_k$, and the tests are successively performed at predetermined fractions of the total "information" (for continuous endpoints the information fraction is roughly the proportion of patients in the current analysis, and for survival trials, the information fraction is roughly the proportion of events (see Lan & Zucker [10] for a detailed account). The alpha level is the cumulative probability under successive testing, and under the null hypothesis, of the calculated z value exceeding the boundary z values. In other words, it is the accumulated probability of rejecting the null hypothesis after the sequence of tests has been performed *assuming the null*. Similarly, the power is the accumulated probability of rejecting the null hypothesis after the sequence of tests has been performed *assuming the alternative*. What is important here is that to calculate the power, one generally needs to integrate, numerically, under the alternative hypothesis. It is also important to note that a lower bound on the power can be calculated without numerical integration. This is because the probability of rejecting the null at the final analysis must be less than or equal to the combined probability of rejecting it over all analyses. Thus, if the final boundary value for a group sequential procedure is $z_k = 2.10$, then an upper bound on the sample size is $n_{\text{adj}} = n[(1.28 + 2.10)/(1.28 + 1.96)]^2 = 1.088n$; here the 1.28 corresponds to 90% power, and the 1.96 to a two-sided 0.05 level test. Since the very popular O'Brien–Fleming final boundary [11] value is usually less than 2.10 (*see* **Data and Safety Monitoring**), the sample size inflation factor is usually less than 8.8%. In contrast, the sample size adjustment factor when noncompliance, drop-in, lag in treatment effect, and loss to follow-up are expected may be 100% or more (cf. Lakatos & Lan [9]). Therefore, when using the O'Brien–Fleming procedure, if the exact sample size incorporating group sequential and all other expected effects would be difficult to calculate, it is generally better to use a sophisticated procedure for calculating the effects of noncompliance and the like, and a *post hoc* inflation for the group sequential testing, than to use a sophisticated group sequential sample size method and a *post hoc* inflation for noncompliance.

Unequal Allocation between Treatment Groups

While most trials allocate patients to the treatment groups in equal proportions (e.g. 50% to group A, 50% to group B), this rule is not universally applied. If there are two or more active groups and the primary objective is to compare each active group with control, then optimal power is achieved with unequal allocation. This occurs because a disproportionately large fraction allocated to the control group will benefit all tests. Formulas for optimal allocation can be found in [3]. Frequently, in drug trials there may be a disproportionately high allocation to the active groups, simply to obtain more safety experience with a new investigational drug.

Sample Size Determination in Survival Analysis

Many survival studies are designed to compare two alternative treatments, but information on the values of certain **explanatory variables** may also be available. It has been shown by Schoenfeld [6] that the expression for calculating the required number of deaths is the same whether or not account is taken of supplementary explanatory variables. For this reason, an efficacy study to compare the survival times of individuals who receive a new treatment with those who receive a standard will be the focus for this article.

Suppose that there are two groups of individuals, and that the standard treatment is allocated to the individuals in Group I, while the new treatment is allocated to those in Group II. Assuming a **proportional hazards model** for the survival times, the hazard of death at time t for an individual on the new treatment, $h_{\mathrm{N}}(t)$, can be written as

$$h_{\mathrm{N}}(t) = \psi h_{\mathrm{S}}(t),$$

where $h_{\mathrm{S}}(t)$ is the **hazard** function at t for an individual on the standard treatment and ψ is the unknown **hazard ratio**. We will also define $\theta = \log \psi$ to be the log-hazard ratio. If θ is zero, then there is no treatment difference. On the other hand, negative values of θ indicate that survival is longer under the new treatment, while positive values of θ indicate that individuals survive longer on the standard treatment.

In a survival study, the occurrence of **censoring** means that it is not usually possible to measure the actual survival times of all individuals in the study. However, it is the number of actual deaths that is important in the analysis, rather than the total number of subjects. Accordingly, the first step in determining the required number of individuals in a study is to calculate the number of deaths that must be observed.

Calculating the Required Number of Deaths

To determine the sample size requirement for a study (*see* **Sample Size Determination for Clinical Trials**), we calculate the number of individuals needed for there to be a certain chance of declaring θ to be significantly different from zero when the true, but unknown, log-hazard ratio is θ_{R}. Here, θ_{R} is the *reference value* of θ. It will be a reflection of the magnitude of the treatment difference that it is important to detect, using the test of significance (*see* **Hypothesis Testing**). In practice, θ_{R} might be chosen on the basis of the increase in the **median survival time** that is to be detected, or in terms of the probability of survival beyond some specific time.

The required number of deaths is taken to be such that there is a probability of $1 - \beta$ of declaring the observed log-hazard ratio to be significantly different from zero, using a hypothesis test with a specified significance level of α, when in fact $\theta = \theta_{\mathrm{R}}$ (*see* **Level of a Test**). The quantity $1 - \beta$ is the probability of rejecting the null hypothesis when it is in fact false, and is the **power** of the test. Both α and β are taken to be small, and the values chosen will depend on the circumstances of the study; typical values are $\alpha = 0.05$ and $\beta = 0.1$.

The required total number of deaths, d, can be found using

$$d = \frac{4(z_{\alpha/2} + z_{\beta})^2}{\theta_{\mathrm{R}}^2}, \qquad (1)$$

where $z_{\alpha/2}$ and z_{β} are the upper $\alpha/2$- and upper β-points, respectively, of the standard normal distribution.

This result appears in many papers, although the assumptions on which the result is based can be different. For example, Bernstein & Lagakos [1] obtain (1) on the assumption that the survival times in each of the two groups have **exponential distributions**. However, Schoenfeld [5] obtains the same result when the **logrank test** is used as a basis for comparing the treatments, without making the assumption of exponentiality; this derivation is included in [2].

A variant on the formula for the required number of deaths is given by Freedman [3], who has $[(1 + \mathrm{e}^{\theta_{\mathrm{R}}})/(1 - \mathrm{e}^{\theta_{\mathrm{R}}})]^2$, in place of $4/\theta_{\mathrm{R}}^2$. However, when θ_{R} is small,

$$\left(\frac{1 + \mathrm{e}^{\theta_{\mathrm{R}}}}{1 - \mathrm{e}^{\theta_{\mathrm{R}}}}\right)^2 \approx \left(\frac{2 + \theta_{\mathrm{R}}}{\theta_{\mathrm{R}} + \theta_{\mathrm{R}}^2/2}\right)^2 = \frac{4}{\theta_{\mathrm{R}}^2},$$

and so the two expressions will tend to give similar results. Freedman's expression is the basis for the extensive tables of sample size requirements in Machin & Campbell [4].

The derivation of the result in (1) assumes that the same number of individuals is to be assigned to each treatment group. If this is not the case, a modification has to be made. In particular, if the proportions of individuals to be allocated to Groups I and II are π_1 and π_2, respectively, then the required total number of deaths becomes

$$d = \frac{(z_{\alpha/2} + z_\beta)^2}{\pi_1 \pi_2 \theta_R^2}.$$

Notice that an imbalance in the number of individuals in the two treatment groups leads to an increase in the total number of deaths required. The derivation also includes an approximation which means that the calculated number of deaths could be an underestimate. Some judicious rounding up of the calculated value is therefore recommended to compensate for this.

Example: Comparison of Two Treatments

A clinical trial is to be designed to compare a new form of chemotherapy with a standard for the treatment of patients with ovarian carcinoma. The time from randomization to death is the response variable of interest.

As a first step, information is obtained on the survival times, in months, of patients who have received the standard treatment. The **Kaplan–Meier** estimate of the survivor function derived from such data is shown as the step function drawn with a solid line in Figure 1.

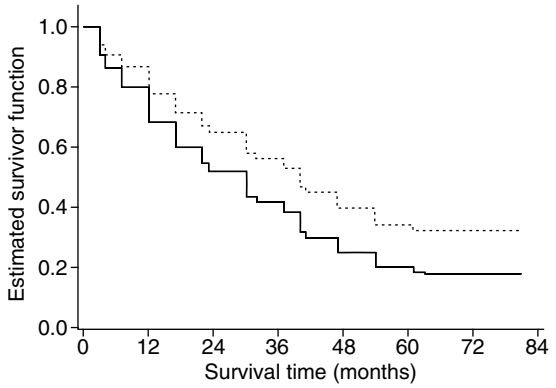

Figure 1 Estimated survivor functions for individuals on the standard treatment (—) and the new treatment (- - -)

From this estimate of the survivor function, the median survival time is 30 months, and the survival rates at 1, 3, and 5 years can be taken to be given by $S(12) = 0.68$, $S(36) = 0.42$, and $S(60) = 0.20$.

The new treatment is expected to increase the survival rate at 4 years from 0.25, the value under the standard treatment, to 0.40. This information can be used to calculate a value for θ_R. To do this, we use the result that, if the hazard functions are assumed to be proportional, then the survivor function for an individual on the new treatment at time t is

$$S_N(t) = [S_S(t)]^\psi, \tag{2}$$

where $S_S(t)$ is the survivor function for an individual on the standard treatment at t and ψ is the hazard ratio. Therefore,

$$\psi = \frac{\log S_N(t)}{\log S_S(t)},$$

and so the value of ψ corresponding to an increase in $S(t)$ from 0.25 to 0.40 is

$$\psi_R = \frac{\log(0.40)}{\log(0.25)} = 0.66.$$

With this information, the survivor function for an individual on the new treatment can be estimated by $[S_S(t)]^{\psi_R}$. In particular, $S_N(12) = 0.76$, $S_N(36) = 0.56$, and $S_N(60) = 0.35$. The estimated survivor function for the new treatment is shown as a dotted line in Figure 1.

The median survival time under the new treatment can be found from this estimate of the survivor function. Using Figure 1, the median survival time under the new treatment is estimated to be about 40 months.

To calculate the number of deaths that would be required in a study to compare the two treatments, we take $\alpha = 0.05$ and $\beta = 0.10$. With these values of α and β, $z_{\alpha/2} = 1.96$ and $z_\beta = 1.28$, and taking $\theta_R = \log \psi_R = \log 0.66 = -0.416$, the number of deaths required to have a 90% chance of detecting a hazard ratio of 0.66 to be significant at the 5% level is then given by

$$d = \frac{4(1.96 + 1.28)^2}{0.416^2} = 243.$$

Allowing for possible underestimation, this can be rounded up to 250 deaths in total.

Calculations such as those used in this example are only going to be of direct use when a study is to be continued until all patients entered into the study have died. In most trials, the analysis will take place before everyone has experienced the endpoint, so that some observations will be censored. This has to be taken into account when designing the study, and so we now examine how the required number of individuals can be obtained.

Calculating the Required Number of Individuals

To calculate the actual number of individuals that are required in a survival study, we need to consider the probability of death over the duration of a study. Typically, individuals are recruited over an *accrual period* of length a. After recruitment is complete, there is an additional *follow-up period* of length f. The total duration of a study will therefore be of length $a + f$. Notice that, if f is small, or even zero, then there will need to be correspondingly more individuals recruited in order to achieve a specific number of deaths.

Once the probability of an individual dying in the study has been evaluated, the required total number of individuals will be found from

$$n = \frac{d}{\Pr(\text{death})}, \tag{3}$$

where d is the required number of deaths found from (1). The probability of death can be taken as

$$\Pr(\text{death}) = 1 - \frac{1}{6}[\overline{S}(f) + 4\overline{S}(0.5a + f) + \overline{S}(a + f)], \tag{4}$$

where

$$\overline{S}(t) = \frac{S_S(t) + S_N(t)}{2}, \tag{5}$$

and $S_S(t)$ and $S_N(t)$ are the estimated values of the survivor functions for individuals on the standard and new treatments, respectively, at time t. This result is similar to that given by Schoenfeld [6], and full details of the derivation are included in Collett [2].

A simpler result is based on the assumption that survival times are exponentially distributed. If the mean survival times under the standard and new treatments are λ_S^{-1} and λ_N^{-1} respectively, then the average survivor function, $\overline{S}(t)$, is given by

$$\overline{S}(t) = \frac{e^{-\lambda_S t} + e^{-\lambda_N t}}{2}. \tag{6}$$

Estimates of λ_S and λ_N can be obtained from the corresponding median survival times for each treatment group, using the result that the median, t_m, of an exponential distribution with mean λ^{-1} is such that $\lambda = (\log 2)/t_m$.

Although (6) is based on more restrictive assumptions about the distribution of survival times than (5), it will often lead to quite similar results. Schoenfeld & Richter [7] give nomograms that enable the required number of individuals to be determined on the assumption of exponential survival times.

The tables in [4] follow [3] in assuming that each individual in a study is followed up for some time τ after randomization, and that analysis takes place at time τ after the last person has been recruited. The proportion of individuals expected to survive in each group is then $S_S(\tau)$ and $S_N(\tau)$, and so the probability of death is $1 - [S_S(\tau) + S_N(\tau)]/2$. In many situations, individuals are followed up until the end of the study, rather than for a fixed time. In this case, the value of τ could rather be taken to be the average length of follow-up, given by $\tau_0 = f + (a/z)$. However, this approach does not take account of patient follow-up extending beyond time τ_0, and so the required number of individuals will tend to be overestimated.

The result in (3) shows how the required number of individuals can be calculated for a trial with an accrual period of a and a follow-up period of f. Of course, the duration of the accrual period and follow-up period will depend on the recruitment rate. So suppose that the recruitment rate is expected to be m individuals per month and that d deaths are required. The number recruited in an accrual period of length a is then ma, and so the expected number of deaths in the study is

$$ma \times \Pr(\text{death}).$$

Values of a and f which make this value close to the number of deaths required can then be found numerically – for example, by trying out different values of a and f. This **algorithm** could be computerized and an optimization method used to find the value of a

that makes

$$d - [ma \times \Pr(\text{death})] \tag{7}$$

close to zero for a range of values of f. Alternatively, the value of f that yields the result in (7) for a range of values of a can be found. A two-way table giving the required number of individuals for different combinations of values of a and f will be particularly useful in planning a study. This process is facilitated by software packages for calculating sample size requirements in a survival study, such as nQuery Advisor.

Example: Comparison of Two Treatments (Continued)

Previously, it was shown that 250 deaths needed to be observed for the study on ovarian cancer to have sufficient power to detect a hazard ratio of 0.66 as significant. Suppose that individuals are to be recruited to the study over an 18-month accrual period and that there is to be a subsequent follow-up period of 24 months. From (4), the probability of death in the 42 months of the study will then be given by

$$\Pr(\text{death}) = 1 - \frac{1}{6}[\overline{S}(24) + 4\overline{S}(33) + \overline{S}(42)].$$

Now, using the estimated survivor functions shown in Figure 1,

$$\overline{S}(24) = \frac{S_S(24) + S_N(24)}{2} = \frac{0.52 + 0.64}{2} = 0.58,$$

$$\overline{S}(33) = \frac{S_S(33) + S_N(33)}{2} = \frac{0.42 + 0.56}{2} = 0.49,$$

$$\overline{S}(42) = \frac{S_S(42) + S_N(42)}{2} = \frac{0.30 + 0.44}{2} = 0.37,$$

and so the probability of death is

$$1 - \frac{1}{6}[0.58 + (4 \times 0.49) + 0.37] = 0.515.$$

From (3), the required number of individuals is

$$n = \frac{250}{0.515} = 486,$$

and so nearly 500 individuals will need to be recruited to the study over the accrual period of 18 months. This demands a recruitment rate of about 28 individuals per month.

If it is only expected that 15 individuals can be found each month, the accrual period will need to be extended to ensure that there is a sufficient number of individuals to give the required number of deaths. The number of individuals that could be recruited in a period of a months would be $15a$. Various values of a can then be tried in order to make this approximately equal to the value obtained from (3). For example, if we take $a = 30$ and continue with $f = 24$, then the probability of death during the study is

$$\Pr(\text{death}) = 1 - \frac{1}{6}[\overline{S}(24) + 4\overline{S}(39) + \overline{S}(54)].$$

From Figure 1, the survivor functions for individuals on each treatment at 24, 39, and 54 months can be estimated, and we find that $\overline{S}(24) = 0.58$, $\overline{S}(39) = 0.46$, and $\overline{S}(54) = 0.27$. The probability of death now turns out to be 0.552, and the required number of individuals to give 250 deaths is 453. This would be consistent with an estimated recruitment rate of 15 per month.

Now suppose that it is decided that the study will not have a follow-up period, so that the accrual period is equal to the duration of the study. If the accrual period is taken to be 30 months, so that $a = 30$ and $f = 0$, then the probability of death is given by

$$\Pr(\text{death}) = 1 - \frac{1}{6}[\overline{S}(0) + 4\overline{S}(15) + \overline{S}(30)].$$

Now, $\overline{S}(0) = 1.00$, $\overline{S}(15) = 0.73$, and $\overline{S}(30) = 0.51$, and the probability of death is 0.262. The required number of individuals is now $250/0.262 = 955$, and this would just about be met by a recruitment rate of 32 individuals per month. This shows that the absence of a follow-up period leads to an increase in the number of individuals that must be entered into the study.

Sample Size Determination

Sample size determination refers to the evaluation of the sample size desired or required for a study during the design stage, before data are collected. Such evaluations are based on a consideration of the operating characteristics of the statistical procedures to be employed in the ultimate statistical analysis of the study data. Invariably these operating characteristics depend in part on the sample size.

For example, a **cross-sectional** survey of the prevalence of diabetes (diagnosed or undiagnosed) among native Americans would require a sample size of 1421 to allow **estimation** of the **prevalence** to within a precision of ± 0.02 with 90% confidence, assuming a true prevalence no larger than 30%. Also, a randomized **clinical trial** of a new drug treatment vs. placebo for congestive heart failure would require 652 patients for a two-sided test at $\alpha = 0.05$ to provide 90% **power** to detect a 30% reduction in the risk of mortality after 1 year of follow-up, assumed to be no greater than 40% in the population (*see* **Alternative Hypothesis**; **Level of a Test**; **Null Hypothesis**).

In the first example, the sample size was determined based on the desired *precision* of the **confidence interval** estimate of the prevalence (probability) of the disease on sampling from a large population. In the second example, the sample size determination was based on the desired *power* of the test for the difference between two proportions (probabilities).

In general, the required sample size for any study can be based on the operating characteristics of the statistical procedures to be applied in the analysis of the data. For simple statistical estimates and tests, these relationships can be defined explicitly, for example by the derivation of the expression for the power function of a particular statistical test. In more complex analyses, such as **regression** models, these characteristics can be assessed indirectly through **simulation**, assuming an appropriate population model under which the sampling in the actual study is expected to be performed.

In all cases, the adequacy of the sample size determined depends on the accuracy of the initial specifications of the assumed parameters in the population. For example, if the true prevalence of diabetes in the target population is closer to 50%, then a sample size of 1421 will provide 87% confidence for a precision of ± 0.02. For the purposes of planning a study, therefore, it is always advisable that one consider a range of population parameters over which the operating characteristics are assessed for specific sample sizes.

Since the application of procedures for sample size evaluation is universal to all realms of statistical methods, the literature on this topic is indeed vast. McHugh & Le [11] provide a review of sample size determination for commonly used statistical procedures in biostatistical practice from the perspective of the precision of an estimator. Lachin [7] and Donner [3], among others, likewise provide a review of sample size determination for commonly used statistical tests from the perspective of the power of the test. General texts on the topic include [10, 1, 2, 15], and [12], among others. Many reference texts on general statistical methods, epidemiologic methods, and clinical trials include descriptions of sample size evaluation, or of the operating characteristics of an estimator or test based on sample size. The following presents an introduction to the basic concepts for statistical procedures which are commonly used in biostatistical practice.

Estimation Precision

Consider that we wish to estimate a parameter θ in a large (infinite) population based on a simple **random sample**. Assume that we plan to employ an estimator $\hat{\theta}$ which is normally distributed, at least asymptotically, as $\hat{\theta} \sim \mathrm{N}(\theta, \Sigma^2)$ where Σ^2 is some function of sample size N, such as $\Sigma^2 = \sigma^2/N$, where σ^2 is a **variance component**. Then the following apply:

1. The $1 - \alpha$ confidence interval (CI) for θ is of the form $\hat{\theta} \pm e_\alpha$, where

$$e_\alpha = z_{1-\alpha/2}\Sigma \tag{1}$$

   is the precision of the estimate at level $1 - \alpha$ and $z_{1-\alpha/2}$ is the upper two-sided **standard normal deviate** at level $1 - \alpha/2$. Since Σ is a function of the sample size N, then so also is the precision of the estimate e_α.

2. For a confidence interval $\hat{\theta} \pm e$ with a given degree of precision e, the corresponding level of confidence $1 - \alpha$ is provided by the standardized deviate $z_{1-\alpha/2} = e/\Sigma = \sqrt{N}e/\sigma$. This allows one to evaluate the relationship between the level of confidence and the degree of precision of the estimate for different sample sizes.
3. Solving for N, the sample size required to provide an interval estimate with precision $\pm e$ at confidence level $1 - \alpha$ for a given variance component σ is given by

$$N = \left(\frac{z_{1-\alpha/2}\sigma}{e}\right)^2. \tag{2}$$

For example, the simple proportion with a characteristic of interest, say p, from a sample of N observations is asymptotically distributed as $P \sim \mathrm{N}[\pi, \pi(1-\pi)/N]$, where π is the probability of the characteristic in the population and the **large-sample** variance of p is $\Sigma^2 = \pi(1-\pi)/N$ with $\sigma^2 = \pi(1-\pi)$ (*see* **Binomial Distribution**). The sample size required to estimate a probability assumed to be less than $\pi = 0.3$ (or greater than $\pi = 0.7$) with precision $e = 0.02$ at 90% confidence is provided as

$$N = \left[\frac{z_{1-\alpha/2}[\pi(1-\pi)]^{1/2}}{e}\right]^2$$
$$= \left[\frac{(1.645)[(0.3)(0.7)]^{1/2}}{0.02}\right]^2 = 1421.$$

(Throughout, all calculations of N are rounded up to the next whole integer.)

It may be judged that this sample size is too large. However, using the first relationship, one can determine that a 90% confidence interval with $N = 1000$ provides a degree of precision of $e = 1.645[(0.3)(0.7)]^{1/2}/\sqrt{1000} = 0.024$. Alternatively, using the second relationship, one could show that a sample size of $N = 1000$ provides 83% confidence of estimating π with a precision of ± 0.02, where the corresponding normal deviate is $1.38 = 0.02\sqrt{1000}/[(0.3)(0.7)]^{1/2}$.

Such computations, however, assume that the variance is known a priori, or in this case that the probability is known. These developments can be generalized to allow for sampling variation in the estimated variance, and thus in the precision of the estimate. This leads to expressions which determine the sample size needed to provide probability $1 - \beta$ that the realized $1 - \alpha$ confidence interval will have a precision of no greater than e (cf. [5]).

Clearly, such computations could be applied to a variety of estimation problems. Sample size determination based on the precision of an estimate will not be considered further, in part because the above expressions are analogous to those obtained from a consideration of the power of the corresponding test (see below). Those interested are referred to the article by McHugh & Le [11], or to texts on sampling.

Power

The power of a statistical test refers to the probability that a statistically significant test statistic will be obtained in a study under a specific hypothesis. In any statistical test, one sets out to assess the probability of the data under the null hypothesis H_0, commonly termed the ***P* value**. Usually "the data" are summarized in the form of an estimate of a parameter or a **sufficient statistic** for a parameter, and statistical significance is declared if the resulting P value is less than the a priori stated significance level.

Normal Theory Population Model

The simplest case is that of a statistic, say T, which is normally distributed, at least asymptotically, and for which the mean, μ, and variance, Σ^2, can be specified under the null hypothesis $\mathrm{H}_0 : \mu = \mu_0$ and under an alternative hypothesis $\mathrm{H}_1 : \mu = \mu_1 \neq \mu_0$. In many cases, the variance of the statistic will depend on the mean value, such that the variance under the **null hypothesis**, Σ_0^2, differs from that under the **alternative hypothesis**, Σ_1^2. Thus $T \sim \mathrm{N}(\mu_0, \Sigma_0^2)$ under H_0 and $T \sim \mathrm{N}(\mu_1, \Sigma_1^2)$ under H_1, with Σ_1^2 possibly $\neq \Sigma_0^2$.

The test of $\mathrm{H}_0 : \mu = \mu_0$ is based on the usual z-test $z = (\mathrm{T} - \mu_0/\Sigma_0$, where $z \sim \mathrm{N}(0, 1)$ under H_0. The null hypothesis is rejected against a one-sided alternative in the lower tail ($\mathrm{H}_1 : \mu_1 < \mu_0$) if the obtained z-test value has a corresponding P value $= \Phi(z) \leq \alpha$ at significance level α (one-sided). Likewise, H_0 is rejected against a one-sided alternative in the upper tail ($\mathrm{H}_1 : \mu_1 > \mu_0$) if the corresponding P value $= 1 - \Phi(z) < \alpha$; H_0 is rejected against a two-sided alternative when the two-sided P value $= 2[1 - \Phi(|z|)] \leq \alpha$. The choice of the alternative, one- vs. two-sided, is based on the nature of the questions to be addressed or the desired information, not

the expected direction of the result (*see* **Alternative Hypothesis**).

General Expressions for Power

In this setting, basic expressions for the power function of the statistical test are readily derived. Under $H_1 : T \sim N(\mu_1, \Sigma_1^2)$, and thus

$$Z = \frac{T - \mu_0}{\Sigma_0} \sim N\left[\frac{\mu_1 - \mu_0}{\Sigma_0}, \frac{\Sigma_1^2}{\Sigma_0^2}\right]. \quad (3)$$

The expected value of the test statistic under the alternative is termed the noncentrality parameter, Δ, where in this case $\Delta = (\mu_1 - \mu_0)/\Sigma_0$.

From the distribution under the alternative, the power of the test is obtained as follows. Power $1 - \beta$ is the complement of the probability of a type II error, β, of failing to reject the null hypothesis H_0 when an alternative hypothesis is true. Consider the case where $\mu_1 > \mu_0$ and a one-sided upper-tail test is conducted. Then $\beta = \Pr(z < z_{1-\alpha}|\mu_1, \Sigma_1^2)$ and

$$\beta = \Phi\left[\frac{z_{1-\alpha} - \left((\mu_1 - \mu_0) \;/\; \Sigma_0\right)}{\Sigma_1 \;/\; \Sigma_0}\right]. \quad (4)$$

Thus, $\beta = \Phi(z_\beta)$, where z_β is the standard normal deviate corresponding to the probability of a type II error β:

$$z_\beta = \frac{z_{1-\alpha}\Sigma_0 - (\mu_1 - \mu_0)}{\Sigma_1}. \quad (5)$$

Since this is a lower-tail probability, then the upper-area probability corresponding to the level of power is obtained from $z_{1-\beta} = -z_\beta$, so that

$$z_{1-\beta} = \frac{(\mu_1 - \mu_0) - z_{1-\alpha}\Sigma_0}{\Sigma_1}. \quad (6)$$

To allow for a one-sided alternative of the form $H_1 : \mu_1 < \mu_0$, or a two-sided alternative, we employ $|\mu_1 - \mu_0|$. This leads to the general expression for the relationship of power to the noncentral distribution of the test statistic:

$$|\mu_1 - \mu_0| = z_{1-\alpha}\Sigma_0 + z_{1-\beta}\Sigma_1, \quad (7)$$

where $z_{1-\alpha/2}$ is employed for a two-sided test. Some authors have used an abbreviated notation z_α and z_β for $z_{1-\alpha}$ and $z_{1-\beta}$, respectively.

In this formulation, T can usually be defined such that the variances can be factored of the form $\Sigma_i^2 = \sigma_i^2/N$, where σ_i^2 is the variance component ($i = 0, 1$) and N is the total sample size. Substituting into the above yields

$$\sqrt{N}|\mu_1 - \mu_0| = z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_1. \quad (8)$$

From this we can derive expressions to perform the following types of computations:

1. The total *sample size* N required to ensure a power of $1 - \beta$ of detecting a relevant difference $\mu_1 - \mu_0$ with a test at level α (or $\alpha/2$ if two-sided) is
$$N = \left(\frac{z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_1}{\mu_1 - \mu_0}\right)^2. \quad (9)$$
2. The *power* $1 - \beta$ to detect a difference $\mu_1 - \mu_0$ with a test at level α with a specific sample size N is provided by $\Phi(z_{1-\beta})$, where
$$z_{1-\beta} = \frac{\sqrt{N}|\mu_1 - \mu_0| - z_{1-\alpha}\sigma_0}{\sigma_1}. \quad (10)$$
Note that power $1 - \beta$ is 0.50 for $z_{1-\beta} = 0$, > 0.5 for $z_{1-\beta} > 0$, and < 0.5 for $z_{1-\beta} < 0$.
3. The *difference* $\mu_1 - \mu_0$ which can be detected with power $1 - \beta$ with a specified sample size N is provided by
$$|\mu_1 - \mu_0| = \frac{(z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_1)}{\sqrt{N}}. \quad (11)$$

In general, all three relationships may be used in planning the sample size required for a study. The latter relationships are also useful for the assessment of the power of a study post hoc, after it has been completed, especially in the event of a nonsignificant result.

Each of these relationships is a representation of the power function of the statistical test derived from (10). If the variance components under the null and alternative hypotheses are equal (at least approximately so), then (10) reduces to

$$z_{1-\beta} = \frac{\sqrt{N}|\mu_1 - \mu_0|}{\sigma} - z_{1-\alpha} = \sqrt{N}\theta - z_{1-\alpha}, \quad (12)$$

where $\theta = |\mu_1 - \mu_0|/\sigma$ is the standardized difference, termed the *noncentrality factor*.

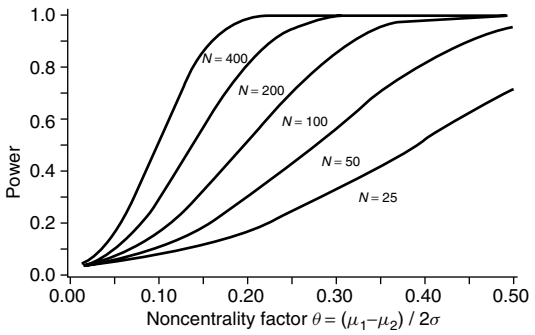

Figure 1 Power curves for the test of a difference in means for $\alpha = 0.05$ (two-sided)

Figure 1 presents the power to detect a difference for a test statistic with various sample sizes as a function of θ. In all cases, for a difference of 0, the probability of a significant test result is simply α, the significance level under the null hypothesis. As the magnitude of the difference increases under the alternative, the power increases, reaching an asymptote at 1.0 as θ approaches ∞. The rate at which power increases is a function of the sample size. Similar power function curves could be computed for any test statistic based on the more precise equation (10) employing the variance components under the null and alternative hypotheses if they differ.

The equation for the determination of sample size (9) can be viewed as the determination of the N for which the corresponding power function intersects the point $(\theta, 1-\beta)$ for a given level α and standardized difference θ, or the point $(\mu_1 - \mu_0, 1-\beta)$ for a specific difference $\mu_1 - \mu_0$ with variance components σ_1 and σ_0. For example, suppose we wish to detect a difference of $|\mu_1 - \mu_0| = 2$ with $\sigma = 8.7 (\sigma_0^2 \cong \sigma_1^2)$, yielding $\theta = 0.23$. Referring to Figure 1, the power function for $N = 200$ provides $\sim 90\%$ power to detect this difference. This is the same sample size that would be provided by a direct computation using (9).

Sample size evaluation in practice, however, is usually an iterative process. In this example it may be that an N of 100 would be financially feasible. The power function (Figure 1) shows that $N = 100$ provides 63% power to detect the originally specified difference $\theta = 0.23$, but that it also provides 90% power to detect a difference of $\theta = 0.33$. If these operating characteristics are considered acceptable, then the smaller N of 100 might be employed.

Such power function curves are also important in evaluating the interpretation of a negative, nonsignificant test result after a study has been completed. For example, suppose that a sample size of only 50 was employed in this study, and that the final result is not significant. Since the power function for $N = 50$ (Figure 1) shows that this sample size has power of 0.90 or greater to detect a standardized difference $\theta = 0.46$, then one can safely conclude that a difference of this magnitude likely does not exist. However, there was less power to detect smaller differences, such as a power of 0.369 for $\theta = 0.23$. Thus, one can only conclude that the study may have failed to detect such differences due to lack of power.

Power and Precision

Most of the literature on sample size evaluation is described in terms of the power function of a statistical test rather than the precision of an estimate. However, there is a simple correspondence between the two approaches. Most z-tests can also be expressed as an estimation-based test of the form $Z = (T - \mu_0)/\Sigma_0$, where T is an estimate of the parameter of interest ($\theta = \mu_1 - \mu_0$, $\hat{\theta} = T$).

Thus, the expression relating N to the precision of the estimate is approximately the same as that relating N to the power of the test, where $\mu_1 - \mu_0$ is replaced by the precision e and $z_{1-\beta} = 0$, so that $e = z_{1-\alpha/2}\Sigma_0$. Therefore, the N derived using a $1-\alpha$ confidence interval to ensure a precision e is approximately the same as the N needed to detect a difference $\mu_1 - \mu_0 = e$ with power = 0.50 using a two-sided test.

However, when constructing a confidence interval, the variance under the alternative is employed, so that (1) is actually $e = z_{1-\alpha/2}\Sigma_1$. To derive the equivalent equations for the precision of an estimate from those for the power of a test, we would employ $z_{1-\alpha/2}\Sigma_1$ when $\Sigma_0 \neq \Sigma_1$, where Σ_1 (or σ_1) is the multiplier of $z_{1-\beta}$ in the sample size equation.

Example: Test for Two Proportions

For a simple **2 x 2 table**, the usual large-sample test is the Pearson contingency **chi-square test** on 1 **degree of freedom** (df) which is directed towards a two-sided alternative. The chi-square value is equal to the square of the usual z-test for two proportions, which is based on the large-sample normal

approximation to the binomial. Either a one- or a two-sided z-test can be performed. Given two samples of sizes n_e and n_c for the experimental and control treatments, respectively, in which x_e and x_c are positive for the characteristic of interest, the corresponding simple proportions are $p_e = x_e/n_e$ and $p_c = x_c/n_c$. Each is the maximum likelihood estimate of the corresponding population probabilities such that $E(p_e) = \pi_e$ and $E(p_c) = \pi_c$, and the large-sample variances of each proportion are $\text{var}(p_e) = \pi_e(1-\pi_e)/n_e$ and $\text{var}(p_c) = \pi_c(1-\pi_c)/n_c$. In the following, it is convenient to present these expressions in terms of the total sample size N and the sample fractions $Q_e = n_e/N$ and $Q_c = n_c/N$, where $Q_e + Q_c = 1.0$.

The null hypothesis is $H_0 : \mu = \mu_0 = (\pi_e - \pi_c) = 0$ such that $\pi_e = \pi_c = \overline{\pi}$. Under H_0 the MLE of $\overline{\pi}$ is $\overline{p} = (x_e + x_c)/(n_e + n_c)$. The test then is based on $T = p_e - p_c$, where $\mu_0 = 0$, and

$$\begin{aligned}\Sigma_0^2 &= \text{var}[(p_e - p_c)|H_0] \\ &= \frac{\overline{\pi}(1-\overline{\pi})}{N}\left(\frac{1}{Q_e} + \frac{1}{Q_c}\right) = \frac{\sigma_0^2}{N}, \end{aligned} \quad (13)$$

which for large samples, can be estimated as

$$\hat{\Sigma}_0^2 = \frac{\overline{p}(1-\overline{p})}{N}\left(\frac{1}{Q_e} + \frac{1}{Q_c}\right).$$

Thus the test for two proportions is of the form $Z = (p_e - p_c)/\hat{\Sigma}_0$.

Under an alternative hypothesis, $H_1 : \mu = \mu_1 = (\pi_e - \pi_c) \neq 0$, and thus

$$\begin{aligned}\Sigma_1^2 &= \text{var}[(p_e - p_c)|H_1] \\ &= \frac{1}{N}\left[\frac{\pi_e(1-\pi_e)}{Q_e} + \frac{\pi_c(1-\pi_c)}{Q_c}\right] \\ &= \frac{\sigma_1^2}{N}. \end{aligned} \quad (14)$$

Substituting these expressions into the general equations relating sample size to power yields

$$\begin{aligned}&\sqrt{N}|\pi_e - \pi_c| \\ &= z_{1-\alpha}\left[\overline{\pi}(1-\overline{\pi})\left(\frac{1}{Q_e} + \frac{1}{Q_c}\right)\right]^{1/2} \\ &\quad + z_{1-\beta}\left[\frac{\pi_e(1-\pi_e)}{Q_e} + \frac{\pi_c(1-\pi_c)}{Q_c}\right]^{1/2}. \end{aligned} \quad (15)$$

Solving for N, $z_{1-\beta}$ or $(\pi_e - \pi_c)$ provides the expressions needed to address the three types of questions described above.

When $n_e = n_c = N/2 (Q_e = Q_c = 1/2)$, this expression simplifies to

$$\begin{aligned}\sqrt{N}|\pi_e - \pi_c| &= z_{1-\alpha}[4\overline{\pi}(1-\overline{\pi})]^{1/2} \\ &\quad + z_{1-\beta}[2\pi_e(1-\pi_e) \\ &\quad + 2\pi_c(1-\pi_c)]^{1/2}. \end{aligned} \quad (16)$$

Furthermore, Lachin [7] shows that $\Sigma_0^2 \geq \Sigma_1^2$. Thus, it is conservative to use

$$\sqrt{N}|\pi_e - \pi_c| = (z_{1-\alpha} + z_{1-\beta})[4\overline{\pi}(1-\overline{\pi})]^{1/2}. \quad (17)$$

For example, suppose we wish to plan a study with two equal-sized groups ($n_e = n_c$) to detect a 30% reduction in mortality associated with congestive heart failure, where the 1-year mortality in the control group is assumed to be no greater than 0.40. Thus, $\pi_c = 0.40$ and $\pi_e = 0.28$ ($= 0.70 \times 0.40$). Under the null hypothesis $\overline{\pi} = 0.34$. We desire 90% power for a two-sided test for two proportions at $\alpha = 0.05$. Using (9) the required total N is obtained as

$$\begin{aligned}N &= \big[\{1.96[4(0.34)(0.66)]^{1/2} + 1.282[2(0.28)(0.72) \\ &\quad + 2(0.4)(0.6)]^{1/2}\} \,/\, (0.4 - 0.28)\big]^2 \\ &= 652.\end{aligned}$$

Using the simplification which employs only the null variance component yields:

$$N = \left[\frac{[1.96 + 1.282][4(0.34)(0.66)]^{1/2}}{0.4 - 0.28}\right]^2 = 656.$$

Alternatively one could solve for $z_{1-\beta}$ to determine the power to detect a difference with a specified sample size, or the magnitude of the difference which could be detected with a given power for a specific sample size. For example, the power to detect this same difference with the smaller sample size $N = 500$ using the more complete equation (10) is provided by

$$\begin{aligned}z_{1-\beta} &= \frac{(500)^{1/2}(0.4 - 0.28) - 1.96[4(0.34)(0.66)]^{1/2}}{[2(0.28)(0.72) + 2(0.4)(0.6)]^{1/2}} \\ &= 0.879,\end{aligned}$$

yielding 81% power.

Finally, we note that the above expressions also provide the basic elements for the corresponding expression relating sample size to the precision of the estimate of the difference in probabilities. For example, to provide a 95% $(1-\alpha)$ confidence interval for $\pi_e - \pi_c$ with precision ± 0.05 requires a total sample size

$$N = \left(\frac{z_{1-\alpha/2}\sigma_1}{e}\right)^2$$
$$= \left[\frac{(1.96)[2(0.28)(0.72) + 2(0.4)(0.6)]^{1/2}}{0.05}\right]^2$$
$$= 1358.$$

Simplifications

As suggested by (17), the expressions for sample size and power can be simplified by using only one variance component rather than that under the null and under the alternative in the cases where the two differ, as where the variance depends on the expectation. Referring to (8), if $\sigma_0 \cong \sigma_1 \cong \sigma$, then the basic equation becomes

$$\sqrt{N}\frac{|\mu_1 - \mu_0|}{\sigma} = z_{1-\alpha} + z_{1-\beta}. \tag{18}$$

The left-hand side is the noncentrality parameter of the noncentral distribution of the test statistic; see (12). Factoring $\sqrt{N}$, the remainder is termed the noncentral factor θ,

$$\theta = \frac{|\mu_1 - \mu_0|}{\sigma}, \tag{19}$$

such that

$$\sqrt{N}\theta = z_{1-\alpha} + z_{1-\beta}. \tag{20}$$

This leads to simple equations for sample size and power as a function of the noncentral factor:

$$N = \left(\frac{z_{1-\alpha} + z_{1-\beta}}{\theta}\right)^2, \tag{21}$$

$$z_{1-\beta} = \theta\sqrt{N} - z_{1-\alpha}. \tag{22}$$

Using these expressions, Lachin [7] presents tables which give the sample sizes required to detect a range of values of θ for different levels of α and β, and the power to detect specific values of θ for a range of sample sizes. Other articles and texts likewise present various tables for sample size and power. In practice, however, direct computation using the appropriate expressions is readily performed.

Variance Components and Noncentral Factors

Within this framework, it is relatively straightforward then to derive the basic equations for sample size or power from the expected value and variance of the test statistic under the null and alternative hypotheses for a test statistic which is normally distributed, at least asymptotically. Expressions can be further simplified by noting that, for two independent group problems with equal sample sizes ($Q_e = Q_c = 0.5$), the term in Σ_0 involving the sample fractions is $(Q_c^{-1} + Q_e^{-1})^{1/2} = 2$. The following is a summary for many common tests, assuming equal sample sizes in the two groups. Below, a simple adjustment is described for the case of unequal sample sizes. In each of the following cases, $\mu_0 = 0$ under H_0.

For a z-test of means between two groups, the test statistic is based on the sample mean, which is assumed to be normally distributed as $N(\nu_i, \gamma^2/N)$ within each group $i = e, c$ with common variance γ^2 between subjects in each group. Then $\mu_1 = (\nu_e - \nu_c)$, $\sigma_0^2 = \sigma_1^2 = 4\gamma^2$, and $\theta = |\nu_e - \nu_c|/2\gamma$. For the paired z-test for means, the statistic is based on the mean of N paired differences assumed to be distributed as $N(\nu, \gamma^2/N)$. Then $\mu_1 = \nu \neq 0$ and $\theta = |\nu|/\gamma$.

The expressions for the z-test for proportions in two independent groups are presented in (15)–(17). From (17), the noncentral factor is $\theta = |\pi_e - \pi_c|/[4\overline{\pi}(1-\overline{\pi})]^{1/2}$. In the case of paired or matched observations, the test (**McNemar test**) is based on the **multinomial** parameters for the 2×2 table with discordant probabilities π_{01} and π_{10} for the matched assessments in N pairs with binary measurements (0 or 1) for each pair member. Thus, for example, π_{01} is the proportion of the N pairs where the first pair member has measurement 0 and the second member a 1. Then $H_0 : \pi_{10} = \pi_{01} = \overline{\pi}$, and under H_1, $\mu_1 = \pi_{10} - \pi_{01} \neq 0$. Various expressions for the power of this test have been proposed for the unconditional case where the number of discordant pairs is not fixed a priori by design. Lachin [8] concludes that it is conservative to use that obtained from the underlying multinomial probabilities where

$$\sigma_1^2 = [(\pi_{10} + \pi_{01}) - (\pi_{10} - \pi_{01})^2] \tag{23}$$

and $\sigma_0^2 = 2\overline{\pi}$, where $\sigma_0 \geq \sigma_1$. Thus the noncentral factor is $\theta = |\pi_{10} - \pi_{01}|/(2\overline{\pi})^{1/2}$.

Although nonparametric rank tests are generally used for the analysis of survival (event-time) data (*see* **Survival Analysis, Overview**), calculation of sample size and power are often performed assuming some simple parametric model. The Mantel or **logrank test** is the most commonly used test in this setting, which is asymptotically fully efficient against a **proportional hazards** or **Lehmann alternative**. The simplest parametric form of this model is the **exponential** model with constant hazard rates λ_e and λ_c over time in each group. Some authors have derived expressions for the power function of the test for exponential hazards using the normal approximation to the distribution of $\hat{\lambda}$ (e.g. [9]), while others have used that for $\ln \hat{\lambda}$ (e.g. [14]). The resulting computations are nearly equivalent, but those using the distribution of $\ln \hat{\lambda}$ are preferred.

Asymptotically, the sample estimate of the natural log **hazard rate** $\ln \hat{\lambda}$ is distributed as $N[\ln \lambda, 1/E(D|\lambda)]$. Thus, the power of the test depends on the expected total number of events $E(D|\lambda)$ to be observed during the study. Here $E(D|\lambda) = NE(\delta|\lambda)$, where δ is a binary variable (*see* **Dummy Variables**) representing observation of the event ($\delta = 1$) vs. not (right **censoring** of the event time, $\delta = 0$), and $E(\delta|\lambda)$ is the probability that the event will be observed as a function of λ and the total exposure of the cohort (patient years of follow-up). Under $H_0 : \lambda_e = \lambda_c = \overline{\lambda}$, or $\ln(\lambda_e/\lambda_c) = 0$, while under H_1, $\mu_1 = (\ln \lambda_e - \ln \lambda_c)$ and

$$\sigma_1^2 = \left[\frac{2}{E(\delta|\lambda_e)} + \frac{2}{E(\delta|\lambda_c)}\right]. \tag{24}$$

Thus $\sigma_0^2 = 4/E(\delta|\overline{\lambda})$. Lachin [7] shows that in this case $\sigma_1 \geq \sigma_0$, so that it is conservative to use $\theta = [\ln(\lambda_e/\lambda_c)]/\{2[E(\delta|\lambda_e)^{-1} + E(\delta|\lambda_c)^{-1}]\}^{1/2}$.

In a study with no censoring of event times, where the event times of all subjects are observed, then $E(\delta|\lambda) = 1$. In the case where each subject is followed for T years of exposure, then $E(\delta|\lambda) = 1 - \exp(-\lambda T)$. In a study with uniform entry over a recruitment interval of R years (*see* **Staggered Entry**), and a total study duration of T years ($T \geq R$),

$$E(\delta|\lambda) = \left[1 - \frac{\exp[-\lambda(T-R)] - \exp(-\lambda T)}{\lambda R}\right] \tag{25}$$

(*see* **Sample Size Determination in Survival Analysis**).

Unequal Sample Fractions

In each of the above cases, the variance component under the null or alternative hypothesis is used to define the noncentrality parameter. For two independent group problems with unequal sampling fractions $Q_e \neq Q_c$, the term in Σ involving the sample fractions is $(Q_c^{-1} + Q_e^{-1})^{1/2} \neq 2$. Thus, the Σ for unequal sample sizes equals $C = (Q_c^{-1} + Q_e^{-1})^{1/2}/2$ times that for equal sample sizes, so that the factor θ with equal sample sizes should be multiplied by $1/C$. Thus, from (21), the sample size for the unbalanced design is $C^2 = (Q_c^{-1} + Q_e^{-1})/4$ times that for equal sample fractions. For example, for Q_e (or Q_c) $= 0.7$, the sample size required for the unbalanced design is $(1/0.7 + 1/0.3)/4 = 1.19$ times the N for the balanced design, so that the unbalanced design requires approximately 19% larger sample size to provide the same level of power as the balanced design.

Power for t, χ^2 and F-Tests

For test statistics which follow the **Student's *t***, **chi-square** or ***F* distributions**, among others, determination of sample size or power is conducted through identification of the noncentrality parameter, $\Delta = N\theta^2$, of the noncentral distribution of the test statistic. For a 1 df χ^2 test statistic, the noncentrality parameter is $N\theta^2$, where θ is the noncentral factor for the test. Thus, from (20), the value of the noncentrality parameter which provides power $1 - \beta$ for a $u = 1$ df two-sided test at level α, designated as $\Delta(1, \alpha, \beta) = N\theta(1, \alpha, \beta)^2 = (z_{1-\alpha/2} + z_{1-\beta})^2$. For example, $\Delta(1, 0.05, 0.10) = (1.96 + 1.2816)^2 = 10.507$.

Values of the noncentrality parameter providing various levels of power for the noncentral chi-square and **noncentral *t* distributions** on u df, $\Delta(u, \alpha, \beta)$, and for the F-distribution on u and v df, $\Delta(u, v, \alpha, \beta)$, are widely tabulated. Programs are also available, such as the SAS functions PROBCHI for the cumulative probabilities and CINV for quantiles of the chi-square distribution, both of which provide computations under the noncentral distribution. Equivalent functions provide these computations for the t distribution (PROBT and TINV), and the F distribution (PROBF and FINV). SAS functions CNONCT, TNONCT, and FNONCT, now available in release 6.07, provide the values of the required noncentrality parameter Δ for specific levels of α and β [4] (*see* **Software, Biostatistical**).

To determine sample size using this approach, one first obtains the value of the noncentrality parameter which will provide the desired level of power, e.g. the value $\Delta(u, \alpha, \beta)$ for the noncentral chi-square distribution. One then evaluates the value of the noncentrality factor θ under the alternative hypothesis. The noncentrality factor is usually defined using the variance under the null hypothesis, often because the expected value of the statistic (the noncentrality parameter) is derived under a sequence of local alternatives. Given the value of θ, the N required to provide power $1 - \beta$ is that value for which $\Delta(u, \alpha, \beta) = N\theta^2$, yielding $N = \Delta(u, \alpha, \beta)/\theta^2$.

Example: Contingency Chi-Square Test

Consider the case of a random sample of N subjects divided among K mutually exclusive categories (cells) with cell frequency x_i in the ith category $l = 1, \ldots, K$. These frequencies are distributed as multinomial with cell probabilities $\pi_l, l = 1, \ldots, K$. These cell probabilities, in turn, can be expressed as a function of M underlying parameters, expressed as $\pi_l(\boldsymbol{\alpha})$, for $\boldsymbol{\alpha} = (\alpha_1 \ldots \alpha_M)$. Under a null hypothesis stated in terms of the $\boldsymbol{\alpha}$, $\mathrm{H}_0 : \boldsymbol{\alpha} = \boldsymbol{\alpha}_0$, with corresponding multinomial probabilities $\pi_l(\boldsymbol{\alpha}_0)$, where the parameters $\boldsymbol{\alpha}$ are estimated from the sample, then the Pearson contingency chi-square statistic

$$\chi^2 = \sum_l \frac{[x_l - N\pi_l(\hat{\boldsymbol{\alpha}}_0)]^2}{N\pi_l(\hat{\boldsymbol{\alpha}}_0)} \tag{26}$$

is distributed as chi-square on $K - M - 1$ df. Under an alternative hypothesis, $\mathrm{H}_1 : \boldsymbol{\alpha} = \boldsymbol{\alpha}_1$, χ^2 is distributed as noncentral chi-square with noncentrality parameter $N\theta^2$, where

$$\theta^2 = \sum_l \frac{[\pi_l(\boldsymbol{\alpha}_1) - \pi_l(\boldsymbol{\alpha}_0)]^2}{\pi_l(\boldsymbol{\alpha}_0)} \tag{27}$$

The most common instance is the $r \times c$ **contingency table** ($K = rc$) under the hypothesis of independence, where $\sum_l$ denotes summation over rows $i = 1, \ldots, r$ and columns $j = 1, \ldots, c$. Then π_{ij} is the probability associated with the ijth cell, with marginal probabilities $\pi_{i.}$ and $\pi_{.j}$ for the ith row and jth column, respectively. The hypothesis of independence then implies the null hypothesis that $\pi_{ij} = \pi_{i.}\pi_{.j}$. Thus, the parameters under the null hypothesis are $\boldsymbol{\alpha} = [\pi_{1.} \ldots \pi_{(r-1).}\pi_{.1} \ldots \pi_{.(c-1)}]$, consisting of $M = (r - 1) + (c - 1)$ parameters to be estimated from the sample. The resulting test is based on $K - M - 1 = rc - (r - 1) - (c - 1) - 1 = (r - 1)(c - 1)$ df.

One way that such a contingency table might arise is the $r \times c$ comparative trial in which r independent groups of sample sizes $n_i = Q_i N$ are compared with respect to the proportions $p_{j(i)}$ in each of c categories, where $p_{j(i)} = x_{ij}/n_i$ and $\mathrm{E}(p_{j(i)}) = \pi_{j(i)}$, $\sum_j p_{j(i)} = \sum_j \pi_{j(i)} = 1.0$ for each group $i = 1, \ldots, r$. The null hypothesis of homogeneity is $\mathrm{H}_0 : \pi_{j(i)} = \alpha_j$ for all i. Under the alternative, these conditional probabilities differ across groups such that under $\mathrm{H}_1 : \pi_{j(i)} = \alpha_j + \delta_{ij}$, where $\delta_{ij} \neq 0$ for some (i, j). Then, Lachin [6] shows that

$$\theta^2 = \sum_j \frac{1}{\alpha_j} \left[\sum_i Q_i \delta_{ij}^2 - \left(\sum_i Q_i \delta_{ij} \right)^2 \right]. \tag{28}$$

For example, let the following be the pattern of conditional probabilities $\{\alpha_j\}$ expected under H_0 for a planned clinical trial comparing three equal-sized ($Q_i = 1/3$) treatment groups with respect to three categories of recovery:

	Complete recovery	Partial recovery	No recovery
$\alpha_j = \sum_i Q_i \pi_{j(i)} =$	0.10	0.15	0.75

Under the alternative, assume we wish to detect the following pattern of differences (δ_{ij}) among the three groups, where $\pi_{j(i)} = \alpha_j + \delta_{ij}$:

$$\{\delta_{ij}\} = \begin{cases} \text{Placebo} & -0.09 & -0.11 & 0.20 \\ \text{Low dose} & -0.01 & 0.01 & 0.00 \\ \text{High dose} & 0.10 & 0.10 & -0.20 \end{cases}$$

Substituting these values into (28) yields $\theta^2 = 0.1456$. From tables of the noncentral chi-square distribution for $\alpha = 0.05$, $\beta = 0.10$, and 4 df, or using the SAS function CNONCT, we require $\Delta(4, 0.05, 0.10) = 15.405$. Solving for $N = \Delta/\theta^2$ yields $N = 106$.

To determine power based on a given sample size N, one simply determines the value of the noncentrality parameter $\Delta = N\theta^2$ and then evaluates the cumulative probability at the critical value under the noncentral chi-square distribution. This approach is employed in the following example.

Example: K-Group ANOVA

Consider the case of the one-way **analysis of variance** (ANOVA) for the test of equality of K independent group means, $H_0 : \nu_1 = \nu_2 = \cdots \nu_K$ vs. $H_1 : \nu_i \neq \nu_j$ for some two groups $1 \leq i < j \leq K$, assuming a common variance σ^2 within groups under the null and alternative hypotheses. Also assume equal sample size n within each group, with a total sample size $N = nK$. Then the K group ANOVA F-test $= MSB/MSE$ on $u = K - 1$ and $v = K(n-1)$ df follows a noncentral F-distribution, where MSB and MSE are the mean squares between and within groups, respectively.

The expected mean squares between groups $\mathrm{E}(MSB)$ and within groups or for error $\mathrm{E}(MSE)$ under the alternative hypothesis that some differences exist among the K population means are:

$$\mathrm{E}(MSB) = \sigma_\varepsilon^2 + \frac{n\sum_i (\nu_i - \overline{\nu})^2}{K-1} = \sigma_\varepsilon^2 + n\sigma_\nu^2, \quad (29)$$

$$\mathrm{E}(MSE) = \sigma_\varepsilon^2.$$

Under the null hypothesis, $\sigma_\nu^2 = 0$ and $\mathrm{E}(MSB) = \sigma_\varepsilon^2$, so that $(K-1)MSB/\sigma_\varepsilon^2$ is distributed as central chi-square. Under the alternative, however, $(K-1)MSB/\sigma_\varepsilon^2$ is distributed as noncentral chi-square with noncentrality parameter $\Delta = n\theta^2$, where

$$\theta^2 = \frac{\sum_i (\nu_i - \overline{\nu})^2}{\sigma_\varepsilon^2}. \quad (30)$$

Thus, under the alternative, the F-test is also distributed as noncentral F with noncentrality parameter $\Delta = n\theta^2$. The values of Δ for given (k, n, α, β) have been tabulated. Some charts and tables present these relationships in terms of the reparameterization $\phi = [\Delta/(u+1)]^{1/2}$, where u is the numerator df$(= K - 1)$.

For example, for $K = 3$ groups, assume that the population means under the alternative hypothesis are $(\nu_1 = 2,\ \nu_2 = 4,\ \nu_3 = 6)$, so that $\sum_i (\nu_i - \overline{\nu})^2 = 8$. Also assume that $\sigma_\varepsilon^2 = 15$. Then $\theta^2 = 8/15 = 0.533$. For $n = 25$ per group, the critical value for the F-test at the 0.05 level on 2 and 72 df, obtained as FINV (0.95, 2, 72), is 3.12391. The noncentrality parameter is $\Delta = (25)(8/15) = 13.333$. The type II error β is then the probability of an Fvalue $<$ 3.12391 on (2, 72) df with $\Delta = 13.33$. Using FPROB (3.12391, 2, 72, 13.33) yields $\beta = 0.09691$ and power $= 0.90309$.

For sample-size determination for an F-test or a t-test, since the denominator df depends on n, an iterative procedure is required. Charts are also widely available relating sample size to the noncentrality factor θ.

Example: Multiple Regression Model

In a **multiple linear regression** model with m **covariates** or **explanatory variables**, a variety of different tests may be conducted, such as an overall model test on p df and tests of each of the individual regression coefficients, each of which will have a different power function. The power for these tests depends on the total N, the residual variance σ_ε^2, and on the joint distribution of the m covariates. For example, in the homoscedastic normal errors model with m covariates (plus the constant term), $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$ and $\widehat{\mathrm{cov}}(\hat{\boldsymbol{\beta}}) = \hat{\boldsymbol{\Sigma}}_{\hat{\boldsymbol{\beta}}} = (\mathbf{X}'\mathbf{X})^{-1}\hat{\sigma}_\varepsilon^2$, where $\hat{\sigma}_\varepsilon^2$ is the MSE on $N - m - 1$ df. Then the test of $H_0 : \boldsymbol{\beta} = \mathbf{0}$ (including the intercept) is provided by the quadratic form $F = \hat{\boldsymbol{\beta}}'(\hat{\boldsymbol{\Sigma}}_{\hat{\boldsymbol{\beta}}})^{-1}\hat{\boldsymbol{\beta}}$ on $(m+1, N-m-1)$ df. Under $H_1 : \boldsymbol{\beta} \neq \mathbf{0}$, F is distributed as noncentral F with noncentrality parameter $\Delta = \boldsymbol{\beta}'(\boldsymbol{\Sigma}_{\hat{\boldsymbol{\beta}}})^{-1}\boldsymbol{\beta} = \mathrm{E}[\mathbf{Y}'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}]/\sigma_\varepsilon^2 = \mathrm{E}(\hat{\boldsymbol{\beta}}'\mathbf{X}'\mathbf{Y})/\sigma_\varepsilon^2$. Thus, to evaluate power or sample size a priori, it is necessary to specify the covariance matrix of $(\mathbf{Y}|\mathbf{X})$ to determine the noncentrality parameter for the test of regression for the model.

Similarly, the test for the jth individual coefficient in the model is $t = \hat{\beta}_j/\hat{\gamma}_j$, which is distributed as t on $N - m - 1$ df, where $\mathrm{var}(\hat{\beta}_j) = \sigma_j^2 = (\boldsymbol{\Sigma}_{\hat{\boldsymbol{\beta}}})_{jj}$, which involves the jj element of $(\mathbf{X}'\mathbf{X})^{-1}$. To determine the noncentrality parameter for the test again requires specification of the joint distribution of $\mathbf{X}$. For analyses involving quantitative covariates, therefore, it is rare that there is adequate prior information on the joint distribution of $(\mathbf{Y}|\mathbf{X})$ to evaluate the size of the noncentrality parameter. For this reason, some authors, e.g. Cohen [1], discuss power and sample size for arbitrarily defined "small" to "large" effect sizes in terms of the values of Δ.

Example: Logit Model

One case in which it is tractable to consider the evaluation of the noncentrality parameter is the logit

(**logistic regression**) model for binary covariates using the power function of the large sample Wald chi-square test (cf. [13]; *see* **Likelihood**). The model relates the logit of the probability of an index characteristic, π, to a linear function of the covariate vector $\mathbf{X}$, including a constant, of the form $\ln[\pi/(1-\pi)] = \mathbf{X}'\boldsymbol{\beta}$, where π is obtained from the inverse logit

$$\pi = \frac{\exp(X'\beta)}{[1+\exp(X'\beta)]}. \tag{31}$$

Suppose we wish to estimate this relationship for $i = 1, \ldots, K$ cells, where the ith cell has sample size $n_i = Nq_i$ (N the total sample size) and covariate vector $\mathbf{X}_i$ consisting of the constant and m discrete covariates with coefficients $(\beta_0, \beta_1, \ldots, \beta_m)$, β_0 being the intercept. For example, for s binary covariates, $K = 2^s$ and $m \leq K$. Within the ith cell, the observed proportion with the index characteristic is p_i. Since $\operatorname{var}\ln[p/(1-p)] = 1/[n\pi(1-\pi)]$ the parameters can be estimated through weighted **least squares** such that $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{Y}$ and $\operatorname{cov}(\hat{\boldsymbol{\beta}}) = \boldsymbol{\Sigma}_{\hat{\beta}} = (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1}/N$, where

$$\boldsymbol{\Omega} = \operatorname{diag}\left\{\frac{1}{[q_i\pi_i(1-\pi_i)]}\right\} \quad \text{and}$$

$$\boldsymbol{\Omega}^{-1} = \operatorname{diag}[q_i\pi_i(1-\pi_i)]. \tag{32}$$

Note that $\boldsymbol{\Omega}$ is directly obtained as a function of $\mathbf{X}_i$ and $\boldsymbol{\beta}$ through (31).

The Wald test for a linear hypothesis of the form $\mathrm{H}_0 : \mathbf{L}'\boldsymbol{\beta} = \mathbf{0}$ for an $r \times (m+1)$ matrix $\mathbf{L}'$ is of the form

$$\chi^2 = \hat{\boldsymbol{\beta}}'\mathbf{L}(\mathbf{L}'\boldsymbol{\Sigma}\mathbf{L})^{-1}\mathbf{L}'\hat{\boldsymbol{\beta}} \tag{33}$$

on r df with noncentrality parameter

$$\begin{aligned}\Delta &= \boldsymbol{\beta}'\mathbf{L}(\mathbf{L}'\boldsymbol{\Sigma}L)^{-1}\mathbf{L}'\boldsymbol{\beta} \qquad (34)\\ &= N\boldsymbol{\beta}'\mathbf{L}[\mathbf{L}'(\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1}\mathbf{L}]^{-1}\mathbf{L}'\boldsymbol{\beta} = N\theta^2.\end{aligned}$$

Since θ^2 is a function of $\mathbf{L}$, $\mathbf{X}$, and $\boldsymbol{\beta}$, sample size and power can readily be obtained as described above.

For example, consider the design matrix $\mathbf{X}$:

$$\mathbf{X} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 1 \end{bmatrix},$$

representing effects for the intercept, three strata (2 df), and two treatments. The expected cell fractions are specified to be $\{q_i\} = (0.075, 0.075, 0.25, 0.25, 0.175, 0.175)$, which assume that there are equal sample sizes for each of the two treatment groups within the three strata, comprising 15%, 50%, and 35% of the total sample, respectively. Under the alternative hypothesis we specify $\boldsymbol{\beta}' = (1.099, -0.251, -0.480, 0.925)$. These are the values of β_j which correspond to a model where the odds ratio for treatment 1 vs. treatment 0 is $\exp(\beta_3) \cong 2.5$ and the associated probabilities for each cell are $\{\pi_i\} = (0.75, 0.923, 0.70, 0.882, 0.65, 0.770)$, such that the odds ratios within each stratum are 4.0, 3.2, and 1.8, respectively. For the test of $\mathrm{H}_0 : \beta_3 = 0$, with vector $\mathbf{L}' = (0 \quad 0 \quad 0 \quad 1)$, the value of the noncentral factor is $\theta^2 = 0.0342$. For a 1 df chi-square test at $\alpha = 0.05$, the noncentrality parameter $\Delta(0.05, 0.10, 1) = 10.5074$ provides power = 0.90. Thus, the total N required to provide 90% power for this test is $N = 10.5074/0.0342 = 307$.

For this and similar examples, one approach to specifying the model under the alternative is first to specify the $\{\pi_i\}$ and then determine the values of β which satisfy the model. This can readily be obtained by generating a set of cell frequencies summing to a large number, say 10 000 – the frequencies being proportional to the corresponding probabilities – and then fitting the logit model to obtain the values of β_j.

Factors which Affect Sample Size

In addition to the variance components and noncentral factors described herein, other features of the observed data may affect precision or power. Two of the more important are missing data and measurement errors.

Missing Data

Precision and power are directly related to the amount of information in the data. In many cases, **information** in the Fisherian sense is proportional to the total sample size. Thus, if one expects $M \times 100\%$ of the observations to be missing completely at random (purely by chance), then the sample size required should be adjusted upwards by the factor $1/(1-M)$. In some cases, however, such as rank tests for survival data, the information is not directly proportional

to N alone, but to other factors, such as the pattern of losses to follow-up over time. In such cases it is necessary to consider the extent to which the process by which the missing data is generated will impact on the power of the test (*see* **Missing Data in Clinical Trials**; **Missing Data in Epidemiologic Studies**).

Reliability of Measurements

In a simple measurement error model one can express the observed measurement as $X_i = \eta_i + \varepsilon_i$, where η_i is the true measurement and ε_i is a random measurement error with expectation 0 and variance σ_ε^2 independent of η_i. Thus, $\sigma_X^2 = \sigma_\eta^2 + \sigma_\varepsilon^2$ and the **reliability** of the measurements is reflected by $\rho = \sigma_\eta^2/\sigma_X^2$. Since $\sigma_X^2 = \sigma_\eta^2/\rho$, power decreases as ρ decreases and the required N increases. For example, if N is needed to provide a desired level of power to detect a given difference in the mean values of the true measurements, with variance component σ_η^2, then N/ρ is required to detect the same difference in the observed measurements. For example, for $\rho = 0.8$, the sample size required to detect a difference between population means is 25% greater than that for measures without error. This is often an important consideration since in many cases the reliability of measurements can be controlled within limits, such as for laboratory assessments (*see* **Measurement Error in Epidemiologic Studies**).

Sample Size in Epidemiologic Studies

Determining the number of subjects to be included in a study is a crucial step in designing the study and writing the protocol. To determine sample size, the study objectives have to be clearly defined, the general design (e.g. cohort, case–control) (*see* **Case–Control Study**; **Cohort Study**) and specific design options have to be selected, the main outcome and exposure variables have to be specified, the planned analysis strategy (i.e. hypothesis testing or estimation) and statistical methods have to be determined. Therefore, sample size determination is a very important aspect of design and cannot be carried out without a thorough and quantitative understanding of the planned study.

The study sample size should be large enough that the estimates will be sufficiently precise and the difference of interest is likely to be detected. It is usually true that the more subjects that are included in the study, the better the precision of the estimates, and the more likely the difference of interest will be detected. However, an oversized study may not always be the best choice because of economic and study time (sometimes ethical) considerations.

Hypothesis Testing and Power: The Case of a Normally Distributed Outcome

The principle of sample size and power considerations can be illustrated by a simple hypothesis test for normally distributed data. The normal case study will build the concepts and form the mathematical basis for most other sample size procedures, which will be discussed in later sections.

Suppose n samples are drawn from a population that has a normal distribution $\mathrm{N}(\mu, \sigma^2)$. To test a null hypothesis $\mathrm{H_0}$: $\mu = \mu_0$ vs. an alternative hypothesis $\mathrm{H_a}$: $\mu = \mu_a (> \mu_0)$, we use a test statistic $Z = \sqrt{n}(\overline{X} - \mu_0)/\sigma_0$, which follows a standard normal distribution under $\mathrm{H_0}$. For simplicity, we assume that the variances are known: under $\mathrm{H_0}$, $\sigma^2 = \sigma_0^2$ and under $\mathrm{H_a}$, $\sigma^2 = \sigma_a^2$. The null hypothesis will be rejected if the observed value of Z falls in an extreme region, i.e. $Z > c$, where c is a constant to be determined (see below).

Two types of error can be made with the test. First, a type I error is that the null hypothesis is true but the observed Z falls in the rejection region (i.e. $Z > c$) such that the null hypothesis is rejected. The type I error is also called the significance level of the test. It is often protected by setting an upper limit, e.g. 0.10 or 0.05, for the significance level. Secondly, a type II error is the probability of failing to reject the null hypothesis when the alternative hypothesis is true. Both error rates depend on the sample size, test statistic Z, and the critical value c. In the normal distribution, for a given $\mathrm{H_a}$: $\mu = \mu_a > \mu_0$ (one-sided test),

$$\text{Type I error} : \alpha = P(Z > c|\mathrm{H_0}) = 1 - \Phi(c),$$

$$\text{Type II error} : \beta = P(Z \le c|\mathrm{H_a}),$$

where $\Phi(\cdot)$ is the standard normal distribution function. Solving the first equation, we have $c = z_{1-\alpha}$, the $(1-\alpha)$th percentile of the standard normal distribution.

The power of a statistical test is defined as the probability that a statistically significant test statistic will be obtained (i.e. reject the null hypothesis), given that the alternative hypothesis is true. It equals one minus the type II error. In the above example,

$$\begin{aligned}\text{Power} = 1 - \beta &= P(Z > c|\mathrm{H_a}) \\ &= 1 - \Phi\left(\frac{z_{1-\alpha}\sigma_0 - \sqrt{n}(\mu_a - \mu_0)}{\sigma_a}\right).\end{aligned}$$

Solving the equation, we obtain the required sample size to ensure a $1 - \beta$ power on detecting the difference of $\mu_a - \mu_0$; that is,

$$n = \left(\frac{z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_a}{\mu_a - \mu_0}\right)^2.$$

This equation can also be used to find the minimum detectable difference for given statistical power $1 - \beta$ and sample size n; that is,

$$\Delta = \mu_a - \mu_0 = \frac{z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_a}{\sqrt{n}}.$$

This is the smallest difference that can be detected with given sample size and power.

Although the sample size formula is obtained from a normal distribution, the relationship among the parameters of sample size, significance level α,

power $1-\beta$, variances, and effect-size Δ is generally true for any type of study and distribution. As the significance level α is getting smaller, or the power is getting higher, or the variances are getting larger, or the effect size is getting smaller, a larger sample size will be required. While the significance level is usually 5% and the power is usually 80% or 90%, it is very important to select suitable values for effect size and variances in designing a study. Investigators should not use overoptimistic values for the effect size or variances to avoid having an underpowered study.

The calculations of sample size, power and minimum detectable difference can be generalized to the case of $\mu_a < \mu_0$ by replacing $\mu_a - \mu_0$ with $|\mu_a - \mu_0|$ in the above formula. The above formulas are based on one-sided tests. For a two-sided alternative hypothesis, H_a: $\mu_a \neq \mu_0$, the sample size formula is essentially the same but $z_{1-\alpha}$ is replaced by $z_{1-\alpha/2}$.

The choice of a one-sided or two-sided test will depend on the problem of interest. If one wants to test only one direction, e.g. $\mu = \mu_0$ against $\mu > \mu_0$, or test whether the population mean is greater than μ_0, then a one-sided test is appropriate. If the interest is to test the deviation from μ_0 from either direction, then a two-sided test is to be used. In this case, the null hypothesis will be rejected when the population mean is either too small or too large statistically compared with μ_0.

Estimation and Precision

In epidemiologic studies, researchers may be interested in estimating the magnitude of the effect from exposure instead of testing the hypothesis of no effect. The precision of an estimate can be measured by the width of a confidence interval that is designed to cover the true parameter of interest with a specified probability (coverage probability), $1-\alpha$. In the normal distribution example, if we want to estimate the mean μ with known variance σ^2, then the $1-\alpha$ confidence interval is $(\overline{X} - z_{1-\alpha/2}\sigma/\sqrt{n}, \overline{X} + z_{1-\alpha/2}\sigma/\sqrt{n})$. With regard to replications of sampling, we have a $1-\alpha$ probability that the true mean μ will be included in this interval. The larger the sample size, the narrower the confidence interval, and therefore the higher the precision of the parameter estimate (*see* **Random Error**).

Over the last decades some researchers have been stressing the advantage of using confidence intervals rather than testing p-values to present study results and make statistical inferences. One reason is that a confidence interval conveys not only information on the point estimation but also an impression of the precision of the estimate. Some further discussions of the pros and cons of hypothesis testing and confidence intervals can be found in Rothman & Greenland [33].

The sample size calculated from the confidence interval viewpoint will depend on the objective of the study. If a study is solely to estimate the effect of a parameter of interest with a given precision, then the sample size can be calculated from the width of the confidence interval. For the normal mean example, if one wants the width of the $1-\alpha$ confidence interval to be no more than 2δ, that is $2z_{1-\alpha/2}\sigma/\sqrt{n} \leq 2\delta$, then $n \geq (z_{1-\alpha/2}\sigma/\delta)^2$.

When the objective of a study is effectively to distinguish the parameter of interest from a specified value or distinguish among specified values, the sample size calculation should consider the expected location of the confidence interval. The sample size based on the width of the confidence interval alone will be insufficient [15]. In this case, the sample size obtained from confidence interval estimation will be similar to the sample size from hypothesis testing. In fact, hypothesis testing (two-sided) and confidence interval estimation are closely related. A study that yields a test p-value (two-sided) of precisely α for testing H_0: $\mu = \mu_0$ will have a $1-\alpha$ confidence interval that has one end at μ_0. In other words, if the $1-\alpha$ confidence interval of μ contains μ_0, then the null hypothesis H_0 will not be rejected with the significance level of α (two-sided).

Practical Considerations and Outline

In this article, we will focus our presentation on the determination of sample size from the traditional hypothesis testing approach and present some limited results based on estimation and precision. For the actual study, the sample size, test significance level, variability, power and minimum detectable difference (effect size) have to be considered at the design stage. The relationship among these parameters will allow investigators to calculate one parameter given the others.

In practice, the test significance level is often 5% and the statistical power is usually 80% or 90%. The variability and expected difference are often obtained from previous studies. Special consideration may be given to the choice of the minimal difference to be detected. The difference should be reasonable and suitable, such that it is practically meaningful and the study can be planned and conducted feasibly. If the assumed difference is too large and the sample size is consequently underestimated, then the study may fail to detect the true difference due to insufficient power. On the other hand, an oversized study may be costly to conduct and sometimes may detect a "tiny" difference that is not practically meaningful. The factors of time, cost and recruitment of subjects from the study population should all be considered, together with the selection of the study sample size, power and expected difference.

In general, the required sample size for a study depends not only on the parameters such as α, power $1-\beta$, and minimal detectable difference but also on the statistical procedures to be applied in the analysis and the study design. For epidemiologic studies, typically cohort studies and case–control studies, many papers and review articles have been published for sample size and power determinations (e.g. [2, 24, 25, 36, 43]). In this article we give a broad overview of sample size determination methods for a variety of epidemiologic designs. The methodologic details are skipped and relegated to the references. In the second section, sample size determination methods for studies with a binomial outcome (in **cohort** and unmatched **case–control studies**) are discussed. Methods for matched case–control studies are discussed in the next section. For cohort studies with Poisson outcomes, the sample size determination methods are presented in the fourth section. The fifth section discusses sample size determination for cohort studies when the outcome of interest is time to event. The sample size required for cohort studies with longitudinal or correlated outcomes is discussed in the sixth section, while the following section highlights some sample size calculations when the problem of interest is estimation and precision. The final section presents some further considerations on sample size and power determination followed by a discussion.

Without loss of generality, we will present the sample size formulas for one-sided tests in the following sections. The two-sided formulas can be obtained by replacing $z_{1-\alpha}$ with $z_{1-\alpha/2}$ in all instances unless otherwise specified.

Studies with Binomial Outcomes

Dichotomous Exposure: Cohort Study

In **cohort studies** with a fixed follow-up time, the main outcome is typically disease occurrence. Let p_0 and p_1 be the proportion of subjects who develop the disease in the unexposed and exposed populations, respectively. For a one-sided test H_0: $p_1 = p_0$ vs. H_a: $p_1 > p_0$, assuming an equal number of subjects n in the exposed and unexposed groups, the required sample size is given as follows (e.g. [36]):

$$n = \frac{\left(z_{1-\alpha}\sqrt{(2\overline{pq})} + z_{1-\beta}\sqrt{(p_1q_1 + p_0q_0)}\right)^2}{(p_1 - p_0)^2}, \tag{1}$$

where $q_1 = 1 - p_1$, $q_0 = 1 - p_0$, $\overline{p} = (p_0 + p_1)/2$, and $\overline{q} = 1 - \overline{p}$. The above formula is obtained from a normal approximation to the test statistic for comparing two binomial proportions. The formula can be represented as

$$n = \frac{\left[\begin{array}{c} z_{1-\alpha}\sqrt{(2\overline{pq})} \\ +z_{1-\beta}\sqrt{(p_0(1+r) - p_0(1+r^2))}\end{array}\right]^2}{[p_0(1-r)]^2} \tag{2}$$

in terms of the risk ratio $r = p_1/p_0$ (*see* **Relative Risk**) to test H_0: $r = 1$ vs. H_a: $r > 1$.

In general, let π_e be the proportion of subjects in the exposed group. Then the total sample size required is given by

$$N = \frac{\left[\begin{array}{c} z_{1-\alpha}\sqrt{(\overline{pq}/\pi_e(1-\pi_e))} \\ +z_{1-\beta}\sqrt{(p_1q_1/\pi_e + p_0q_0/(1-\pi_e))}\end{array}\right]^2}{(p_1 - p_0)^2}. \tag{3}$$

Dichotomous Exposure: Case–Control Study

The sample size required for an unmatched **case–control study** is similar to that for a cohort study. Let p_1 and p_0 now denote the proportions of subjects exposed in the case and control groups, respectively. For a study with one control per case, the sample size required can be calculated by eqs (1)

and (2). For a study with k controls per case, the number of cases required is given by [36]

$$n = \frac{\left(\begin{matrix} z_{1-\alpha}\sqrt{((1+1/k)\overline{p}'\overline{q}')} \\ +z_{1-\beta}\sqrt{(p_1q_1+p_0q_0)}\end{matrix}\right)^2}{(p_1-p_0)^2},$$

where $\overline{p}' = (p_1 + kp_0)/(1+k)$ and $\overline{q}' = 1 - \overline{p}'$.

In practice, the exposure rate among controls, p_0, is usually obtained from previous studies and estimated from the general population. The **relative risk** $r = p_1/p_0$ or the **odds ratio** $(\mathrm{OR}) = p_1q_0/p_0q_1$ is then specified under the alternative hypothesis to calculate the power of the study. For example, consider a case–control study of a potential association between congenital heart defects and oral contraceptives used around the time of conception. An estimate of the exposure rate among controls is 30%. Given $\alpha = 0.05$ and $\beta = 0.10$, in order to detect a relative risk of $r = 1.5$ (so $p_1 = 0.45$), and based on (2), the sample size required is $n = 177$ (per group).

When an OR is specified, the exposure rate among cases can be solved as follows:

$$p_1 = \frac{p_0\mathrm{OR}}{[1 + p_0(\mathrm{OR} - 1)]}.$$

For the above example, the sample size required to detect an $\mathrm{OR} = 2$ (so $p_1 = 0.462$), given $\alpha = 0.05$ (two-sided) and $\beta = 0.10$, will be $n = 153$ (per group).

Continuous Exposure: Cohort Study

For a continuous exposure variable, sample size estimation methods for cohort studies have been derived by several authors (e.g. [24] and [44]). Let $p(x)$ be the probability of developing a disease with exposure level $X = x$ over a fixed follow-up time. Within the framework of **logistic regression**, the association between $p(x)$ and the continuous exposure variable X can be modeled as

$$\log\left[\frac{p(x)}{(1-p(x))}\right] = \delta + \theta x, \qquad (4)$$

where θ is the log OR for a unit increase in X. Testing the null hypothesis of no association is equivalent to testing H_0: $\theta = 0$.

Whittemore [44] derived sample size requirements for Wald tests based on maximum likelihood methods. To approximate the variance of the maximum likelihood estimate of θ, the disease probability is assumed to be small, i.e. $p(x) \approx 0$. Under this assumption, the total sample size for testing $\theta = 0$ with significant level α and power $1 - \beta$ is estimated by

$$N = \frac{\left[z_{1-\alpha}\sqrt{\nu(0)} + z_{1-\beta}\sqrt{\nu(\theta_\mathrm{a})}\right]^2}{[\theta_\mathrm{a}^2 \mathrm{e}^{\delta}]}. \qquad (5)$$

In formula (5), $\nu(\theta) = [m/(mm_{11} - m_1^2)](\theta)$ and $m(t) = \mathrm{E}[\exp(tX)]$ is the moment-generating function of X, and m_1 and m_{11} are the first and second partial derivatives of $m(t)$ with respect to t, respectively. The term e^{δ} is the odds of disease corresponding to $X = 0$ and θ_a is the log OR under the alternative hypothesis for a unit increase in the exposure X. Formula (5) is suitable to use when the sample size N is large. Tables for various distributions of exposure are given in Whittemore [44]. For example, when X has an N(0, 1) distribution, with $p(0) = 0.07$ (the disease probability in controls), $\exp(\delta) = p(0)/(1 - p(0)) = 0.075$, $\alpha = 0.05$ and power $= 0.90$, approximately $N = 543$ observations are needed to detect an OR of $\exp(0.5) = 1.65$ for a unit increase in the exposure X.

Lubin & Gail [24] studied a general method based on the score test statistic

$$U(\theta_0) = \partial \log \frac{L}{\partial\theta} = \sum_i x_\mathrm{i}(d_\mathrm{i} - p(x_\mathrm{i})) \qquad (6)$$

evaluated under the null hypothesis H_0: $\theta = \theta_0$, where L is the likelihood function for the logistic model (4) and d_i is a disease indicator (i.e. $d_\mathrm{i} = 1$ and $d_\mathrm{i} = 0$ for disease and nondisease, respectively). The total sample size required to test the null hypothesis with a significance level α and power $1 - \beta$ is given by

$$N = \frac{\left[z_{1-\alpha}\sqrt{\nu_0(U(\theta_0))} + z_{1-\beta}\sqrt{\nu_\mathrm{a}(U(\theta_0))}\right]^2}{[\Delta(\theta)]^2}, \qquad (7)$$

where $\nu_0(U(\theta_0))$ and $\nu_\mathrm{a}(U(\theta_0))$ are the variances of $U(\theta_0)$ under H_0: $\theta = \theta_0$ and H_a: $\theta = \theta_\mathrm{a}$, respectively; and $\Delta(\theta) = E_\mathrm{a}[U(\theta_0)]/N$. The evaluation will depend on the hypothesized parameters θ_0 and θ_a, as well as the statistical distribution of the exposure variable X. In general, special numerical calculation is needed to estimate the sample size. Details and some examples are given in Lubin & Gail [24].

Continuous Exposure: Case–Control Study

Lubin et al. [25] have derived sample size formulas for **case–control studies** with continuous exposure variables based on the logistic model (4) and score test (6). Let $F_1(x)$ and $F_0(x)$ be the distributions of exposure among cases and **controls**, respectively. It is shown that the number of cases required for a one-sided test with significance level α and power $1-\beta$ is given by

$$n = \frac{(k+1)}{k} \frac{\left[z_{1-\alpha}\sigma_x + z_{1-\beta}\sqrt{\left(\frac{k\sigma_1^2 + \sigma_0^2}{k+1}\right)} \right]^2}{(\mu_1 - \mu_0)^2}, \tag{8}$$

where k is the number of controls for each case (so total sample size $N = (k+1)n$), and (μ_1, σ_1^2) and (μ_0, σ_0^2) are the mean and variance of the exposure variable under F_1 and F_0, respectively; and

$$\sigma_x = \frac{(\sigma_1^2 + k\sigma_0^2)}{(k+1)} + \frac{(\mu_1 - \mu_0)^2 k}{(k+1)^2}.$$

The quantities μ_0, μ_1, σ_0^2 and σ_1^2 may be obtained from preliminary data such as previous studies that give estimates of the distributions of the exposure variable among cases and controls, or calculated from specifying the distribution functions of exposure in cases and controls, in which case numerical integration may be needed. The details are given in Lubin et al. [25].

When continuous exposure variables are dichotomized in the study (cohort or case–control), the required sample size will be increased due to loss of information from dichotomization. The efficacy losses will depend on the nature of the exposure distribution and the choice of the cutoff points for the dichotomization, as discussed in Lubin et al. [25].

Adjustment for Confounding Variables

Whittemore [44] extended the sample size formula (5) to adjust for **confounding** variables. When the joint multivariate variables $\mathbf{X}$ (a vector of the variable of interest X_1 and the confounding variables $X_2, \ldots, X_k$) follow an exponential family distribution, the variance term $v(\boldsymbol{\theta})$ can be obtained from the moment-generating function for $\mathbf{X}$. For example, when $\mathbf{X}$ has a multivariate normal distribution with mean μ and positive covariance matrix Σ, Whittemore showed that

$$v(\boldsymbol{\theta}) = \left[\mathrm{var}(X_1) \exp\left(\boldsymbol{\theta}'\boldsymbol{\mu} + \frac{\boldsymbol{\theta}'\Sigma\boldsymbol{\theta}}{2} \right) (1 - \rho_{1\cdot 2\ldots k}^2) \right]^{-1}$$

where X_1 is the exposure variable of interest, $\rho_{1\cdot 2\ldots k}$ is the multiple correlation coefficient relating X_1 to $X_2, \ldots, X_k$, and k is the total number of variables.

Lubin & Gail [24] proposed a general method for determining the sample size required to test whether exposure is associated with disease outcome, while adjusting for potential confounding variables. The method is based on a regression model and can be applied to both **cohort studies** and **case–control studies**. Let $\mathbf{X}$ be the joint multivariate variables of exposure and potential **confounders**. It is assumed that the probability of disease for $\mathbf{X} = \mathbf{x}$ is given by

$$p(\mathbf{x}; \delta, \theta, \lambda) = \frac{r(\mathbf{x})}{[1 + r(\mathbf{x})]} \text{ and } r(\mathbf{x}) = \mathrm{e}^{\delta} R(\mathbf{x}; \theta, \lambda),$$

where $R(\mathbf{x}; \theta, \lambda)$ is a smooth, positive function satisfying $R(\mathbf{0}; \theta, \lambda) = 1$, θ is the parameter of interest and λ is a vector of parameters (nuisance parameters) associated with the confounding variables. Thus, the **logistic regression model** (4) is a special case of this model when $R(\mathbf{x}; \theta, \lambda) = \exp(\mathbf{x}\theta)$. In fact, the function $R(\mathbf{x}; \theta, \lambda)$ can assume a multiplicative or additive form (*see* **Additive Model**; **Multiplicative Model**). For a one-sided test of the null hypothesis $\theta = \theta_0$ vs. the alternative $\theta = \theta_a$, a score test statistic is again given in (6). The total sample size required for a significance level α and power $1-\beta$ is given in (7). However, $v_0(U(\theta_0))$, $v_a(U(\theta_0))$ and $\Delta(\theta) = E_a[U(\theta_0)]/N$ contain the nuisance parameters δ and λ. For statistical analysis after data are collected, these parameters can be estimated by maximum likelihood. For sample size evaluation at the design stage, these parameters are replaced by δ_0 and λ_0 to which the maximum likelihood estimates $\hat{\delta}$ and $\hat{\lambda}$ (obtained under H_0: $\theta = \theta_0$) converge when the alternative hypothesis is true. The method works in general for both continuous or categorical variables as long as a joint distribution of $\mathbf{X}$ is specified. However, the sample size formula needs specialized numerical calculations based on the model specification for $R(\mathbf{x}; \theta, \lambda)$ and the joint distribution of $\mathbf{X}$.

An example discussed in Lubin & Gail [24] is to test the effect of radon exposure on lung cancer after

adjusting for smoking. They considered a multiplicative joint OR model,

$$R(\text{WLM, SMOK}) = (1 + \theta\ \text{WLM})(1 + \lambda\ \text{SMOK}),$$

where SMOK denotes the mean number of cigarettes smoked per day and WLM denotes exposure to radon decay products measured in working level months. They illustrated the use of this model to test the null hypothesis $\theta_0 = 0$, against the alternative hypothesis $\theta_a = 0.015$ for a five-year study assuming $\lambda_a = 0.3$. Based on prior knowledge, a five-year lung cancer mortality rate among nonsmokers is 0.00471. Therefore, $\delta = \log[0.00471/(1 - 0.00471)] = -5.354$. For a case–control study with $k = 5$ (number of **controls** per case), $\alpha = 0.05$ and power $1 - \beta = 0.90$, they showed that $n = 251$ cases are needed (number of controls $= 5n = 1255$). This is slightly larger than the 218 cases and 1086 controls required when the SMOK factor is ignored. This is because the confounding variable SMOK brings additional variability into the **multiplicative model**. The calculation assumes independence of the radon and smoking exposure distributions. Lubin & Gail [24] showed that the required sample size would be much larger if the radon and smoking exposures were highly and negatively correlated.

Adjustment for Stratification Factors

When samples are drawn from several strata, the **stratification** factors should be considered in the data analysis as well as in the sample size calculation at the design stage. When the probability of disease can be modeled in a **logistic regression**, the method for adjusting for **confounding** variables described above [24] can be used to estimate sample size. Smith & Day [40] provided extensive tabulation for the required sample size. They concluded that if the stratification factor is not strongly related to the exposure or disease status, then an increase of more than 10% in the sample size is unlikely to be needed.

Logistic regression is a special case of generalized linear models. Therefore, the methods proposed by Self & Mauritsen [38] and Self et al. [39] for generalized linear models can be used for sample size and power calculations. The methods are based on a score test and a likelihood ratio statistic, respectively. The sample size is estimated by treating the **stratification** factors as nuisance parameters. Their methods require, in general, specialized numerical calculations based on a specified joint distribution for the covariates in the model. See the section on a **cohort study** with Poisson outcomes for further discussion.

Other methods for sample size estimation for stratified studies can be found in the literature. For testing unity of a common OR for a collection of several 2×2 tables, Munoz & Rosner [28] studied sample size determination based on the Mantel–Haenszel test for stratified data (*see* **Mantel–Haenszel Methods**). Their method is appropriate when all margins of each table are fixed. Woolson et al. [45] and Nam [29] considered sample size calculations based on Cochran's test that do not require fixed margins of the 2×2 tables in each stratum. Nam used a continuity correction to guarantee that the actual type I error rate of the test does not exceed the nominal level.

Test for Interaction and Trend

When the question of interest is whether the relative risks among different strata (or levels of **confounding** factors) are equal, the problem becomes a test of **interaction** between exposure and the **stratification** factors (or confounding factors). Smith & Day [40] presented methods for evaluating power and sample size for testing the interaction between a dichotomous stratification variable and a categorical exposure. They showed that in order to detect an interaction effect of the same magnitude as a specified main effect, a sample size at least four times as large as for testing the main effect is required.

In general, tests for interaction can be addressed by testing appropriate coefficients in a **logistic regression** model. Within this framework, the methods developed by Lubin & Gail [24] and Self et al. [38, 39] can be used to estimate the required sample size. The methods will treat the interaction terms as the parameters of interest and treat all other factors as nuisance parameters. Usually, the methods need specialized numerical calculations. Garcia-Closas & Lubin [11] compared several methods for sample size calculations on testing gene-environmental interactions.

Testing for trend can also be addressed (*see* **Dose–Response**) within the framework of generalized linear models. For example, when an exposure variable X is ordered categorical, a trend test is to test whether the disease odds are proportionally increased as the exposure level increases. This is

equivalent to testing for a nonzero value of parameter θ in the logistic model (4). The methods developed by Lubin & Gail [24] and Self et al. [38, 39] can be used to estimate the required sample size.

Matched Case–Control Study

To improve comparability and efficiency in **case–control studies**, one may match **controls** with cases on potential **confounders**. A pair-matched study matches one control with each case, which is the simplest matched case–control design. When the number of cases is limited, more than one control can be matched to each case to increase statistical precision. For the matched case–control studies, the matching should be considered in the data analysis as well as in the sample size and power calculations (*see* **Matched Analysis**).

Pair-Matched Study

The probabilities of outcomes of a pair-matched case–control study are laid out in the following 2×2 table:

	Control		
Case	+	−	
+	π_{11}	π_{10}	$\pi_{1.}$
−	π_{01}	π_{00}	$\pi_{0.}$
	$\pi_{.1}$	$\pi_{.0}$	1

The "+" and "−" signs denote exposure and nonexposure status, respectively. Let m_{01} and m_{10} denote the number of (−+) and (+−) pairs for (case, control), and $m = m_{01} + m_{10}$ be the total number of discordant pairs. Conditional on m, the observation m_{10} has a binary distribution with $p = \pi_{10}/(\pi_{01} + \pi_{10}) = \psi/(1 + \psi)$, where $\psi = \pi_{10}/\pi_{01}$ denotes the disease–exposure OR.

The test of no disease–exposure association, i.e. H_0: $\pi_{01} = \pi_{10}$, is equivalent to testing H_0: $p = 1/2$. Schlesselman [36] gave a formula for the total number of discordant pairs m required to detect a relative risk R based on a normal approximation to McNemar's test,

$$m = \frac{\left[z_{1-\alpha}/2 + z_{1-\beta}\sqrt{(p(1-p))}\right]^2}{[p - 1/2]^2}. \qquad (9)$$

Suppose $\pi_d = \pi_{01} + \pi_{10}$ is the probability of obtaining discordant pairs. Then the total number of pairs for the study is estimated by

$$n = \frac{m}{\pi_d}. \qquad (10)$$

To estimate π_d, some additional information is required other than the OR ψ and the marginal exposure rate for **controls**, $\pi_{.1}$. When exposure for cases and controls within each pair is statistically independent, Schlesselman gives the following estimate:

$$\pi_d = \pi_{.1}(1 - \pi_{1.}) + \pi_{1.}(1 - \pi_{.1}),$$

where $\pi_{1.} = \psi\pi_{.1}/[1 + (\psi - 1)\pi_{.1}]$.

For example, Schlesselman shows that to detect an OR of $\psi = 2$, from (9) one requires $m = 90.3$ discordant pairs for $\alpha = 0.05$ (two-sided) and $\beta = 0.10$. For a control exposure rate $\pi_{.1} = 0.30$, assuming independent exposures, $\pi_{1.} = 0.46$, $\pi_d = 0.485$, and the total number of pairs required for the study is $n = 187$.

When the independence assumption does not hold, Schlesselman's sample size estimate may be severely biased (often underestimated). Several corrections have been proposed to allow for correlation between the exposure status within pairs that is often induced in the case of efficient matching. To allow for exposure association, Fleiss & Levin [7] used the exposure OR $\omega = \pi_{11}\pi_{00}/\pi_{01}\pi_{10}$ and corrected the estimation of discordant probability π_d given by Schlesselman. Under the independence assumption, $\omega = 1$. In the case of $\omega \neq 1$, the corrected estimate of the discordant probability is

$$\pi'_d = \pi_d \frac{\sqrt{(1 + 4(\omega - 1)\pi_1(1 - \pi_{1.}))} - 1}{2(\omega - 1)\pi_{1.}(1 - \pi_{1.})}.$$

In the above example, if $\omega = 2.5$, then the corrected $\pi_d = 0.376$. Therefore, the required number of pairs for the study is $n = 241$ rather than 187.

Dupont [6] presented another correction based on the contingency coefficient

$$\phi = \frac{\pi_{11}\pi_{00} - \pi_{10}\pi_{01}}{\sqrt{(\pi_{1.}(1 - \pi_{1.})\pi_{.1}(1 - \pi_{.1}))}}$$

for the case–control exposure association within a pair. The discordant probability π_d is adjusted as follows for specified ψ, $\pi_{.1}$ and ϕ,

$$\pi'_d = \pi_d - 2\phi\sqrt{(\pi_{1.}(1 - \pi_{1.})\pi_{.1}(1 - \pi_{.1}))},$$

where

$$\pi_{1\cdot} = \frac{\left[\begin{array}{c} 2\psi\pi_{\cdot 1}(\psi\pi_{\cdot 1} + 1 - \pi_{\cdot 1}) \\ +(\psi-1)^2\pi_{\cdot 1}(1-\pi_{\cdot 1})\phi^2 \\ -(\psi-1)\pi_{\cdot 1}(1-\pi_{\cdot 1})\phi\sqrt{(\phi^2(\psi-1)^2+4\psi)} \end{array}\right]}{2[(\psi\pi_{\cdot 1}+1-\pi_{\cdot 1})^2+(\psi-1)^2\pi_{\cdot 1}(1-\pi_{\cdot 1})\phi^2]}.$$

Several other methods are discussed and reviewed by Lachin [17] and Wickramaratne [39]. Lachin recommended always using a corrected procedure for sample size estimation. He pointed out that Dupont's correction and Fleiss & Levin's correction give very similar results. Qiu et. al. [32] proposed a sample size calculation method to test interaction between a specific exposure and a risk factor in a pair-matched case–control study.

Multiple Control per Case Study

For studies calling for k matched **controls** for each case (i.e. $1:k$ **matching**), Schlesselman gave an approximation for the required number of matched sets, $n' = (k+1)n/2k$, where n is calculated from (10) with given $\pi_{\cdot 1}$, ψ, test level α and power $1-\beta$. This approximation is valid when the exposure rates in cases and controls are similar.

Taylor [41] and Lui [26] studied other approximations that do not assume that the exposure rates in cases and controls are similar. Lui provided simulation results showing that when the OR of exposure between cases and controls is small ($\leq$4), his method gives more accurate results than that of Taylor; when ORs are large, the formula given by Taylor is recommended.

All three approximations (i.e. Schlesselman, Taylor and Lui) are based on the assumption of homogeneity of exposure among different matched sets. That is, the probabilities of exposure for cases and controls are constant across matched sets. Tables for the required number of case–control sets are given in Breslow & Day [2] for different values of power, significance level, relative risk and different matching ratios.

Two remarks are given as follows. First, a matched **case–control study** can be regarded as a special case of general stratified study in which each matching category is treated as a unique stratum. The methods discussed in the previous sections for unmatched case–control studies with confounding or **stratification** variables can therefore be used for sample size estimation. However, the methods may break down when the number of strata is large and data in each strata are sparse. Secondly, selection of the number of controls per case is more of a practical consideration (e.g. availability, time and cost) than a statistical power concern. In fact, the power gain is diminished when the number of controls is increased to beyond four controls per case (see [2]).

Cohort Study with Poisson Outcomes

When the number of events for a **cohort study** (e.g. diseases or deaths) is relatively small compared with the total number of subjects, the probability of events occurring may be modeled by a Poisson distribution (*see* **Poisson Regression**). In such studies, it is often interesting to test the rate of event incidence rather than the overall probability of events.

Dichotomous Exposure

In a cohort study with dichotomous exposure, Gail [9] presents methods to calculate power for studies with Poisson outcomes when the number of exposed and unexposed samples are equal. Let μ_1 and μ_0 be the incidence rate per unit time for the exposed and unexposed groups, respectively. We want to test H_0: $\mu_0 = \mu_1$ vs. H_a: $\mu_1 > \mu_0$. Two study designs are considered by Gail. Design A is to follow subjects until a predetermined total number of events is observed. Design B is to follow subjects up to a predetermined length of time. For design A, Gail provides a table for the total number of events for given **relative risk** $r = \mu_1/\mu_0$, significance level α and power $1-\beta$. Brown & Green [4] extend the method to the case of unequal group sizes. Tables are provided for the total number of events. For Design B, the event rate for the unexposed group, λ_0, is estimated from given relative risk, significance level α and power $1-\beta$. Tables are provided in Brown & Green [4]. Then, the expected duration of a study can be estimated as $t = \lambda_0/(\mu_0 n_0)$, where n_0 is the number of subjects in the unexposed group for the study that is specified by investigators.

When the expected number of events in the study is large, approximation formulas are presented in Gail [9], Brown & Green [4], as well as in

Breslow & Day [2]. Let k be the ratio between the numbers of subjects in the exposed and unexposed groups. For design A, subjects are followed until a certain number of events, say m, is observed. Conditioning on m, the number of events observed in the exposed group, follows a binomial distribution with probability $k\mu_1/(k\mu_1 + \mu_0) = rk/(rk + 1)$. On the basis of a normal approximation to the arcsine transformation of the square root of a binomial proportion, Brown & Green [4] give

$$m = \frac{[z_{1-\alpha} + z_{1-\beta}]^2}{4\left[\sin^{-1}\sqrt{(rk/(rk+1))} - \sin^{-1}\sqrt{(k/(k+1))}\right]^2},$$

where r is the relative risk between exposed and unexposed groups.

On the basis of a normal approximation to a binomial proportion, Breslow & Day [2] give

$$m = \frac{\left[z_{1-\alpha}\sqrt{k}/(k+1) + z_{1-\beta}\sqrt{(rk)}/(rk+1)\right]^2}{[rk/(rk+1) - k/(k+1)]^2}. \tag{11}$$

A more accurate estimate is obtained by using Yates' correction to the chi-squared significance test [42], which results in multiplying the right-hand side of (11) by $(1 + \sqrt{(1 + A)})^2/4$, where

$$A = \frac{2[rk/(rk+1) - k/(k+1)]}{\left[z_{1-\alpha}\sqrt{k}/(k+1) + z_{1-\beta}\sqrt{(rk)}/(rk+1)\right]^2}.$$

Brown & Green [4] present an example of a study to compare **incidence rates** of congenital malformations among children born in a specific town. A control population is identified that is twice as large as the town under study ($k = 0.5$). To have 90% power to detect a fourfold relative risk, $r = 4$, it is estimated that a total of $m = 20$ events will be needed (based on the table given in Brown & Green with $\alpha = 0.05$). Similar results are obtained from the approximation formulas. With Brown & Green's approximation, one obtains $m = 19$. With Breslow & Day's approximation, one obtains $m = 18$ without Yates' correction, and $m = 20$ with Yates' correction.

Loglinear Models

A loglinear model may be used to associate the event rate $\lambda(x)$ with the exposure level x; namely

$$\log[\lambda(x)] = \delta + \theta x. \tag{12}$$

A test of no association is equivalent to testing H_0: $\theta = 0$.

Sample size and power calculations for this model have been studied by Self et al. [38, 39]. They developed methods for generalized linear models based on the score test in their first paper and based on the likelihood ratio test in their second paper. The loglinear model for Poisson outcomes is a special case of the models they discussed. For a categorical exposure variable X (or a finite number of categorized configurations for a continuous variable), the required sample size is estimated from a noncentral chi-square approximation to the test statistic. However, there is no explicit sample size or power formula in general. Sample size determination is performed numerically for given nuisance parameters and distribution of X. Simulations are recommended to check the accuracy of the estimated sample size. Simulation results [39] show that the method based on the likelihood ratio statistic usually gives better results than that based on the score test.

Test for Trend with Categorical Variable

When the exposure variable X is ordered categorical with K levels ($K > 2$), a trend test can be used to assess whether the event rate $\lambda(x)$ changes monotonically with exposure (*see* **Dose–Response**). Breslow & Day [2] presented a method to estimate the sample size based on a chi-square trend test statistic. The test is based on a score statistic under a loglinear model for a Poisson distribution (*see* **Poisson Regression**). It contrasts the observed number of events, O_k, with the expected number of events, E_k, calculated from external rates. Let x_k be the kth exposure level of X. Then the power of the test is the probability such that

$$\sum_{k=1}^{k} O_k \left[x_k - \frac{\sum_j x_j E_j}{\sum_j E_j} \right] - z_{1-\alpha}\sqrt{V} \geq 0,$$

where $z_{1-\alpha}$ is the $(1-\alpha)$th percentile of the standard normal distribution and

$$V = W \sum_k O_k$$

and

$$alW = \frac{\left[\sum_k x_k^2 E_k - \left(\sum_k x_k E_k\right)^2\right]}{\sum_k E_k}.$$

Under an alternative of a linear trend in relative risk such that $r(x) = 1 + \theta x$, the left-hand side of the probability equation will have mean μ approximated by

$$\mu = \sum_k \theta x_k E_k \left[x_k - \frac{\sum_j x_j E_j}{\sum_j E_j}\right] - z_{1-\alpha}\sqrt{\left(W \sum_k (E_k + \theta x_k E_k)\right)}$$

and variance σ^2 approximated by

$$\sigma^2 = \sum_k (1 + \theta x_k) E_k \left[x_k - \frac{\sum_j x_j E_j}{\sum_j E_j}\right]^2 - z_{1-\alpha} \sum_k \theta x_k E_k \left[x_k - \frac{\sum_j x_j E_j}{\sum_j E_j}\right] \times \sqrt{\frac{W}{\sum_k E_k} + \frac{z_{1-\alpha}^2 W}{4}}.$$

Therefore, the expected number of events for given test level α and power $1-\beta$ should satisfy $\mu = \sigma z_{1-\beta}$. This equation can be used to solve for the number of events required for the study under a given distribution for the exposure variable X and alternative hypothesis $\theta = \theta_a$. Numerical methods are needed, in general, except for some special cases; see [2] for details and examples.

Survival Study

In a cohort study, when the time to an event (e.g. disease or death) is observed exactly or within a certain interval, survival analysis can be used for the comparison of incidence rates (*see* **Survival Analysis, Overview**; **Proportional Hazards, Overview**; **Cox Regression Model**). Survival analysis uses not only the number of events but also the time when an event occurs. This often brings more information for comparing event rates than a method using the number of events alone. The survival function $S(t)$ is a probability function that an individual will survive or be disease free up to a certain time point t. The hazard function is defined as

$$\lambda(t) = -\frac{\mathrm{d}S(t)/\mathrm{d}t}{S(t)}.$$

It measures an instantaneous mortality or morbidity risk relative to a survival probability at that time. A commonly used model for survival analysis is the proportional hazard model, which assumes that hazard functions for two groups satisfy

$$\lambda_1(t) = \psi \lambda_2(t).$$

It is of interest to test the constant hazard ratio $\psi = 1$ or the constant log hazard ratio $\theta = \log(\psi) = 0$ (*see* **Hazard Rate**; **Relative Hazard**).

In a survival study, it is uncommon to observe the actual event time for all subjects. Usually, for some subjects, time to event is censored by the end of the study or at some time point when the subject is lost to follow-up. The statistical power of testing $\theta = 0$ depends principally on the number of events actually observed.

Calculating the Number of Events

For a given alternative on the log hazard ratio, $\theta = \theta_a$, test significance level α and statistical power $1-\beta$, the required total number of events is estimated as

$$D = \frac{4(z_{1-\alpha} + z_\beta)^2}{\theta_a^2} \qquad (13)$$

based on a score test under the proportional hazard model [37]. For example, to detect a hazard ratio of 1.5 with $\alpha = 0.05$ (two-sided) and $1 - \beta = 0.90$, the required number of events is $D = 256$.

An alternative approximation to the required total number of events based on a normal approximation to the log rank statistic, assuming constant hazard ratio $\psi_a = \exp(\theta_a)$, is given by Freedman [8] as

$$D = \frac{(z_{1-\alpha} + z_\beta)^2(\psi_a + 1)^2}{(\psi_a - 1)^2}. \qquad (14)$$

Simulation results show that this approximation usually provides a slight overestimate for the total number of events [8]. When θ_a is small (close to 0), expressions (13) and (14) will give similar estimates for the total number of events. For the above example, $\psi_a = 1.5$, the required number of events based on (14) is $D = 263$ instead of $D = 256$ from formula (13).

The sample size formulas (13) and (14) are obtained assuming an equal number of subjects allocated in the two study groups. If this is not the case, then the required total number of events corresponding to formula (13) is

$$D = \frac{(z_{1-\alpha} + z_\beta)^2}{\pi_1 \pi_0 \theta_a^2},$$

where π_1 and $\pi_0 = 1 - \pi_1$ are the proportions of subjects to be allocated to the two groups. The corresponding formula for (14) under unequal number of subjects in the two groups is

$$D = \frac{(z_{1-\alpha} + z_\beta)^2(\pi_1 \psi_a + \pi_0)^2}{\pi_1(\psi_a - 1)^2}.$$

Calculating the Number of Subjects

Suppose P is the average probability of an individual having an event in the study population. Then the total number of subjects required for the study is approximately $N = D/P$, where D is the total number of events required for the study.

If a study enrolls all subjects at once (e.g. a **cohort study**) and follows every subject up to time f, then the probability P can be estimated by $P = 1 - S(f)$, where S is an average of the two survival functions for the two study groups; that is, $S(t) = [S_0(t) + S_1(t)]/2$ at any time t.

In many cases, the survival function is approximated by an exponential distribution; that is, $S_0(t) = \exp(-\lambda_0 t)$ and $S_1(t) = \exp(-\lambda_1 t)$. The parameters λ_0 and λ_1 can be obtained from the specified median survival time for the corresponding survival functions. Continuing from the example above, where the hazard ratio to be detected is 1.5, suppose the median survival times for the unexposed and exposed subjects are two and three years, respectively. Then $\lambda_0 = 0.347$, $\lambda_1 = 0.231$ and $S(t) = [\exp(-0.347t) + \exp(-0.231t)]/2$. If the study has a three-year follow-up, then the required total sample size can be estimated as $N = 256/0.573 = 447$ based on (13), and $N = 263/0.573 = 459$ based on (14).

In experimental and cohort studies, subjects may be enrolled within a period of time, say from 0 to time T (*see* **Cohort Study**; **Experimental Study**). The follow-up time for subjects in the study can be anywhere between f (for the last recruited subject) and $T + f$ (for the first subject in the study). The probability of events for the study can be approximated by an average using Simpson's rule [37]; that is,

$$P = 1 - \frac{1}{6}[S(f) + 4S(0.5T + f) + S(T + f)],$$

where $S(t)$ is again the average of the two survival functions.

Lachin & Foulkes [18] presented a sample size and power calculation method based on exponential distributions. Their method allows for adjustment on the staggered entry of subjects, loss to follow-up (including deaths from **competing risks**), **stratification**, drop-in and lag in the effectiveness (or exposure effect) during the course of study. Lakatos [19] extended the method using the log rank statistic. Simulation studies show that Lakatos's method [19] is robust even when the proportionality assumption is not satisfied [20]. Other factors can influence sample size, including lack of **sensitivity** in making diagnoses and alternative methods of analysis such as comparison of two Kaplan–Meier curves (see, for example, [10]).

Longitudinal Studies

Longitudinal studies have become popular as the methods for longitudinal data analysis became available (see, for example, [5]). In a longitudinal study, repeated measures are taken from a subject over

a period of time. A longitudinal study will provide information (e.g. time effect for individuals) that cannot be obtained by a **cross-sectional study**. This type of study can be used for time-dependent exposures (e.g. smoking, alcohol use, diet, stress, blood pressure) and/or recurrence outcomes (e.g. pain, allergy, asthma, depression). Data from a longitudinal study require special statistical methods because the repeated measures from the same subject tend to be correlated. It is therefore required to consider the correlation among repeated measures while planning the sample size and power for a longitudinal study.

Dichotomous Exposure

The impact of repeated measures on sample size calculations can be illustrated by comparing the average differences in a continuous response. Suppose k repeated measures are taken from each subject, assume the correlation coefficient between any two measures is ρ, then the average of the k measures has variance

$$\text{var}(\overline{Y}) = \frac{1}{k}[1 + (k-1)\rho]\sigma^2,$$

where σ^2 is the variance of each response measure. Assume the variance and correlation are the same under the null and alternative hypotheses. Then the sample size required to detect a difference Δ with significance level α (one-sided) and power $1 - \beta$ is

$$n = \frac{2(z_{1-\alpha} + z_{1-\beta})^2[1 + (k-1)\rho]\sigma^2}{k\Delta^2} \qquad (15)$$

for each group [5, Chapter 2]. The correlation ρ will usually be positive. Therefore, the larger the value of ρ, the larger the required sample size for the study. This is because there is less independent information gained from each repeated measurement as ρ approaches 1. When $\rho = 1$, the number of subjects required is the same as in a study with one measurement per subject.

For example, consider a **cohort** (or **experimental**) **study** to investigate the association of a certain diet with total cholesterol level. Subjects in the study will have their total cholesterol measured quarterly for a period of a year. Suppose a standard deviation of 80 is assumed for each measure and the correlation between any two measures is $\rho = 0.5$. With $\alpha = 0.05$ and power = 90% to detect a 20-point difference, we will need $n = 172$ per group based on (15).

For a binary response variable, the sample size for a longitudinal study with repeated measures can be obtained similarly. Suppose p_0 and p_1 are the proportions of subjects who develop the disease in the unexposed and exposed groups, respectively. Then the required sample size for a longitudinal study with k repeated measures is estimated as [5, Chapter 2]

$$n = \left(z_{1-\alpha}\sqrt{(2\overline{pq})} + z_{1-\beta}\sqrt{(p_1q_1 + p_0q_0)}\right)^2 \times \frac{[1 + (k-1)\rho]}{[k(p_1 - p_0)^2]}, \qquad (16)$$

where $q_1 = 1 - p_1$, $q_0 = 1 - p_0$, $\overline{p} = (p_0 + p_1)/2$, and $\overline{q} = 1 - \overline{p}$. The quantity ρ is the correlation coefficient of the binomial response variable between any two repeated measures. It is assumed to be the same for all subjects under the null and alternative hypotheses. Because the binomial response takes values of 0 or 1, unlike for normal distributed data, the correlation coefficient ρ is constrained in complicated ways (see [5]). For repeated measures, the correlation ρ is usually positive and its value may range in $[0, b]$, where b can be less than 1.

In the above example, if the total cholesterol is dichotomized and the threshold for elevated total cholesterol is 200, then the response will be binomial (yes/no). If one assumes a correlation of 0.5 between any two responses, with $k = 4$ repeated measures, $p_1 = 60\%$ and $p_0 = 70\%$, a sample size of $n = 243$ per group is required to detect a 10 percentage point difference in elevated total cholesterol, with $\alpha = 0.05$ and power = 90%.

Generalized Estimating Equation Method

In general, Liu & Liang [23] presented a method for computing sample size and power for studies with longitudinal observations using the generalized estimating equation (GEE) method. Suppose μ_{ij} is the mean of the ith subject at the jth measure. The generalized linear model with a link function of g is given as

$$g(\mu_{ij}) = X_{ij}\boldsymbol{\theta} + Z_{ij}\boldsymbol{\lambda},$$

where $\boldsymbol{\theta}$ is a vector of parameters of interest, $\boldsymbol{\lambda}$ is a vector of nuisance parameters, and X_{ij} and Z_{ij} are covariates related to study design. The sample

size required for testing H_0: $\boldsymbol{\theta} = \boldsymbol{\theta}_0$ vs. H_a: $\boldsymbol{\theta} = \boldsymbol{\theta}_a$ is derived based on a quasi-score test statistic.

The method can be applied to generalized linear models with longitudinal observations such as linear models for continuous responses, logistic models for binomial response, and loglinear models for Poisson responses. However, there is no explicit sample size formula except for some simple special cases, for which the sample size formulas are provided in Liu & Liang [23]. The sample size or power values are estimated numerically, in general.

To calculate sample size and power, we have to specify the values of the parameters of interest as well as the nuisance parameters under the alternative hypothesis. In addition, the element of the correlation matrix for the longitudinal observations has to be specified, and this is usually the most difficult part. Information about correlation may be obtained from previous studies. In the case of no prior information about the correlation, a sensitivity analysis may be performed using various correlation values based on the investigator's judgment. The sample size for the study may be taken conservatively based on the sensitivity analysis.

On the basis of the GEE method, explicit sample size formulas are obtained by Liu et al. [22] for comparing two means, two slopes and two proportions under several simple correlation structure.

Estimation and Precision

The sample size determinations discussed so far are based on achieving a certain probability (power) to detect a given alternative for a specified statistical hypothesis test. When the problem of interest is to estimate the magnitude of the effect, e.g. the disease–exposure **odds ratio**, the study planning must focus on the precision of the estimate, which is often measured by the width of a confidence interval. In general, the sample size required for the study should be increased if the confidence level is increased, the variability associated with the measure is increased, or the total width of the confidence interval is reduced.

There are two different approaches to determining sample size based on the width of a confidence interval. One is to have the expected width of the confidence interval sufficiently small. Another is to have a tolerance level to guarantee that the width of the confidence interval will be within a given precision limit. In the latter case, the width of a confidence interval is regarded as a random variable. The latter approach usually requires larger sample sizes than the former. In this section we illustrate the two approaches to determining sample size for estimating ORs and standardized mortality ratios.

OR

Consider a 2×2 table generated from an unmatched case–control study:

Exposure	Case	Control	
Yes	n_{11}	n_{10}	$n_{1.}$
No	n_{01}	n_{00}	$n_{0.}$
	$n_{0.1}$	$n_{0.0}$	n

The OR is estimated by

$$\mathrm{OR} = \frac{n_{11}n_{00}}{n_{01}n_{10}}.$$

For the first approach, O'Neill [31] derived a sample size equation by replacing the cell counts with their expected values and then using a logit method to calculate the confidence interval width. To have the expected width of the $1-\alpha$ confidence interval less than 2δ, for given values of true OR, exposure rate π_0 for the control group, and the case–control ratio k (i.e. $k = n_{.0}/n_{.1}$), the number of cases required is

$$n_{.1} = \left[\frac{1}{\pi_1(1-\pi_1)} + \frac{1}{\pi_0(1-\pi_0)}\right]\left[\frac{z_{1-\alpha/2}}{\delta}\right]^2,$$

where π_1 is the exposure rate for the case group, which can be calculated as $\pi_1 = \pi_0\mathrm{OR}/[1 + \pi_0(\mathrm{OR} - 1)]$.

For the second approach, a $1-\alpha$ confidence interval for ln(OR) is obtained from the normal approximation (e.g. [1, Chapter IV]),

$$\ln(\mathrm{OR}) \pm z_{1-\alpha/2}\left[\frac{1}{n_{11}} + \frac{1}{n_{00}} + \frac{1}{n_{10}} + \frac{1}{n_{01}}\right]^{1/2}.$$

The precision of the estimate can be evaluated by the probability of the confidence interval being within $[-\delta, \delta]$. That is,

$$P\left(z_{1-\alpha/2}\left[\frac{1}{n_{11}} + \frac{1}{n_{00}} + \frac{1}{n_{10}} + \frac{1}{n_{01}}\right]^{1/2} \le \delta\right) = 1 - \beta.$$

The probability $1 - \beta$ is called the tolerance probability. The sample size required for the study is obtained by solving this equation for given values of the true OR, α, β, δ, the exposure rate π_0 for the control group, and the case–control ratio k. Numerical computation is needed to solve the equation for n. Satten & Kupper [35] provided tables (as well as a computer program) for the minimum sample size required to produce a 95% confidence interval of total width not greater than 2δ with probability $1 - \beta$ for various values of δ, k, OR, and π_0.

Satten & Kupper [35] also gave an example for a case–control study. The anticipated OR for the study population is no smaller than 3. For a probability of exposure in controls $\pi_0 = 0.05$, with tolerance probability $1 - \beta = 0.90$, $k = 1$, and in order to have the width of the 95% confidence interval no more than 1.5, $n = 271$ cases are required (with $k = 1$, the number of controls is the same). With O'Neill's method, the required number of cases is $n = 202$.

Standardized Mortality Ratio

The standardized mortality ratio (SMR) is the ratio between the observed number of events and the expected number of events. The latter quantity is usually derived from external studies or vital statistics and is assumed to be known and fixed (*see* **Vital Statistics, Overview**). The SMR is a common measure of **relative risk** in occupational epidemiologic studies (*see* **Occupational Epidemiology**).

Assume the observed number of events d in a cohort study follows a Poisson distribution with mean λ. The confidence interval of the SMR is obtained by finding the corresponding confidence limits for λ and then dividing these limits by the expected number of events. Using the relation between the Poisson distribution and the chi-squared distribution, Gordon [12] derived the $1 - \alpha$ confidence interval for λ as

$$(\lambda_L, \lambda_U) = \left[\tfrac{1}{2}c_{\alpha/2}(2d), \tfrac{1}{2}c_{1-\alpha/2}(2d+1)\right],$$

where $c_\alpha(k)$ is the αth quantile of a chi-squared distribution with k degrees of freedom.

The expectations of λ_L and λ_U, and the expected width of the interval are

$$E(\lambda_L) = \sum_{d=1}^{\infty} \frac{1}{2} c_{\alpha/2}(2d) \frac{\lambda^d}{d!} \exp(-\lambda),$$

$$E(\lambda_U) = \sum_{d=0}^{\infty} \frac{1}{2} c_{1-\alpha/2}(2d+1) \frac{\lambda^d}{d!} \exp(-\lambda),$$

$$E(w) = E(\lambda_U) - E(\lambda_L).$$

Tables are given by Gordon [12] for these expected values for various values of λ, which can be used to determine the expected number of events given the true SMR and an upper limit, a lower limit or the width of the confidence interval.

The sample size obtained by Gordon is based on the first approach without having a tolerance level to guarantee the precision. The estimated sample size will be too small to distinguish the SMR from a specified value [15]. For example, to have the upper bound of the 95% confidence interval no more than 1.0 when the true SMR is 0.7, the expected number of events estimated by Gordon's method is 42.9. However, this sample size will have only a 50% chance of yielding a 95% confidence interval, which will exclude the value 1.0 when the true SMR is 0.7.

On the basis of the second approach, Greenland [15] provided a method to estimate the sample size needed so that the confidence interval can reliably distinguish between two different values of the SMR. He concluded that the sample size obtained will be similar to that based on a hypothesis test to compare the two specified SMR values. For the above example, in order to have a 90% chance that the upper 95% confidence interval be smaller than 1.0 when the true SMR is 0.7, the required number of events is 98.4. This sample size can also be obtained from a hypothesis test that compares SMR = 0.7 vs. SMR = 1.0, with significance level 0.05 and power of 90%.

Further Issues and Discussion

Exact Methods

As computing technology advanced in recent years, exact methods were developed for analyses of studies with categorical observations. These methods provide exact test p-values that may be quite different from the asymptotic p-values when the sample size and/or the probability of events is small. If it is planned to use exact methods for the analysis, then it is preferable to estimate the sample size for the study based on the same exact approach.

For pair-matched **case–control studies**, a number of papers have been published for calculating sample size and power based on McNemar's test. Lachin [17] compared several unconditional sample size and power calculation methods (*see* **Matched Analysis**). Royston [34] published tables of sample sizes based on the conditional and unconditional approaches.

For ordered categorical data, Hilton & Mehta [16] developed an algorithm for computing sample size and exact power. They also considered a Monte Carlo method for power estimation. They pointed out that the asymptotic power function works well when the number of categories is not too small (e.g. more than five categories).

Lui [27] considered sample size estimation for the exact conditional test under inverse sampling, in which one continues to sample subjects until one obtains a predetermined number of index subjects (e.g. events). Under inverse sampling, the number of events to be observed for each exposure group is fixed, and the number of subjects to be sampled follows a negative binomial distribution. Conditional on the total number of subjects, a conditional test is used to compare event rates for the two groups. On the basis of a numerical approximation, tables are provided for the minimum required number of events given events rates, significance level = 0.05 and power = 0.80 or 0.90.

Adjustment for Loss to Follow-up and Missing Data

In studies where loss to follow-up or **missing data** occur, the planned sample size should reflect the information loss to maintain the desired statistical power. If loss to follow-up or missing data are purely by chance (missing completely at random), then a simple adjustment on the sample size is to enlarge the required sample size by the proportion of information loss. For example, suppose the required sample size for a cohort study is 400 subjects per group and a 20% loss to follow-up rate is assumed, then the total number of subjects for the study may be enlarged to 500 (= 400/(1−0.2)) per group. This simple adjustment provides a conservative sample size estimate if the partial data obtained from the lost to follow-up subjects can be used in the statistical analysis (e.g. in longitudinal analysis models). If we know that 25% data from the 20% lost to follow-up subjects can be used in the analysis, then a refined sample size adjustment is $n = 400/(1-0.15) = 471$.

This simple adjustment can also be used for the case when missing data are missing at random, i.e. the probability of missingness depends on at most the data already observed but not on the missing data [21]. However, when data are not missing at random (nonignorable missingness), the probability of missingness will depend on the missing data. In this case, it can be difficult to compute the proportion of missing information. Further discussion of missing data is beyond the scope of this article and can be found in Little & Rubin [21] (*see* **Missing Data in Epidemiologic Studies**).

Computation and Software

Several commercial software packages are currently available for sample size and power calculations (*see* **Software, Biostatistical**; **Software, Epidemiological**). They include EGRET-SIZ by Cytel Software Corporation, SamplePower by SPSS Inc., nQuery Advisor by Statistical Solutions, and PASS by Number Cruncher Statistical Systems. EGRET-SIZ is the only package for sample size and power calculations with the main focus on epidemiologic studies. It provides sample size estimates for four specialized statistical models including **logistic regression** (for **cohort** and unmatched **case–control studies**), **Poisson regression**, **conditional logistic regression** and **Cox** proportional hazards **regression**. A good feature of EGRET-SIZ is that there is a Monte Carlo procedure for one to verify the estimated sample size and obtain empirical power. SamplePower, nQuery Advisor and PASS provide sample size estimates for a broad range of statistical models including tests for means, proportions, analysis of variance (ANOVA), regression and survival analysis. Most of the software packages can be used to estimate one of the parameters among sample size, power, minimum detectable effect, variances, and test significance level, provided the other parameters are specified. Some of the packages (e.g. nQuery, SamplePower) have modules to estimate sample size from the given width of a confidence interval.

Other "freeware" may be found in public health service organizations or from individual statisticians. For example, "Epi info" from the Centers for Disease Control and Prevention provides some sample size estimation routines for cohort and case–control studies. A SAS module/macro for sample size analysis, "UnifyPow", has been developed and distributed

by O'Brien [30]. Many computer codes for some specific and complex statistical methods may be obtained directly from the authors who developed these methods. For example, a power and sample size module for testing **interaction** has been developed by Lubin and colleagues at the National Cancer Institute based on a paper by Lubin & Gail [24]. A sample size calculation module is included in EPITOME, an epidemiologic data analysis package developed at the National Cancer Institute.

Although many approaches and software packages can be used to calculate sample size, care should always be taken to formulate the study problem in the framework that the computer software requires. It is necessary to follow the program instructions or user's manual to provide input parameters for the computer packages. In all cases, it is important to understand the statistical procedures for which the computer package is calculating the sample size or power. Otherwise, the calculated sample size can be erroneous and lead to an underpowered or overpowered study.

Discussion

Sample size determination is a very important aspect of the design of any study. It often helps to clarify important features of a study protocol. Investigators will not be able to calculate sample size without fully understanding the nature of the measurements to be taken, specifying the planned analysis (test statistic or estimation procedure, significance level and study power), and obtaining preliminary information on the effect to be detected and the variability of the measurements. Some important information can often be obtained from reviewing the literature or discussions with other investigators who conducted previous studies.

In practice, sample size and power evaluation may be an iterative learning process. The parameters and distribution characteristics obtained from previous studies can be used to estimate the required sample size for planning the current study. If there is no previous information for a new investigation, then a pilot study may be designed to gain some knowledge about the parameters and distribution. The results from this pilot study will then provide information for designing the main study. The iterative process may be integrated to form a two-stage design in which the results from the pilot study (first stage) will be used to guide the sample size estimation for the second stage. The data from both stages will be used for the final data analysis. For instance, the impact of additional follow-up in cohort studies was investigated by Brookmeyer et al. [3]. In randomized clinical trials, Gould [13] and Gould & Shih [14] presented methods to adjust the sample size during the course of a study.

Group sequential procedures have been considered for experimental studies by health researchers, in which investigators are allowed to have several interim analyses. Each interim analysis not only provides a preliminary estimation of the parameters of interest before the completion of the study, but also offers a chance to terminate the study early when there is sufficient evidence to reach a conclusion (either positive or negative). Although this sequential approach has mainly been used and advocated for **experimental** and **case–control studies** (*see* **Case–Control Study, Sequential**), the idea can be used in **cohort studies** by performing interim analyses when partial follow-up data are available. However, there is usually less ethical pressure for early termination of **observational** epidemiologic studies than **experimental studies** such as randomized clinical trials. Furthermore, the need for a large sample size is often stressed in epidemiologic studies in order to estimate the parameters of interest with precision. For these reasons, sequential methods have not gained widespread acceptance and use in epidemiologic studies.

Usually, new statistical methods are developed for data analysis before they are considered in sample size estimation for designing studies. For some complicated study designs and statistical models, sample size estimation methods may not be available (e.g. case–cohort design, two-stage case–control studies, and structural models for causal inference; see [33]). Further research will be needed on sample size estimation for these specialized study designs and statistical models (*see* **Case–Cohort Study**; **Case–Control Study, Two-phase**).

Two approaches may be considered to estimate sample size for a complicated study when there is no sample size estimation method available. First, a Monte Carlo simulation may be conducted to estimate the power empirically for several fixed sample sizes and thus to find the sample size that yields the required power. Today's powerful computation tools make this approach feasible. The second approach is

to approximate the sample size by using a simplified study design and/or statistical model for which a sample size estimation method is available. The simple model should be chosen so that it requires at least as large a sample size as would be required by the more complex and presumably more efficient analysis. There is a tradeoff between using simpler methods and using more sophisticated models for sample size estimation. At the design stage, prior information about the parameters of the statistical models may be limited. Sample size estimation requires fewer assumptions with simplified statistical models than with more sophisticated models. Unless the assumed values of parameters and forms of distributions are accurate for the designed study, the sample size estimated from the sophisticated models may be inaccurate due to misleading assumptions. Simplified methods, on the other hand, can be more robust because of fewer assumptions.

Sample Surveys in the Health Sciences

Reasons for Conducting Sample Surveys

Perhaps the most compelling argument for using a sample survey rather than complete enumeration is that for the same cost a sample survey can provide results more accurately, with greater scope, and faster. Studying a well-chosen sample can increase accuracy by reducing **bias** and by increasing precision of the results. By reducing the number of people to be studied, a sample survey can devote more resources to finding and persuading nonresponders to participate, thus reducing **nonresponse**. Fewer interviewers are required, so that more effort can be devoted to training and monitoring them for accuracy. Replicate measurements may be made to increase the precision. Sample surveys can also take advantage of the smaller sample size and more intensive effort for each person to ask more questions or make more detailed measurements, thus broadening the scope of the questions addressed. Finally, sample surveys may be able to reduce the total time to collect and analyze the data, thus providing more timely answers to important questions.

A second important reason for the use of sample surveys is feasibility. When the **target population** is very large, such as the entire population of the United States, a moderate-sized sample survey, if well designed, can provide highly accurate results at substantially less cost than a complete enumeration. The cost of a complete enumeration can be substantial both for the researchers and for the participants; one motivation for using sample surveys is when the respondents are institutions such as hospitals.

The desire to study certain subgroups in more depth also leads people to use sample surveys. Policy issues may require valid estimates for children, people aged 65 and older, women, African-Americans, Hispanics, rural residents, or other subgroups in the population. A sampling design can oversample from important subgroups to increase precision and to ensure that their health can be characterized accurately.

Recently, epidemiologic studies have begun to take advantage of the ability of sample survey designs to increase **power** and reduce bias in studies of risk factors for disease onset and progression (*see* **Observational Study**). The power to conduct comparative analyses of risk factors is largely determined by the number of **prevalent** or **incident** disease cases identified for study. To increase the number of cases, researchers can increase the sample size or the length of follow-up, an expensive strategy, or try to increase the proportion of disease cases in the sample by oversampling groups at high risk. A clever design can improve power substantially. Sample surveys also help reduce bias for epidemiologic studies by providing a truly comparable group of unaffected people, sampled from exactly the same population in which the affected group was identified (*see* **Controls**). A recent study of Alzheimer's disease in people aged 65 and older in the community in East Boston, Massachusetts, used a **stratified sample** design to oversample from the oldest age groups and those with poor performance on a simple memory test. When a neurologist examined the resulting sample, about 35% were found to have clinical Alzheimer's disease, compared with an estimated prevalence of 10% in the community. In addition, the **mean** age of the unaffected comparison group was much closer to that of the Alzheimer's group in this sample than in the community, and both diseased and disease-free participants had received the same interviews and clinical evaluation [13].

Some History of Sample Surveys

Early Developments at the US Bureau of the Census

In the early part of the twentieth century, the importance of using **random sampling** in surveys was not generally recognized. Units to be canvassed were still selected purposively, with the survey managers deciding which units would be most "representative" of the population of interest (*see* **Quota, Representative, and Other Methods of Purposive Sampling**). **Probability theory** had yet to be applied. In the 1930s, more attention was being paid to **R. A. Fisher's** work on the importance of **randomization** in **experimental design** In 1934, **J. Neyman's** paper [43] arguing in favor of random sampling and establishing the theoretical foundation for it, appeared in the *Journal of the Royal Statistical Society* (see also [55]). These developments in statistical theory laid the groundwork for modern sample surveys. However, the key

catalyst for the incorporation of probabilistic sampling into the selection of units in sample surveys (*see* **Probability Theory**) was the increasing need for reliable estimates to use in policy-making.

At the US Bureau of the Census, the first application of probabilistic sampling was in a 1937 "check census" of unemployment. The Bureau used postmen as canvassers, choosing two out of every 100 postal routes. The success of this early foray into probabilistic sampling was possibly a decisive moment for those decision makers who were skeptical of the value of nonpurposive methods [11].

In the 1940 decennial **census** of population and housing, the first "long form" sample was introduced: 5% of the population was asked a set of questions in addition to the key census battery. This approach is still an integral part of the decennial census, enabling the Census Bureau to collect more detailed data without overburdening all respondents, and at a moderate cost [1, 18, 49].

In 1942, the Bureau was given the Work Projects Administration's Monthly Report on the Labor Force (MRLF), from which were derived unemployment estimates. In order to develop an efficient sample design for this survey, the Bureau statisticians under the direction of Morris Hansen and William Hurwitz found that they had to develop totally new theory for the design of sample surveys. Major new developments included sampling with unequal probabilities, **cluster sampling**, optimization in **multistage sampling**, and **estimation** methods. These are now considered standard sampling methods for face-to-face household surveys. Under the direction of Hansen and Hurwitz, a relatively small research staff made further contributions to sampling methods. One of the more public products of this work, a two-volume text by Hansen, Hurwitz, and William G. Madow published in 1953 [22], still stands as a classic work in statistics.

The MRLF, later named the Current Population Survey, provided a laboratory for research into sampling and other statistical aspects of survey methods. It also became a model for household surveys all over the world. Other current US demographic surveys have used the same basic design. These include: The National Crime Survey (now The National Crime Victimization Survey), The National Health Interview Survey, The Survey of Income and Program Participation, The American Housing Survey (formerly The Annual Housing Survey), and The Consumer Expenditure Quarterly and Diary Surveys. Data for all of these surveys are collected by the Bureau of the Census, typically for sponsoring agencies who publish the estimates from the surveys. Most of these surveys use as their basic frame (*see* **Sampling Frames**) the list of housing units obtained from the decennial census; this list is supplemented by frames for new construction and other special categories. Characteristics of those housing units and their occupants are used to stratify units within counties and to group counties within primary strata.

Extensions of the Survey Methodology to Other Fields of Study

The combination of the success of the sample survey method developed and used by the Census Bureau in the 1940s and 1950s in providing population, housing and economic data, and the need for new data on health characteristics of the population led to the adoption of sampling techniques in conducting national health surveys, beginning in 1957 and continuing until the present time (*see* **Surveys, Health and Morbidity**).

It had been established in the 1920s that community studies of illness and disability were feasible, and a major health survey to obtain data on diseases, injuries, and impairments in the general population of the United States was conducted from 1935 to 1936 [41]. Following this survey, additional community studies on morbidity led to the formation of the US National Committee on Vital and Health Statistics in 1949, which ultimately recommended "That a continuing national morbidity survey be conducted... Its purpose would be to obtain data on the prevalence and incidence of disease, injuries and impairments, on the nature and duration of the resulting disability, and on the amount and type of medical care received. The data would be obtained from a probability sample of households" [41]. Thus, what is now known as the National Health Interview Survey (NHIS) was begun.

The data from these continuing surveys have been used extensively by the US Federal government in setting policy and developing programs for the continued benefit of the population. Perhaps, the largest such program ever enacted is the national health insurance program for the elderly, known as **Medicare**, which came into existence some eight years after the NHIS began producing relevant data on the health of the general population. In addition, data

derived from the NHIS were used in developing the 1964 recommendations of the US Surgeon General regarding **smoking and health**.

Today, data from both national surveys and community population studies are being used to understand causes and prevention of disease. For example, most of what we know about the **risk factors** for coronary heart disease came from the results of the long-standing community study known as the **Framingham Heart Study** Currently, community studies utilizing sampling techniques are being conducted in Hawaii, Illinois, Washington (state), and other areas to determine risk factors for Alzheimer's disease and other dementing illnesses, which may aid researchers in developing preventive strategies for the future. Data from a longitudinal supplement to the NHIS and from a national long-term care survey have suggested that a decline in disability among older people has been taking place over time [33]. These data will be useful for planning health care services for the elderly for the future.

Design and Objectives of Sample Surveys in Health and Medical Studies

The specification of the design and objectives of a sample survey form a very important part of the planning of the study. A clear statement of objectives is essential for the researcher to be able to stay on track and design the study effectively. One can become so engrossed in the details of planning that one loses sight of the overall purpose for the study, and perhaps makes decisions that may contradict the objectives that were originally set.

Objectives of Sample Surveys

As surveys are usually of two types, **descriptive** and **analytic**, the statement of objectives should include the main purpose. Most large-scale surveys are usually of the descriptive type, although analytic uses of the data may ultimately be made. An example of a statement of objectives that follows comes from a publication of the **National Center for Health Statistics** (NCHS) regarding the redesign of the NHIS in 1995 [2]:

> Improving the reliability of estimates for Hispanic persons
>
> Improving the reliability of estimates for subnational areas, including states
>
> Continuing to have NHIS serve as a sampling frame for follow-on surveys

These objectives along with others were used in developing the criteria for the redesign of the survey, and, while they serve as an example for us, the careful statements enabled the NCHS statisticians to work through the design phase without losing sight of where they should be going.

Major Design Features of Sample Surveys

While there are numerous features of sample surveys that could be discussed in this article, space dictates that we limit our discussion to only a few of the main features seen in most sample surveys executed in practice. Recall the textbook definition of **simple random sampling** in a finite population, namely, a method of selecting n units out of N such that each of the possible combinations of N units taken n at a time has an equal chance of being chosen (see, for example, [5]). In addition to simple random sampling, survey statisticians often employ methods of sampling including, but not limited to, stratification (*see* **Stratified Sampling**) and clustering (*see* **Cluster Sampling**), and compute estimates using techniques such as ratio estimation (*see* **Ratio and Regression Estimates**) and **poststratification** Following discussion of these topics, we will conclude the section with some information about sources of error in surveys.

Stratification. Use of **stratification** in sample surveys involves first the division of the population of N units into L nonoverlapping subpopulations, called strata, of size $N_1, N_2, \ldots, N_L$. In order to obtain maximum benefit from selecting a stratified sample, the number of units, N_i, in each stratum must be known. The sample is then drawn independently from each stratum.

There are numerous reasons for using stratification in sample surveys. As stated in the introductory section, one reason for stratification is to insure that one can make estimates of a certain level of precision for subgroups of the population under study, by fixing sample sizes separately for each subgroup. Secondly, if it is known in advance of conducting the survey that characteristics to be estimated from

the survey vary at substantially different rates from one subgroup to another, it is possible to achieve increased precision in the overall population estimates by creating strata in which within-stratum variability is small and between-stratum variability is large. For example, in the National Hospital Discharge Survey [9], larger hospitals (in terms of number of beds) tend to be more alike among themselves than they are like smaller hospitals, and similarly for the smaller hospitals. The **variance** of within-stratum estimates of a discharge rate may be quite small compared to the variance of rates among strata. A third reason for stratification is that the population may have natural divisions that lend themselves to stratification, or layering. For example, field offices for a given survey may be scattered throughout a large geographic area, thus dictating that the sample be stratified according to the geographic breakdowns inherent in the total population.

To illustrate the computations involved in estimating a population mean from a stratified sample and its sampling variance, consider a population that is divided into two strata with N_1 units in the first stratum and N_2 units in the second. The **unbiased** estimate of the mean is $\overline{x}_{\text{st}} = F\overline{x}_1 + (1 - F)\overline{x}_2$, where $\overline{x}_1$ and $\overline{x}_2$ are the respective within-stratum sample means and $F = N_1/N$ and $1 - F = N_2/N$. The variance of the estimate of the sample mean is

$$s_{\overline{x}_{\text{st}}}{}^2 = F^2 s_1{}^2 \left(\frac{1}{n_1} - \frac{1}{N_1}\right) + (1 - F)^2 s_2{}^2 \left(\frac{1}{n_2} - \frac{1}{N_2}\right), \qquad (1)$$

where $s_1{}^2$ and $s_2{}^2$ are the sample variances within the two strata, and n_1 and n_2 are sample sizes within the strata. If the within-stratum variances are sufficiently small, the overall variance of the estimated mean could turn out to be smaller than the mean of a simple random sample. Finally, the results shown here can be extended to estimation of population totals, proportions, or other characteristics by algebraically manipulating the formulas given here for the mean.

As an example of the increased precision that can be achieved through stratification, consider the following data set taken from the Honolulu Asia Aging Study (HAAS), a study of dementing illness among Japanese-American men living in Hawaii [57]. The sample to be studied was selected from three groups based on the individuals' performance on a screening test for cognitive function. Those persons who performed the poorest – and therefore were at highest risk of dementia – were chosen at the highest rate. The "good" performers were selected at the lowest rate, and those in the middle at an intermediate rate, the objective being to obtain the largest number of diseased cases possible while not ruling out the possibility that at least a few of the "good" performers may also have been at risk for dementia. The overall estimate of the prevalence of dementia among these men was 9.3% with a **standard error** 1.6% when a simple **binomial** model was used to calculate the variance. However, when the stratified sampling assumptions were taken into account, as above, the standard error estimate was reduced to 0.83%. Thus, the stratified design in this case led to a standard error slightly more than half that of a simple random sample.

Clustering. Clustering, or sampling in which the units sampled are chosen in groups or *clusters* of smaller units, called elements, is used for two reasons. First, for many surveys a *sampling frame*, or list of population units to be sampled, does not exist. For example, if one were asked to design a sampling plan for estimating the number of trees in a given geographic area, say the state of California, clearly no list of population units exists. Furthermore, the construction of such lists might be impossible for some studies, while for others it might be feasible but prohibitively expensive. However, from maps of geographic regions or lakes or whatever areas are to be sampled, it is possible to divide the region into subregions with definable boundaries. These subregions, which contain clusters of the sampling units of interest, are selected for study because they solve the problem of constructing a list of sampling units.

The second reason for selecting cluster samples is purely economic. Suppose that one were interested in studying the characteristics of physicians in office-based practices in the United States. It is known that the American Medical Association maintains an up-to-date listing of all such physicians for the United States. However, if one were to select a simple random sample of these physicians and send interviewers to collect the data from them, the interviewers would be traveling all over the country at tremendous expense to reach what would undoubtedly be a widely scattered sample of physicians. A more practical approach to conducting the study would be to select a relatively small sample of geographic areas

around the nation and conduct interviews with a sample of physicians limited to those selected areas. Clearly, a simple random sample of 3000 physicians would cover the nation more evenly than 100 counties or metropolitan areas containing an average of 30 physicians each, but greater field costs in locating the doctors and traveling from place to place to interview them would outweigh the precision obtainable with the simple random sample.

The choice of cluster size involves balancing costs versus precision for a given survey and can become rather complicated, especially if the design involves several stages of sampling. Rather than becoming engrossed in an overly complicated analysis regarding cluster sampling, let us look at a simple design in which a simple random sample of n clusters is selected from N clusters in the population, with simple random selection of m elements (out of M) within each cluster. Let x_{ij} represent the observed value for the jth element in the ith cluster and let x_i be the cluster total. Here we need to distinguish between two kinds of means: the mean per cluster $\overline{X} = \sum x_i/N$ and the mean per element $\overline{\overline{X}}/M = \sum x_i/NM$. Sampling at two levels thus introduces **variance components** for the effect of sampling clusters and elements within clusters. The between-cluster component can be calculated from the sample as

$$s_b^2 = \sum_{i=1}^{n} \frac{(x_i - \overline{x})^2}{n-1} \tag{2}$$

and the within-cluster component as

$$s_w^2 = \sum_{i=1}^{n} \frac{1}{m-1} \sum_{j=1}^{m} (x_{ij} - \overline{x_i})^2, \tag{3}$$

where $\overline{x_i}$ is the cluster mean for the ith cluster. Then an unbiased estimator of the variance among all elements in the population is

$$V = \frac{(N-1)s_b^2 + N(M-1)s_w^2}{NM-1}. \tag{4}$$

As stated earlier, these considerations can be extended to multiple levels of sampling, unequal numbers of elements within the clusters and stratification of clusters prior to sampling, and stratification of elements within clusters before sampling.

One other aspect of cluster sampling deserves mention here, namely, the concept of intracluster, or intraclass, **correlation** Characteristics of individuals occupying the same cluster are often likely to be correlated. For example, in a household health survey, it would not be unusual to find correlated responses among members of a household. The intracluster correlation coefficient is defined to be

$$\rho = \frac{\mathrm{E}(x_{ij} - \overline{x})(x_{ik} - \overline{x})}{\mathrm{E}(x_{ij} - \overline{x})^2}. \tag{5}$$

Then, for the sampling design described above, the variance of the sample mean per element can be written in terms of the intracluster correlation coefficient as

$$V(\overline{x}) = \frac{1-f}{n} \frac{NM-1}{M^2(N-1)} V[1 + (M-1)\rho], \tag{6}$$

where $f = n/N$, the sampling fraction, and ρ is the intracluster correlation coefficient. As a final note, intracluster correlation is closely related to the idea of **overdispersion** For further information on cluster sampling and related topics, the reader is referred to classic sampling texts such as [5] or [22].

Ratio Estimation. Ratio estimation is a method in which the statistician takes advantage of known correlation between a characteristic to be estimated from a survey and an auxiliary variable available from a source independent of the survey in order to increase the precision of the survey estimate. Suppose that a variable y_i is available for every unit in the sample and that y_i is correlated with x_i, the variable of interest in the survey. Suppose further that the population total Y of the auxiliary variable is known. Then the ratio estimator of X, the population total of the x's, is

$$\hat{X}_R = \frac{x}{y} Y = \frac{\overline{x}}{\overline{y}} Y, \tag{7}$$

where x and y are the totals of the x_i and y_i, respectively. Similarly, the population mean could be estimated by replacing the total Y by the population mean of the auxiliary variable. The gain in precision obtained by calculating a ratio estimate can be seen in the approximate formula for the variance of the ratio, given by

$$V(\hat{X}_R) = \frac{N^2(1-f)}{n}(S_x^2 + R^2 S_y^2 - 2R\rho S_x S_y), \tag{8}$$

where ρ is the correlation between x and y and $R = X/Y$. Notice that if x and y are highly correlated, the

variance of the ratio estimator is diminished by the large value of that correlation. The ratio estimator is also biased in most applications, but in large samples the bias is negligible.

Sources of Error in Surveys. In what we have presented so far, the only errors ascribed to sample surveys have been those arising from the fact that only a sample of units are measured instead of the entire population. However, in complex surveys that involve multiple measures of quantities, which may be difficult to measure, additional errors not related to sampling may be present. In what follows, we describe four sources of such errors, sometimes referred to as **nonsampling errors**.

First, the sample may not adequately cover the universe of units of interest. Secondly, it may not be possible to measure some of the units in the population chosen for the sample. This may occur for a variety of reasons, including inability of the fieldwork team to locate certain individuals selected for the sample, or the respondents' refusal to answer some or all of the questions being asked in the survey. Thirdly, the measuring device may not be able to determine accurately the characteristics being measured, or sample individuals may not understand the question or may not know the correct answer to the question. Finally, errors may arise in the recording, coding, editing, and tabulation of the data (*see* **Data Management and Coordination**). The statistician may find it necessary to modify standard statistical procedures to account for the occurrence of such errors in order to make valid inferences from the data when nonsampling errors are present.

Errors of *coverage* arise when the sampling frame does not fully cover the universe of units to which the sample estimates are to be generalized (i.e. the target population). For example, suppose that in 1996 one uses the list of housing units from the 1990 decennial census as a frame for a sample of households for a US survey. Without supplemental frames, this list would exclude housing units constructed since the census. Thus, any estimates based on the sample would be generalizable only to the list of units, whereas the true population of interest is "all housing units in the US in 1996". Such coverage error could bias the results, because the people living in the newly constructed units might be different, on the variables of interest, than those living in the older housing units. Even if we supplemented the list with a frame that captured new construction since the census (for example, based on an ongoing survey of building permits or new construction), we might still have coverage error. This is because even the best lists are subject to errors. Lists constructed from door-to-door canvassing and listing of units could be incomplete if some unusual housing units were missed (e.g. a carriage house turned into a rental unit). Some lists, such as those constructed from a census, may not be complete if there was nonresponse to the census. And commercial providers of lists, such as professional associations, will only be able to supply lists that are as complete as the information their members provide.

A related problem is the potential discrepancy between the true population of inference, such as "all people in the US over the age of 18", and the target population, which might be "all people in the US over the age of 18 at a particular point in time". Although not a coverage error *per se*, it is an important issue to consider when defining the research question.

Both types of problems are related to the concept of "external validity".

Nonresponse, or failure to measure some of the units in the sample, is probably the most common nonsampling error incurred in survey practice. There are few, if any, surveys that do not experience at least some level of nonresponse. In the case of household surveys or surveys involving human respondents, one way of dealing with nonresponse is recontact with the nonrespondents in an attempt to obtain the required data. This may take the form of repeated visits to the household or repeated telephone calls (*see* **Callbacks and Mail-backs in Sample Surveys**). In some cases, it is possible to make a valid estimate of the characteristic under study by recontacting a sample of the nonrespondents. Whatever method is used to obtain complete data, it is likely that a "hard core" of nonrespondents will persist in failing to provide the requested data. If the percentage of nonresponse is relatively large, say greater than 5%, it is quite likely that the results of the study will be biased an unknown amount by the exclusion of those individuals who did not provide complete data. As an example, consider a disability survey in which persons are asked about their ability to perform certain activities of daily living. Studies have shown that the people who have the most difficulty in performing those activities are the ones who are most likely to refuse to answer the questions. Therefore, estimates of the prevalence of disability based on complete

responses to the questions are lower than they would be if the more disabled individuals had answered the questions. Also, because the sample size is smaller than if complete response had been obtained, the standard errors of the estimates will be correspondingly larger. This, however, can be remedied if the statistician anticipates the loss of sample size and increases the sample size accordingly at the design stage.

A considerable body of literature on the adjustment of survey estimates for **missing data** exists. These techniques mostly involve weighting adjustments and so-called imputation procedures, which have been studied by numerous authors (*see* **Multiple Imputation Methods**). For a useful summary of these methods, see [32].

Analysis of variance models have been applied in the study of **measurement errors** in sample surveys in much the same way as in **experimental studies** The simplest models assume that a measurement includes the true value of what is being measured plus an error term. However, when the errors depend in some way on the value of the characteristic or are correlated with the item being measured, the models must necessarily become more complicated. One way to attempt to determine the correct value for an item is to remeasure it by an independent method that is more accurate than the original method. In many surveys, for example, a subsample of respondents will be reinterviewed by the best interviewers to assess the correctness of the data obtained in the original interview. Other methods might involve embedding controlled experiments in surveys or subdividing the sample into groups so that there is no correlation between the groups. Many of these topics have been carefully reviewed in articles in the literature, such as [20, 21].

The fourth area of nonsampling errors dealing with recording, coding, editing, and tabulating data will be discussed in the section on data management, later in this article.

Examples of Large-scale Surveys in Current Use in Health Research

Surveys of the US National Center for Health Statistics

The National Health Interview Survey. As stated previously in this article, NHIS was begun by the US Public Health Service in 1957, and has continued on an annual basis since that time. It is one of the major components of the National Center for Health Statistics of the **Centers for Disease Control and Prevention** The NHIS produces information on the health of the US civilian noninstitutionalized population, collected by the US Bureau of the Census in household interviews throughout the United States. The sample design for this study has been evaluated and modified after each succeeding census during the survey's existence, but currently available data do not yet reflect the redesign completed following the 2000 census. The description that follows pertains to the design used to collect the current data, a design developed following the 1990 decennial census.

In concept, the design of the NHIS has remained essentially the same since 1957. That is, the sampling plan follows a stratified multistage probability design, which permits continuous sampling of the target population. The sample of households interviewed each week is representative of the nation and the weekly samples are additive over time. This allows great flexibility in the agency's ability to respond to rapidly changing data needs.

The basic features of the design include a first-stage selection of a large number of primary sampling units (PSUs) (*see* **Sampling in Developing Countries**). This is accomplished by **sampling with probability proportional to size** (**pps**) from an area frame supplemented by a frame of building permits to enable the inclusion of housing units constructed since the completion of the previous census. Approximately one-quarter of the PSUs are self-representing; that is, they are chosen with certainty. These PSUs are primarily metropolitan statistical areas, which usually consist of a large city and its suburban areas. The non-self-representing PSUs are single counties, or groups of contiguous counties. Within the PSUs, clusters of approximately eight households are selected in the area frame and four households in the permit frame. This results in a yearly expected number of interviewed households of about 40 000 and about 110 000 interviewed persons.

The respondent rules for the NHIS allow a single individual over the age of 17 to respond for all persons dwelling in the household. However, if other persons over age 17 are available, they are invited to respond for themselves. Historically, between 65 and 70% of adults have been self-respondents. They answer questions for a set of basic health and demographic items. In addition, one or more sets of

questions on current health topics are typically asked. Also, a random subsample of adult respondents is generally asked to respond to additional questions on current health topics, which vary from year to year. Questionnaire topics include demographic characteristics such as age, sex, race, education, marital status, and family income. Health characteristics measured include disability days, physician visits, acute and chronic conditions, long-term limitations of activity, and short-stay hospital utilization. In addition, subsets of households are asked about selected chronic conditions. In the supplements that vary from year to year, special health items are asked in such areas as alcohol use, dental care, health insurance, aging, health promotion and disease prevention, vitamin and mineral intake, functional limitations, and risk factors for certain chronic diseases. Data from the survey are regularly published in the NCHS Vital and Health Statistics Series 10 reports, as well as in professional journals in the scientific literature. Standardized public-use micro-data tapes and CD-ROMs are also made available for purchase.

As a final word on the NHIS, it should be pointed out that the redesign developed and implemented in 1985 and continued in 1995 includes a feature that enables NCHS to integrate the survey designs of several of its population surveys. This was accomplished by using the NHIS sample as a sampling frame for the other surveys. In this way, the surveys could be linked analytically and possibly duplication of data collection could be avoided. Also, NHIS information could be used to oversample subgroups of the population in order to achieve sufficient sample size for studying groups, which otherwise would have been underrepresented in the surveys. The successful application of this method to the design of the NHIS has led to considerably increased efficiency in the overall designs of NCHS surveys in recent years. For more details on the research leading to the current NHIS design, the reader is referred to [2]. The updated design that was put in place in 1995 will be used until 2004.

The National Health and Nutrition Examination Survey. The National Health and Nutrition Examination Survey (NHANES) is one of the NCHS surveys now linked to the NHIS through the integrated survey design concept. At its inception in 1971, however, the NHANES was conducted using an independent design. The purpose of the initial cycle of NHANES, now known as NHANES I, was to measure the nutritional status of the US population and monitor changes in that status over time. The nutrition component represented an expansion of a previous series of three cycles of national health examination surveys, which had been completed on subsets of the US population between 1959 and 1970. As in the previous cycles and in the NHIS, the target population was the civilian noninstitutionalized population of the US, only for this survey, the population was limited to ages from 1 to 74 because of a belief that older individuals would not respond to an examination survey as readily as younger people. It was also determined at the outset that emphasis should be placed on studying individuals believed to be at increased risk of having poor nutritional status, including segments of the population classified as at or below the poverty level, young children, and the aged. Hence, oversampling of these segments of the population yielded a sample with sufficient numbers to study these characteristics.

Examinations were carried out in three mobile examination centers that traveled to the primary sampling units (PSUs) chosen in the first stage of sampling for the survey. Within each PSU, a sample of households was drawn – as in the NHIS – but a single individual from each household was selected to be examined in the mobile clinic. Because of the limited time frame of two years for completing a cycle of the NHANES, the number of PSUs was limited to 65. Approximately 30 000 persons were selected to be examined.

Data collection included both questionnaires and examinations. All sample persons received general medical history and dietary intake (both 24-hour recall and food frequency) questionnaires. A subsample received supplementary questionnaires on selected medical conditions, health care needs, and general well-being. The nutritional component examination included general medical and dental examinations, dermatological and ophthalmic examinations, anthropometric measurements, hand–wrist X rays, and an extensive battery of laboratory determinations. In addition, a subset of sample persons in the so-called "detailed" component received an extended medical examination, X rays of major joints, audiometry, electrocardiography, goniometry, spirometry, pulmonary diffusion, a tuberculin test, and additional laboratory determinations. Additional details of the design and content of NHANES I are available in Miller [37].

A second cycle of the NHANES was conducted between 1976 and 1980. A major purpose for NHANES II was to monitor changes in health and nutritional status since the first cycle. The assessment of nutritional status was carried out using methods that were essentially the same as those used in the first cycle, with some modification. Again high-risk segments of the population were oversampled. The most important change in nutritional assessment in NHANES II concerned anemia, which was discovered to be a significant health problem for the US population. The approach included additional questionnaire items on symptoms, signs and causes of anemia, and additional laboratory measurements.

In the realm of the detailed health examination, new emphases were placed on diabetes, kidney pathology, liver disease, osteoarthritis and disk degeneration, cardiovascular conditions, and the effects of environmental exposures on health, as measured by pulmonary function and blood levels of carbon monoxide, lead, and pesticides. As with NHANES I, details of the design and content of this cycle are available in [36].

A third cycle of NHANES was completed between 1988 and 1994, but since 1999, the NHANES has been conducted on a continuous basis. More information on NHANES III is contained in [42] and [24].

One other aspect of the NHANES deserves mention here. Several components of the **National Institutes of Health** led by the National Institute on Aging, combined resources to fund a recontact of the original NHANES I respondents in 1982, thus invoking a longitudinal component to the study. Of approximately 21 000 sample persons examined in NHANES I, some 14 000 were either located and reinterviewed or their vital status was determined. This longitudinal follow-up allowed one of the first nationally representative epidemiologic studies of its type to be conducted. A wide variety of data analyses have been completed and published in both the epidemiologic journal literature and in government publications. For more information concerning the design and objectives of this follow-up, see [6].

The National Hospital Discharge Survey. The NCHS has conducted the The National Hospital Discharge Survey(NHDS) continuously since 1965. The original sample was selected from a sampling frame consisting of a listing of health facilities known as the National Master Facility Inventory. The basic design of the NHDS, with minor periodic updates, was followed until a major redesign in 1988. Hospitals were stratified by bed size and were sampled with probabilities ranging from certainty in the largest hospitals to 1 in 40 in the smallest. Eligible hospitals included those with an average length of stay of less than 30 days and excluded Federal, military, and Veterans Administration hospitals. Within each hospital, discharges were selected using a **systematic random sampling** plan. Information was abstracted manually at each sample facility, until 1985, at which time the NCHS began using dual methods for collecting the in-hospital data. This involved purchasing data tapes from commercial abstracting services, sampling from those data tapes for hospitals where such services were used, and continuing the manual abstracting of the data in those hospitals that did not use the abstracting services.

The NHDS was redesigned in 1988 to conform to the integrated survey design paradigm described earlier for the National Health Interview Survey. The new sampling frame consisted of hospitals listed in the SMG Hospital Market Data Tape [9, 19]. As in the past, large hospitals (i.e. those with 1000 or more beds or 40 000 or more discharges per year) were sampled with certainty. The remaining strata were sampled using a three-stage design, which began with a sample of PSUs as in the NHIS, selected proportional to the projected 1985 population in the PSU, and a subsample of hospitals within the PSUs. Hospitals in the PSUs were then stratified by geographic region and ordered by PSU, abstracting service status, and hospital specialty-size group. A systematic sample was selected with a probability proportional to SMG annual numbers of discharges for the most recently available year. Finally, a systematic random sample of discharges was selected according to the hospital's stratum, and to whether the manual or automated abstracting system was used in the hospital. This procedure resulted in a 2001 sample of 504 hospitals, of which 448 were eligible and responded to the survey. The number of patient records in the 2001 sample was approximately 330 000 discharge medical record abstracts. Currently, the NHDS has been merged with other record-based surveys and expanded into one integrated survey of health care providers, including ambulatory surgical centers, hospital outpatient departments, emergency rooms, hospices, and home health agencies.

Data collected in the survey include personal characteristics of the patients, including date of birth, sex, race, ethnicity, marital status, and expected sources of payment; administrative data, including admission and discharge dates, and discharge status; and medical information, including diagnoses, surgical and nonsurgical operations and procedures, and dates of surgery. Medical information is coded using the **International Classification of Diseases** 9th Revision, Clinical Modification (ICD-9-CM). The large number of medical records in the sample each year makes possible the study of relatively rare conditions, particularly when it is feasible to combine several years of NHDS data.

The National Ambulatory Medical Care Survey. The NCHS conducted the National Ambulatory Medical Care Survey (NAMCS) from 1973 to 1990 as a survey of nonfederal office-based physicians in private and group practices throughout the United States. The purpose of the surveys was to provide national estimates of the characteristics of patient visits to physicians' offices, where the overwhelming majority of ambulatory care is rendered. A multistage stratified probability sample of approximately 3000 physicians was selected to be interviewed each year. The design consisted of a first-stage selection of geographically defined primary sampling units, as in the NHIS and other surveys. Within each PSU, a sample of physicians was selected from frames provided by the American Medical Association and the American Osteopathic Association, stratified by specialty type. During a randomly selected week of the year, an interviewer visited the physicians assigned to that week and selected a sample of patients seen that week. Typically, about 65 000 patient records were sampled for the year. Interviewers – sometimes with the aid of the physician's staff – collected information on such topics as the patient's reason for the visit, relevant diagnoses made in the office, laboratory procedures performed, treatment(s) received, and disposition of the visit. National estimates of the characteristics of interest were computed by weighting the weekly estimates from the sample physicians and aggregating over time.

One of the limitations of the NAMCS is that it does not cover visits to hospital emergency and outpatient departments, the second largest segment of the ambulatory care system. In 1991, the NCHS began the National Hospital Ambulatory Medical Care Survey (NHAMCS) to fill a gap in the coverage of ambulatory medical care data. It is known, for example, that hospital ambulatory patients differ from office patients not only in their demographic characteristics but likely in their medical characteristics as well. The need for the new study was also related to increased efforts at medical care cost containment, the burgeoning aging population, large numbers of persons without health insurance, and emerging medical technologies. The result of a series of planning efforts by the NCHS and its contractors was a sample design that involved four stages of sampling. The first stage was a subsample of the NHIS PSUs chosen for the integrated sample design described above. Within PSUs, samples of hospitals were selected, then clinics within hospitals, and finally patient visits within clinics. The resulting sample included 474 eligible hospitals, 854 clinics from outpatient departments, 462 emergency service areas, 35 114 outpatient visits, and 36 271 emergency service visits. Data were collected by hospital staff, who had been trained by survey field staff. They recorded the information on one of two patient record forms designed to account for the differences in emergency and outpatient care. The items on the forms included the demographic characteristics of the patient and medical items relating to the patient's reason for the visit and physician diagnoses. The outpatient form resembles that used in the original NAMCS, whereas the emergency service form was designed to reflect the types of services provided in that setting. Finally, medical coding follows the ICD-9-CM classification, and reason for visit is coded according to the NAMCS reason for visit classification. For further information on the NHAMCS, see [34].

The National Nursing Home Survey. What is now known as the National Nursing Home Survey (NNHS) began in 1963 with the first Institutional Population Survey conducted by the NCHS. This was originally intended to complement the NHIS, which covered only the noninstitutional population. The sampling frame for the study was the 1962 Master Facility Inventory (MFI) maintained by the NCHS and described earlier in this article. The sample contained institutions of four types: nursing care homes, personal care homes with nursing, personal care homes without nursing, and domiciliary care homes. The sample design was a multistage stratified design on which strata were defined by type of service

and bed size. The sample was selected systematically within each of the basic strata. The second stage of the sample was a systematic selection of residents or patients living in the sample establishments. A number of published reports have provided information on the characteristics of the homes and of the residents. For a more complete reading of the data, see, for example, [4].

A second cycle of the National Nursing Home Survey was conducted from 1973 to 1974 by the NCHS. The design was similar in nature to that of the first cycle, but emphasis was placed on the certification status of the homes. Certification status was determined by whether the facility was allowed to admit patients whose care was covered by the Medicare or Medicaid programs, which were not in existence at the time of the first survey. Thus, the design was changed to include certification status as a stratification variable. As one might expect, only nursing care homes were certified by Medicare for reimbursement.

The third cycle of the NNHS was conducted in 1977. Again, the design was constructed to reflect Medicare and Medicaid certification status. Many of the reports published using the data from this cycle involved trends in characteristics of the homes as well as the patients, comparing results from 1977 and the 1973 to 1974 cycle. A fourth cycle was completed in 1985 and provided additional trend data on the use of long-term care.

New cycles of the NNHS were conducted in 1995 [54] and 1997 [17]. Data from these suggest that a movement away from institutional care has begun, with more older and disabled persons utilizing newer forms of long-term care, including home-based care, visiting nurses, and the like. However, as the aging population continues to grow, it is expected that additional demands on the long-term care delivery system will grow as well. For further information on these survey results, see [17] and [54].

Surveys of Other Health Agencies

The National Medical Expenditure Surveys. To meet the growing demand for data on current health policy issues, the US government has sponsored three national household surveys of the utilization of health care services received and the expenditures related to use of those services (*see* **Health Care Utilization Data**). First, in 1977 the National Center for Health Services Research (later named the Agency for Health Care Policy and Research and subsequently the Agency for Health Research and Quality) and the NCHS conducted a National Medical Care Expenditure Survey (NMCES). A second survey, cosponsored by the NCHS and the Health Care Financing Administration and named the National Medical Care Utilization and Expenditure Survey (NMCUES), was completed in 1980. Both surveys were based on multistage stratified probability designs, and both were **panel surveys** in the sense that the data were collected by a series of periodic interviews with the initial sample of households during the year of interest. The principal data items of interest included each dental, doctor, clinic, or emergency room visit, and each hospital stay. These data include dates and services received; charges for the services received; prescribed medicines purchased and their costs; other medical expenses, and finally sources of payment, including out-of-pocket and insurance amounts, both public and private. For more detailed information on the methodological issues involved in conducting these surveys, see [27].

A third survey, the National Medical Expenditure Survey (NMES), was conducted by the Agency for Health Care Policy and Research in 1987. Many of its characteristics were similar to the NMCES and NMCUES (see above), but a second component was added to include information on the population residing in or admitted to nursing homes and facilities for the mentally retarded. Furthermore, oversampling was used to insure greater representation of population groups of special policy interest including poor and low income families, the elderly, the functionally impaired, and black and Hispanic minorities. A detailed description of the design of this survey is given in [7].

Finally, this series of expenditure surveys has once again expanded to a survey now known as the Medical Expenditure Panel Survey (MEPS). In addition to many of the features of the previous surveys, the MEPS has now incorporated measures of the quality of care received by the participants, as indicated by the change of name of the agency. For further information on specific statistical features of the MEPS, see [52].

The National Long Term Care Survey. The 1982, 1984, 1989, and 1994 National Long Term Care Surveys (NLTCS) were designed to measure the point

prevalence of chronic (90 days or more) disability in the US elderly Medicare enrolled population, as well as changes in chronic disability and institutionalization over time. The 1982 design was a list sample randomly drawn from Medicare administrative files. Screening interviews identified 6393 individuals, each with at least one chronic impairment, in seven Instrumental Activities of Daily Living (IADL) or nine Activities of Daily Living (ADL). Interviews were completed with 95% of the sample individuals.

The 1984, 1989, and 1994 surveys included both **cross-sectional** and longitudinal components because new samples of persons who had reached age 65 and survived since the last interview were drawn from the Medicare files and screened. The three later surveys also included an institutionalization component for those persons who were admitted to nursing homes during the course of follow-up. A striking and somewhat unexpected finding from these surveys was that a slight decline in age-standardized disability and mortality (*see* **Standardization Methods**) was observed between the 1982 and 1989 surveys [33].

The National Longitudinal Mortality Study (NLMS). The NLMS is a long-term prospective study of mortality in the United States. The study is funded and directed by the National Heart, Lung, and Blood Institute, and is carried out with the help of the Bureau of the Census and the National Center for Health Statistics. The basic objective of the study is to investigate socioeconomic, demographic, and occupational differentials in mortality within the United States.

The main study population consists of 13 **cohorts** of data of over two million records, drawn from the Census Bureau's Current Population Survey and from the 1980 census. The data records are periodically matched to the National Death Index (NDI), a centralized, computerized index of death records in the United States. The NDI is maintained by the National Center for Health Statistics and was begun in 1979. A public-use file of the NLMS data is available. For more information, see [46, 47].

Sample Surveys in Other Countries

Sample surveys in health research are not limited to the US, although many of the methodologies presented here stemmed from work done in the United States. Probably, the best known international effort in sample survey work is the World Fertility Survey, conducted in several countries, including developing countries beginning in the mid-1970s and continuing into the 1980s. The studies have been described in several publications, including a large number dealing with the results of individual countries themselves. For an overall description, see [59]. A description of the use of hand-held computers in conducting surveys in developing countries is provided by Forster & Snow [16]. Other aspects of the World Fertility Survey, including implications for future such studies, are discussed by Cornelius [8].

Health surveys are also conducted in developed countries. Two examples from Canada include the heart health surveys [40] and the Canadian Health Survey [25, 26]. Other studies relate to drinking behavior [10]. Still other countries, such as the United Kingdom, Sweden, the Netherlands, Israel, and others, maintain national central bureaus of statistics, many of which are responsible for designing, conducting, and analyzing social surveys, which often include questionnaire items pertaining to health and well-being.

Data Collection and Management

In many studies, biostatisticians play a very active role in the collection and management of data. At a minimum, the statistical group needs to be represented as the data collection and **data management** systems are designed and implemented, so that the statisticians know how the data reached them for analysis. Decisions made at the data collection stage can have substantial impact on the analytic process.

Data Collection

Two key decisions about data collection will affect the statistician directly: how will the participant communicate responses to the researcher, and how will the researcher record and transmit the responses? Sample surveys can collect data by mail, by telephone, or in person; each approach has both advantages and drawbacks. Furthermore, data can be recorded on paper forms and keyed in later, or directly entered into a computer at the time of the interview. Other means of recording data that has been in more common use in recent years for some surveys is to have the respondents record answers

to questions directly using a touchtone telephone or the Internet.

Contact with Participant. Mail questionnaires are used for some sample surveys because they offer a simple and economical way to request data. However, they have serious drawbacks. The most crucial one is the possibility of sampling **bias**. Bias can occur because the mailing list used as a frame may not adequately reflect the target population, or because of poor response rates in some or all of the communities, or because of difficulty in interpreting and filling out the forms. A second serious problem is that some health issues cannot be addressed without in-person assessment of the participant. Blood pressure, for example, needs to be measured in person, and self-reported diagnosis of hypertension is a far less reliable alternative. Mail questionnaires may be useful for some highly motivated and sophisticated populations; mail surveys of physicians and nurses have been used successfully to study many chronic diseases of major public health importance (stroke, breast cancer, myocardial infarction, and so on). In addition, mail surveys may be useful for interim tracking of participants in longitudinal studies.

Telephone interviews avoid some of the problems of mail questionnaires, in that direct conversation may help clarify concerns or confusion of the participants (*see* **Telephone Sampling**). Bias remains a problem, both because some people in the population do not have telephones and because response rates may be low and may be different for important subgroups. In addition, data requiring direct measurement of the participant cannot be collected over the telephone. In one particular survey conducted by the National Institute on Aging, the Survey of the Last Days of Life, the use of the telephone was instrumental in securing an acceptable overall response rate for the study. Many of the participants – recently bereaved individuals following the death of a spouse or other family member – were reluctant to be interviewed in person. In spite of a sometimes lengthy interview, lasting as long as 45 minutes to an hour, the response rate and the overall quality of the data remained good [3].

In-person interviews allow the greatest variety of data to be collected on a participant. Direct measurements, performance tests, and blood samples for laboratory work can all be carried out even in participants' homes. Developing a suitable frame may be challenging, and participation rates may be low. In addition, in-person interviews are the most costly to conduct. Some studies use a combination of telephone interviews with in-person interviews of a subsample (*see* **Interviewing Techniques**).

Data Recording and Transfer. Recording the data and transferring to the computer are key steps, on which much of the data quality will depend. Perhaps, the simplest approach is to record the answers on a preprinted form and have the forms keyed in to the computer at a later date. In this procedure, there is no way to check data at the time of collection and prompt for correction of implausible answers. Some data checking can (and probably should) be programmed into the data-entry keying program. Turnaround time depends on the data-entry service. If the number of questions is small and the possible responses are simple, a scanner form can be filled out by the participant or the interviewer, but this is practical only for the briefest of questionnaires. Careful design of a paper form is essential to make it clear and easy to fill out, and to key for data entry. It is useful to have a standardized header for paper forms, identifying the study, the batch, and sequence to record when a form was sent to data entry for keying, the staff member filling out the form and the date on which it was filled out. This information can be vital for data management (*see* **Questionnaire Design**).

Computer-assisted interviews for in-person and telephone interviews (CAPI and CATI) are becoming more widely used, especially for large-scale sample surveys, where they offer preprogrammed checks for accuracy and rapid turnaround of data. The greatest drawbacks are the cost of the equipment and its support and maintenance, the need to train interviewers in use of the computer and the program, and the initial investment in time and effort for programming. It is important to recognize that a CAPI or CATI instrument is a program, and as such needs close attention to the overall architecture as well as to the details of branches, range checks, and logic checks. Developing a computer-assisted data collection instrument requires close collaboration between the programmer, the subject-matter specialist, and someone who is familiar both with computing and with forms design.

Data Management

Data management is the process that takes the data for the study from the point of its entry into the

computer system to the time of analysis. The goal in data management is to build a system that handles quality control, tracking of study progress, linking of study components, and access for statistical analysis. In addition, the data management system needs to protect the data against loss, corruption, and unauthorized access. Each participant in the study should be assigned a study Identification Number (ID) at the time of sample selection, and the data management process should track and refer to participants by ID rather than by any personal identifier such as name, social security number, or address.

Quality Control. The goal of quality control is to ensure that the data to be analyzed are as faithful as possible a representation of the participant's true responses, and that any errors in responding, transcribing, uploading, or processing the data are identified and corrected. One common and potentially disastrous error is having a wrong ID on a form. IDs can be generated to include one or more "check digits", so that an invalid ID can be caught at the time of data keying or, if computer-assisted data collection is used, at the time of the interview. Other checks that can be carried out at the time of the first computer entry of the form are range checks (Is the value of the variable within the permitted limits for that question?), logic checks (Is the value for this variable logically consistent with the value entered for a previous related variable?), and branch checks (Has an answer been given for a question that should not have been asked or, conversely, has a question been skipped that should not have been skipped?). CATI and CAPI systems can be programmed to prompt the interviewer to correct the error at the time of data entry or, in some cases, to override the prompt if the response was unlikely but nonetheless correct. However, these checks can only be carried out within a single form collected at the same time – not across multiple forms. Thus, additional checks are probably needed at the time the data are uploaded into the main computer in which they are to be stored for analysis.

The quality control process also needs to include a standardized procedure for error correction. This should include both global corrections, where all records with a given value are changed to a new value, and person-specific corrections. It is useful to keep a system log of corrections, including the staff ID of the person who made the correction.

Database Management. Until fairly recently, data were usually stored on the computer in ASCII files or flat files, which were simply records in which each variable was identified by the columns that it occupied (a legacy from an era when data were stored on punch cards.) More sophisticated options now range from spreadsheets, to add-ons for statistical packages, to relational databases (*see* **Database Systems**). The greatest advantage of a relational database is the ability to link data across studies and across forms within a study. The database chosen should be able to meet both operational and analytic needs, as well as being large and flexible enough to handle all the data collected in a given study. Operational needs include tracking completion of data for participants, tracking performance of interviewers, generating routine reports, and providing authorized people with interim access to the data. For statistical analysis, a friendly link to the statistical package is helpful (*see* **Software for Sample Survey Data**). Some relational databases have a feature permitting some statistical packages to access the study directly, including variable labels. Again, it is crucial that the participant be identified by a study ID across all forms in the study.

Use of the database requires that the statistician know all the forms used in the study, the variable names for each form and the question to which they correspond, and the meaning of all possible values of the response, including missing value codes. One useful format for this information is a codebook – having on-line codebooks can be extremely helpful. The importance of good documentation of the database and the management process cannot be overemphasized.

A final word on maintaining and managing data files for a survey involves keeping backup files for each type of record created for the study. An example of a disaster that occurred at one statistical agency serves as a reminder of the importance of keeping the data properly backed up. Some years ago, seven cartons containing data tapes from a multi-million-dollar survey were being moved from one location to another for "safe keeping". In the course of this movement, the cartons were inadvertently left on the building's loading dock and were taken by trash collectors to the city's sanitary landfill. In spite of a valiant effort on the part of the agency to recover, clean, and reprocess the tapes, more than half of the total data set could not be recovered. Had the data been properly backed up prior to the movement of

the tapes, such a disaster could have been avoided. Attention to such details is of utmost importance.

Analysis

Two considerations should determine the analytic strategy: What is the scientific question to be addressed? How was the sample obtained? Surveys conducted primarily for policy purposes often have as their primary goal the description of the health status of the country or state and important component groups. Examples would include the types of statistics described in the section on the NHIS: **frequency distributions** and cross tabulations of disability days, prevalence and incidence of acute and chronic conditions, physician visits, hospital utilization, and so on. Other examples might include national norms for certain measured quantities such as cholesterol level, blood pressure, height, and weight (*see* **Normal Values of Biological Characteristics**). Epidemiologic surveys, however, often are designed with the goal of analyzing the relationship between characteristics of the population and the risk of prevalent or incident disease or disease prognosis. The analytic strategies for accounting for the sample design in epidemiologic studies may differ from those in studies where the main goal is to characterize a specific population (*see* **Epidemiology, Overview**).

Descriptive Analyses

These analyses usually consist of the presentation of population estimates of the characteristics under study and some indication of the sampling variability of the estimates. Most standard texts on survey sampling (e.g. Cochran [5]) provide the necessary information to construct the desired estimates. Typical analytic reports from descriptive surveys include a variety of standard tables containing estimates of means, totals and percentages, or proportions. If the survey designs are relatively simple, estimates of sampling variance can be computed using algebraic formulas. For more complicated designs, however, approximation techniques such as Taylor series representations (see, for example, [50]) (*see* **Linearization Methods of Variance Estimation**) or pseudoreplication methods [12, 29, 39] (*see* **Resampling Procedures for Sample Surveys**) are usually used to estimate sampling variability. In the estimation of variances, one needs to be aware of the possible necessity of applying a **finite population correction** factor, if the sampling rate for the survey is, say, more than 5 to 10% in a given stratum, even though the overall sampling rate is much lower than that.

Two other areas of descriptive analysis deserve mention. First, a considerable amount of work has been done on the topic of small domain, or **small area estimation** Here, one is interested in providing estimates of health characteristics for either small strata (such as a subgroup of the population at high risk for disease) or for small geographic areas, which are subgroups of the larger area covered by a given survey. When the sample sizes in the small area are too small to allow the computation of reliable direct estimates from the survey, some researchers have proposed the use of so-called synthetic estimators, based on **regression** relationships between the characteristic of interest and ancillary variables available from the survey. Others have proposed the use of **composite** or **"shrinkage" estimators** that combine direct and synthetic components. For additional information on this topic, see [15, 44].

The final topic on descriptive analysis concerns the description of change from one time period to another. Estimates of change are usually desired to study the effects of forces that are known to have acted on the population under study. For example, if a hypertension intervention is initiated in a community, we would like to know whether the intervention has influenced the prevalence of hypertension in the community. In such an instance, it is necessary to estimate the prevalence both before and after the intervention, and it is best to retain the same sample for both occasions. However, if the goal is to estimate the aggregate average blood pressure level at the two occasions, it is best to select a new sample each time. Each of these alternatives has advantages and drawbacks. The first alternative requires careful maintenance of the sample over the time period for the study and the statistician must deal with dropouts and other losses to follow-up. The second alternative necessitates the drawing of a second sample and all the work required to recruit and to inform new sample members. More information on this topic is available in [5].

Epidemiologic Studies

Studies of potential risk factors for the onset and progression of health problems, in contrast to

descriptive studies, are likely to rely on regression models to measure the **association** between **risk factors** and disease and to adjust for other factors thought to affect the risk. There is general agreement that descriptive summaries based on survey data must adjust for the sample design, but there has been less of a consensus on how to estimate regression parameters and calculate standard errors for regression analysis of survey data. One possible approach for estimation is to analyze the data by a standard approach such as **maximum likelihood** treating them as if they arose from a **simple random sample** (i.e. ignoring the sampling design). A second approach is to assume that the design influences the results primarily through key variables related to the sampling design, such as age, sex, or race, and to adjust for those by including coefficients for those variables as predictors in the model. In a stratified design, the variables chosen are typically the stratum definitions, at minimum. A third approach, more complicated to implement and thus used less frequently, is to modify the basic approach to reflect all features of the design, for example, maximizing the likelihood over the complete probability distribution associated with the sampling design (design-based analysis) (*see* **Superpopulation Models in Survey Sampling**). Finally, a more widely-used approach is to modify the estimation approach to reflect the sampling weights, in particular, for example, by weighting the score function components to obtain so-called **pseudo-maximum-likelihood** estimates (model-based analysis). The estimation of standard errors associated with the point estimates is challenging and usually relies on some asymptotic assumptions. In the past, the ability of some researchers to adjust for complex sampling was limited by the lack of commercial software. Software is now available, however, to adjust for complex samples for many different kinds of regression models (see, for example, [50, 56] (*see* **Software for Sample Survey Data**; **Software for Sample Survey Data, Misuse of Standard Packages**).

Some researchers have argued that adjustment is important when describing the parent population from which the survey sample was drawn, but not for estimating regression parameters for comparing risk groups [53]. For example, for standard **linear regression** the usual estimator

$$\hat{\beta} = (X'X)^{-1}X'Y \tag{9}$$

is shown in standard texts to have commendable properties. If the sampling design is ignored, the estimator is the best linear unbiased estimator (*see* **Least Squares**). In the survey data setting, however, as Sarndal et al. [48] point out, there are distinct theoretical drawbacks to the usual estimator. First, its optimal properties only hold if the model is correct. Secondly, obtaining standard error estimates that reflect the true variability from the sampling design is difficult. These authors recommend using a sample-weighted estimator. Other authors [23] have also stated that "the design is relevant, including especially the effects of intraclass correlations from cluster sampling, and perhaps also variable sampling fractions and other aspects of design. Failure to recognize such effects may lead to serious understatement of confidence intervals and overstatements of precision in inferences to the causal system".

The sample-weighted estimator for **likelihood**-based estimators from regression models makes use of the sampling weights, reflecting how much larger a segment of the population an individual would represent than in the sample. In a simple random sample, the log likelihood would just be the sum of the **score** contributions from each individual in the sample. The sample-weighted estimators assume that each individual should contribute to the total log likelihood by an amount reflecting the composition of the whole population; thus, the estimated log likelihood is a weighted sum of the individuals' contributions. This weighted sum is not typically the exact log likelihood for the full sample design. In fact, the design likelihood can rarely be calculated explicitly. However, the weighted sum can be thought of as an unbiased estimate of the log likelihood for the population from which the sample was drawn, and thus its root is called the **pseudo-maximum-likelihood** estimator [51]. For linear regression, the sample-weighted estimator or pseudo MLE is given by

$$\hat{\beta}_w = (X'WX)^{-1}X'WY. \tag{10}$$

Pseudo-maximum-likelihood estimators have been worked out for a number of standard procedures including **logistic regression** The correct point estimators can be obtained by using weights in standard software packages (*see* **Software, Biostatistical**), but the standard error estimates obtained by simply adding weights to a procedure for simple random samples will not be correct. More complicated

standard error estimates, described below, must be used for pseudo MLEs.

The sample-weighted estimates typically give different parameter estimates for stratified designs with unequal sampling weights than do the unweighted estimates, but are not affected by clustering. The conventional standard errors based on the usual estimates, however, may systematically underestimate the true sampling variability in the presence of clustering if there is within-cluster correlation. In this case, the usual regression estimators assume independent and identically distributed errors, and overestimate the effective sample size. A more conservative approach is to take account of the clustering by using a Taylor series approximation to the design-adjusted variance, as described in [51] or [48]. Such estimates can also take account of the sample weights used in the sample-weighted estimators. Commercial software is now available that calculates sample-weighted regression estimators, and calculates the Taylor series approximation for the standard error for linear regression, logistic regression, and so on [50].

Another approach to standard error estimation for sample surveys is **resampling** or replication. Balanced repeated replication and **jackknife methods** have been used for some time in survey sampling [29, 35]; more recently, these methods have been extended and, additionally, **bootstrap methods** have been applied [12, 28, 31, 45, 58]. These methods differ from the Taylor series approach in two key ways: First, unlike the Taylor series approximation, it is not necessary to write down an explicit differentiable expression for the variance. Second, replication methods may perform better in small samples than the Taylor series approximation [48]. Owing to recent improvements in computing, software is now available to implement replication-based methods (e.g. WesVar [38, 39, 56]; VPLX [14]). A widely used statistical software package, SAS (SAS Institute, Cary, NC), has added new procedures for analyzing survey data in its most recent release.

The effect of clustering on the variance can be substantial if the number of primary sampling units is not large relative to the number of strata, but clustering does not affect the parameter estimates. Sample weighting can affect both the parameter estimates and the variance. If sampling weights are very unequal, the standard error of the sample-weighted estimates is typically substantially larger than that of the unweighted estimates, reflecting the uncertainty in weighting a small number of observations very heavily in the analysis. Korn & Graubard [30] have examined these effects for a study based on the NHANES I survey, and found that different analyses led to very different conclusions. They suggest that the clustering should generally not be ignored. However, if extremely unequal sampling fractions were used, one way to obtain reasonable point estimates without reducing the **power** of the study is to include those factors related both to the design and to the regression variables as **covariates** in the analysis. Korn and Graubard note in conclusion, however, that a better solution might be to plan studies in advance to have adequate sample sizes in all strata (*see* **Sample Size Adequacy in Surveys**). This would permit regression models to use the design in the analysis – the more conservative approach, and one that addresses directly the difficulties of making inferences about risk factors in a population using data from a complex survey design.

Sampling Distributions

The concept of a sampling distribution is an essential feature of statistical inference. A sampling distribution is a **probability** distribution that describes the behavior of a statistic calculated from a **random sample** of a particular size. To understand it, we need to consider briefly the issues of sampling variability and parameter estimation. We will then see that the sampling distribution provides the all-important connection between probability models and statistical inference.

Data collected for research studies in medicine, public health, and other fields are used for the making of inferences about unknown parameters. Consider two examples. Researchers in obstetrics may wish to evaluate the effect of maternal smoking on infant birthweight among babies born at full term to mothers between the ages of 18 and 40. Research oncologists might need to determine the proportion of lung cancer patients who experience tumor shrinkage when administered a chemotherapeutic drug. As we set out to study these problems, it is often assumed that the parameter of interest (average birthweight or probability of tumor response) has some "true" value in the population as a whole. It is not practicable (and is usually impossible) to attain the "true" parameter value by assessing the entire population, since its number is essentially infinite in most instances. Instead, we choose individuals at random from the population under study, and make our assessments on the members of our sample (*see* **Simple Random Sampling**). We use the data from this sample of subjects in order to guess at the true parameter value. The population or "true" value of the parameter is unknown and unknowable. What can be obtained is the sample value of the parameter, estimated from the data collected during the study. The two values (population and sample) will almost certainly not be identical, but we hope that they will be close. One of the major determinants of the accuracy of a sample statistic is whether the subjects selected for the study are representative of the subjects in the population. Other determinants include the size of the sample and the probability distribution of the original measurement in the population.

In the frequentist's approach to statistical **inference**, the population (true) parameter value is assumed to be a fixed quantity. In contrast, its sample value is a random quantity, since it is a function of the data collected. For example, suppose we record the birthweights of 100 infants born at full term. From these data we compute the mean birthweight, say $\overline{X}$. Provided that our sample is representative of the population we wish to characterize, the sample mean, $\overline{X}$, represents a reasonable guess as to the average birthweight in the population. Suppose that another research group assembles a random sample of 100 full-term newborns, and computes the mean birthweight. Surely the two mean values will differ, simply due to chance. If we conducted the same study a third time, a fourth time, and so on, then we would obtain a new estimate of the sample mean for each group of 100 randomly selected subjects. This feature is known as *sampling variability*. Because the individual birthweight measurements are random, any function of them (i.e. any sample statistic) is also random. The behavior of a sample statistic, then, can be characterized by a probability distribution, just as the behavior of the individual variable under study can be described by a probability distribution.

To continue, let us assume that birthweights in the specified population (babies born at full term to mothers aged 18–40) are well characterized by the normal distribution, with a mean of 3500 g and a standard deviation of 400 g. Remember that these population parameter values are unavailable to us in practice; we must instead rely on estimates from a random sample. How accurate an estimate of the average birthweight of full-term babies born to mothers aged 18–40 could we obtain from, say, a random sample of size 100? Because of sampling variability, it is very unlikely that the sample mean based on 100 subjects would be identical to the overall population mean of 3500 g. It would be useful to know, however, how precise we can expect our estimate to be. This is where the sampling distribution comes into play. It tells us how variable a sample mean is expected to be in successive samples of a specified size, and allows us to make statements about the likelihood of the true mean value falling within a certain range of the sample mean.

The sampling distribution of a statistic calculated from n observations is derived from mathematical principles. This distribution tells us not about the behavior of the individual observations (e.g. birthweight or occurrence of tumor shrinkage), but about the behavior of the summary statistic based on these values. If we were to take random samples of size n

repeatedly and compute a particular summary statistic (say, the **mean**, **median**, proportion of positive responses, or **standard deviation**), then the distribution of the summary statistic would be described by a sampling distribution. Of course, we do not, in practice, repeat the same study again and again. This idea is conceptually important as a means of interpreting the distribution of the resulting summary statistic from a single sample of size n. If we consider the sample mean, then there is an important statistical result which tells us that the sampling distribution of $\overline{X}$ is approximately normal, with mean equal to the true population mean, and variance depending on the sample size (n) and the variability of the measurement in the population (*see* **Central Limit Theory**). This result holds regardless of the probability distribution of the original measurements, so long as n is sufficiently large.

If the population mean of the variable of interest is μ and its standard deviation is σ, then $\overline{X}$ is approximately normally distributed with mean μ and standard deviation $\sigma/\sqrt{n}$. The standard deviation of the sample mean (referred to as the **standard error** of the mean) is clearly a smaller quantity than the standard deviation of the original measurements, and decreases as n increases. Thus, the larger the sample size, the less variable (i.e. more precise) our estimate of the sample mean. Knowledge of the sampling distribution allows us to appropriately design a study, as well as to generate confidence intervals (*see* **Estimation, Interval**) and to conduct **hypothesis testing** for the parameters under consideration once the data have been collected.

Consider again the birthweight example. We assumed earlier that the unknown mean birthweight for all full-term babies born to mothers aged 18–40 to be 3500 g, with a standard deviation of 400 g. If we plan to collect birthweight data from a random sample of size 100, then there is a 95% probability before the study is conducted that the true mean will be within about 80 g of the sample mean. If we increase the sample size to 500, then there is a 95% chance before the study is conducted that the true mean will be within 36 g of the sample mean. The result of increasing the sample size is to tighten the sampling distribution around its mean, allowing us to make more precise inferences about the population mean.

Properties of the sampling distribution also permit meaningful comparisons of parameters across different groups. For example, we might want to compare the probability of tumor shrinkage for a standard chemotherapy regimen vs. an experimental one in patients with lung cancer. Even if the true, group-specific parameter values were the same in the two populations, we would not expect to obtain identical sample statistics across sample comparison groups because of sampling variability. However, we do need some way of deciding when a difference in sample statistics between groups is large enough for us to conclude that the population parameters are probably different. The sampling distribution of the statistic of interest helps us to answer this question. The difference in parameter estimates is gauged against the expected variability of the sample statistics, giving us a formal method by which to make inferences about the parameter values in the population. Without knowledge of the sampling distribution, this would be impossible.

The sampling distribution, then, is a key element in the conduct of statistical inference. It describes, in probabilistic terms, the behavior of a statistic computed from a random sample of size n. Among the most commonly encountered sampling distributions are the normal distribution, **Student's *t* distribution**, **chi-square distribution**, and ***F* distribution**.

MELISSA D. BEGG

Sampling Frames

Probability sampling allows one to make **inferences** about large, sometimes infinite, populations without observing every member. In a probability sample every member of the population has a known, nonzero probability of selection. Knowing these probabilities, it is possible to select a subset of the population from which to make estimates (*see* **Estimation**) about the entire population with specific degrees of precision. To draw a probability sample from a population it is necessary to have a list or other selection process, called a *sampling frame*, that ensures some probability of selection for each element in the population. The sampling frame defines the portion of the population from which the sample is selected. Hence, the quality, completeness, and availability of possible sample frames are major considerations when selecting a population for study using statistical inference.

Frames are usually defined by geographic listings of blocks or other topographic units, maps, directories, membership, or other kinds of lists, or they may be defined from telephone or other electronic formats. The United Nations Statistical Office [11] defines the frame content as maps, lists, directories, and other sources that permit the construction and selection of sample units. A frame's specifications "should define the geographic scope of the survey; categories of material covered; and include the date [the frame was constructed] and the source of the frame" [11]. Wright & Tsao [14, p. 26] also recommend that the frame should include "any auxiliary information (measures of size, demographic information) that might be used for (i) special sampling techniques such as stratification or selection with probabilities proportionate to size sample selections or for (ii) special estimation techniques such as ratio or regression estimation". In other words, a frame contains listings or other relevant demarcations of the population from which sampling units can be selected and provides related documentation that helps describe the selection process. Sampling units may be individual elements or they may be clusters of elements [6].

In the US or other countries where there is extensive telephone coverage, telephone interviewing has become the data collection mode of choice, particularly in urban areas, because of cost and related problems with accessibility of respondents for face-to-face interviews (*see* **Telephone Sampling**). Although telephone directories are used sometimes for frames, usually they are incomplete and **random digit dialing** (RDD) [12] surveys are now commonly used. The frames for RDD studies are constructed by random selection of ten-digit numbers comprised of the area code, prefix, and suffix of individual telephone numbers, or lists that have been screened to eliminate banks defined by area code and prefix that include only business listing, or that contained unassigned numbers. (Note that in the US the 10 digit format is the sampling unit. In other countries the unit may be some other combination of numbers that constitutes the full telephone number.) In the US it is possible to purchase lists that have been purged of most business numbers and are adjusted for the proportions of households by county consistent with an equal probability of selection of element model (epsem) [13].

Frame Coverage

While there should be a one-to-one correspondence between the list and population, few lists meet this requirement. There are two potential sources of variation between the population of inference and the sample frame described in the literature [3, 6, 11]. One source of variation results from how the *eligible* population is defined [3]. This source of variation is often deliberately introduced for reasons of feasibility and cost. It amounts to a redefinition of the population about which inferences are to be made, by specifically excluding subsegments of the population that – for reasons of cost or efficiency – may not be included in the final sampling frame. For example, a RDD sample for a telephone survey deliberately redefines the population to include only those households with telephones.

Deliberate differences between what Groves [3] calls the *population of inference* and the actual population elements that comprise the frame might be introduced for several reasons. For example, if inferences are to be drawn about the general US population, there may be subgroups within that population that may be difficult or impossible to interview, or who differ from the general population in ways that make them nonrepresentative of the population that is relevant for the study (i.e. they may be cognitively impaired or foreign nationals), or they may be housed or located in ways that make them never available for

interview during the study period (i.e. they may be in prison, in college, or permanent residence abroad) or they may be very rare groups or may reside in inaccessible places, making the cost of interviewing them prohibitive.

Individuals in the population of inference, who might otherwise be available, might not be available during a particular study because the sample is selected and interviewed at a specific point in time in order to fix a point of estimation; for example, the Current Population Survey is conducted during the week containing the 19th of the month [3], or the US Decennial Census is carried out every tenth year ending in zero during which all residents of the US are enumerated at their residences as of 1 April. In these cases, elements of the population not available during the study period have zero probability of selection. Groves [3] refers to the population resulting after excluding these groups as the **target population**, which represents the actual population about which inferences can be drawn based on the available sampling frame.

The second source of variation results from flaws in the actual listings of the eligible population that comprise the frame. A perfect frame is one in which there is a one-to-one correspondence between the listing and each element; that is, "every element appears on the list separately, once, only once, and nothing else appears on the list" [6]. Perfect frames are rare. Most often, there are problems which must be detected and modified, or the frame will produce a **biased** sample. In fact, many times there is no existing frame and one has to be created from other, imperfect, sources. In such cases, the date the frame is created and the methods by which the frame is modified or constructed are included as elements of the documentation of the frame [11]. However, whether the variations between the two populations are deliberately introduced for reasons of efficiency or result from flaws in the correspondence between the elements and the listing, these variations need to be ascertained and decisions made about how to treat them.

Coverage error, according to Groves [3], is the difference between statistics based on the population defined by the sampling frame and statistics based on the target population. In other words, coverage error occurs most often in population estimates when there is a lack of correspondence between the frame population and the target population. One of the clearest examples would be differences in population statistics calculated based on data from a population defined by telephone numbers and those calculated based on household data, including those without telephones.

Kish [6] describes four basic frame problems that might lead to coverage error in survey data. These include: (i) missing elements (*see* **Missing Data**), noncoverage, or an incomplete frame; (ii) **clustering** in which more than one element is in a single unit; (iii) blank or foreign elements (ineligible units); and (iv) duplicate listings. Overall, Kish [6] suggests three strategies. (i) The problems can be ignored if their potential impact is small compared with other sources of error, and correcting them would be too costly given the value of the corrections in reducing bias. (ii) As noted above, the target population can be redefined to fit the frame, assuming that the redefinition still permits accurate estimates of the parameters of interest in the population. (iii) The frame can be corrected by splitting clusters or selecting individual units and weighting the clusters, deleting blanks, duplicates, or ineligible or foreign elements. In some cases, such as with duplicates or blanks, the corrections need to be made in advance. The effects of clustering or of missing or under-represented elements can sometimes be corrected through weighting the data after the interviewing is completed.

Until the advent of telephone interviewing (*see* **Telephone Sampling**), frame coverage problems were pretty much as described above. However, telephone frames have inherent coverage problems that require special consideration before they are used. One problem mentioned above is the fact that telephone frames contain many foreign elements in the form of business numbers, telephone company service numbers, nonworking numbers, and computer and FAX modems [3, 13]. As noted earlier, it is now common to purchase prescreened lists of "seed" telephone numbers from which RDD samples can be generated by deleting the last one to four digits of the number's suffix and replacing them with one to four numbers selected from a table of random numbers. This strategy is increasingly being employed in the US as an inexpensive way of creating a RDD frame [13]. According to the vendors, the resulting biases in such samples are about 3% due to missed households. However, the use of these prescreened banks is an instance in which the cost in terms of potential bias is very low compared with

the costs of creating a RDD sample by randomly selecting and screening full 10-digit numbers using the Waksberg–Mitofsky method [12].

Groves also notes that telephone frames also suffer from "over coverage" because some households may have more than one listing, such as a business telephone, an adolescent telephone, or a second household number. His estimate, however, was published almost 20 years ago and suggested that 3%–4% of US households have second telephones [4]. This estimate is probably low by current standards, particularly if households with computer modems are included in the estimates.

However, by far the greatest concern with telephone frames is the amount of under-coverage due to the number of households that do not have working telephones. Under-coverage is a source of considerable bias, because it is correlated with sociodemographic characteristics such as race and income [9]. Although the number of households without a telephone has varied, it could be as high as 15%–20% among minority and rural households, and even higher among households in which the income is very low. Clearly, there are indications that households without telephones differ substantially from those with telephones, and these differences are often correlated with other important substantive variables [3, 4, 9]. Thus, the potential bias cannot always be ignored by using a telephone sample frame and designating only households with telephones as members of the target population, although this is commonly done. An alternative solution might be to obtain data on the demographic characteristics of households without telephones and then post-weight the sample to accommodate the potential bias. In the US the Decennial **Census** is the most easily accessible source for such weights, but it too has biases.

Clustering and Stratification Effects

In most large-scale, national household surveys, the frame includes clusters and strata at various levels. The effects of these characteristics of the frame are taken into account by weighting and/or by calculating design effects on the variances of the key variables. These effects are included as part of the documentation of the frame.

When the sampling unit is a household, then usually the differences between the population of inference and the target population also concern definitions of eligibility of individual members of the household. In most cases the target population will include residents of households in the geographic area of the survey at the time of the survey. Thus, following Groves' [3] conceptualization, the *frame population* would be those in the target population who can be enumerated prior to the survey. The *survey population* would be those in the frame population; "who, if they were selected for the survey, would be respondents"; that is, they would be accessible to an interviewer. This is, as Groves notes, a hypothetical population, since if they are not asked to participate in an interview there is no way to know whether they would consent. However, those not asked might also exclude as potential members of the frame persons who reside in the frame population but who – due to incapacity, continuing absence from any enumeration unit (i.e. a student residing in a dormitory), speaking a foreign language that has not been translated for interview, or for some other reason – might not be able to consent to an interview. The survey population is always determined after the household is contacted and those in the frame population who are excluded from the survey population would usually be those designated as ineligible [3].

Ineligibles affect the probability of selection of the eligibles and, therefore, fall into the second category of coverage problems described above (clustering of units). By defining residents of households as the target population, other residents of the population of inference with no permanent household residence or those who are institutionalized would be excluded. Also excluded might be residents of households in remote areas, where the cost of obtaining an interview would be prohibitive relative to the potential bias due to failing to interview them. Including those who do not consent to be interviewed, the difference between the target population and the survey population is **nonresponse** [3].

Once the household is established as the enumeration unit, it becomes necessary to define what constitutes a household and, beyond that, who is a member of the household once it is identified. The definition of a household and its membership are key elements of the sampling frame. The elements of the target population are individuals, whereas the elements of the frame population are households. This means there is not a one-to-one correspondence between the frame population and the target population. Hence, a rule is required to

establish correspondence between the elements in the two populations. Groves describes two alternative correspondence rules [3]. The *de jure* rule attaches each person to a single housing unit based on where they live; and the *de facto* rule attaches each person to the residence where they are staying at the time of the survey. The distinction between these two rules focuses on what constitutes a dwelling unit or household and the difference between "living" vs. "staying somewhere" at the time of the interview. Failure to make these decisions results in coverage error due to poor frame specification.

The process of selecting the member of the target population has also been the subject of much discussion. There are several ways of going about this process of defining the eligible respondents in the target population. The most rigorous is prescribed by Kish [6], in which all members of the household are listed in order of age in a table and then one is randomly selected for interview based on a prespecified selection procedure. This procedure generally works well in face-to-face interviewing situations, but does not work well on the telephone, where it requires respondents to name all members of the household to an anonymous telephone caller. Other techniques which seem more acceptable for use with the telephone have been proposed by Trodahl & Carter [10], Salmon & Nichols [7], and Czaja et al. [1]. These methods require less information about the entire household and rely on selection by most recent birth date and, sometimes, gender.

In the cases in which respondents are rare elements in the target population, techniques designed to improve the probability of locating a respondent have been proposed. These are generally described as multiplicity or **network sampling** methods [2, 8]. This technique takes advantage of clustering and depends on linkages between members of a family or close friends for locating rare respondents. Initial respondents are asked to list members of the household plus other selected members of the family living at other addresses. Then each member listed is considered part of a cluster of persons and the probability of selection is determined by the probability of being listed. The use of weights allows for unequal probabilities of selection based on family size.

Where frames are incomplete or do not otherwise match the population of inference, it is sometimes an option to select multiple frames. The use of multiple frames is sometimes used to allow for uneven telephone coverage in which a telephone and an area frame are used. In the instance described by Groves & Lepkowski [5], a random-digit dialed sample was drawn and screened for household members. Interviews were conducted with an eligible respondent by telephone. A second area frame survey was also conducted face-to-face. During these interviews, information was obtained about telephone coverage in the sample. The overall mean for each variable was estimated by a weighted average of the mean values obtained from households with telephones and those without them.

This strategy does offer some reduction in coverage error, but also poses some administrative problems that can affect cost and themselves produce error if not appropriately addressed. Most obviously, there will be duplicates in the frames. If attempts are made to identify and eliminate duplicates before data collection, there is the risk of increased costs and error due to mismatching. On the other hand, if no matching is attempted prior to the interviewing, then duplicates may not be detected, thereby increasing interviewing costs and error. A second problem could result from the necessity to initiate more than one data collection procedure. A list frame may contain more information about the elements than an area frame, since the latter is derived from listing. Thus, the use of area frames often requires greater expense. Finally, duplicates are usually not purged but, rather, they are dealt with by weighting. Thus, the estimates from multiple frames require calculations based on different combinations of weights because individuals may be covered by different frames – hence the calculations are more complex than those from a single frame survey.

Finally, under certain circumstances, coverage error may be dealt with through post-weighting the data to adjust for coverage error. However, this strategy is only useful if there is some way of estimating the extent of coverage error. As noted above, national censuses, if they exist, may be the best source, but biases are also likely in any census listing, and they are probably the same as those an investigator might be trying to correct by weighting. The cost of arriving at those estimates has to be weighed against the gain in precision of estimates derived from adjusting the data. Also, the benefits of adjusting are generally greatest for simple linear statistics such as a mean or proportion [3].

Sampling in Developing Countries

The objective of this article is to discuss issues that are important in the design and implementation of sample surveys that are undertaken in developing countries. Our approach is to discuss the major elements that anyone planning a sample survey in a developing country should take into consideration. For some of these elements, there are no special differences between planning a sample survey in the Third World and planning one in a developed country. Where there are differences, we will attempt to outline the special problems that are likely to occur in Third World surveys.

Objectives of the Survey

From a sampling point of view, it is not enough to state that a survey aims to provide information about, for example, potential users of family planning. The survey objectives must state precisely who will be sampled (sampling or selection unit), who will be interviewed (measurement or observation unit), and about what population will inferences be drawn (analysis unit) (*see* **Target Population**).

For example, a household survey might sample households, interview all female household members of childbearing age, and draw national inferences about children born.

Universe definition is also a very basic concept in sampling. For example, the objective might be to draw national inferences, but certain regions of the country might be considered unsafe or inaccessible because of reasons such as war, guerrilla activity, political unrest, disease, and so on. Under these circumstances, the universe might be redefined to include the country without certain regions.

Sample Size

Sample size refers to the total number of completed interviews. Because of a variety of factors such as **nonresponse**, it is almost always necessary to select an original sample larger than the targeted number of final completed interviews. The basic three issues that need to be considered in setting the sample size are:

1. available resources;
2. desired level of precision; and
3. analysis plans.

The relationship between *available resources* and sample size is the easiest to grasp. If, for example, the desired precision calls for a sample size of 1000 and the budget allows for 800, then the choice is a simple one of sampling the maximum permitted by the budget.

With respect to *desired precision*, there is fortunately a very simple "family" of statistical formulae that can be used to determine the sample size. These formulae permit one to establish a desired level of precision in terms of a **confidence interval** and use this target to derive the necessary sample size. It is important to note that, in most real-life situations, the *sampling precision does not depend on the population size* (*see* **Sample Size Determination**). It should also be noted that paying for a larger sample size has the benefit of reducing the **standard error** and increasing the precision of the results.

The third and final consideration with respect to sample size is the *analysis plan*; most importantly, the subclasses to be analyzed. The researcher first needs to decide for which major subclasses will results and **inferences** be desired. For example, in a national survey of condom sale and usage, it might be important to draw conclusions about individual cities. In this case, it will be necessary to establish sample sizes separately for each city and then cumulate these individual samples to arrive at the total sample size.

A second part of the analysis plan involves anticipating cross-classifications that will be carried out for each population of interest. For example, let us consider a survey whose objective is to study the relationship between education and condom usage. This goal suggests a cross-classification of the two variables, and it is important that the expected cell sizes be sufficiently large to permit the required analyses. A useful rule of thumb is to aim for minimum cell sizes of 20.

Sampling Frame

The first step in any sample selection is to produce a list of the population elements from which the sample is to be drawn. This is known as the **sampling frame**. Whereas samples based on telephone lists and **random digit dialing** schemes have become

part of the sampler's repertoire, it is highly unlikely that these methods could be used effectively in most developing countries. Not only is it often true that large portions of these countries' areas simply do not have telephone service, but even in areas where telephones are prevalent, the coverage is far from complete, and hardly a source for reaching targeted groups such as urban residents.

This leaves the sampler in a developing country to choose between a *list sample* and an *area sample*. However, again, it is doubtful that accurate and complete lists of population elements exist in these countries. Samplers therefore resort to designs based on area frames, whereby the first stage of sampling involves selecting relatively large geographic areas such as counties, districts, zones, municipalities, and so on. In order to implement this sample design, lists are required for the total number of such areas in the country.

Following are some criteria for evaluating sampling frames.

Frame Coverage, Accuracy, and Duplication

Starting with a good sampling frame is extremely important for a successful sample design. How complete is the frame? Are there elements of the population that are missing? If there are known missing elements, then the frame suffers from *undercoverage*. For example, a list of tobacco retail outlets, no matter how small, in a large city in a developing country is highly likely to be incomplete.

Are there foreign elements in the frame? That is, are there elements on the frame that should not be there? If so, then the frame suffers from *overcoverage*. For example, a list of schools in an urban area should not contain buildings that are not schools, for example, teacher colleges, kindergartens, and so on.

The information on the frame should be *accurate* and up-to-date. A sample drawn from an error-prone frame will not reflect the population that is the target.

Finally, the frame should be free of duplicates. If duplicates are known to be present, they should be removed or the selection probabilities should be adjusted.

In many developing countries it is often a major challenge to locate a reliable source to serve as a sampling frame. Recent **censuses** can often provide one solution but, if this source is unavailable, one must define and select large geographic units based on the most accurate measures of size that are available. Once these units are selected, one has to update constantly their counts (e.g. population, households, schools).

Not only are sampling frame unit counts often unavailable or unreliable, but the cartographic details can also be missing or defective. Accurate limits of the areas have to be specified and mapped, and the first visit to these areas necessitates careful cartographic work, which needs to be maintained and updated as part of future surveys in these areas.

With respect to establishment surveys in developing countries, it is worth pointing out that there is usually a less-skewed distribution of the units by size than is found in more industrialized nations. For example, there is likely to be a higher proportion of small farms in developing countries as well as lower concentration of total land and revenue in the larger agricultural holdings.

Sample Design

Probability sampling designs can include any or a combination of the following sampling techniques: **simple random sampling, systematic sampling**, **stratified sampling, cluster sampling**, or **multistage sampling**. At any stage in the sampling process, survey units may be selected with either equal or unequal probabilities.

Simple random sampling (SRS) and systematic sampling are two basic methods for randomly selecting samples. Both lead to equal probabilities of selection for every unit in the population, but systematic sampling is easier to implement.

In a single stage design, every sampled unit is surveyed. In a multistage design, selections are made first of larger units and then, in subsequent stages, subselections are made within these first-stage units. The units selected in the first stage are called Primary Sampling Units (PSUs); units selected in the second stage are called Secondary Sampling Units (SSUs). A typical household survey employs two to five stages of selection, the last of which is usually the selection of one eligible member from the household. The overall probability of selection of a multistage sample is equal to the product of the probabilities of selection at each sampling stage.

One popular sample design leading to equal probabilities of selection is known as **sampling with**

probability proportional to size (PPS) by which first-stage units (PSUs) are selected with probabilities proportional to some measure of size (e.g. number of households) and a constant number of second stage units are selected within each selected PSU. This approach is often particularly effective for developing countries where PSUs can vary considerably in size. Unfortunately, the drawback is that measures of size are often unknown or known poorly. The solution is to estimate and record accurately the measures during the first visit to the PSUs.

Stratification and Clustering

Stratification and clustering are two techniques utilized to group population elements before sample selection for the purpose of improving the practicality or the efficiency of the sample design.

Stratification involves the division of a population into parts called strata. Ideally, each stratum contains units that are homogeneous with respect to the survey variables of interest. A **random sample** is selected from each stratum. Examples of strata are large geographic areas such as districts, urban and rural areas in a country, and high and low socioeconomic status areas in a city.

Clustering also involves the division of the population into groups but, unlike strata, clusters are groups of heterogeneous population units. Ideally, each cluster should be a microcosm of the population. Some naturally occurring clusters are provinces, city blocks, and classrooms.

Briefly, stratification is "good" and clustering is "bad". Stratification tends to increase precision and to ensure representativity. Clustering decreases precision.

Implicit stratification can be very useful when the sample is being drawn from a list of units. For example, suppose that one has a list of administrative areas in a country and for each we have a reasonably accurate estimate of the total population. Stratification could be implemented by simply ordering the list of areas from smallest to largest and then systematically sampling every *n*th area starting at the top. Since small areas are at the beginning of the file and largest at the end, it is very unlikely that only small or only large areas will be in the sample. This procedure is known as implicit stratification, since the objective of stratification has been achieved without creating explicit strata.

Another useful concept is the *self-representing stratum*, which refers to strata in which no subsampling takes place at the first stage. For example, it is typical in a national area-based sample for large cities to be defined as self-representing strata. Self-representing strata are usually large densely populated areas. Once a city has been defined as a self-representing stratum, sampling is carried out in that city during subsequent stages of the sample design.

Allocation

Once the strata are created, it is necessary to decide what size sample to allocate to each (*see* **Stratified Sampling, Allocation in**). One approach is called *equal allocation* which consists of assigning to each stratum an equal sample size. For example, a total sample of 200 over 10 strata would require 20 sample elements per stratum. Another approach is *proportionate allocation*, which calls for allocation of the total sample to the strata in proportion to the stratum population sizes.

In practice, there is often a need for *oversampling* in certain strata. This would call for a strategy that is neither equal nor proportionate. This approach can be justified especially if the analysis calls for separate reports for the strata being oversampled.

Selecting Households and Respondents in Household Surveys

One of the most important types of survey is the household survey, in which households are usually selected in the penultimate stage and a respondent or several respondents in the last stage. It should be pointed out that in many developing countries the definition of what constitutes a household and family differs sometimes markedly from concepts commonly used in more industrialized nations. Care must be taken that the definition of household is specific, unambiguous, and easy to implement in the field.

At some stage in the survey process it is necessary to select households to interview. This can be done basically in two ways. One approach would be for interviewers (or *listers*) to visit each selected block and make a complete listing of all households in those blocks. Clearly, this is a time-consuming and expensive operation. However, once completed, the

lists can be used to draw accurate samples, to monitor field progress, and to draw samples for subsequent surveys.

A less resource-intensive strategy and one very often employed in sample surveys in developing countries is called *co-listing*, whereby interviewers both list and interview in one operation. They are given a map of the block, they are told where to start, in what direction to proceed (usually "serpentine"), and with what frequency to select households.

Once a household has been selected, it is often required to interview one adult in the household, and this person has to be selected at random. Many procedures have been devised to implement this procedure, the most rigorous one involving a complete listing of all persons in the household.

Execution

All sampling procedures need to be tested before production. Part of the design (PSU creation and selection) can often be implemented in the head office, but other stages – for example, selection of final sampling units – have to be tested and carried out in the field.

Even the best planned design will be subject to unpredictable deviations during the execution stage. Reasons are numerous: nonresponse, imperfect frame and population data, real change, human error, and so on. There are at least two corrective actions that can mitigate the effect of these problems. First, a focused attempt should be made to predict as many of these factors as possible and to make contingency plans. The second part of the solution is to keep meticulous, accurate, well-organized, and preferably computer-based quantitative records of all steps in the sampling process.

As with any large-scale and complex operation involving teamwork, it is imperative that rigorous monitoring and quality control be included as an integral and important part of the survey process. The work of all field staff, including interviewers – especially new ones – should be regularly checked for errors, both accidental and intentional.

The question that is asked almost as often as the one about sample size is "What level of response rate is considered acceptable?" First of all, it is not the response rate *per se* that is the danger – it is the nonresponse bias; that is, the extent to which responders differ from nonrespondents (*see* **Bias from Nonresponse**). It is conceivable, albeit unlikely, that a 20% response rate sample manifests little bias.

Secondly, there is no substitute for high response rates, both at the level of the respondent and at the level of the individual questions. A large part of the survey resources, training, and overall effort should be directed to increasing the response rate as much as possible. Many statistical procedures (weighting and imputation (*see* **Multiple Imputation Methods**)) have been developed to overcome nonresponse, but these should be considered imperfect solutions to a problem that is much better solved in the field.

At the risk of sounding arbitrary, we would suggest that surveys that are to be conducted in developing countries strive to achieve at least a 50% response rate and preferably a minimum of 60%.

Data Processing

Once data are collected in the field, they have to be processed; that is, edited, coded, keyed, cleaned, and analyzed (*see* **Data Management and Coordination**). Between the editing and analysis phases, it is necessary to calculate survey weights.

Weighting

Before the analysis phases, it is necessary to calculate survey weights to account for unequal probabilities of selection (planned or otherwise), other deviations from the design, and to make final adjustments that bring the sample results in line with known population distributions.

Unequal probabilities may arise at any stage of the sampling process. A separate weight is required for each stage of the sampling process in which differing probabilities are used.

The sampling weight is further adjusted to account for nonresponse. This entails knowing something about nonresponding outlets, information which can be gleaned from looking at response rates across various subclasses.

In the final stage in the weighting process a **post stratification** weight is derived by comparing the sample and population distributions for basic, known variables, such as region, age, race, sex, and income.

Analysis

It would be convenient, although unrealistic, if all surveys could be based on simple random samples with no stratification or clustering. However, this is almost never the case. It then becomes an important, although often overlooked, requirement of analyses based on sample survey data to include the complexity of the design in the analysis. The two components of complexity are stratification and clustering. They work in opposite directions, the first raising precision and the second lowering it. Unfortunately, in typical area-based surveys, the effect of clustering is dominant, and the overall result is that ignoring the complexity of the design will result in an underestimation of the true sampling **variance**. What this means is that results that might seem statistically significant are in fact not, if one takes into account the true sampling variability.

The complexity of the design can be incorporated by running specific software (*see* **Software for Sample Survey Data**) or by including design effects in the calculation of sampling errors.

Dissemination

As part of the dissemination plan, in addition to standard analyses, tables, and other products, it is very important to include a complete description of the sample design and all deviations that occurred in the field (e.g. nonresponse rates). This will help readers to determine how much confidence they can have in the results and the conclusions.

As a matter of course, it is also advisable to include standard errors (correctly calculated) in the tables.

Sampling With and Without Replacement

Sampling with replacement is a class of sampling procedures in which the selected elements are replaced in the selection pool following each "draw" and may be reselected on subsequent draws. In contrast, *sampling without replacement* is a class of procedures in which the already selected elements are not replaced in the pool and cannot be selected again [1, p. 37].

Under **simple random sampling** without replacement of a sample of size n from a population of size N, the first element of the sample is selected with a probability of $1/N$; the second element of the sample is then selected from the remaining $N-1$ elements with a probability of $1/(N-1)$; and so on. Finally, the nth element of the sample is selected with a probability of $1/(N-n+1)$. It can also be shown from elementary combinatorial theory that the probability of the kth element of the population being included in the sample, under simple random sampling without replacement is n/N.

Under simple random sampling with replacement of a sample of size n from a population of size N, n independent draws are made such that in each draw, each element of the population has an equal probability, $1/N$, of being selected. Since, after each draw, the selected element is replaced into the population, some elements in the sample may be drawn more than once. Thus, the probability that the kth element of the population is *not* included in the sample is $(1-1/N)^n$ and its inclusion probability is $1-(1-1/N)^n$ [2, p. 49].

Some further points concerning the relationship between sampling with and without replacement are as follows:

1. The **variance** of conventional estimators (e.g. means, total, or ratios) under simple random sampling without replacement is $(N-n)/(N-1)$ times its value under simple random sampling with replacement (*see* **Finite Population Correction**), when conventional estimators are applied [3, pp. 29–30]. That is, the variance in sampling without replacement is smaller than that in sampling with replacement. However, the variances under the two sampling schemes are nearly equal when the population size, N, is large and the sample size, n, is small.
2. In practice, almost all sampling is conducted without replacement, and the "classical" methods of finite population sampling theory were developed primarily for this class of sampling designs.
3. Under certain conditions, results derived under the assumptions of sampling with replacement are approximately equivalent to those that would have been obtained under sampling without replacement. One example is **sampling with probability proportional to size**.

Sampling With Probability Proportional to Size

There are a number of reasons for selecting a sample with probabilities proportionate to size (PPS). As the name "proportionate to size" implies, the sampling elements are aggregated or arranged into groups or units of different sizes. Examples include students in schools, people in cities or counties, and patients served by hospitals. Sampling PPS is an efficient design when: (i) a list of the population is not available but ancillary information is; (ii) the elements are in clusters or groups which differ greatly in size; (iii) it is important to control the sample size; (iv) costs and equalizing interviewer workloads are important; (v) the use of natural divisions is possible and supplementary information is available by the natural divisions; and (vi) the sample must be drawn in multiple stages.

The quintessential example of PPS sampling is a multistage area probability sample (*see* **Multistage Sampling**). A typical study might be of individuals that reside in households and the research objectives might be to estimate a health characteristic, action, or belief. An area probability sample satisfies all of the above conditions. In the US, for example, no complete list of the general population exists. Lists are available of telephone subscribers, registered voters, property tax payers, people with driver's licenses, and others, but all of these have major omissions/exclusions and have varying degrees of currency and turnover. As a result, they are not acceptable **sampling frames** for most studies. The most comprehensive listing of the US population is the count of the population in various types of domiciles every 10 years by the US Census Bureau. The decennial **census** provides counts by various civil and political areas: in other words, states; counties, parishes, or boroughs; Indian reservations, towns, or townships; census tracts or block numbering areas; and blocks. This information is used to construct the initial phases of a PPS sampling frame. Social and economic characteristics of the population are used to stratify (*see* **Stratified Sampling**) and order the geographic entities before selection.

Because no list of the population exists, the sample is drawn in stages using population or housing unit count data. These data indicate how many people reside in a defined geographic area and how many households there are in the same area, but they do not tell us where and what types of housing unit structures are located within the area, how many people reside in each household, or which households are occupied or vacant. The sample design is nested in that subsequent selections are made within areas selected in previous stages. At the next to last stage of selection, which is typically blocks or segments of blocks, a person trained in the listing of housing units and households is sent to each selected area. A comprehensive list of all dwelling units within every commercial and residential structure is made. The final sampling rates are applied to these lists of dwelling units.

An advantage of PPS sampling over **simple random sampling** is control of the final sample size and the workload for interviewers. We will illustrate the first point after a brief explanation of the latter point. Selecting and training interviewers is usually handled in one of two ways. One approach is to hire and train in one location and then send the interviewers to each sample location. This works well when travel costs and distances are not very great. When the sample covers a large geographic area (e.g. several states or the entire US) a better approach is to hire interviewers in multiple locations. Training is then carried out at a number of regional locations to reduce travel costs. With either approach, it clearly makes sense to equalize the workload across interviewers. It is not cost effective to hire and train an interviewer to conduct only a few interviews if the average workload is 25–40 cases.

In densely populated areas, interviewers are usually assigned cases in their home counties. In small towns and rural areas, they are given cases not only in their home county but also in adjacent or nearby counties. The travel distances are longer but the travel times are comparable to large urban areas. Interviewers are typically paid for both travel time and expense from their homes to the sample locations; the actual time to conduct the interviews is estimated to be only 25%–40% of the total interviewing costs [7]. A major portion of the total cost is attributable to interviewer travel time and expenses. Thus, selecting more than one household at each sample location is a way to reduce interviewer costs; however, it typically increases sample **variances**. Considerations for addressing this issue are discussed later.

With the above points in mind, we can now illustrate why using a PPS design is more efficient than using an equal probability of selection method (epsem) at all stages of selection in a multistage design. Assume that we want to select a sample of 1200 individuals in the State of North Carolina. Further assume that we want the design to satisfy the following conditions: (i) the sample should be epsem or self-weighting; (ii) the sample size should yield approximately 1200 interviews; and (iii) the workload among interviewers should be fairly equal. There are two important design components in a multistage epsem sample: (i) the overall probability of selection, f, where $f = n/N$, with n being the sample size and N being the population size; and (ii) determining the number of units selected at the first stage of sampling – the primary sampling units (PSUs) – or choosing the average number of sampling elements to be interviewed at the last stage of selection – which is usually the block level. When the number of PSUs is large and expensive to subdivide, the number of PSU selections should not exceed one-fifth of the total number of units; otherwise, the expense for this stage of selection cannot be justified [3]. Counties are frequently used as PSUs because there are a large number of them (more than 3000 in the continental US), they are important administrative and governmental units, they are stable, and measures of size and other useful sampling information for them are readily available [3].

North Carolina contains 100 counties. If we want 1200 interviews from a population of approximately 8 million people, the overall probability of selection $\Pr_T = n/N = 1200/8\,049\,313 = 0.000149$, or a sampling rate of 1/6707. If we select an epsem sample of 20 counties at the first stage of selection, the sampling rate within counties will be 1 in 1341 people, because $1/6707 = (20/100)(1/1341)$.

Table 1 presents the results from a systematic random sample of 20 counties and the number of cases to be selected within each county using a rate of 1 in 1341. The results show that instead of 1200 cases being selected, there are only 881: a shortage of 319 cases or approximately 27%. The number of cases selected per county varies widely, from a high of 110 cases in Davidson County to a low of three cases in Tyrrell.

A related inefficiency of this design is the estimate of variance of the sample **mean**. If we assume equal population variances by county, a PPS sample of 20 counties and 60 persons per county would give the following estimate [7]:

$$\sum_{i=1}^{n} \frac{\sigma^2}{n_i} = \frac{20\sigma^2}{60} = 0.33\sigma^2.$$

The estimate from Table 1, however, is $0.9638\sigma^2$, or 2.92 times greater.

A few additional comments about these results, and about using an epsem when PSUs vary in size, are in order. The population of North Carolina counties ranges from a low of 4149 in Tyrrell County to a high of 695 454 in Mecklenburg; the latter being more than 167 times larger than the former. Among the 100 counties, five have a population of 250 000 or more and 23 have a population greater than 100 000. The important points to note about the results in Table 1 are that none of the five largest counties was selected, only three of the counties with a population over 100 000 were selected, and counties with the fewest sampled cases contribute disproportionately to the higher estimated variance. Sampling with probabilities proportionate to size at all stages except the last stage in a multistage design can correct these design deficiencies.

Table 1 Expected sample sizes and $1/n_i$ from 20 randomly selected counties.

Table 2 illustrates one method of preparing the sample frame for the selection of PSUs in a PPS sample. To conserve space, only 40 of the 100 counties are listed. The counties are arranged in descending order by a **stratification** variable, **median** household income. The number of people in each county is listed and the cumulative total is calculated. We can see, for example, that Wake County has the highest median household income of 54 988 and a population of 627 846, which is the second largest. The cumulated subtotals are required because at this stage of selection each county receives a probability of selection which is proportionate to its population size.

Table 2 shows county population and median household income data for the 15 counties with the highest median household incomes and the 25 counties with the lowest median household incomes. As in Table 1, we want to select 20 counties systematically, but this time by probabilities proportionate to their population sizes. To do this we divide the total

cumulative population (8 049 313) by the desired number of PSUs, $a = 20$. This gives a sampling interval of 402 465. A random start between 1 and 402 465 is selected (126 599), and the sampling interval is added to the random start until the cumulated total is exceeded.

The results in Table 2 indicate that four of the five counties (Cumberland is not shown and was not selected) with populations exceeding 250 000 were selected in the sample and that only two of the last 25 counties were selected. There is a moderate **correlation** between population size and household income and all but two of the 23 largest counties (population of 1 000 000+) are in the first 55 counties listed. Note that the sampling interval falls twice within Mecklenburg and Wake Counties. If we select approximately 60 cases per county, a double sample or 120 cases would be selected in these two counties. Also, because Mecklenburg and Wake were selected twice, only 18 different counties were selected. Counties such as Mecklenburg, Wake, and Guilford are selected into the sample "with certainty" because their population sizes exceed the sampling interval.

In situations in which some of the PSUs are larger than the sampling interval, each certainty PSU should be treated as a separate stratum. The overall sampling rate is applied to each certainty PSU and the number of selected cases per PSU is allowed to vary depending on the size of the PSU. The noncertainty counties are treated as a separate group. With this approach, the certainty PSUs are sampled using the initial overall selection rate and the noncertainty counties are allocated the remaining cases and sampled PPS with a new sampling interval.

To illustrate this approach we proceed as we did in Table 2. We want to select 20 PSUs and a sample size of 1200. We calculate the sampling interval as before, but before we select a random start, we look over the list of counties to see how many will fall into the sample with certainty; that is, have a population greater than 402 465. There are three counties: Wake, Mecklenburg and Guilford. We now subtract the total population of these three counties (1 744 348) from the state total (8 049 313) and divide the new total (6 304 965) by the number of PSUs that we still want to select (17). This gives a new interval of 1 in 370 880. Again, we check the list of 97 counties to see if any are now certainty counties and we see that none are. If any counties were certainty, we would deal with them as we did the first three. This process would continue until no counties were certainty selections. When that occurs, the final PSUs are selected.

We can see that at this stage in the selection process the probabilities of selection among the PSUs are unequal and, therefore, a fixed sampling rate must be used at the final stage of selection [6]. Since the PSUs were selected proportionate to size, the final elements must be selected inversely proportionate to size in order to give each element the same overall probability of selection. This is demonstrated as follows [7]:

$$\Pr_{\mathrm{T}} = \frac{n}{N}$$

is the overall probability of selection;

$$\Pr_{\mathrm{PSU}} = \frac{MOS_{\mathrm{PSU}}}{(N/a)}$$

is the probability of a PSU being selected, where MOS_{PSU} is the population count for the county and a is the desired number of PSUs to be selected;

$$\Pr_{\mathrm{W}} = \frac{\Pr_{\mathrm{T}}}{\Pr_{\mathrm{PSU}}}$$

is the probability of selection within the PSU.

$\Pr_{\mathrm{W}}$ is known as the selection equation [2]. Essentially, it is the probability of a PSU being selected multiplied by the probability of an element within the PSU being selected if its PSU was selected at the initial stage. This can be seen more clearly by solving for $\Pr_{\mathrm{W}}$:

$$\Pr_{\mathrm{W}} = \frac{\Pr_{\mathrm{T}}}{\Pr_{\mathrm{PSU}}} = \frac{n}{N} \times \frac{N}{aMOS_{\mathrm{PSU}}} = \frac{n}{aMOS_{\mathrm{PSU}}}.$$

The number of selected elements in a PSU is determined by the PSU size multiplied by the probability of selection within:

$$n_i = MOS_{\mathrm{PSU}} \left(\frac{n}{aMOS_{\mathrm{PSU}}} \right) = \frac{n}{a}.$$

Thus, the same number of elements will be selected from each noncertainty PSU regardless of the size of the PSU. For certainty PSUs, $\Pr_{\mathrm{W}} = \Pr_{\mathrm{T}}$ because $\Pr_{\mathrm{PSU}} = 1$. The number of elements to be selected within a certainty PSU is $MOS_{\mathrm{PSU}} \times n/N$. Assume that Wake County and Mitchell County are selected. Wake is a certainty and Mitchell is a noncertainty county. For Wake, the number of selected elements is determined by $\Pr_{\mathrm{T}} = n/N = 0.000149 \times$

$MOS_{\text{PSU}}(627\,846) = 93.6$. The sample size not allocated to the certainty counties will be allocated equally among Mitchell and the other noncertainty counties. Thus, 940 cases allocated to 17 counties is approximately 55 per county. We can illustrate this with Mitchell County. The noncertainty selection interval is 370 880. Mitchell County's *MOS* and probability of selection are $15\,687/370\,880 = 0.042297$.

$$\text{Pr}_{\text{W}} = \frac{\text{Pr}_{\text{T}}}{\text{Pr}_{\text{PSU}}} = \frac{0.000149}{0.042297} = 0.00352.$$

The estimated number of selected elements in Mitchell County is $15\,687 \times 0.00352 = 55.2$ or 55, or 57.

The same PPS procedures are used when there are two or more stages to the selection process. This is illustrated as follows [7]:

$$\text{Pr}_{\text{PLACE}} = \frac{MOS_{\text{PLACE}}}{MOS_{\text{PSU}}/b}$$

is the probability of a place within a PSU being selected;

$$\text{Pr}_{\text{BLOCK}} = \frac{MOS_{\text{BLOCK}}}{MOS_{\text{PLACE}}/c}$$

is the probability of a block within a place being selected;

$$\begin{aligned}\text{Pr}_{\text{HOUSE}} &= \frac{\text{Pr}_{\text{T}}}{\text{Pr}_{\text{PSU}}\text{Pr}_{\text{BLOCK}}\text{Pr}_{\text{PLACE}}} \\ &= \frac{n}{N}\left(\frac{MOS_{\text{PSU}}}{N/a} \times \frac{MOS_{\text{PLACE}}}{MOS_{\text{PSU}}/b}\right. \\ &\quad \left. \times \frac{MOS_{\text{BLOCK}}}{MOS_{\text{PLACE}}/c}\right)^{-1} = \frac{n}{abcMOS_{\text{BLOCK}}}\end{aligned}$$

is the probability of a household within a block or block area being selected. Here, a is the desired number of PSUs, b is the desired number of places to be selected per PSU, and c is the desired number of blocks to be selected per place. The expected number of cases per block or block area is

$$\begin{aligned}MOS_{\text{BLOCK}} \times \text{Pr}_{\text{HOUSE}} &= \frac{MOS_{\text{BLOCK}} \times n}{abc \times MOS_{\text{BLOCK}}} \\ &= \frac{n}{abc}.\end{aligned}$$

The number of places and blocks selected within a PSU is based on costs and the degree of homogeneity within clusters for the variable being estimated. These factors will be discussed shortly. If we had determined that in noncertainty PSUs seven places and two blocks per place should have been selected, the number of households selected per block would be approximately: $n/abc = 940/17 \times 7 \times 2 = 3.95$. For certainty PSUs, where the sample sizes are larger, the number of places selected is increased while the number of households selected per block remains the same.

A number of design considerations from the foregoing example need to be addressed. Many of the points raised in the following five items apply to **cluster sampling** in general.

1. Very seldom do we know the exact sizes of our sampling units. This is especially true when dealing with human populations because areas change in size due to growth, migration, or demolition of housing units. In most situations, good estimates are available from a recent census, real estate or neighborhood groups, city and county governments, and other groups that monitor or are involved in population change. It is important that measures of size be reasonably accurate so that serious selection problems are avoided. A serious problem would be selecting a block with an expected 25 housing units and, upon visiting the block, finding that a 500-unit condominium has been built. For a sample to remain epsem, the cluster size at the final stage of sampling must be allowed to vary to reflect the differences between the expected and the actual sizes. Detailed discussions of listing blocks and areas and how to deal with high growth and zero household blocks can be found in Kish [3] and Sudman [7].
2. When we use estimated measures of size, the sample size becomes a random variable. The sample mean is estimated by $r = y/x$, where y is the sample total for the variable being estimated and x is the total sample size. This estimator is not unbiased, but the **bias** can be ignored when the coefficient of variation of x (*see* **Standard Deviation**) is less than 0.2 [2]. The general form of the variance estimator is

$$v(r) = \frac{[v(y) + r^2 v(x) - 2rc(x, y)]}{x^2},$$

where $c(x, y)$ is the sample covariance between x and y, and $v(y)$ and $v(x)$ are sample variances. This formula holds whether or not PSUs are

stratified and the method of subsampling within PSUs does not matter [2, 3] (*see* **Ratio and Regression Estimates**).

3. When elements are selected in clusters, two things occur. The elements are not selected independently of each other as in simple random sampling and elements that are grouped together usually have some degree of similarity or homogeneity. The degree of homogeneity within clusters and the average cluster size typically cause an increase in sampling error. Levy & Lemeshow [5] provide the following formula for the standard error of the element mean from a two-stage cluster sample:

$$\text{se}(\overline{\overline{x}}_{\text{CLU}}) = \left(\frac{\sigma_x}{\sqrt{n}}\right)[1 + \delta_x(\overline{c} - 1)]^{1/2}.$$

The only difference between the **standard error** for a simple random sample and the above formula is the expression in the square brackets. This is known as the **design effect**. It is the ratio of the variance from a cluster sample to that from a simple random sample of the same size. $\overline{c}$ is the average number of households sampled per block and δ_x is the intraclass **correlation** coefficient. δ_x is a measure of the homogeneity among all possible pairs of elements. This parameter can take values between $+1$, when all the elements are similar on the characteristic, and $-1/(\overline{c} - 1)$, which would indicate that there is more variability among the elements within a cluster than in a simple random sample. The intraclass correlation is typically small, positive and below 0.15 [2].

4. Costs need to be considered when determining the number of PSUs to select and the average cluster size per block. A cost function for the sampling and field costs for a two-stage design is

$$C_{\text{T}} = aC_1 + nC_2,$$

where C_{T} is the total cost of sampling and fieldwork; a is the number of PSUs; C_1 is the average cost of sampling, listing, and hiring, selecting, training, and supervising interviewers at each PSU; n is the total sample size; and C_2 is the average cost of each interview. The optimum cluster size per block can be determined from

$$\overline{c}_{\text{opt}} = \left[\frac{C_1}{C_2}\left(\frac{1-\delta}{\delta}\right)\right]^{1/2}.$$

This expression shows that when C_1 is much larger than C_2 and δ is small, the optimum cluster size can be large. Sudman [7] indicates that the optimum cluster sizes per block for many social science variables ranges from three to eight. The number of PSU selections can be determined from [1]:

$$a_{\text{opt}} = \frac{C_{\text{T}}}{(C_1 + C_2\overline{c}_{\text{opt}})},$$

where C_{T}, C_1, C_2, and $\overline{c}_{\text{opt}}$ are defined above.

5. The same measure of size information need not be used at every stage of selection in a multistage design. For example, PSUs can be selected using population count data and places within PSUs can be selected using household count data. This is possible because there is a very high correlation (0.97) between these items of information [7].

Sampling PPS for Telephone Surveys

One of the most innovative **random digit dialing** (RDD) telephone sample designs uses PPS sampling [8] (*see* **Telephone Sampling**). Early national RDD samples were designed to select a **systematic sample** of area code/prefix combinations from a national list frame. Four random digits were added to these six-digit numbers to form a complete ten-digit telephone number. The problem with the design is that 75%–80% of the telephone numbers generated are not residential household numbers. Waksberg [8] proposed a two-stage procedure which increases the proportion of working residential household numbers by subsampling within banks of numbers where a household is found at stage 1. Essentially, ten-digit numbers are formed as described above; however, if a household is contacted, a new sample number is created based on the initial number. The Mitofsky–Waksberg procedure suggests keeping the first eight digits (the area code + prefix + first two random digits) and substituting two random digits for the last two digits to create a new ten-digit telephone number. New numbers are created at the second stage of sampling until a fixed number of households are contacted. This is a PPS design because the first-stage selection probabilities are determined by the number of residential telephone households in the 100-number bank selected and, since a fixed number of households are called at the second stage,

the probabilities at this stage are inversely proportional to size. With this design, about 60% of the numbers generated at the second stage are residential households. Lepkowski [4] and others [5] discuss difficulties encountered with this design and a much simpler design, list-assisted RDD, that has, in general, near complete telephone population coverage and a small bias (*see* **Telephone Sampling**).

RONALD CZAJA

Savage, Leonard Jimmie

Born: November 20, 1917, in Detroit.
Died: November 1, 1971, in New Haven.

Leonard Savage lived all his life with very bad eyesight. As a result, whenever he read anything, and he read a lot and widely, he read with deep concentration and understanding. Not for him the superficial appreciation that the modern information revolution often imposes. He gained a Ph.D. in mathematics from the University of Michigan in 1941. His future career was determined by working in the Statistical Research Group at Columbia University. This he described as "one of the greatest hotbeds statistics has ever had". Thereafter, his main professionalism was in statistics. From 1946 to 1960 he was at the University of Chicago. After a brief period at the University of Michigan, he moved to Yale in 1964.

He gained an international reputation as a result of the publication in 1954 of his book *The Foundations of Statistics* [1]. Prior to 1954, statistics had been a collection of separate techniques. He felt that it should be treated like any other branch of mathematics, with its axioms, proofs and theorems. Inspired by the success of von Neumann in developing an axiom system for **utility**, Savage was able to construct a system for **inference** and decision making (*see* **Decision Theory**). In particular, he showed that uncertainty must be described probabilistically. The axioms of Kolmogorov became theorems in the new system. He has been described as the Euclid of statistics.

Savage set out to justify the separate techniques of statistics, like **confidence intervals**. They were to appear as theorems in his deductive system. While the first half of the book is a triumph, the second, in which he attempts to justify contemporary statistics, is a failure. By 1960 he had realized that what he had done was to destroy frequentist statistics. In its place, he had constructed what we now call Bayesian statistics (*see* **Bayesian Methods**). In particular, the confidence interval (a probability statement about an interval, given the value of a parameter) is replaced by a probability statement directly about the parameter. Savage, thus unwittingly, produced a revolutionary paradigm for inference and decision making. This revolution is, almost 50 years later, affecting the whole of statistics and much decision making. The plethora of significance tests (*see* **Hypothesis Testing**) is being replaced by probabilities of hypotheses. These probabilities, as Savage and **de Finetti** showed, are personal, or subjective. Objectivity in science arises only through the accumulation of data and the bringing together of different opinions.

Savage was a scholar of the old school. He was meticulous in his appreciation of the work of others. He was the first to understand the work of de Finetti and Frank Ramsey, done in the 1930s. He discovered independently some of their results and, by his work, was the first fully to understand what they had done. Although Bayesian statistics is often in disagreement with the ideas of **Fisher**, Savage's article on his work [2] is perhaps the best from which to understand the genius of Fisher. Savage's collected works, with further biographical details, appeared in 1981 [3]. He was a superb writer and lecturer who spoke and wrote with the scrupulous care that he devoted to his reading.

DENNIS V. LINDLEY

Scan Statistics for Disease Surveillance

Epidemiologists investigating disease incidence are drawn to clusters of cases occurring within a short period of time (*see* **Clustering**). Public health specialists as well as the media focus on clusters of cases of birth defects, cancer or suicides. Investigators seek to determine whether such clusters are more than just chance bunching, and search for common causative factors. Statistical tests are used to provide the researcher with a measure of the unusualness (statistical significance) of the cluster relative to chance bunching (*see* **Hypothesis Testing**). A popular statistic used in **disease surveillance**, first investigated in detail by Naus [37], is the scan statistic, the maximum number of events in a window of predetermined width, w. Formally, if we rescale time to [0, 1], and let $Y_w(t)$ be the number of events in time $[t, t + w]$, then the scan statistic, S_w, is

$$S_w = \max_{0 \le t < 1-w} Y_w(t). \tag{1}$$

(Alternatively, without rescaling time, set T to be the time frame of interest, r the duration of the window in actual time units, $w = r/T$, and let S_w be the maximum of $Y_r(t)$ over $0 \le t \le T - r$.)

The most common application of the scan statistic is testing for clustering conditional on N, the total number of events observed. Under the **null hypothesis**, H_0, the times of the N events have a **uniform distribution** on the unit interval. Rejection of H_0 for large values of the scan statistics is a generalized **likelihood ratio test** [38] for testing against the pulse alternative H_a: that for some unknown τ, representing the start of the increase, $0 \le \tau \le 1 - w$, and some **relative risk** $\theta > 1$, the density is given by

$$f(t) = \begin{cases} \theta/(1 - w + w\theta), & \tau \le t < \tau + w, \\ 1/(1 - w + w\theta), & \text{otherwise.} \end{cases} \tag{2}$$

The scan statistic has been used to detect clustering of a wide variety of reproductive and other outcomes, including congenital heart disease [41] and poisonings [20], and is used routinely in the Ontario Cancer Registry [27]. Applications to a wide variety of topics including cancer clusters, clusters of inflammatory bowel disease, parasuicide clustering, clusters of HIV in dialysis patients, and visual perceptions are described in [18].

The unconditional version of the statistic could be used to sound an alarm in real time in prospective surveillance applications, and requires the investigator to specify, a priori, the duration of the interval under study, and λ, the expected number of events over the entire time period. The null hypothesis for this model assumes that events occur at random according to a **Poisson process**. An analogous pulse-type alternative is that for some unknown τ, and unknown $\theta > 1$, $\mathrm{E}[Y_w(\tau)] = \theta\lambda w$, while for $t < \tau - w$ or $t > \tau + w$, $\mathrm{E}[Y_w(t)] = \lambda w$. However, since, in practice, the purpose of monitoring is to stop when a cluster is observed, the test could be applied when there are two intensities with an unknown change point Kulldorff [30] describes a generalization of the scan statistic for surveillance, in which w, the interval of the presumed increase, need not be specified in advance.

Often the scan statistic cannot be exploited fully since the precise times of the events are not known, but rather the data are grouped in discrete intervals. The most frequent application is when data are tabulated monthly, but clustering over 3, 6 or 12 months is of interest. The ratchet scan statistic [29, 51] maximizes $Y_w(t)$ when t can only take on values starting at the beginning of a calendar month.

Weinstock [54] modifies the scan so it can be used even when there is some underlying temporal trend to the disease specified by the density $f_0(t)$, or if the population at risk changes. He tests the hypothesis H_0: $f(t) = f_0(t)$ by replacing the constant window, w, by a variable window width $\omega(t)$, where

$$\int_t^{t+\omega(t)} f_0(s)\,\mathrm{d}s = w.$$

The statistic, however, thus loses its simple interpretation, and the associated optimal properties related to detecting pulses of length w.

A defect of the scan statistic is that w must be specified before the data are observed and should not be based on examination of the data. (For the surveillance model, both w and the time frame must be specified in advance.) Cressie [9] notes that it is better to choose an interval slightly larger than

the true pulse rather than one slightly smaller. Some protection against missing a cluster can be achieved by choosing two window widths and utilizing the **Bonferroni bounds** to test each at the $\alpha/2$ level. Loader [35] and Nagarwalla [36] present a statistic for testing H_0 against (2) in the case when w is unknown.

The Exact Distribution

Since the scan statistic does not have a **normal distribution** even for large N, and, furthermore, moments are unavailable, most of the literature has focused on finding critical values, k, so that under H_0 the occurrence of k or more events in any window of width w is unlikely to be due to chance. Naus [37] calculates $\Pr(S_{1/2} \geq k)$, $\Pr(S_{1/3} \geq k)$, and $\Pr(S_w \geq k)$, $w \geq 1/2$, under the null distribution of no clustering. General formulas for the exact distribution under both the null and the alternative are based on a generalized ballot problem [6] dealing with the amount of lead among L candidates. Naus [38] applies the result to express the distribution under the null, when $w = 1/L$, L an integer, as the sum of $L \times L$ determinants. The result was extended to arbitrary w [23], and to the distribution under a pulse alternative [9]. In general, these exact formulas are difficult to implement for moderate or large samples and small w, except in specialized cases, because they involve a large number of summations over many large determinants.

Approximations and Bounds

Many approximations or bounds are based on generalized Bonferroni-type inequalities involving intersections of up to J events, or on tighter versions of these inequalities for $J = 1$ [22] or $J = 2$ [33]. Especially for $J = 1$ and 2, these methods yield good approximations for small values of $\Pr(S_w \geq k)$, but are generally poorer for approximating the median of S_w or upper tail probabilities. Wallenstein [48] applies the simple bounds with $J = 1$ and 2 to $D_i = \sup_{0 \leq s \leq w} Y_w(iw + s) \geq k$, $i = 0, 1, \ldots, [1/w]$, to tabulate probabilities for a range of values of w common in disease surveillance applications. Berman & Eagelson [7] apply the upper bound with $J = 1$ based on $E_i = \{X_{(k+i-1)} - X_{(i)} < w\}$, $i = 1, \ldots N - k$, where $X_{(1)}, X_{(2)}, \ldots, X_{(N)}$ are the **order statistics** for the N events. Glaz [14, 15] derives tighter, but computationally more difficult approximations, by applying Bonferroni-type inequalities with larger J. An approximation that is both simple and accurate, involving sums and alternating sum of binomial coefficients, is given in [17].

Naus [40] develops a highly accurate formula for type I error for several types of scan statistic, by noting that conditioning on the recent past is approximately the same as conditioning on the entire past, or formally that $\Pr(D_i^c | D_1^c, \ldots, D_{i-1}^c) \cong \Pr(D_i^c | D_{i-1}^c)$. Thus, $\Pr(S_w \geq k)$ can be approximated based only on $\Pr(S_{1/2} \geq k)$ and $\Pr(S_{1/3} \geq k)$. Huffer & Lin [21] define M_k to be the number of k-clusters of length w, note that $\Pr(S_w \geq k) = \Pr(M_k \geq 1)$, and approximate this probability using the **method of moments**.

Applying the Hunter [22] bounds to $\Pr(\cup D_i)$, and then performing further approximations, a simple approximation for the null distribution of the scan statistic is [49]

$$\Pr(S_w \geq k) \cong (k/w - N + 1)\Pr(Z = k) + 2\Pr(Z > k), \quad (3)$$

where $Z \sim \text{bin}(N, w)$, i.e. Z is a **binomial random variable** based on N trials with probability of success, w. The first term (with coefficient $(k/w - N)$) in this approximation is implicit in asymptotic work by Cressie [10], while Loader [35], based on large deviation theory, gives an analogous but slightly more complicated approximation which, at least for $w = 1/2$, improves precision.

For the conditional scan, Alm [2] uses asymptotic theory to find that under the null hypothesis, given $E(N) = \lambda$,

$$\Pr(S_w \leq k) \cong \Pr(Z \leq k) \exp\{-\lambda(k + 1 - \lambda w) \times (1 - w)\Pr(Z = k)/(k + 1)\}, \quad (4)$$

where Z has a **Poisson distribution** with mean value λw.

Wallenstein et al. [52] approximate the **power** of the scan statistic against a pulse alternative for the conditional and unconditional cases. A further approximation for the conditional case yields that for relative risk $\theta \gg 1$,

$$\text{power} \cong \Pr(Z \geq k) + 2\Pr(Z = k)/(\theta - 1), \quad (5)$$

where $Z \sim \text{bin}(N, \theta w/(1 - w + \theta w))$. Based on **simulation** results, Sahu et al. [43] suggest sample sizes to achieve adequate power and compare power for triangular and rectangular pulses.

Space–Time Clustering, Moments

The scan statistic can be modified [50] to test for space–time clustering, for the case where "space" consists of g discrete geographical areas (towns, schools, cities, etc.) and there is no overall time trend. The statistic can be viewed as a variant of the Ederer–Myers–Mantel [11] statistic, where the maximum number of events within a calendar year is replaced by the maximum within any 365-day interval. The numerator of the statistic is the difference between the scan statistic for each geographical area and its expected value, and the denominator is the square root of the sum of the **variances**. When the number of geographic regions is moderately large, the **central limit theorem** indicates that the statistic has approximately a normal distribution.

Using both exact probabilities ($N < 19$) and simulation, the first two moments of the scan are tabulated [50] for six window widths and a range of Ns from 2 to 1000. Values of N not tabulated can be obtained from interpolation, or by use of the suggested linear approximations $\text{E}[S_w(N)] = wN + b_w N$, where the coefficients, b_w, are estimated from the tabulated data. Anderson and Titterington [3] extend the theoretical concept of the two-dimensional scan to geographic clustering by stretching or contracting geographic regions so that they have equal density. They display some empirical critical values and power for the spatial scan statistic, and compare it to a statistic based on squaring differences between the observed and expected densities and then integrating over the region. Kulldorff and Nagarwalla [32] describe a generalization of the scan, which is applicable for arbitrary spatial distributions and does not require specification of an a priori critical distance. The concept is extended by Kulldorff et al. [31] to detecting space–time clustering.

Seasonal Clustering

For detecting seasonal clustering (*see* **Seasonal Time Series**), data from several years are merged. The resulting 365-day period is viewed as a circle, with December 31 adjacent to January 1. The circular scan statistic, C_w, is the maximum number of events in a fraction, w, of the year. Ajne [1] finds $\Pr(C_{1/2} \geq k)$ in terms of an infinite sum, in contrast to the much simpler expression for the line [37]. He also points out that $C_{1/2}$ is the most powerful invariant test for the pulse alternative as θ approaches infinity, while Cressie [9] extends this result to general w and finds some interesting asymptotic results.

The pulse alternative differs from the sinusoidal alternative (peak followed by a trough 6 months later) for which Edwards' statistic [12] is often used as a test of seasonal clustering. The statistic $C_{1/2}$ is related to Hewitt's statistic [19] in which the monthly totals are replaced by their **ranks**, and the test statistic is the maximum over the sums of six consecutive monthly ranks. Rogerson [42] compares the statistics $C_{1/4}, C_{1/3}$, and $C_{5/12}$ with his generalizations of Hewitt's statistic based on the maximum of the sum of the ranks over 3, 4 or 5 consecutive months.

Except for special cases, the exact distribution of the circular scan statistic is very difficult to obtain since it cannot be cast in the form of a ballot problem, as the first and last "candidates" are the same. Nevertheless, the computation of $\Pr(C_w > k)$ can be reformulated so that the single probability that cannot be derived, involving an intersection of $[1/w]$ events, is very small, and approximations [51] can be obtained using methods similar to those described for the line.

Wallenstein et al. [51] propose a modification of the circular scan, termed the ratchet scan, which is applicable when only monthly totals are available and give a figure plotting ***P* values** against values of the statistic. Krauth [28] gives bounds based on the Bonferroni inequality, so that the P values need not be read off a figure.

A Generalized Scan Statistic, with Application to Assessment of Inhomogeneities in DNA Sequence Data

Glaz & Naus [16] generalize the scan statistic to the case of N independent random variables, $X_1, X_2, \ldots, X_N$, where N could be fixed or a random variable. They let $Y_m(t)$ be the sum of m consecutive random variables X_t to X_{t+m-1}, and define the scan statistic, S_m, as the maximum of $Y_m(t)$ over the integers $t = 1$ to $N - m + 1$. The special case $\{S_m = m\}$ is related to the runs test (*see* **Clustering**).

The special case where X is a **binary** random variable could be applied in the context of clustering of disease. For example, letting $X = 1$ denote the event that a birth is associated with a congenital malformation, and $X = 0$ otherwise, the statistic S_m is the maximum number of cases of congenital malformations in a series of m consecutive births. Fu & Curnow [13] show that S_m is a function of the log **likelihood ratio** for testing the hypothesis of a constant probability of disease, against the pulse alternative of a higher probability for m consecutive trials and a lower one elsewhere. Under both the null and pulse alternatives, they give a method to obtain exact probabilities, which, however, is difficult to implement for $m > 20$. Saperstein [44] and Naus [39] relate the distribution of S_m to a generalization of the birthday problem, and give results concerning the null distribution conditional on N. Chen and Glaz [8] describe and compare several approximations for the distributions of discrete scan statistic for one and two dimensions Wallenstein et al. [53] give an approximation for the power against a pulse alternative.

Recently, the generalized scan statistic has been applied to problems in **DNA sequencing** in which DNA can be viewed as a sequence of letters from a four-letter alphabet of nucleotides, a 20-letter alphabet of amino acids derived from triplets of these four nucleotides, or a three-letter alphabet of charges of amino acids. Exact or approximate probabilities for the length of the longest almost matching subsequence, or the largest net charge within any series of m consecutive amino acids, are given by Glaz & Naus [16], Sheng & Naus [46], and Karwe & Naus [26]. Asymptotic results for the distribution of the generalized scan statistic, based on methods such as the Chen–Stein method of Poisson approximation, are given by Arratia et al. [4, 5], Karlin & Macken [25], and Karlin & Brendel [24].

These results are often phrased in term of r-scans, the width of the smallest interval containing $\mathrm{r} + 1$ events, or equivalently the sum of r interarrival times. Su, Wallenstein and Bishop [48] use a compound Poisson approximation of Glaz et al. [17], as well as a modified binomial approximation to approximate the number of nonoverlapping r scans, and use the procedure for identifying gene regulatory regions. Leung and Yamashita [34] describe applications of r-scans to DNA sequence analysis focusing on identifying nonrandom clusters of palindromes. Segal and Wiemels [45] compare the scan statistic, bandwidth tests, and gap statistics for detection of translocation breakpoints.

S. WALLENSTEIN

Scedasticity

Homoscedasticity is the condition in which a random variable or its observed values have the same degree of variation for all sampling units in the mathematical model or data set. By "constant variation" we usually mean a common variance for all sampling units. When that condition is not met, the random variable or data are called *heteroscedastic*. The origin of these terms is from the Greek word $\sigma\kappa\varepsilon\delta\acute{\alpha}\nu\nu\upsilon\mu\iota$, "to scatter or disperse", and the Greek words for "same" and "different".

Linear Regression Analysis

Homoscedasticity is an essential assumption in the **linear regression** model and its fit by **least squares**. For the simplest case of a single dependent variable Y and one independent (or **explanatory**) variable X, the model is

$$Y_i = \alpha + \beta X_i + e_i, \qquad i = 1, \ldots, N.$$

The e_i are random variables with $\mathrm{E}(e_i) = 0$, and if the homoscedasticity condition holds, $\mathrm{var}(e_1) = \cdots = \mathrm{var}(e_N) = \sigma^2$. If the random disturbance terms are heteroscedastic and have different variances ${\sigma_i}^2 = \mathrm{var}(e_i)$, the ordinary least squares estimators of α and β, while still unbiased, no longer have the Gauss–Markov property of minimum variance (*see* **Least Squares**). If the individual variances are known up to a proportionality constant, a weighted least squares fit of the linear model can be obtained by using the scaled data

$$\frac{Y_i}{\sigma_i} = \frac{\alpha}{\sigma_i} + \frac{\beta X_i}{\sigma_i} + \frac{e_i}{\sigma_i}.$$

The usual ordinary least squares estimation process is applied to the scaled values, with the intercept also scaled by the known standard deviations σ_i.

The weighted least squares estimators are easily displayed by the matrix form of the multiple regression model with an intercept and p independent variables:

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}.$$

$\mathbf{Y}$ is the $N \times 1$ vector of observations on the dependent variable. $\mathbf{X}$ is the $N \times (p+1)$ matrix of predictor variable values of full rank $p+1$, with a first column of ones for the intercept term. $\boldsymbol{\beta}$ is the $(p+1) \times 1$ parameter vector with the intercept $\boldsymbol{\alpha}$ in the first position. The $N \times 1$ vector of random disturbances $\mathbf{e}$ has $\mathrm{E}(\mathbf{e}) = \mathbf{0}$ and diagonal covariance matrix

$$\boldsymbol{\Sigma} = \mathrm{cov}(\mathbf{e}, \mathbf{e}') = \begin{bmatrix} {\sigma_1}^2 & \cdots & 0 \\ \cdot & \cdots & \cdot \\ 0 & \cdots & \sigma_N^2 \end{bmatrix}.$$

The weighted least squares estimator of $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}}_w = (\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Y},$$

where $\boldsymbol{\Sigma}^{-1}$ is the $N \times N$ diagonal matrix, the diagonal elements of which are the reciprocals $1/\sigma_i^2$ of the corresponding elements in $\boldsymbol{\Sigma}$. Unfortunately, since the variances of the disturbance terms are rarely known, these results are mainly only of theoretical interest.

Two-Sample *t* Test

The hypothesis that two independent normal distribution means are equal frequently arises in practical data analysis. The Student–Fisher t test of that hypothesis requires that the two populations have a common unknown variance (*see* **Student's *t* Statistics**). That assumption is easily tested by the ratio $F = {s_1}^2/{s_2}^2$ of the independent sample variances. Hsu [3] calculated the true type I error probabilities for selected ratios of the population variances $\theta = {\sigma_1}^2/{\sigma_2}^2$ and sample sizes $R = N_1/N_2$ for a 0.05 level test (*see* **Level of a Test**). If θ is less than one and R is larger than one, the true type I error rate will be larger than the nominal 0.05 value. If θ and R are both larger than one, the true type I probability will be less than 0.05. These and other properties of the t test in the presence of unequal variances have been described by Scheffé [4].

The test of the equality of two means of independent normal populations is called the **Behrens–Fisher problem**, after its original investigators. Welch [5, 6] has proposed an alternative test with an approximate t distribution when the population variances are unequal (*see* **Aspin–Welch Test**).

The Analysis of Variance

Box [1, 2] has investigated the effect of heteroscedastic disturbance terms on the one- and two-way **analysis of variance** type I error rates. As in the two-sample t test, the effect of unequal variances in the

one-way layout is exacerbated by unequal sample sizes. When the sample sizes are equal, the true type I error rates are only slightly higher than the nominal 0.05 value. If the treatments with the smaller variances have larger sample sizes, the type I error rate may be much greater than 0.05. If the opposite condition holds, or if the ratios of the variances roughly follow those of the sample sizes, the true type I error rate may be smaller than the nominal 0.05. For the two-way layout with a single observation in each cell, Box showed that unequal column variances led to row test type I error rates slightly below the nominal 0.05 value, and to column test type I error rates slightly above 0.05. Further remarks on heteroscedasticity in the analysis of variance have been given by Scheffé [4].

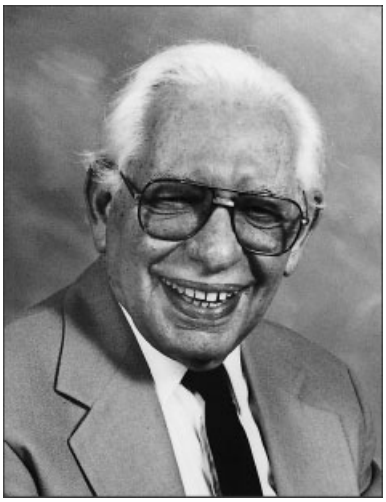
DONALD F. MORRISON

Schneiderman, Marvin Arthur

Born: December 25, 1918, in Brooklyn, New York.
Died: April 1, 1997, in Bethesda, Maryland.



Marvin A. Schneiderman had a distinguished career as a statistician and scientific administrator at the National Cancer Institute (NCI) from 1948 to 1980. During this period, he made several notable contributions to statistical methods and applications, including the early development of the **cooperative cancer clinical trials** program at NCI, some of the first work on closed sequential boundaries (*see* **Sequential Analysis**) for **clinical trials**, the evaluation and application of the Coulter counter and related methods for quantifying peripheral blood elements, **low dose extrapolation** for the establishment of "safe" levels of exposure to potential carcinogens, and the analysis of cancer trends (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**). He made an even greater contribution, however, in increasing awareness of the utility of biostatistics in many areas of application, and in fostering an environment in which statisticians could thrive and become independent scientists and respected collaborators.

After graduation from New Utrecht High School in Brooklyn, Schneiderman attended City College of New York, where he received his B.S. degree in Mathematics and Statistics in 1939, graduating as a member of Phi Beta Kappa. After a short period of work at the National Container Corporation, he joined the US Census Bureau in April 1940 and served as a clerk in the 1940 census of agriculture. During this period, he also studied sampling theory and statistics with **Jerome Cornfield** and Duane Evans at the Department of Agriculture Graduate School.

From 1940 to 1944, he worked in the War Department as a quality control officer in the Office of the Quartermaster General of the Army. From June 1944 to December 1945, he served as a member of the US Army Air Corps, rising to the rank of Second Lieutenant. While in the Air Corps, he studied management sciences, economics, and statistics at the Harvard University Graduate School of Business. Following his military service, he held a civilian position as a Statistical Control Officer in the Army Air Corps until 1948. During this period (1946–1947), while stationed at Wright Field, he studied economics at the Ohio State University Graduate School.

In 1948, Jerome Cornfield left the Bureau of Labor Statistics to work at the National Cancer Institute (NCI) for **Harold Dorn**, the demographer and population expert. Cornfield hired Schneiderman as a (junior) consulting statistician in the NCI's Biometrics Section. At that time, the attitude of many laboratory research workers was "if I need statistics to show that something has had an effect, then the effect is too small to be bothered with". Schneiderman began to demonstrate the use of statistics to scientists who until that time, did not see its practical use. His work as a statistical consultant to such basic research workers as George Brecher and Fred Stohlman on problems of counting blood cell elements or in measuring the production of erythropoietin, the red blood cell stimulating hormone [20, 24], was reflected in hematologic research world-wide. He was one of the first statisticians on the editorial board of *Blood*. He was one of many statisticians who made it respectable for scientists to consult statisticians. Work with Walter Heston and Michael Shimkin led to models of **dose–response** that formed the basis for the Environmental Protection Agency's (EPA's) regulation of toxic materials. While in the Biometry Branch, he received the M.S. in Statistics from American University in 1953.

Statisticians count things. As a counting specialist, Schneiderman was involved in the evaluation and

propagation of a simple device to count platelets [3], the blood element involved in blood clotting. The visual counting of blood cells by a laboratory technician eventually gave way to the Coulter counter, a device for measuring the flow of electric current across a narrow aperture while a blood sample was passed across the aperture [4]. He also worked in other areas such as industrial carcinogenesis [6] and drug toxicity.

In 1954, C. Gordon Zubrod joined the NCI. Under his leadership and with Schneiderman as chief statistician, plans were begun for a national program of cooperative clinical trials in cancer. The US Congress at this time created a Cancer Chemotherapy National Service Center (CCNSC), [11], which served as the major organizational unit for the development and conduct of the first randomized clinical trials in cancer. The clinical trials program at NCI enlarged rapidly from 1955 to 1960, requiring statisticians for each of the cooperative groups that were established. Part of Schneiderman's responsibility included recruitment of statisticians all across the country. He was able to bring to these trials Irwin Bross, **Bernard Greenberg**, and James Grizzle (North Carolina); Will Dixon (UCLA); **Donald Mainland** (NYU); and several others. The North Carolina connection was especially productive. Several graduates of Greenberg's program, including Edmund Gehan, joined the NCI group.

From 1955 to 1959, Schneiderman served as Acting Chief of the NCI Therapeutic Trials Section and coauthored the paper reporting the first randomized control trial in cancer research [10] and similar subsequent studies [28]. In cooperation with a young visiting scientist at the NCI, Peter Armitage, a multistage sequential scheme was developed for screening candidate materials using mice as a biological model. This was the first of the so-called "rational" **screening** programs and could be modified to produce a minimum of **false negatives** (while producing some **false positives** – which would be discarded when tested in humans), or a minimum of false positives – so that the very ill patients on whom these drugs were tested would be most likely to receive active, effective agents [1].

From 1959 to 1960, Schneiderman attended the London School of Hygiene and Tropical Medicine under a Rockefeller Public Service Award, continuing his work with Peter Armitage on epidemiology, medical research involving humans, controlled trials, and biostatistics [19]. During his military service in World War II, he had come upon the work of **Abraham Wald** and his student Milton Sobel on sequential testing. Their aim was to minimize destructive testing of military supplies (often ammunition) while attempting to insure the quality and potential effectiveness of the batches that "passed". Recognizing a related problem in humans with strong ethical overtones, Schneiderman and his colleagues wished to test, in a controlled way, potential anticancer drugs, while minimizing the number of patients exposed to the less effective drug when making a comparison of two drugs. They considered it unethical to delay ending a trial long after enough evidence had been developed to convince that one treatment was superior to another. The Wald–Sobel schemes provided a starting place for such trials – with the drawback that the potential existed for quite long trials if the evidence indicated that no firm decision had yet been reached. What was needed were closed sequential designs. I.D.J. Bross developed a small number of closed sequential designs. Armitage modified the Wald–Sobel designs to give an upper limit to the number of participants in a trial. Under the mentorship of Armitage at the London School of Hygiene, Schneiderman developed a family of sequential schemes that encompassed the Armitage designs at one extreme and the Wald designs at the other. Theodore Colton, as a summer fellow at NCI soon thereafter, developed another scheme for the early termination of a comparative trial, as part of a continuing treatment-development program, which are sometimes referred to as "horizon" trials.

Returning from London, Schneiderman received his Ph.D. in Statistics from American University in 1961 and served as Associate Chief of the Biometry Branch under William Haenszel until 1970. There he worked with many physicians and statisticians on a wide range of topics [5, 7, 13–16, 21, 26, 27]. The Biometry Branch at one time or another included Marvin Zelen, Sally Fand, Nancy Brombacher, Polly Feigl, and Emanuel Landau.

The positive effects of having MD-statisticians working on controlled trials led to recruiting additional MDs. These included John Bailar (who in turn recruited **David Byar**), Sylvan Green, David Levin, Robert Huse, Mitchell Gail, and Elia Kazam. The use of these physician–statisticians epitomized the structure and process whereby research in the

statistics-related fields proceeded at NCI. The process involved recruiting very bright young people, having them work for a short time as juniors and then giving them their heads – with a minimum of supervision. When they worked as collaborators or consultants, Schneiderman was insistent that they be included as coauthors in the publications that followed. Publication was extremely important for advancement at the **National Institutes of Health** (NIH).

In 1970, Schneiderman was appointed to head NCI's Field Studies and Statistics Program, which consisted of three branches: the Biometry Branch with William Haenszel as Chief, the Environmental Epidemiology Branch with Joseph Fraumeni, Jr. as Chief, and the Clinical Epidemiology Branch with Robert Miller as Chief. Schneiderman's philosophy was to hire good people and to give them the freedom and authority to succeed. He provided resources and support for the Surveillance, Epidemiology, and End Results (SEER) Program that grew out of the Third National Cancer Survey, under the guidance of William Haenszel, John Bailar, and **Sidney Cutler**. He needed to defend this program vigorously, as it appeared to be quite expensive to those accustomed to funding laboratory research.

Schneiderman encouraged the extension of statistical methods to many areas and he continued to write in a variety of areas [2, 9, 12, 17, 18, 22, 23, 25]. He was among the first to support the work of a young Commissioned Officer, Fred Burbank, who pioneered the use of computer-generated maps and **regression** methods to study US cancer rates. He supported work on **risk assessment**, including statistical methods for analyzing animal studies by Drs John Gart and Robert Tarone, and methods for low dose extrapolation and interpretation by Dr Charles Brown and Mr Nathan Mantel. He supported methodological work and "hands on" experience for statisticians such as David Byar and Mitchell Gail on clinical trials and on the **evaluation of diagnostic tests**. He helped to develop the randomized trial to evaluate the usefulness of mammography screening to reduce breast cancer mortality (the "HIP" study; *see* **Screening Trials**). He supported epidemiologic work leading to pathbreaking findings in cancer genetics (for example, the Li–Fraumeni syndrome; *see* **Genetic Epidemiology**) and **environmental epidemiology**.

From 1978 until he retired from the NIH in 1980, Schneiderman served as Associate Director for Science Policy in the Office of the Director of NCI. There, he continued to advocate the wide application and support of statistical methods, and was a vigorous spokesman for this cause among scientific administrators and decision-makers, on numerous advisory panels, and in the media.

After leaving the NCI, Schneiderman joined the Environmental Law Institute, where he helped to develop environmental legislation and prepared several papers with Devra Davis, an environmental activist [8]. After a brief excursion into the work of an environmental consulting firm, he followed Dr Davis into a position with the National Academy of Sciences, National Research Council Board on Environmental Studies and Toxicology. He had in the past been a member of many NAS/NRC committees. While on one of the committees, and again as a staff member, his emphasis was on how a statistician viewed the problem. He continued to be active until his death in 1997.

Perhaps Marvin Schneiderman's view of his professional life can best be summarized in the following, which he wrote just before his death:

> What pleased me most in my 50 or so years as a statistician – with its occasional side excursions into epidemiology – was that it was fun. It was exciting. It seemed to me that it had a positive impact on this country's health and environment. First my work brought me face-to-face with some of mankind's most important and intractable problems – problems of disease and problems of life and death on which I believe I had a positive effect. Second it enabled me to work with persons exploding with intellectual fire and originality. Some were other statisticians and some were the laboratory research workers for whom I was a consultant and at times a collaborator. Third it enabled me to merge my own concepts of appropriate human behavior with scientific needs so that I could participate in ethical research on humans – and make it possible (or perhaps imperative) that those who followed me would treat their patients who happened to be seriously ill as humans and not only as research subjects. Finally it brought into my sphere brilliant young men and women whose lives and professional careers I influenced, and – I hope – enlarged.

DAVID L. LEVIN

Scientific Method and Statistics

The word "statistics" has multiple meanings. For example, it can refer to numeric summaries obtained from a body of data, and it can also refer to methods for analyzing data. This article is chiefly concerned with the second of these two meanings, and in particular with how these methods relate to the scientific enterprise in general. To explore this relationship, we begin by examining the idea of "scientific method", and later see how statistical methods fit in. We shall see that it is no accident that statistics has been described as "the science of doing science" [20].

The notion of scientific method has changed over time but, like the models used within science, models of the way in which scientists work are idealizations. They skip such things as serendipity and focus on the pattern of behavior. Some models are descriptive, seeking to show how scientific advance occurs in practice, while others are proscriptive, seeking to show how things should be done. Early views – a perspective variously attributed to William of Ockham, John Herschel, and John Stuart Mill – saw the growth of (scientific) knowledge as an essentially inductive process. That is, they saw science as a process of accumulating facts by observation, classifying these facts according to observed regularities, and hence generalizing them into scientific laws. This view was formalized in various ways. For example, Mill's *Canon of Agreement* conveys ideas familiar to all statisticians: "If an instance in which the phenomenon under investigation occurs, and an instance in which it does not occur have every circumstance in common save one, that one occurring only in the former, the circumstance in which alone the two instances differ is the effect, or the cause, or an indispensable part of the cause of the phenomenon." [13, Book III, Chapter 8].

Although experimentation featured in these views, the emphasis put on its central and fundamental role is normally attributed to Sir Francis Bacon [8]. The twin pillars of observation and experiment that Bacon emphasized presented a practical alternative to the notion that truth lay in ancient authority – whose conclusions were tacitly assumed to be based on thought rather than observation. At the time, Bacon's approach was even termed "the experimental philosophy" to contrast it with theorizing.

These views regard observation and experiment as essentially *confirmatory* exercises: that is, each supporting result is regarded as adding weight to the hypothesis under investigation. From this perspective, science generalizes or abstracts from many particular observations. We note how long an iron ball takes to strike the ground when released from various heights and hence formulate a general *law* which fits the observations very well: that is, it is a process of induction (different from *mathematical induction*, which is a more formal procedure), from the particular to the general.

Inductivism is all very well, but it misses something important. It leads to a *description* of phenomena, not an *explanation*. Moreover, as **Popper** [16, 17] pointed out, one cannot in fact logically *prove* anything by induction: the mere fact that all the swans you may have seen are white does not imply that all are white (in fact, black swans were discovered in Australia at a time when all known swans were white). On the other hand, one can *disprove* a universal statement by example: observation of a black swan disproves the statement that all swans are white. Thus theories, in general, can be disproven, but not proven. Scientific method, Popper argued, thus seeks the *falsification*, not the *verification*, of scientific theories. One successively formulates hypotheses or theories and tests their predictions against experimental observations. When an hypothesis fails a test, it is modified, refined, or replaced. Advance occurs because a new hypothesis must pass not only those tests passed by its predecessor, but also tests that the predecessor fails. This means that very radical revisions become more difficult as time passes, because of the mass of accumulated evidence. A key aspect of this Popperian view is the alternation of theory and observation: theories are postulated and experiments/observations test them. Like the chicken and the egg, neither is pre-eminent.

Note that this Popperian view of how science does and should work is, as we have remarked above, like all scientific models, an idealization. In reality, given a conflict between theory and data, we do not necessarily reject the theory. Data may be subject to error. The lack of a match may simply be due to error in measurement, not because of a faulty theory. Thomas Kuhn [10, p. 81] gives a nice example of this:

> ... during the sixty years after Newton's original computation, the predicted motion of the moon's perigee remained only half of that observed. As Europe's best mathematical physicists continued to wrestle unsuccessfully with the well-known discrepancy, there were occasional proposals for a modification of Newton's inverse square law. But no one took these proposals very seriously, and in practice this patience with a major anomaly proved justified. Clairaut in 1750 was able to show that only the mathematics of the application had been wrong and that Newtonian theory could stand as before.

If scientific theories themselves become more difficult to replace by radical alternatives as time passes (because the theories have already passed more tests), so also do theories of science. So, Kuhn's notion of *paradigm shifts*, in which the scientific constructs are jettisoned in favor of a complete reformulation, is really a refinement of Popper's notion of refutations. Kuhn [10, p. 10] defines "normal science" as "research, firmly based upon one or more past scientific achievements, achievements that some particular scientific community acknowledges for a time as supplying the foundation for its further practice". Paradigms are [10, p. viii] "universally recognized scientific achievements that for a time provide model problems and solutions to a community of practitioners". A paradigm shift describes the process of moving from one paradigm to another. Kuhn has emphasized that most scientists do not find such shifts, but instead are concerned with normal science, working within a dominant paradigm.

Statistics relates to all this in various ways. Statistical methods assist in the precise formulation and selection of theories or models, the quantification of errors, and in examining the match between the theory and the data. Formulation of models includes such things as **variable selection** and parameter **estimation**. Implicit within this are comparisons between alternative models. Both falsification and accumulation of supportive evidence occur through the blurring spectacles of the necessary simplifications in the modeling process. It is in helping to control and remove this blurring or error that statistics plays one of its key roles in science. Finally, the match between theory and data may be examined informally, perhaps by graphical methods such as **residual** plots, or more formally, perhaps via significance tests (*see* **Hypothesis Testing**). Again, for the reasons mentioned above, we cannot expect perfect matches or perfect mismatches – and again statistical methods enable us to judge the quality of a match.

Perspectives on the role and purpose of statistical methods seem to parallel the development of ideas about how science progresses. For example, early statisticians such as **Karl Pearson** adopted an inductivist perspective: "The classification of facts and the formation of absolute judgments upon the basis of this classification – judgments independent of the idiosyncrasies of the individual – essentially sum up the *aim and method of modern science*" ([14, p. 11], his italics). Modern **exploratory data analysis**, techniques aimed at examining data in order to discern patterns and structure, without specifying too closely exactly what sort of patterns are sought, might naturally be thought of as an inductive process. Moving on, however, we find inductivism combined with the hypothetico-deductive strategy. **Fisher** [4], for example, described how statistical analysis is essentially what we would regard as the Popperian view of scientific method writ small: "The statistical examination of a body of data is thus logically similar to the general alternation of inductive and deductive methods throughout the sciences. A hypothesis is conceived and defined with all necessary exactitude; its logical consequences are compared with the available observations; if these are completely in accord with the deductions, the hypothesis is justified, at least until fresh and more stringent observations are available" [4, 4th Ed., p. 9]. Similarly, Box [2, p. 383] describes science as proceeding in what is essentially a Baconian/Popperian way and statistics as playing a central role in this:

> It seems that scientific knowledge advances by a practice–theory iteration. Known facts (data) suggest a tentative theory or model, implicit or explicit, which in turn suggests a particular examination and analysis of data and/or the need to acquire further data; analysis may then suggest a modified model that may require further practical illumination and so on .... New knowledge thus evolves by an interplay between *dual* processes of induction and deduction in which the model is not fixed but is continually developing .... The statistician's role is to assist this evolution .... In doing so he [*sic*] employs two inferential devices: *Criticism* and *Estimation*.

The Bayesian strategy (*see* **Bayesian Methods**) may also be seen as fitting the Popperian framework. Essentially, the Bayesian approach takes prior beliefs and modifies them in the light of the data. This

modification may be rather more subtle than a crude hypothesis test, in that a distribution of strength of posterior belief results, so that an initial theory is not "rejected" or "refuted", but the basic idea is the same.

If the statistical model fitting process provides a parallel to the scientific process, it can also shed light on that process. One of the driving forces in selecting between scientific theories is simplicity. From a set of explanations, each equally effective at explaining a collection of facts, the most simple is to be preferred. This principle goes under various names, such as *Ockham's razor* or the *principle of* **parsimony**. In science, a simple theory is sometimes said to be *elegant*, and to be a preferred explanation because of its elegance. In statistical model building (*see* **Model, Choice of**), a similar preference is accorded to simpler models. For example, a set of ten different points in a plane could be modeled by an infinite number of curves that pass through all the points. However, if one of these curves is a straight line, then that, being the simplest, will often be the preferred model (unless, for example, there is some extra aspect to the theory, leading to some more complicated curve being preferred). Some approaches to statistical inference, such as the *Minimum Message Length* [22] and *Minimum Description Length* approaches [18, 19] are based directly on this principle. They essentially provide a formalism for combining measures of the complexity of a theory and the complexity of the data (the facts) in terms of that theory. Current work on computational learning theory and machine learning [9, 21] is directly concerned with these issues of how well models, based on a finite set of observations *(a training set)* will generalize to other data.

Statistical models come in (at least) two types: *mechanistic* and *descriptive*. The former are based on some underlying theory or mechanism which purports to explain the observed phenomena. The latter seek merely to summarize the data in a convenient way. One can argue that the term "model" should be restricted to the former, but common usage applies it to both. Descriptive models have a role in theory formulation, and also in pragmatic situations. For example, a **prediction** rule may be based on empiric observation of relationships between variables, without there being any underlying theory or explanation for why those relationships should exist. Bacon distinguishes models that give light from those that bear fruit (see [8, p. ix]), and this seems very close to our mechanistic and descriptive distinction.

If mechanistic models aim to represent some underlying process, they might be regarded as "true" or "false" according as they are or are not faithful representations of that process. In both science and statistics, this view is no longer generally held. For example, in discussing this issue in statistics, Durbin [3] says that "Undoubtedly most applied workers have always been aware that any statistical model is at best an approximation to reality. There is in real life no such thing as a 'true model' ". He goes on to criticize debates about the different schools of statistical **inference** because of this misconception:

> . . . much of the discussion of the foundations of statistical inference that has taken place over the past half century has been predicated on the assumption that the model is "true". The alternative formulations of the inference problems that have been considered relate mainly to the properties of models and there has been too little discussion of the interaction with the underlying statistical reality. Statements about parameter values have been discussed as if parameters had a clearly-defined tangible existence, whereas in most cases they are at best mathematical artifacts introduced only in order to provide the most useful approximation available to the behavior of the underlying reality. It is all too easy to lose sight of the fact that the real purpose of the analysis is to make statements about this reality rather than about the models that approximate it.

Durbin [3] continues:

> Of course I appreciate that a standard procedure in science is to postulate a model and make inferences about the behavior of the phenomena under study on the assumption that the model is an accurate one. My point is that because of the manifest imperfections of many statistical models as descriptions of the reality under investigation, this process has been carried a bit too far. The obsessional desire to make "best possible" statements about parameter values in artificially small models has been over-indulged to an extent that seems out of proportion to the true interests of users of statistical models.

Just as other sciences are not static, but progress as new theories and new discoveries require their modification, so statistics, as science or technology [6], is not static. A glance back over recent decades shows new problems, new methods, and new ideas changing the way statistical methods are thought about

and applied (**survival analysis**, **generalized linear models**, and **multidimensional scaling** provide just a few clear examples). Much of this development, in recent decades, has been the consequence of the growth in readily available computational resources. This has had the further consequence that modern statistics might more naturally be thought of as a computational science than as a mathematical science. And, of course, these developments continue. Examples of current new perspectives stimulating the development of new methods are not hard to find. One is the impact of feedforward **neural networks**, originally introduced as complex structures of individually simple interacting components, but now seen as a highly parameterized and very flexible models for function estimation. Another is the growing interest in issues of multiple data sets, in contrast to the earlier situation, in which the focus was on the single data set to hand (see, example, [7]). **Meta-analysis** is one manifestation of this in the statistical literature. A third, also arising as a consequence of computational advances, is a concern with very large data sets, perhaps with many millions or even billions of observations; here significance tests tend to lose their relevance.

While clearly (one would hope!) statistics has had a positive impact on the development of science via its methods of data collection and analysis, it has also had a more subtle, and not necessarily beneficial impact. The theories of scientific method outlined above say nothing of the social and cultural environment in which the scientist works. In particular, modern scientists communicate their results via published papers and there is evidence that papers have sometimes been accepted for publication with a less than rigorous attitude to the statistical methods employed. Misapplication of statistical methods in medical research has been examined by several authors (see, for example, [1, 5, 11, 12, 15], and [23]) – the depressing results being perhaps a partial consequence of the fact that doctors are primarily trained in the technology of medicine, rather than the principles of science. From another perspective, sometimes in research standards are imposed and practices adopted which most statisticians would regard as dubious (the classic example is the tendency to require significance tests – and then to favor papers that show significant results in those tests). We have already commented about how the computer has changed, and continues to change, the face of statistical practice. In the present context, we should also add the remark that electronic communication, in the form of the **Internet**, is already beginning to change scientific practice.

DAVID J. HAND

Scores

We primarily consider the situation where both the dependent (or **response**) variable and independent (**explanatory** or predictor) variable are **categorical**. When either the independent or dependent variable is ordered, or when both variables are ordered, use of the standard χ^2 test is inappropriate because it does not exploit the ordering. To increase the power of tests when the alternative is related to the ordering, we assign numbers, called scores, to the ordered categories. The scores should reflect the scientific meaning of the categories.

Predictor Variable Scores

Scores for the predictor variable (if it is ordered) arise from the underlying process, i.e. from the model generating the data. For example, Graubard & Korn [14] considered the use of midpoints of the category boundaries, midranks, and equally spaced scores for the predictor variable (alcohol consumption in mothers) in the analysis of the data in Table 1 on occurrence of congenital malformation in offspring. The midpoint scores for these data are 0.0, 0.5, 1.5, 4.0, and 7.0. Midranks, or average category **ranks**, may be computed by ranking the observations as if they were ungrouped, and then taking the mean of the ranks within each category. Suppose there are K categories with N_i observations in category $i, i = 1, \ldots, K$. Then the midrank of the ith category is $\sum_{j=1}^{i-1} N_j + (N_i + 1)/2$. For the data in Table 1, the midranks are 8557.5, 24 365.5, 32 013.0, 32 473.0, and 32 555.5. The equally spaced scores are 1.0, 2.0, 3.0, 4.0, and 5.0. The standardized scores, i.e scores linearly transformed so that they have zero mean and unit variance, are plotted in Figure 1. The closeness of the midrank scores for the three heaviest drinking categories is inappropriate from the underlying science which suggests greater relative effect with higher levels of alcohol consumption. Hence midrank scores should not be used to analyze the data [14]. Indeed, the one-sided significance levels varied considerably according to the scores used (midpoints, $P = 0.02$; midranks, $P = 0.29$; equally spaced, $P = 0.10$). In general, one should assign reasonable scores based on the substantive meaning of the categories [1, 3, 8, 14].

If there are two or more sets of plausible scores, then a single procedure that combines the tests based on each set seems appropriate. One such procedure is the maximin efficiency robust test (MERT) [12, 23]. For example, the standardized scores for the MERT based on the midpoints, midranks, and equally spaced scores for the above data are also plotted in Figure 1. The combination property of the MERT is clearly visible (and its associated P value is 0.05).

Table 1 Occurrence of congenital sex organ malformation categorized by alcohol consumption of the mother [14]

	Alcoholconsumption (average numberof drinks per day)				
Malformation	0	<1	1–2	3–5	≥6
Absent	17 066	14 464	788	126	37
Present	48	38	5	1	1
Total	17 114	14 502	793	127	38

Response Variable Scores

Response variables can be ordered quantitatively and qualitatively. The scale of measurement of these variables (*see* **Measurement Scale**) is also referred to as interval and ordinal, respectively [1, 21]. Quantitatively ordered variables arise when an underlying continuous variable, e.g. blood pressure, is grouped into ordered categories. Data that are ordered but

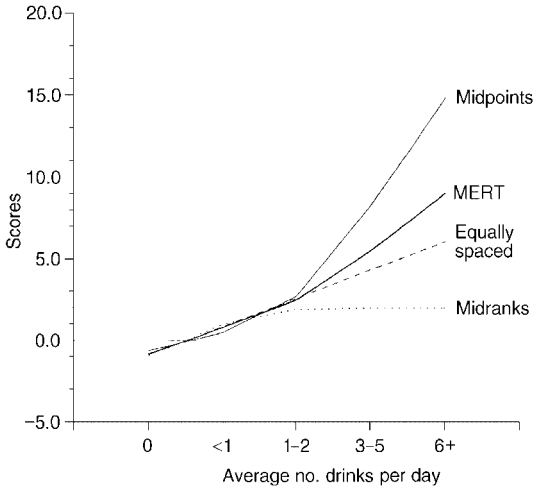

Figure 1 Standardized scores for several scoring systems for the Graubard & Korn [14] data (Source: [23])

without an apparent underlying continuous measurement scale are qualitatively ordered. An example is patient response to choices: "How do you feel: poor, fair, good, or excellent?" (*see* **Ordered Categorical Data**).

Quantitatively Ordered Variables

Quantitatively ordered variables arise from data typically reported with category boundaries such that N_i observations are in the interval $[b_{i-1}, b_i)$, $i = 1, \ldots, K$. We first discuss the assignment of optimal scores if the investigator has some knowledge of the underlying distribution of the data. We then discuss the perhaps more usual case where less formal assignment methods are employed. Optimal category scores are derived from general rank test theory for grouped data [10, 11, 25, 27]. Consider the linear rank statistic $S = \sum_{l=1}^{N} c_l a_l$, where the c_l are regression constants and the a_l are scores. For example, in the two-sample problem with continuous data, $c_l = 1$ when the lth order statistic is a Y and $c_l = 0$ otherwise. The scores are derived from $a_l = J[l/(N+1)]$, where $J(\cdot)$ is a score function that may be selected by the investigator. In particular, if we know the underlying distribution F (with density f), and we want to test for a shift in location, then the optimal score function [7, 15, 24] is $J(u) = -f'[F^{-1}(u)]/f[F^{-1}(u)]$. For grouped data the assigned scores are the average of the rank test scores in each category. Suppose there is grouping of the N outcome observations into K categories with N_i observations in category i. Then we may estimate the ith fractile, u_i, by $\sum_{j=1}^{i} N_j/N$, letting $u_0 = 0$, and we estimate $F^{-1}(u_i)$ by b_i. We obtain the estimated scores a_i, $i = 0, 1, 2, \ldots, K-1$, from

$$a_i = \frac{f(F^{-1}(u_i)) - f(F^{-1}(u_{i+1}))}{u_{i+1} - u_i} = \frac{1}{u_{i+1} - u_i} \int_{u_i}^{u_{i+1}} J(u)\, \mathrm{d}u. \quad (1)$$

Note that Eq. (1) corresponds to the mean of the scores that would be assigned to the individual observations in the interval $[b_i, b_{i+1})$ if we had them.

Table 2 presents ELISA absorbance ratios in AIDS patients and healthy blood donors [5, 13, 29] and the estimated optimal **Wilcoxon–Mann–Whitney**, $J(u) = 2u - 1$, and inverse Savage (or exponential or **logrank**), $J(u) = -1 - \ln(1-u)$, scores. To illustrate the use of formula (1) we calculate the first Wilcoxon score, a_0, in Table 2: $u_0 = 0$, $u_1 = 202/385 = 0.5247$, the value of the integral is $u(u-1)|_0^{0.5247} = -0.2494$, and therefore $a_0 = -0.475$. Both sets of scores yield highly significant results ($Z = 15.1$ using Wilcoxon scores and $Z = 16.0$ using inverse Savage scores).

The above procedure generates asymptotically **most powerful rank tests**. For small samples, one might use scores derived from locally most powerful tests (LMPRT) [16, 24]. Now the score given to the observations in the ith group is the mean of the LMPRT scores if the individual observations were available.

Nevertheless, some investigators may prefer to assign scores based on less formal methods. For example, as in the discussion above for ordered predictor variables, midpoints of the category boundaries or equally spaced scores may be assigned. If the investigator has some idea of the relative distances between categories, which are perhaps only loosely

Table 2 Distribution of ELISA absorbance ratios in healthy blood donors and AIDS patients [5, 13, 29] and the estimated optimal Wilcoxon and inverse Savage scores

	Absorbanceratio							
	<2	2–2.99	3–3.99	4–4.99	5–5.99	6–11.99	≥12	Total
AIDS patients	0	2	7	7	15	36	21	88
Healthy blood donors	202	73	15	3	2	2	0	297
Total	202	75	22	10	17	38	21	385
Wilcoxon scores	−0.475	0.244	0.496	0.579	0.649	0.792	0.945	
Inverse Savage scores	−0.674	−0.016	0.381	0.559	0.744	1.30	2.91	

dependent on the actual scale of measurement, then he or she may be able to assign reasonable scores [2]. These are valid procedures, if scores are assigned prior to examining the data [8]. That is to say, one must avoid choosing scores to obtain a desired result. If more than one scoring procedure seems plausible, then a combination procedure, such as the MERT mentioned above, is a reasonable approach.

Qualitatively Ordered Variables

Regardless of the form of the underlying distribution, when the data are continuous, a measure of the difference between two distributions F_X and F_Y is $\Pr(X < Y)$. This is the probability that a randomly selected X is less than a randomly selected Y and is the basis of the Mann–Whitney form of the Wilcoxon rank sum test (*see* **Wilcoxon–Mann–Whitney Test**). For data grouped into K categories, let $q_k = \Pr(X = k)$, $p_k = \Pr(Y = k)$, and $r_k = \sum_{j=0}^{k-1} q_j + \frac{1}{2}q_k$, where $q_0 = 0$. Then [4],

$$\Pr(X < Y) + \frac{1}{2}\Pr(X = Y) = \sum_{k=1}^{K} r_k p_k. \qquad (2)$$

When the underlying data are qualitatively ordered, Bross [6] used (2) to measure the difference in the two distributions. He introduced the term ridit for the partial sum r_k and called (2) the mean ridit. The measure has been used to compare one sample with a known larger population or to compare two samples. Formulas for appropriate variances and large sample normal approximation to the distribution are given in [4]. Worked examples are given in [6] and [26].

Selvin [26] demonstrated the relationship between the mean ridit (2) and the Wilcoxon rank sum test (which uses midranks). Let w_i be the midrank of category i. If n_i is the number of Y observations in category i, then the Wilcoxon statistic $W = \sum_{i=1}^{K} w_i n_i$. Selvin showed that the mean ridit (2) is equal to $[W - n_{\cdot}(n_{\cdot} + 1)/2]/[(N - n_{\cdot})n_{\cdot}]$, where $n_{\cdot} = \sum_{i=1}^{K} n_i$. Indeed, since the right-hand side of (2) is in the form of a linear rank statistic, with the ridit r_k playing the role of a score assigned to the kth category, some researchers have used it to analyze quantitatively ordered data. Although this is a valid procedure, one might be able to obtain more power via the methods of the previous section, i.e. using scores derived from grouped data theory or from the scientific judgment of the investigator.

Related Topics and Recent Developments

While we have separately considered ordered predictor variables and ordered outcome variables, we note that the procedures outlined above may be applied simultaneously when both are ordered. Here one would employ the linear-by-linear association procedure [1].

Analytic procedures employing scores are discussed more fully in the entry on ordered categorical data. Binary outcome data arise in dose–response settings (*see* **Quantal Response Models**), and, more generally, when the predictor variable is ordered (*see* **Trend Test for Counts and Proportions**), for example, in epidemiologic studies.

Suppose covariate adjustment is needed in the two-sample problem with ordered outcome data or in dose–response data with a binary outcome. In either case, one can form strata based on covariate levels, where each stratum is a $2 \times C$ table [19, 28]. For the stratified two-sample problem, a test is constructed by computing stratum-specific linear rank tests and summing them to obtain a combined test. One may assign scores independently within each stratum [17] or, if the category boundaries are the same across all strata, pool the strata and assign scores to the pooled observations [19, 20]. In the continuous case for moderate to large strata the first assignment method may have power advantages over the second [22], and this is likely to carry over to the grouped data situation. In the dose–response setup, Tarone & Gart [28] show that the optimum test depends on the underlying response function, e.g. logistic, probit, or extreme value. If there are several plausible underlying response functions, then one can develop an efficiency robust procedure [12].

While our focus is scores in categorical data analysis, many practitioners assign scores to qualitatively ordered responses as though the scores were observations from continuous distributions. Lipsitz [18] discusses parameter estimation under a **general linear model** using **maximum likelihood**, ordinary **least squares**, and generalized least squares with estimated weights when the scores are used that way. His suggestion that the applied statistician use ordinary least squares is based in part on its relative simplicity.

The occurrence of data where the observations are correlated, e.g. blood lead levels in children within households, has stimulated the development of appropriate analytic methods. Fay & Gennings [9]

present a ridit permutation test and a permutation test based on means using predefined scores for clustered ordinal response data.

MARVIN J. PODGOR & JOSEPH L. GASTWIRTH

Scree Test

The scree test is a technique for determining the number of factors to retain in a **factor analysis** or a **principal components analysis**. It was proposed by Cattell [1] in 1966. He noticed from practical observation that the variance of the factors levels off when the factors are mainly measuring random error. The scree test consists of plotting the **eigenvalues** (in descending order of their magnitude) against their factor numbers and determining this "leveling off". In particular, the scree plot typically shows a distinct break between the steep slope of the larger factors and the gradual trailing off of the rest of the factors. The name "scree test" comes from the resemblance of such a plot to the rubble that accumulates at the foot of a mountain. Two examples of scree plots are given in Figures 1 and 2.

The eigenvalues presented in Figures 1 and 2 are obtained, respectively, from applying a principal components analysis and a factor analysis to the Framingham depression data (for data description, *see* **Principal Components Analysis**). Figure 1 (principal components analysis) suggests retention of five factors, while Figure 2 (factor analysis) suggests retention of four factors. In general, a factor analysis provides a better scree plot solution than a principal components analysis.

Instead of examining the scree plot, an alternative version of the scree test involves an examination of the eigenvalues and their differences [2]. This also provides excellent evidence for the number of salient factors. In this approach, we first set up a table having the eigenvalues (in descending order of their magnitude) as the first row. Then, we calculate the successive differences of the eigenvalues and put them in the second row. When the differences decrease consistently up to a point, followed by a substantially larger difference, and followed then by later differences that are all small (usually less than 0.1), this version of the scree test suggests that the last nonrandom factor is the one immediately preceding the substantially larger difference. There is no precise definition of "substantially larger difference". Tables of eigenvalues and their successive differences are shown in Tables 1 and 2. The eigenvalues from Tables 1 and 2 are obtained, respectively, from performing a principal components analysis and a factor analysis on the Framingham depression data.

In Table 1 (principal components solution), the differences decrease regularly from 2.067 to 0.077, then there is a substantially larger difference (0.168), and all the later differences are well below 0.1, except for the last difference. This suggests retaining the first

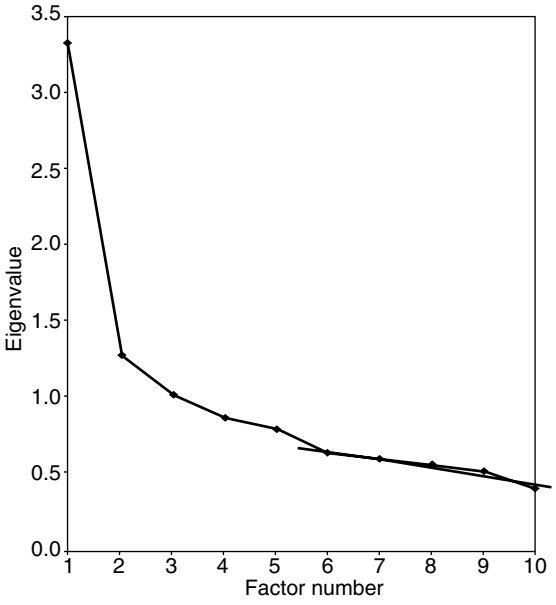

Figure 1 A scree plot from principal components analysis

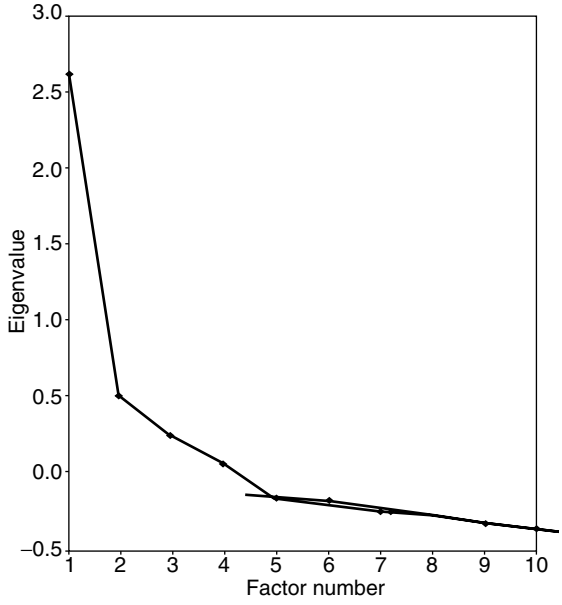

Figure 2 A scree plot from factor analysis

Table 1 Eigenvalues and differences (principal component analysis solution)

	prin1	prin2	prin3	prin4	prin5	prin6	prin7	prin8	prin9	prin10
Eigenvalue	3.358	1.290	1.022	0.872	0.795	0.628	0.590	0.552	0.509	0.386
Difference	2.067	0.268	0.150	0.077	0.168	0.038	0.038	0.043	0.123	
Proportion	0.336	0.129	0.102	0.087	0.080	0.063	0.059	0.055	0.051	0.039
Cumulative	0.336	0.465	0.567	0.654	0.734	0.797	0.855	0.911	0.961	1.000

Table 2 Eigenvalues and differences (factor analysis solution)

	FACT1	FACT2	FACT3	FACT4	FACT5	FACT6	FACT7	FACT8	FACT9	FACT10
Eigenvalue	2.686	0.505	0.254	0.131	−0.042	−0.053	−0.128	−0.155	−0.209	−0.247
Difference	2.182	0.250	0.123	0.173	0.011	0.075	0.027	0.054	0.039	
Proportion	0.979	0.184	0.093	0.048	−0.015	−0.019	−0.047	−0.057	−0.076	−0.090
Cumulative	0.979	1.163	1.256	1.304	1.288	1.269	1.223	1.166	1.090	1.000

five components. In Table 2 (factor analysis solution), the differences decrease from 2.182 to 0.123, then there is a substantial larger jump (0.173), and all the later differences are well below 0.1. Therefore, Table 2 suggests retaining four factors.

The scree test does not always provide a clear solution to the number of retained factors. Sometimes, the break in the scree plot is not as distinct as is shown in Figure 1, or the substantially larger difference is not followed by all small differences in a table of successive eigenvalue differences. In that case, we need to rely on other methods to determine the number of factors to retain (for procedures to determine the number of factors, *see* **Factor Analysis, Overview**).

Screening Benefit, Evaluation of

Screening is the testing of apparently healthy individuals from a population for the purpose of separating them into groups with high and low probabilities of having a given disease such as cancer. The screening is usually initiated by those who offer the tests, and there is thus an implicit promise that those who are screened will benefit. Therefore those individuals screened positive should receive diagnostic follow-up and treatment of proven efficacy if they are diagnosed to have disease [43]. The early detection of cancer and other chronic diseases through screening has long been viewed as a worthwhile public health goal. Many believe that diagnosing disease earlier means that the treatment will be more effective than treatment occurring at the usual time. Unfortunately, the presumption of benefit may not be correct, and the value of a screening program must be demonstrated. This article examines various issues encountered in assessing the benefit of screening. The discussion is in the context of cancer screening.

There are two basic types of studies that can be used to evaluate cancer screening programs, **experimental** and **observational** [8, 29, 35]. The experimental study, commonly termed the randomized controlled trial (RCT), is the method of choice, as it alone produces an **unbiased** assessment of effect (*see* **Clinical Trials, Overview**; **Screening Trials**). When an RCT is not possible, observational or **quasi-experimental designs** may be used. They may be similar to experimental studies in many respects but, because they lack **randomization**, they are generally difficult to analyze and interpret. Nevertheless, both **cohort** and **case–control** observational studies have been used for evaluation of screening for several types of cancer, and the design and interpretation of these studies have been discussed [28, 29, 37, 38, 44, 51].

In the evaluation of cancer screening programs, both the effectiveness of offering screening and the efficacy of screening are important measures. The effectiveness of offering screening is the ratio of the cancer mortality rate for those offered screening to what their cancer mortality rate would have been had they not been offered screening. Effectiveness is of particular importance in considering public health policy. The efficacy of screening is the ratio of the cancer mortality rate for those actually screened to what their cancer mortality rate would have been had they not been screened. Efficacy is of interest in considering the value of screening to those who accept the screening test.

The effectiveness of offering screening can be estimated directly from a comparison of the mortality rates between the randomized groups in an RCT. An indirect estimate of efficacy can also be obtained [10]. Observational study designs typically provide estimates of efficacy. To achieve this goal, the design features typically used in an RCT, such as clearly established criteria for inclusion or exclusion (*see* **Eligibility and Exclusion Criteria**), a well-defined **target population**, a carefully defined intervention protocol with quality control provisions (*see* **Clinical Trials Protocols**), and a clear definition of the study end point (*see* **Outcome Measures in Clinical Trials**) with careful (possibly blind) ascertainment, should be met by an observational study just as for an experimental study.

Selection Bias and Observational Studies

The deficiency of all observational studies is the lack of a **control** group constructed by a chance mechanism. The purposes and advantages of randomization are well known [6]. Use of a control group chosen by any method other than randomization requires the assumption either that the control and intervention groups are identical in all important variables except the intervention under study, or that one can correct for all relevant differences. In the latter case, one must further assume that all factors affecting the course of the disease are identified and measured. These assumptions are rarely, if ever, justified.

In the screening setting, the ability to make valid **inferences** inferences from studies of patient groups or observations of changes in community rates is severely limited by the difficulty of defining appropriate comparison groups, by the lack of detailed knowledge of disease natural history, and by the inadequate understanding of reasons for changes over time in incidence, survival, and mortality rates for various diseases (*see* **Morbidity and Mortality, Changing Patterns in the Twentieth Century**).

The essence of the problem with observational studies is the potential noncomparability of the populations being compared. In screening, a strong **selection bias** may operate with regard to the characteristics of individuals who agree to participate in a screening program compared to those who refuse to participate. This has been demonstrated in the HIP study [46]. The HIP study was designed to evaluate screening with clinical examination plus mammography by comparing breast cancer mortality between a control group and a total study group, the latter including those who were screened and those who refused screening. Examination of the data revealed substantial differences in disease characteristics between the respondents and the refusers. Overall, among study screened women over a five-year period, the rate of case detection was about 2.3 per 1000. By contrast, the incidence rate among study women who refused screening was 1.59 per 1000 per year, while the rate in the control group was 1.95 per 1000 per year. This suggests that women with a higher risk of breast cancer tended to select themselves for screening. In addition, the death rates from all causes excluding breast cancer per 10 000 per year after five years of follow-up were: control group 56.4; total study group 55.1; study screened group, 42.4; study refused screening group, 81.0. Thus, general mortality excluding breast cancer was far lower among the respondents. Given this self-selection bias, construction of an appropriate comparison group for the women who elected to be screened was not possible [4, 46]. In contrast, it is generally recognized in North America that women who participate in cervical cancer screening are at lower risk for cervical cancer incidence and death.

Lead Time and Length Bias

There is only one outcome variable known to be valid in cancer screening studies: the cancer mortality rate. This is the number of cancer deaths per unit time per unit population at risk (*see* **Person-years at Risk**) [8, 29, 35, 37, 38, 42]. For some screening procedures which detect presumed precursor lesions, such as the Pap smear for cervical cancer, a reduction in cancer incidence is also a useful outcome to assess, but it is still important to know that the prevented cancers were those that would have led to death. Obtaining an accurate estimate of the mortality measure requires a careful study design and long-term follow-up of large populations, which is usually a costly undertaking. Consequently, intermediate or surrogate outcome measures have been sought, such as a shift to a more favorable stage at diagnosis distribution (*see* **Surrogate Endpoints**). There are, however, critical shortcomings associated with these endpoints [29, 35, 37, 42]. The shortcomings can be traced to lack of knowledge about the preclinical **natural history** of disease and well-known **biases** which occur in screening programs, lead time bias, and **length bias**.

If an individual participates in a screening program and has disease detected earlier than it would have been in the absence of screening, then the amount of time by which diagnosis is advanced is termed the *lead time*. Because of the lead time phenomenon, the point of diagnosis is advanced and survival as measured from diagnosis is automatically lengthened for cases detected by screening, even if length of life is not increased. This is referred to as *lead time bias* and renders the case survival endpoint invalid [23, 29, 35, 37, 38, 42, 55].

Length bias refers to the phenomenon that cases of disease detected by a screening program are not a random sample from the general distribution of cases of preclinical disease in the screened population. Instead, the longer-duration preclinical disease cases are overrepresented among the detected cases [1, 29, 35, 37, 54]. The importance of this bias is that if disease with long preclinical duration is slow-growing preclinical disease, which then progresses to slow-growing clinical disease, cases of disease with more favorable progression rates are the ones more likely to be detected by screening. Thus, screen-detected cases will tend to have characteristics of good **prognosis**, such as lack of involvement of regional lymph nodes and a more favorable outcome even in the absence of screening.

Related to the concepts of lead time bias and length bias is overdiagnosis bias. There exists the possibility of a nonprogressive or regressive preclinical disease state in which some cases of the disease are detectable by the screening test but would not progress to clinical disease during the individuals' lifetimes in the absence of screening. This is potentially a major problem in screening for prostate cancer, where the autopsy **prevalence** of prostate cancer in elderly men can approach 50% [25]. Clearly,

the detection of such a case is of no benefit to the individual, but such cases remain preclinical over a long time and with repeated screenings are therefore more likely to be detected. Because the counterparts to these lesions do not surface in a control population, a screened population will contain a higher proportion of early-stage cases even if there is no mortality effect from screening.

Study Endpoints

Three of the most frequently proposed alternative endpoints are case-finding rate or yield, stage of disease, and case–survival rate. Consider first the case-finding rate or the **incidence rate**. This quantity may provide an early clue as to whether or not screening might be doing something, in the sense that more cases should be detected in the presence than in the absence of screening. However, this rate yields no information on the effect of the screening on disease outcome. One would expect case finding to increase in a screened population, at least initially, relative to an unscreened population, because of lead time bias. This can happen in the presence or absence of a mortality effect. Furthermore, care must be taken about the definition of discovered cancer in an early detection program. Many borderline lesions found by screening may not be progressive disease. This results in overdiagnosis bias, as noted above. If so, individuals may be unnecessarily treated and exposed to other possible risks of screening.

Stage

The stage of a disease at diagnosis can also be used as an early indicator that screening might be accomplishing something, but it can be misleading and is unsatisfactory as a final endpoint for various reasons. The measurement and definition of stage can be subjective, and its proper use requires strict guidelines and tight control over pathology, each of which may be difficult to implement in practice. More importantly, the relationship of stage to survival or mortality has not been generally established in the screening setting.

The problem is likely to be most pronounced for Stage I or localized cases, particularly if a study has a cutoff point after which new cases are not accrued. In this circumstance, lead time and length bias can result in slow-growing, even nonprogressive, cases being detected in Stage I in a screened group to a greater extent than in a control group. Their counterparts in the control group may not surface by the cutoff point, if ever, and as a result the screened group will contain a higher proportion of Stage I cases even if screening has no effect on mortality. If there is a mortality effect, the magnitude could be exaggerated by confining an analysis to stage of disease. Thus, while observation of a stage shift in a screened group is a sign of early detection, it is insufficient evidence of an effect on disease outcome.

Survival

A further alternative endpoint is survival, specifically the case–survival rate. In contrast to mortality, which is a population measure, the case–survival rate refers only to cancer cases within a population, being the proportion of cases alive after some time period. Because there are losses to follow-up, this endpoint is ordinarily calculated using **life table** methods (*see* **Survival Analysis, Overview**). While this endpoint does address the final outcome of disease and gives suggestive evidence of screening effectiveness, it cannot be relied upon to reflect mortality accurately. Because diagnosis occurs earlier in a screening program, any observed increase in survival from time of diagnosis is, at least in part, simply a reflection of lead time. For any given case of the disease, it is impossible to distinguish between a true increase in survival time and an artificial increase due to lead time because lead time cannot be observed directly for ethical reasons. Further, there is as yet no universally accepted procedure available to estimate lead time or to adjust survival for lead time, although research in this area has appeared [50, 53]. Consequently, case survival is not a valid measure of screening effectiveness.

Furthermore, even if one could adjust for lead time, the problem of length bias would still exist in making survival comparisons. For example, the length bias effect may be different between two subgroups of cases detected by different screening modalities. That is, the cases in one subgroup may have a different distribution of natural histories than the cases in another subgroup because of a modality-dependent sampling effect. Thus, even if one could adjust for lead time, any remaining

survival difference could be real, or could simply be a consequence of the difference in disease natural history between the groups, or a combination of the two factors. Unfortunately, no general methodology exists to either estimate the magnitude of a length bias effect or to adjust the survival for length bias.

An alternative approach is to consider survival time measured from entry into a study instead of from time of diagnosis. In this way, all cases of disease have their survival time starting from the same time origin, thereby eliminating the lead time bias. Survival times and survival distributions calculated in this way are not comparable to survival calculated in the usual way, but their use can lead to a valid comparison of time in study between the cases in an intervention group and the cases in a control group. While this procedure avoids the lead time problem, one must still be concerned about length bias [2].

Rate of Advanced-Stage Disease

Another measure which has received increasing attention as an endpoint in screening studies is the population incidence rate of advanced-stage disease [7, 11, 34, 41, 49]. The overall incidence rate or the rate of early-stage disease should increase with screening, and could be artificially inflated because of length bias and overdiagnosis bias as discussed above, rendering these measures invalid as endpoints. However, if screening reduces the rate of advanced disease or disease which has metastasized and/or is likely to lead to death, then it is reasonable to expect that the death rate from the disease will also be reduced. Whether this is a valid substitute for mortality must be established for each cancer separately, by first defining advanced-stage disease for a particular cancer and then assessing the relationship between advanced disease and mortality in properly designed studies.

Randomized Controlled Trial

In the typical RCT of screening, individuals or groups are randomized to either a study (screening) group or a **control** group. Screening is offered to those in the study group and no screening is offered to those in the control group. Alternatively, the groups may be offered different screening modalities. At the conclusion of the trial, the difference in the cancer mortality from entry to the end of follow-up for the two groups is assessed. If screening does detect preclinical disease and if treatment initiated earlier than usual is more effective than treatment given at the usual time of diagnosis, then the intervention group should have fewer cancer deaths than the control group.

Several authors [9, 26, 27, 40] maintain that the screening RCT with mortality endpoint is the only way to ensure that inferences are not subject to selection, length, and lead time biases, and that all other designs are suspect in this regard. Familiarity with basic screening RCT designs is therefore important. Four basic RCT designs are described and their relative advantages and disadvantages discussed. In principle, each of these designs can be used to address a single question in a two-arm design or multiple questions in a multiple-arm design [16, 36].

Continuous Screen Design

A natural design for a cancer-screening RCT is to randomize individuals either to an intervention or a control arm, with the intervention consisting of periodic screening throughout the trial. Those in the control arm are not offered the periodic screening; they follow their usual medical care practices. This is called the "Continuous screen" design since screening continues for the duration of the study. The NCI Cooperative Lung Cancer Screening RCT done in the mid 1970s to the mid 1980s essentially followed this design [17]. The major goal of the study was to determine whether screening for lung cancer with sputum cytology and chest X-ray was more effective in reducing lung cancer mortality than screening using chest X-ray. One drawback of the continuous screen design is that the cost involved in screening all intervention group participants for the duration of the trial may be prohibitive. With this in mind, an alternative, namely the "stop screen" design, has been proposed.

Stop Screen Design

The "stop screen" design is similar to the continuous screen design, except that screening is offered for only a limited time in the intervention group. However, both arms are followed for disease incidence and mortality until the end of the trial. This design is suggested when it is anticipated that a long follow-up will be required before a reduction in mortality can be

expected to emerge, and when it would be expensive or difficult to continue the periodic screening for the entire trial period. The HIP study [47] followed this design. Sixty-two thousand women aged 40–64 from the HIP population were randomized. The intervention arm was offered four annual screens consisting of two-view mammography and clinical breast examinations. The screens were offered at entry and for the next 3 years. Women in the control arm followed their usual medical practices. Evaluations were done at 5 and 10 years, but women in both arms were followed for 15 years to assess long-term effects of screening.

By stopping screening, the stop screen design can result in a considerable saving in cost and effort relative to the continuous screen design. However, analysis of the stop screen design can be more complex than that of the continuous screen design because the difference in disease-specific mortality between the two arms may be diluted by deaths among the cancers that develop in the intervention arm after screening stops. In addition, the stop screen design is the only one that allows for assessment of overdiagnosis by screening because, by stopping screening and continuing follow-up, one can determine if any excess of cases existing at the time screening stops persists (overdiagnosis) or disappears.

Split Screen Design

The "split screen" design is a variant of the stop screen design. The difference is that at the time the last screen is offered to the intervention arm, a screen is also offered to all those in the control arm. The Stockholm Breast Cancer screening trial is an example of this design [20]. Women were randomized to intervention or control, beginning in 1981. The intervention consisted of two single-view mammograms, performed roughly 28 months apart. The control group was offered a single screen, at approximately 4.5 years after study entry.

One advantage of the split screen design is that there is greater potential to identify comparable groups of cancer cases in the control and intervention arms for the analysis, since the screen in the control arm presumably identifies the counterparts to the cases previously identified in the screened arm. However, at least some of the control arm cancers detected by screening may benefit from being screened and, if so, this benefit may cause some dilution of effect.

Delayed Screen Design

The "delayed screen" design is a variant of the continuous screen design. The difference is that periodic screening is offered to the control arm starting at some time after the start of the study and continuing until the end of the study. This design allows one to estimate the marginal effect of introducing screening at an early time or age, relative to starting the screening at a later time or age. The UK Breast Cancer Screening Trial of women under 50 is basically following this design [30]. Specifically, women in the intervention arm are offered annual screening starting at age 40–41 and continuing to age 47–48, then at age 50 all women in both arms are offered periodic screening as part of the National Health Care Program in the UK. This study is being conducted to evaluate starting periodic screening at age 40–41 relative to waiting until age 50 to start the screening.

The delayed screen design is particularly well suited for the situation where screening is already the standard of care in an older population, and the research question concerns the benefit of introducing screening at an earlier age. Otherwise, the additional costs associated with implementing this design may render it infeasible.

Observational Study Designs

One useful observational study design involves a comparison of cancer incidence and mortality in a defined population before and after the introduction of a screening program. An alternative is to compare geographic regions, established to be as comparable as possible with respect to disease mortality. Time trends in incidence and mortality can be examined and interarea comparisons of intensively screened areas with nonscreened areas can be made. Both approaches require rapid introduction of the screening program and virtually full coverage of the population at risk. For cancer screening, reliable incidence and mortality data, which are available for at least a 10-year period prior to the start of screening and which are predictable for the future, should be available. Ideally, this would be total incidence and mortality data, not simply for the cancer of interest. For other diseases, shorter time spans might apply. Another requirement is the capability for accurate, long-term follow-up of the entire population

at risk. Such an observational study may require substantially larger populations than an RCT and may eventually prove more costly than the more rigorous design. Apart from the potential biases involved in such an observational study, this design offers the possibility of estimating either screening effectiveness or efficacy, depending upon whether the intervention population involves only screened individuals or is a population offered screening in which some individuals accept the testing and some refuse. This approach has been used to evaluate cervical cancer screening [21].

The case–control study is another observational design which can serve as an approach to screening evaluation [8, 28, 44, 51]. In principle, such studies can be used to evaluate the efficacy of screening in the prevention of death, or of invasive disease and consequently death in situations where the screening test detects precursor lesions. A number of such studies have been undertaken, mainly aimed at evaluation of cervical and breast cancer screening [10, 14, 19, 33, 45, 48]. In addition, papers have appeared which address methodologic issues that arise in the screening case–control design [3, 5, 10, 13, 15, 22, 28, 29, 31, 44, 51, 52].

For this purpose, appropriate definition of cases and controls is required. As the primary measure of cancer screening efficacy is mortality, eligible cases should be deaths from the disease of interest in the population under study, irrespective of the means of diagnosis. Eligible controls are all living individuals in the population from which the cases were derived, including individuals with the disease. One then determines whether or not exposure to screening is associated with a reduction in the risk of death from the disease.

This approach also has potential for evaluating the **sensitivity** of screening tests, and may yield information on the relative effectiveness of different screening strategies. However, the approach is only applicable for screening tests which have been in use for several years because screening histories of cases and controls are required.

A particular concern with both the cohort and case–control designs involves selection bias among individuals who choose to be screened as against those who do not, and the impact of this bias on the validity of the inference drawn [10, 18, 24, 32]. The case–control design and the related cohort design in which screened individuals are compared with refusers both assess whether or not screening reduces the mortality of those individuals who elect to be screened relative to those who do not so elect. This comparison does not estimate efficacy since the self-selected comparison group does not in general provide an estimate of the mortality rate of the screenees if they had not been screened. However, both designs can provide a valid efficacy comparison if those refusing to be screened have the same cancer mortality rate as those accepting screening would have had had there been no screening, i.e. if there is no self-selection bias [10].

Information Requirements for Evaluation

Several key data items must be defined and carefully collected in order to achieve a complete evaluation of a screening program [7, 11, 12, 36].

1. *Population characteristics*. The demographic, socioeconomic, and risk characteristics of the target population or study population should be ascertained. In some circumstances, dietary and occupational history may also be pertinent, such as in a study of colorectal cancer, where diet may play an etiologic role, or of bladder cancer, where occupational exposure to carcinogens may influence the evaluation of screening.
2. *Coverage and compliance*. The proportion of the population offered screening who actually undergo the initial and subsequent screening tests should be determined. This indicates the level of interest in, and acceptability of, the screening procedure, and whether or not the level is high enough to have a chance of achieving an impact in the population.
3. *Test yield*. The number and proportion of cases found by screening, particularly in relation to the cases not discovered by screening (the so-called interval cases) is important for evaluating how successful the screening test is in finding the disease.
4. *Stage of disease*. This should be ascertained for each case of the disease in the population under surveillance, whether detected by screening or diagnosed clinically. This information can be used to compare the stage distribution of screen detected cases vs. other case subsets to determine if screening might have an impact on mortality,

and is necessary for defining stage-specific incidence rates.

5. *Case survival*. Survival time should be determined for each case of disease. As with stage information, the survival distribution of screen-detected cases can be compared with that of other case groups to seek some indication that screening might have an impact on disease outcome.
6. *Incidence and prevalence rates*. As noted above, the rate of advanced stage disease may be a good intermediate indicator of the impact of screening on mortality. The ratio of prevalence to incidence yields an estimate of the preclinical duration of disease and can be used to estimate the average lead time gained by screening [23] (*see* **Incidence–Prevalence Relationships**).
7. *Mortality rates*. Mortality rates provide the primary evidence on the effectiveness of screening. Mortality rates for the disease of interest can be calculated and compared between a screened group and a control group to measure the impact of screening. In addition, the death rates from other causes should be scrutinized to assess the comparability of the groups with regard to causes of death other than the one of interest.
8. *Therapy*. The therapy used for each case of the disease should be recorded. At a minimum this should be the initial therapy, but adjuvant therapy or treatment for recurrence could be noted as well. This information should be recorded in the same way in the screened and control populations within each disease stage, and is relevant for separating the early detection effect from the treatment component of any screening impact.
9. *Procedures and costs*. To perform an assessment of the cost or cost-effectiveness (*see* **Health Economics**) of a screening program, it necessary to collect data on the costs of all phases of the program. Alternatively, one can record the procedures done in each phase so that costs can be assigned at a later date. Procedures to be included are efforts to recruit the population, the screening tests, all diagnostic procedures following a positive screen or those used to diagnose a case clinically, all treatment procedures, and any efforts expended to follow the population [39].

PHILIP C. PROROK

Screening Trials

The early detection of cancer and other chronic diseases has long been a goal of medical scientists. Many believe that by moving the point of diagnosis backward in time so that the disease is diagnosed earlier than usual, treatment will be more effective than treatment given at the usual time. However, this presumption may not be correct and the effect of any screening program must be evaluated. **Cohort studies** and **case–control studies** have been used for evaluating **screening** for several types of cancer, and the design and interpretation of these studies have recently been the topic of increasing discussion (*see* **Screening Benefit, Evaluation of**). However, an **observational study** rarely yields definitive answers or permits solid conclusions with regard to the public health consequences of cancer screening. The most rigorous approach is the randomized **clinical trial**. There are special design and analysis issues for such screening trials.

Design Issues

The randomized controlled trial involves the prospective testing and long-term follow-up of defined populations according to a protocol (*see* **Clinical Trials Protocols**). There are several major design and implementation aspects that should be considered. First, the target disease(s), the screening test(s), and the diagnostic and therapeutic regimens must be determined. Then, the appropriate outcome variable (*see* **Outcome Measures in Clinical Trials**) must be chosen and the sampling unit (*see* **Unit of Analysis**) (individual or group) selected. Next, the admission and exclusion criteria need to be established (*see* **Eligibility and Exclusion Criteria**) and a **randomization** procedure chosen to allocate eligibles to the study and **control** groups (*see* **Randomized Treatment Assignment**). The study and control groups should be followed up with equal intensity and in the same time frame, with the outcome variable measured in a blind fashion (*see* **Blinding or Masking**), if possible. Every effort should be made to maximize adherence to the study protocol for both groups (*see* **Compliance Assessment in Clinical Trials**). It is also important in the analysis that all individuals in the control group be compared to all individuals in the study group, including both individuals accepting the offer of screening and those rejecting the offer (*see* **Intention to Treat Analysis**).

A decision on the number of screening examinations and the interval between examinations (screens) must be made. The number of screens depends on the tradeoff between a sufficient number to realize an effect, if there is one, and the cost of additional screens. Trials may incorporate screening for essentially the entire follow-up period [35], or employ an abbreviated screening period typically involving four or five screening rounds, with a subsequent follow-up period devoid of screening [22, 32]. Several modeling efforts have addressed these issues [6, 16, 18, 19].

Another design problem involves the relationship between study duration, sample size, and the expected timing of any effect. Sample size and study duration are inversely related. If these two parameters were the only ones to consider, the relationship between follow-up cost, on the one hand, and recruitment and screening cost, on the other, would determine the design. However, the time at which a reduction in mortality may occur must also be considered. For those cancer screening trials that have demonstrated a reduction in mortality, a separation between the mortality rates in the screened and control groups did not occur until four to five years or more after randomization [32, 35]. Furthermore, the difference may continue to increase with time, even after screening stops [32]. Thus, even with a very large sample size, follow-up may have to continue for many years to observe the full effect of the screening. A follow-up period of at least 10 years is appropriate, but a longer period may be required if the screening effect is manifested primarily among a subset of patients with slowly growing cancer (*see* **Sample Size Determination for Clinical Trials**).

Determination of the appropriate endpoint in a cancer screening study is intimately related to the disease natural history. For a screening trial, the relevant natural history is from the time the cancer is screen-detected to death. This natural history is usually not well understood, and potential early indicators of outcome such as a shift in disease stage or a lengthening of survival among cases, which depend on knowledge of this natural history for their validity, cannot provide a definitive assessment of screening in the absence of this knowledge.

There is only one outcome variable known to be valid in a cancer screening trial, namely the population cancer mortality rate. This is the number of cancer deaths per unit time per unit population at risk [23, 27]. The mortality rate provides a combined assessment of early detection plus therapy. No improvement in mortality will be seen if either the screening does not lead to earlier detection or therapy at the time of earlier detection confers no extra benefit.

Intermediate or surrogate outcome measures have also been considered (*see* **Surrogate Endpoints**). However, these have critical shortcomings that can be traced to the well-known **biases** that occur in screening programs: lead time bias, **length bias**, and over-diagnosis bias [23, 27] (*see* **Screening Benefit, Evaluation of**). Among the most frequently proposed alternative endpoints are the case–finding rate or yield, stage of disease, and case–survival rate.

Another measure that has been proposed as an endpoint in screening studies is the population **incidence rate** of advanced stage disease [1, 5], since, if screening reduces the rate of advanced disease, disease that has metastasized, or is likely to lead to death, then it is reasonable to expect that the death rate from the disease will also be reduced.

Sample Size

In the **hypothesis-testing** framework, the sample size can be calculated from the appropriate formula if one knows the event rate, effect size, and statistical procedure, all of which depend on the choice of endpoint for the study (*see* **Sample Size Determination**). In cancer screening trials, this is the cancer mortality. Since the analysis involves a comparison of the numbers or rates of deaths, methods for **Poisson-distributed** data can be used [34, 36]. Other factors that must be taken into consideration are noncompliance in the screened and control groups, randomized groups of different sizes, and lower than expected event rates among the individuals who participate in the study. Several approaches have been formulated to address these problems [23, 25].

One approach to sample size estimation is based on the method suggested by Taylor & Fontana [36], modified to allow for an arbitrary magnitude of screening impact, an arbitrary sample size ratio between the screened and control groups, and arbitrary levels of compliance in the screened and control groups. Let N_c be the number of individuals randomized to the control group, and N_s the number randomized to the screened group, with $N_s = fN_c$. Assume the study is designed to detect a $(1-r) \times 100\%$ reduction $(0 \le r \le 1)$ in the cumulative disease-specific death rate over the duration of the trial. Also, let P_c be the proportion of individuals in the control group who comply with the control group intervention and P_s be the proportion of individuals in the screened group who comply with the screened group intervention.

Using a model in which the death rate in the presence of noncompliance in the screened group is a linear combination of the screened and control group death rates, weighted by the compliance levels, one finds that the total number of disease-specific deaths, D, needed for a one-sided α-level significance test with power $1-\beta$ is given by

$$D = \frac{[(\Theta_1 + f\Theta_2)Z_{1-\alpha} - (\Theta_1\Theta_2)^{1/2}(1+f)Z\beta]^2}{f(\Theta_1 - \Theta_2)^2},$$

where $\Theta_1 = r + (1-r)P_c$, $\Theta_2 = 1 - (1-r)P_s$, and $Z_{1-\alpha}$ and Z_β are the $1-\alpha$ and β **quantiles** of the standard **normal distribution**, respectively. The number of participants required in the control group is $N_c = D/(\Theta_1 + f\Theta_2)R_cY$, where Y is the duration of the trial from entry to end of follow-up in years, and R_c is the average annual disease-specific death rate in the control group expressed in deaths per person per year.

Calculation of N_c requires an estimate of R_c. Individuals recruited for a screening trial are expected to be healthier than the general population due to **selection** factors and eligibility criteria. Hence, the usual cancer mortality rate obtained from national or registry (*see* **Disease Registers**) data is likely to overestimate the mortality rate of the participants, at least for the early part of a trial. An ad hoc approach to this problem is to use the relationship between the observed and expected death rates in previous screening trials. Alternatively, one can calculate an expected event rate using the age-specific incidence rates of a cancer-free population combined with the survival rates of these incident cases to arrive at the expected mortality [23, 25, 26].

Study Designs

Classic Two-Arm Trial that Addresses a Single Question

In this design, the study population is randomized to a group offered screening according to a protocol and a control group not offered screening. At the end of follow-up, the mortality rates in the two groups are compared [28]. The prototype trial for this design is the Health Insurance Plan (HIP) trial of breast cancer screening [32].

Designs for Investigating more than One Question in the Same Study

Extensions of the classic two-arm design have been used or suggested for cancer screening trials to answer more than one question in the same study. This topic has also been discussed for cancer **prevention trials** [11]. For example, the National Study of Breast Cancer Screening in Canada involves two different study populations, but under the same administrative and scientific umbrella (i) to determine in women aged 40–49 at entry whether annual screening by mammography and physical examination, when used as an adjunct to the highest standard of care in the Canadian health care system, can reduce mortality from breast cancer, and (ii) to evaluate in women aged 50–59 at entry the additional contribution of routine annual mammographic screening to screening by physical examination alone in reducing breast cancer mortality. This involves separate randomizations of women in the two age groups [22] (*see* **Randomized Treatment Assignment**). In some circumstances, several related questions can be addressed by including additional randomized groups in the trial. An example is the colon cancer screening trial at the University of Minnesota [14]. Two basic issues are being addressed; namely, whether screening can reduce mortality, and whether there is a different effect at different screening frequencies. Three randomized groups were formed: a control group, a group offered annual screening with a test to detect occult blood in the stool, and a group offered the occult blood test every two years. Another extension of the basic design is a two-group trial in which the intervention group includes multiple interventions, known as the all-versus-none design [11]. One version of this design involves several interventions, with each intervention aimed at early detection of a different type of cancer. Use of this design requires two assumptions: first, that the test for any given cancer does not affect the case detection or mortality of any other cancer site, and, secondly, that disease-specific mortality is independent among the cancers under study. An example is the Prostate, Lung, Colorectal and Ovarian Cancer (PLCO) Screening Trial sponsored by the National Cancer Institute [15], the objectives of which are to determine whether: (i) in females and males, screening with flexible sigmoidoscopy can reduce mortality from colorectal cancer, and screening with chest X-ray can reduce mortality from lung cancer; (ii) in males, screening with digital rectal examination plus serum prostate-specific antigen (PSA) can reduce mortality from prostate cancer; and (iii) in females, screening with pelvic examination plus CA 125 and transvaginal ultrasound can reduce mortality from ovarian cancer. Another design option to answer more than one question at a time is the reciprocal control design [11]. In this design, the participants in each arm of a trial receive an intervention, but also serve as controls for an intervention in another arm of the trial. This requires the assumption that the intervention aimed at a given cancer does not affect any of the other cancers under study.

Within each of the above design types there are options for the relationship between screening and follow-up [9]. A natural design is to randomize individuals either to an intervention or a control group, with the intervention consisting of periodic screening throughout the trial. Those in the control arm are not offered the periodic screening; they follow their usual medical care practices. This is called the continuous-screen design. The NCI Cooperative Lung Cancer Screening RCT, conducted in the mid 1970s to the mid 1980s, essentially followed this design [10].

One drawback of the continuous-screen design is that the cost involved in screening all intervention group participants for the duration of the trial may be prohibitive. An alternative is the stop-screen design in which screening is offered for a limited time in the intervention group and both groups are followed for disease incidence and mortality until the end of the trial. This design is used when it is anticipated that a long follow-up will be required before a reduction in mortality can be expected to emerge, and when it would be expensive or difficult to continue

the periodic screening for the entire trial period. The Health Insurance Plan (HIP) of Greater New York Breast Cancer Screening Study followed this design [32]. The stop-screen design can result in a considerable saving in cost. However, the analysis can be more complex than that of the continuous-screen design, because the difference in disease-specific mortality between the two groups may be diluted by deaths from cancers that develop in the intervention group after screening stops.

The split-screen design is a variant of the stop-screen design in which a screen is also offered to all those in the control group at the time the last screen is offered to the intervention group. The Stockholm Breast Cancer screening trial, conducted in the 1980s, is an example of this design [13]. An advantage of the split-screen design is that there is greater potential to identify comparable sets of cancer cases for the analysis (discussed below).

The delayed-screen design is a variant of the continuous-screen design in which periodic screening is offered to the control group starting at some time after the start of the study and continuing until the end of the study. This design allows the estimation of the marginal effect of introducing screening at some standard time or age, relative to starting the screening at a later time or age. The current UK Breast Cancer Screening Trial of women under 50 is basically following this design to evaluate the effect of beginning screening before the age of 50 years [24].

Analysis

Screening trials involve special issues in their analysis, both for the continuous-screen and stop-screen designs, and for primary and secondary analyses. Primary analyses are concerned with evaluating whether there is a statistically significant difference in disease-specific mortality between the control and intervention groups. Secondary analyses are concerned with ascertaining the magnitude of the mortality difference, and with gaining a deeper understanding of the underlying mechanisms [9].

Primary Analysis

Proposed statistical methods for primary analysis include a Poisson test statistic comparing the observed death rates [33], a **Fisher exact test** comparing the observed proportions of cancer deaths [2], and a **logrank test** comparing disease-specific death rates over time in the two groups [2, 3]. For example, the **Poisson process** test statistic for comparing cumulative mortality rates is

$$\frac{Z_r = (PY_S D_C - PY_C D_S)}{[PY_C PY_S (D_C + D_S)]^{1/2}},$$

where D_C = the number of deaths from the cancer of interest in the control group through the time of analysis, D_S = the corresponding number of deaths in the screened group, PY_C = the number of **person years at risk** of death from the cancer of interest in the control group through the time of analysis, and PY_S = the corresponding number of person years in the screened group [34].

Logrank test analysis may be based on the disease-specific mortality experience of all randomized participants, termed the overall mortality analysis, or it may be based on the mortality experience of comparable groups of cancer cases in the two arms of the trial, in which case it is termed the limited mortality analysis [3].

Overall Mortality Analysis

Overall mortality analyses possess the advantage of comparability of comparison groups formed by randomization. However, logrank tests comparing disease-specific mortality can be relatively inefficient. This is because the logrank test is optimal under proportionality of the disease-specific mortality hazards in the two groups, whereas, in cancer screening trials, there is generally a delay from the beginning of the intervention program to the time that effects on cancer mortality can be observed, and the magnitude of any effect may vary over time. In addition, in stop-screen designs, cases continue to accrue in both groups after screening stops. The cancer deaths in the intervention group that are due to cancers developing after screening dilute the screening effect. Thus, the ratio of hazards decreases with time after some point in the trial. If the specific form of departure from proportional death rates is known, then efficiency can be gained by use of a weighted logrank statistic instead of the usual (unweighted) logrank statistic [8].

Zucker & Lakatos [42] propose a method to accommodate a possible lag until full screening effect within a continuous-screen design. They specify a

range of plausible lag times to full screening effect and then identify the weighted logrank statistic that minimizes the worst possible efficiency loss over this range. Self [29] and Self & Etzioni [30] propose **adaptive** testing methods for stop-screen designs. Their suggestion is to use the observed departures from constancy of the relative hazards to improve the efficiency of the test procedure. These methods are also weighted logrank tests, but the weights are identified in a data-dependent fashion. Sequential versions of these procedures are not yet available.

Limited Mortality Analysis

In a limited mortality analysis, one restricts analysis to comparable sets of cancers, one set consisting of cancers from the intervention group diagnosed through some designated time interval after the start of the study, and the other consisting of their counterparts in the control group diagnosed during the same interval. Limited mortality analyses are typically only applied to split-screen or stop-screen designs. The split-screen design leads naturally to two presumably comparable case sets; namely, those diagnosed up to and including the final screen offered. In the stop-screen design, however, determination of comparable case sets is less straightforward. The main question is how to choose the time interval for ascertainment of cases for analysis. The end of the case ascertainment period should not be too long after screening stops, because the continued accrual of clinically detected cases in both groups may lead to dilution of the observed screening effect as described previously. If, however, we exclude all cases diagnosed after screening has stopped, another form of dilution can arise. Among the cases diagnosed in the control group after screening has stopped, some may correspond to cases in the intervention group that were screen-detected and therefore diagnosed earlier than they would have been without screening. If this set of cancers benefits from the earlier diagnosis due to the screening, then excluding the control group counterparts to these cancers also dilutes the screening effect [8].

Comparability

Whatever the method used to select comparable case sets, the true comparability of the sets selected must be fully investigated. Both the cases in the selected sets and the cases that are diagnosed after the time used to define the selected sets must be evaluated. Methods have been proposed for assessing the comparability of case sets in a stop-screen study [3]. They consider the numerical as well as the biological comparability of the sets. Numerical comparability concerns the numbers of cancers in the case sets. Biologic or qualitative comparability concerns the composition of the cancer case sets with regard to their natural history, and especially their survival characteristics in the absence of screening. Qualitative comparability of candidate sets is assessed by **covariates** defined at randomization associated with the cancer cases.

The identification of comparable case sets is not straightforward. In a stop-screen design, it may be impossible to identify comparable sets if screening is available outside of the trial, and the use of outside screening differs between the two arms after trial screening stops. In a continuous-screen design, it is unlikely that equalization will ever occur. In such cases, appropriately weighted overall mortality analysis may be the only valid option.

In summary, the overall analysis is the most **unbiased** as it compares all randomized individuals. However, this approach may assess a diluted relative effect of screening in a stop-screen design and it requires follow-up of all randomized trial participants. Alternatively, the limited analysis requires follow-up of only selected case sets after a certain point in time and so is less costly. However, the approach is subject to **bias** if the case sets are not truly comparable.

Secondary Analyses

Secondary analyses of cancer screening trials typically involve information related to the outcome of cancer cases captured in survival data, and indications of earlier diagnosis, captured by estimates of the screening program's lead time, **sensitivity**, and the degree of shifting to an earlier clinical stage at diagnosis in the screened group.

Estimates of survival differential are based on the postdiagnosis survival curves in the two case sets (*see* **Survival Analysis, Overview**). The postdiagnosis survival of screen-detected cases includes lead time, which must be explicitly removed to avoid lead-time bias. Initial approaches were developed for the HIP trial assuming a fixed lead time of one year and considering the k-year actuarial survival from

diagnosis of control group cases and interval cases (cases diagnosed in the intervals between screens because of signs or symptoms) as equivalent to the $k + 1$-year survival from diagnosis of screen-detected cases [33]. Walter & Stitt [39] allowed lead time to be a **random variable** with a known distribution. This approach was extended to **nonparametric** estimation procedures by Xu & Prorok [40].

Explicit adjustment for lead time requires knowledge of its probability distribution. Direct estimates of mean lead time have been presented by Shapiro et al. [31], Morrison [23], and Kafadar & Prorok [17]. The approach of Shapiro et al. and Morrison yields crude estimates of average lead time based on comparing disease incidence in the control and intervention groups. Kafadar & Prorok used differences in survival from entry and from diagnosis between screened and control group cases to estimate benefit time and lead time assuming two comparable case sets like those identified for a limited mortality analysis.

Other methods for estimating lead time have been developed by Zelen & Feinleib [41] and Walter & Day [38]. These approaches may be thought of as statistical modeling efforts (*see* **Model, Choice of**). **Simulation** modeling is also being increasingly employed to estimate screening program properties and disease natural history, and to project the costs and benefits (*see* **Health Economics**) of alternative screening strategies [7, 37].

The information on shifts in the distribution of clinical stage at diagnosis should be interpreted with caution, since shifts may be due to overdiagnosis or length bias and therefore need not imply disease-specific mortality benefit. However, a stage-shift model has been developed that allows the estimation of the amount of shift between and within stages due to screening, as well as the associated mortality benefits. The model requires comparable case sets [4].

Trial Monitoring

Various categories of data and information become available at successive stages of a screening trial. These relate to the population under study, acceptance of the screening test by the population, outcomes and characteristics of the screening test, and intermediate and final effect measures or endpoints used for determining the value of screening. These variables can be examined on a regular basis for evidence to alter the protocol or stop the trial, and are also valuable in assessing the consistency of findings or conclusions. More specifically, the data that can be used for monitoring include: population descriptors such as demographic, socioeconomic, and risk characteristics of the population; the proportion of the study population offered screening who undergo the initial screening, the level of compliance with scheduled repeat screens, and the level of screening contamination in the control group; the yield of cancers as a result of screening, the interval cancer rate, and screening test characteristics including sensitivity, **specificity** and **predictive value**; diagnostic and therapeutic follow-up among individuals designated suspicious or positive by the screening test and the costs involved in these procedures; cancer case characteristics such as stage, histologic type, grade, and nodal involvement; survival of cancer cases; incidence and prevalence rates of the cancer of interest; the incidence rate of advanced stage cancer; and mortality rates from the cancer of interest and other causes [28].

Another aspect of the monitoring process of a trial is the use of formal statistical stopping rules. These include various methods aimed at accounting for repeated looks at the data such as the Lan–DeMets technique and stochastic curtailment procedures, as well as **Bayesian** approaches [12, 20, 21] (*see* **Data and Safety Monitoring**).

PHILIP C. PROROK

Screening, Models of

Screening asymptomatic people to allow the early detection and treatment of chronic diseases is an important part of modern medicine and public health. For screening to be both an efficient and cost-effective medical intervention, it must be carefully targeted and evaluated. Mathematical models of disease screening constitute one of the major tools in the design and evaluation of screening programs.

The purpose of this article is to describe models for disease screening and how they have developed in recent years. The discussion will focus on screening for cancer, because most of the methodologic advances in screening design and evaluation have concerned cancer screening. In the first part of the article we will describe the characteristics of these models and illustrate them with a discussion of a simple screening model. In the second part we will describe the development of the two main types of model. In the third part we will discuss model fitting and validation, and in the final part we will briefly describe models for diseases other than cancer and discuss the current state and possible future directions for models of disease screening.

This is not intended to be an exhaustive study of all modeling of disease screening. Rather, it is intended to be a description of the main approaches used and their strengths and weaknesses. For more detailed reviews of modeling disease screening, see Eddy & Shwartz [30], Shwartz & Plough [56], Prorok [50, 51], Alexander [5], and Baker et al. [9].

What is Screening?

Screening for disease control can be defined as the examination of asymptomatic people in order to classify them as likely or unlikely to have the disease that is the object of screening. People identified by a screening test as likely to have the disease are then further investigated to arrive at a final diagnosis [45]. The objective of screening is the early detection of a disease where early treatment is either easier or more effective than later treatment.

Figure 1 is a schematic representation of the main features of the natural history of a disease which are relevant to screening. The *preclinical* phase of the disease is the phase in which a person has the disease

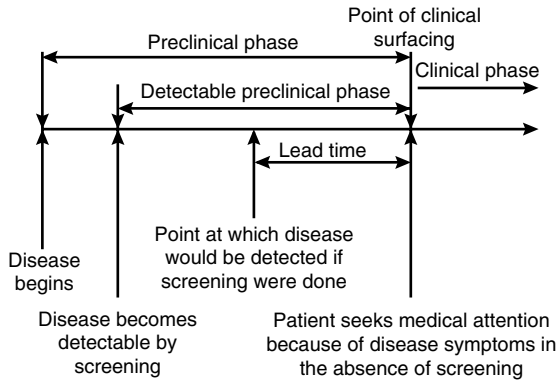

Figure 1 The natural history of a disease with and without screening

but does not have any clinical symptoms and is not yet aware of having it. Screening aims to detect the disease during this phase. In principle, the preclinical phase starts with the beginning of the disease, but, in practice, modeling focuses on the phase commencing at the earliest point at which the disease is detectable with a screening test. This is known as the *detectable preclinical phase*.

The preclinical phase finishes with the *clinical surfacing* of the disease. This is the point at which the person develops clinical symptoms of the disease, seeks medical attention for these symptoms, and the disease is diagnosed. The disease then enters the *clinical phase*, where the person has a diagnosable case of the disease.

The outcome of a screening test is designated either *positive*, if the person is identified as likely to have the disease, or *negative* if they are not. All screening tests are open to error either from the test itself or its interpretation. These errors are designated as **false positive**, where a person without the disease has a positive screening result, and **false negative**, where a person with the disease has a negative screening result. The **sensitivity** of a screening test is the probability that a person with the disease has a positive screening result. The **specificity** of a screening test is the probability that a person without the disease has a negative screening result. Cases of the disease which clinically surface following a false negative result (i.e. where the screening test missed the disease) are known as *interval cases*.

It is important to note that sensitivity and specificity are not properties of the test alone. For example,

mammography is used to screen for breast cancer in women. In this case the sensitivity and specificity will depend on characteristics of the test, such as the nature of the mammography machine and the number of views taken, as well as on factors such as the skill of the person interpreting the mammogram, the size of any tumor in the woman being screened, the density of her breast tissue, and so on.

The *reliability* of a test is its capacity to give the same result, either positive or negative, on repeated application in a person with a given level of the disease. The *survival time* is the length of time between disease diagnosis, either by clinical surfacing or detection by screening, and death. The *lead time* is the time between the detection of a disease by screening and the point at which it would have clinically surfaced in the absence of screening.

The lead time is an important issue in the examination of screening benefits. The immediate focus of screening is to detect an early form of the disease. Hence the lead time can be used as an index of benefit in its own right. It is also important in examining survival benefits conferred by screening. A simple comparison of survival times between screened and unscreened populations is likely to show spurious screening benefits, since the survival time for a screen detected disease includes the lead time while that for a disease which surfaced clinically does not.

There is another, more subtle, reason why such survival comparisons may be spurious, even if adjusted for lead time. Screening will tend to detect people with a longer preclinical phase. This is known as **length-biased** sampling. Usually this will equate to a more slowly progressing disease. Since the disease behavior before clinically surfacing is likely to be correlated with that after surfacing, this is likely to result in screen detected diseases having a longer survival time than clinically surfacing diseases.

Why Use Modeling?

The evaluation of screening usually focuses on whether or not the screening program has led to a fall in mortality from the disease in question. As with most medical interventions, randomized controlled trials (RCT) (*see* **Clinical Trials, Overview**) provide the most satisfactory empirical basis for evaluating screening programs. However, they do have significant limitations.

RCTs for screening are expensive and time-consuming to run – typically requiring very large sample sizes and having long time lags until benefits are apparent (*see* **Screening Trials**). For example, the RCT of mammography screening carried out in the two Swedish counties of Kopparberg and Ostergotland had a total sample size of 134 867. A statistically significant mortality differential between the control and study groups did not appear until after six years of follow-up, with a further four years of follow-up before the results could be considered definitive [58]. Twenty years of data would be required to yield results on some aspects of screening program design [21].

Any one trial cannot address all the issues involved in designing a screening program. For example, the Minnesota Colon Cancer Control Study used an RCT to demonstrate a statistically significant fall in mortality due to screening with a Fecal Occult Blood Test (FOBT), followed by colonoscopy in those with a positive screen [43]. However, Lang & Ransohoff [39] have subsequently suggested that the sensitivity of FOBT is considerably less than that reported in the Minnesota study. FOBT has a high false positive rate, and they argue that one-third to one-half of the fall in mortality could be due to chance selection for colonoscopy where an early cancer or large adenomatous polyp is present but not bleeding and the FOBT is positive for other reasons. The original RCT provides no basis for deciding on the role of FOBT separately from that of colonoscopy.

Models are one way in which the information on the disease and screening tests from a number of different sources – including RCTs and other clinical and epidemiologic research – can be combined with known and hypothesized features of the specific population to be screened. They can be used to investigate the effect of different screening regimes on different subgroups of the population, both on disease mortality and program costs. For example, one use of modeling has been to investigate the inclusion of different age groups in the population to be screened. They can also be used to project the future course of the disease and screening program, to evaluate the changes in costs and benefits over time.

The modeling approach does have limitations. The extra information is obtained from models only by imposing assumptions about the screening process. These include assumptions about the natural history of the disease, about the characteristics of the

screening test and about the behavior of the population under study. These assumptions can only rarely be verified, although they can be evaluated as part of the modeling process.

A further complication in making these assumptions is that the natural history of most diseases is not completely understood, particularly in the asymptomatic preclinical phase, which is the main focus of screening. This means that one may hypothesize a disease model that meets the constraints of current knowledge but which is still ultimately misleading.

Characteristics of Screening Models

Types of Model

Bross et al. [14] proposed a classification of models used to analyze screening strategies into two types: *surface models* and *deep models*. Surface models consider only those events that can be directly observed, such as disease incidence, prevalence, and mortality. Deep models, on the other hand, incorporate hypotheses about the disease process that generates the observed events. Their intent is to use the surface events as a basis for understanding the underlying disease dynamics. This implies models that explicitly describe the disease natural history underlying the observed incidence and mortality.

Deep modeling permits generalization from the particular set of circumstances that generated the surface events. As a result, whereas surface models provide a basis for interpreting the observable effects of screening, deep models provide an explicit basis for determining the outcomes of screening scenarios that have not been directly studied in clinical trials [56]. This article will focus on the application of deep models to population screening.

These models can be further grouped into two broad categories – those that describe the system dynamics mathematically and those that entail computer simulation. The first of these, designated *analytic* models, uses a model of the disease to derive direct estimates of characteristics of the screening procedure and its consequent benefits. The second, designated **simulation** models, uses the disease model to simulate the course of the disease in a hypothetical population with and without screening and derives measures of the benefit of screening from the simulation outcomes.

Markov Framework for Modeling

Most screening models use an illness–death model for the disease which is developed within the framework of a **Markov chain**. A sequence of **random variables** $\{X_k, k = 0, 1, \ldots\}$ is called a Markov chain if, for every collection of integers $k_0 < k_1 < \cdots < k_n < \nu$,

$$\Pr(X_\nu = i | X_{k_0}, \ldots, X_{k_n}) = \Pr(X_\nu = i | X_{k_n}), \quad \text{for all } i. \tag{1}$$

In other words, given the present state (X_{k_n}), the outcome in the future $(X_\nu = i)$ is not dependent on the past $(X_{k_0}, \ldots, X_{k_{n-1}})$.

The Markov chain formulation is applied to an illness–death model in the following way [16]. The population under study is classified into n states, the first m of which are *illness states* and the remaining $n - m$ of which are *death states*. An *illness* state can be broadly defined to be the absence of illness (a *healthy state*), a single specific disease or stage of disease, or any combination of diseases. In modeling screening, these states typically refer to a healthy state and preclinical and clinical phases of the disease.

A *death* state is defined by **cause of death**, either single or multiple. Emigration or loss to follow-up may also be treated as a death state. In modeling screening, typically there will be one death state due to death from the disease and another due to death from any other competing cause (*see* **Competing Risks**). Entry to a terminal stage of the disease is also sometimes treated as a death state. Transition from one state to another is determined by the *transition probabilities*, p_{ij}, where

$$p_{ij} = \Pr(X_{k+1} = j | X_k = i), \quad i, j = 1, 2, \ldots, n; \quad k = 1, 2, \ldots. \tag{2}$$

Death states are *absorbing* states, since once one reaches that state, transition to any other state is impossible (i.e. $p_{ij} = 0$, for $i = m + 1, \ldots, n$, and $j \neq i$). The disease model is said to be *progressive* if, once one enters the first stage of the disease, in the absence of interventions (such as screening) and competing risks, the only valid transitions are through the remaining disease stages. Because the disease is modeled using a Markov chain, the future path of an individual through the illness and death states depends only on his or her current state, and the future distribution of individuals between illness and death

states depends only on the present distribution and not on any past distributions.

This basic model can be varied in a number of ways. The Markov chain treats time as increasing in discrete steps corresponding to the index k. Thus a transition between states can only occur at discrete time intervals. Most screening models extend this to allow transitions to occur in continuous time. In this case, the transition probabilities for any two points in time t_1 and t_2 are

$$p_{ij}(t_1, t_2) = \Pr(X(t_2) = j | X(t_1) = i), \quad i, j = 1, 2, \ldots, n. \tag{3}$$

If $p_{ij}(t_1, t_2)$ only depends on the difference $t_2 - t_1$ but not on t_1 or t_2 separately, the model is *time homogeneous*. The simple Markov chain described above is time homogeneous. This can be varied to allow the transition probabilities to vary with time. The probabilities can also be allowed to vary with age and other relevant characteristics of the individual. Some of the model formulations also allow the probability of transition out of a state to depend on the sojourn time in that state.

A Simple Disease and Screening Model

In this section we describe a simple model presented (and discussed in greater detail) by Shwartz & Plough [56], based on a characterization of the disease process proposed by Zelen & Feinleib [65]. We assume that a person can be in one of three states – a healthy state, the preclinical phase of the disease, or its clinical phase. This characterization also implicitly assumes a death state following the clinical phase, but since the focus of the analysis is on the preclinical phase, the death state is not explicitly used.

The model is progressive in that once a person enters the preclinical state, in the absence of screening or death from another cause, the disease will ultimately surface and enter the clinical phase. If the person is screened while in the preclinical state, then the disease may be detected with a probability depending on the sensitivity of the screening test.

The main assumption underlying this model (and the whole screening process) is that the earlier in the preclinical phase the disease is found, the better will be the prognosis. Hence, the screening benefit is directly related to the lead time.

For this model we define the following:

1. L is the lead time;
2. $g(y)$ is the **hazard rate** for entering the preclinical state at age y;
3. $p(t)$ is the hazard rate for clinical surfacing after the disease has been in the preclinical phase for time t;
4. $f(t)$ is the false negative rate of the screen when the disease has been present for time t; and
5. $b(t)$ is the probability of ultimately dying from the disease if it is detected when it has been present for time t.

For simplicity, we ignore the possibility of death from other causes.

If we let m and σ^2 be the **mean** and **variance** of the sojourn time distribution, then Zelen & Feinleib [65] show that if we assume a constant hazard rate for disease initiation (i.e. $g(t) = g$) we obtain the following expression for the mean lead time:

$$\mathrm{E}(L) = \frac{m^2 + \sigma^2}{2m} = \frac{m}{2}\left[1 + \left(\frac{\sigma^2}{m}\right)\right]. \tag{4}$$

Note that $\mathrm{E}(L) > m/2$ for $\sigma^2 > 0$. This illustrates the effect of length-biased sampling, since, if the screen detected cases were selected at random from all of the cases, one would expect the mean lead time to be $m/2$.

This expression also illustrates one of the central difficulties with this form of modeling. The lead time, which is the main index of screening benefit, is a function of the distribution of the sojourn time in the preclinical phase (*see* **Screening, Sojourn Time**). However, the preclinical phase is, by definition, unobservable. The question of how to estimate characteristics of the sojourn time distribution has been at the center of most of the work done in this area.

For a person to be in the preclinical state at age a, then they must have entered the preclinical state before age a and not leave it until after age a. Hence the probability of this is a function of the hazard rates $g(\cdot)$ and $p(\cdot)$. Thus

$$\Pr(\text{preclinical phase at age } a) = \int_0^a g(u) \exp[-G(u)] \exp[-P(a-u)]\, \mathrm{d}u. \tag{5}$$

Furthermore, the probability that the disease clinically surfaces in some time interval δa following a is

$$\Pr(\text{clinical surfacing in } (a, \delta a)) = \int_0^a g(u)\exp[-G(u)]\exp[-P(a-u)] \times p(a-u)\delta a\,\mathrm{d}u. \quad (6)$$

We combine this with the prognosis measure $b(\cdot)$ to calculate a baseline probability of death from the disease in the absence of screening:

$$\Pr(\text{death in the absence of screening}) = \int_0^\infty \int_0^a g(u)\exp[-G(u)]\exp[-P(a-u)] \times p(a-u)\delta a b(a-u)\,\mathrm{d}u\,\mathrm{d}a. \quad (7)$$

Now we introduce the effect of screening. We will consider the case of one screening test performed at age s. There are four possibilities:

1. the disease is detected by the screening test;
2. the disease clinically surfaces before the test (i.e. at age $a < s$);
3. the disease is missed by the screening test and clinically surfaces after the screen (i.e. it is an interval case); or
4. the disease both enters the preclinical phase and clinically surfaces after the screening test.

For the disease to be detected by this test, it must be in the preclinical phase and the test must not give rise to a false negative. The probability of this is

$$\Pr(\text{disease detection at age } s) = \int_0^s g(u)\exp[-G(u)]\exp[-P(s-u)] \times (1 - f(s-u))\,\mathrm{d}u. \quad (8)$$

We have already calculated the probability that the disease clinically surfaces at age $a < s$ in (6). For the disease to have been missed by the screen, the person must be in the preclinical state at age s, the test must have produced a false negative, and the disease must have clinically surfaced after the screen. The probability of this is

$$\Pr(\text{disease missed by test}) = \int_s^\infty \int_0^s g(u)\exp[-G(u)]\exp[-P(a-u)] \times f(s-u)p(a-u)\delta a\,\mathrm{d}u\,\mathrm{d}a. \quad (9)$$

The probability that the disease both enters the preclinical phase and clinically surfaces after the screening test is

$$\Pr(\text{disease both develops and surfaces after the screen}) = \int_s^\infty \int_s^\infty g(u)\exp[-G(u)] \times \exp[-P(a-u)]p(a-u)\delta a\,\mathrm{d}u\,\mathrm{d}a. \quad (10)$$

Once again we can combine these probabilities with our prognosis measure to obtain the probability of death from the disease in the presence of screening:

$$\begin{aligned}\Pr(\text{death in the presence of screening}) &= \int_0^s g(u)\exp[-G(u)]\exp[-P(s-u)] \times (1 - f(s-u))b(s-u)\,\mathrm{d}u \\ &+ \int_0^s \int_0^a g(u)\exp[-G(u)]\exp[-P(a-u)] \times p(a-u)\delta a b(a-u)\,\mathrm{d}u\,\mathrm{d}a \\ &+ \int_s^\infty \int_0^s g(u)\exp[-G(u)]\exp[-P(a-u)] \times f(s-u)p(a-u)\delta a b(a-u)\,\mathrm{d}u\,\mathrm{d}a \\ &+ \int_s^\infty \int_s^\infty g(u)\exp[-G(u)]\exp[-P(a-u)] \times p(a-u)\delta a b(a-u)\,\mathrm{d}u\,\mathrm{d}a. \quad (11)\end{aligned}$$

This expression gives us our screening figure to compare with the baseline figure in (7).

Although none of the models used for disease screening is exactly like the simple model presented here, they all incorporate its fundamental ideas. In particular, they all depend on knowing in one form or another the transition probabilities into and out of the preclinical state, the distribution of the sojourn time in the preclinical state, the sensitivity of the screening test, and the disease prognosis as a function of the development of the disease (*see* **Natural History Study of Prognosis**).

Analytic Models for Cancer

A mathematical disease model with two states was first proposed by Du Pasquier [24], but it was Fix & Neyman [32] who introduced the stochastic version and resolved many problems associated with the model (*see* **Fix–Neyman Process**). Their model has

two illness states – the state of "leading a normal life" and the state of being under treatment for cancer – and two death states – deaths from cancer and deaths from other causes or cases lost to observation. Chiang [15] subsequently developed a general illness–death stochastic model which could accommodate any finite number of illness and death states (*see* **Stochastic Processes**). Some of the major analytic models developed for cancer screening are listed in Table 1.

Lincoln & Weiss [41] were the first to propose a model of cancer as a basis for analyzing serial screening, in this case screening for cervical cancer. They did not explicitly use a Markov framework, but their model implicitly uses a classification of the disease into illness states.

Zelen & Feinleib [65] proposed the simple three-state, continuous-time, progressive disease characterization described in the previous section and used it in model screening for breast cancer. In a modification to this basic model, the authors further divide the preclinical state into two parts, defined as:

1. a preclinical state in which the disease never progresses to the clinical state (i.e. the sojourn time is allowed to be infinite); and
2. a preclinical state in which the disease is progressive and will eventually progress to the clinical state.

These are used to allow for the possibility that some individuals with the disease in a preclinical state will never have the disease progressing to a clinical state. This approach has been generalized in a number of ways by subsequent authors, with most focusing on simple disease models and the estimation of specific screening characteristics.

Prorok [48, 49] extended the lead time estimation to multiple screens. Blumenson [10–12] calculated the probability of terminal disease as a function of disease duration to date, and used this as a prognostic measure to evaluate screening strategies. Shwartz [54, 55] modeled disease progression for breast cancer using tumor size and number of axillary lymph nodes involved to define the preclinical and clinical states. He then determined screening benefit measures (*see* **Screening Benefit, Evaluation of**), from data on five year survival rate and five year disease recurrence rate for patients, as a function of tumor size and lymph node involvement.

Albert and his co-workers [3, 4, 42] developed a comprehensive model for the evolution of the natural history of cancer in a population subject to screening and natural demographic forces. In its general formulation, the model uses Zelen & Feinleib's classification of the disease into preclinical and clinical phases, but divides the preclinical phase into states corresponding with prognostic tumor staging schemes. It also has two death states which correspond to clinical surfacing of the disease or death from a competing risk. The model is progressive, but allowance is made for staying indefinitely in any given state.

This model is then applied to breast and cervical cancer. Breast cancer is modeled with two illness states, state 1 corresponding to disease with no lymphatic involvement and state 2 corresponding to disseminated disease (the contrary case). Cervical cancer is modeled with three illness states, state 1 corresponding to neoplasms *in situ*, state 2 corresponding to occult invasive lesions, and state 3 corresponding to frankly invasive lesions. The authors then impose on this model a screening strategy with a particular probability of a positive screen, depending on a person's age and disease state. Using this, they derive equations describing how the natural history of cancer (depicted by the distribution of numbers in each state and associated sojourn times) evolves over time in the presence of screening. These, in turn, are used to derive equations for measures of benefit from screening in terms of the disease status. These benefit measures include the percentage reduction in the cumulative number of observed cases of late disease due to screening and the percentage decrease in lost "salvageables" due to screening. A salvageable is a person who would have benefited from screening but who, in the absence of screening, progresses to a late stage of the disease before discovery.

Dubin [25, 26] developed a general multistage disease model similar to that of Chiang [15], and applied this to breast cancer using the same two stage classification as Albert et al. [4]. He noted the difficulty in estimating parameter values for detailed disease models from existing data from screening programs. His model aimed to avoid these difficulties by maintaining comparability between the model and the observable characteristics of a screened population. He did this by focusing on age and stage-specific incidence and survival times in the presence and absence of screening. He derived formulas for the proportion

Table 1 Selected analytic models of cancer screening

Literature references for model	Model inputs	Key features	Model output/measures of screening benefit
Lincoln & Weiss [41]	The probability density for the beginning of the detectable preclinical phase and the probability of a false negative screen at time t after entering the detectable preclinical phase – calculated by assuming specific functional forms rather than by direct estimation	Two illness states – a "healthy" state, in which the disease is not detectable, and a state covering the time between when the disease is first detectable and when it is actually detected by a screening examination	Distribution of time to discovery of tumor
		Symptoms assumed never to appear, with all disease detected by screening	
		Model applied to cervical cancer screening	
Zelen & Feinleib [65]	Disease prevalence and incidence data	Progressive three-state illness model – a healthy state, the preclinical phase, and the clinical phase	Mean lead time
		Assumes single screen	
		Applied to breast cancer screening	
Prorok [48, 49]	Preclinical state sojourn time distribution and disease prevalence and incidence data	Uses the Zelen & Feinleib illness model and develops theory for application to multiple screens	Mean lead time and proportion of preclinical cases detected
Blumenson [10–12]	Disease incidence data	Similar three-state illness model to Zelen & Feinleib, with a point occurring in either the preclinical or clinical phase where the disease becomes incurable	Number of cases of diseases becoming incurable before detection
	Preclinical state sojourn time distribution	Applied to breast cancer screening	
	Screening parameters including age at first screen, screening sensitivity, and screening interval

Table 1 (*continued*)

Literature references for model	Model inputs	Key features	Model output/measures of screening benefit
Shwartz [54, 55]	Specific functional forms and associated parameters governing tumor growth rate and lymph node involvement – chosen to be consistent with published results and available data	Model developed specifically for breast cancer	Changes in life expectancy as a result of screening
	Breast cancer incidence and death rates and death rates from other causes	Progressive illness model with a healthy state, 21 disease states defined in terms of the tumor size and lymph node involvement and two death states – death from breast cancer and death from any other cause	The probability that there will be no disease recurrence and the probability of detection before nodal involvement
	Screening parameters	Transition from preclinical phase to clinical phase possible in any disease state, with probability dependent on tumor size and tumor rate of growth	The probability of disease detection before death from other causes
		Model predictions validated against independent data source (third-order validation)	
Albert et al. [3, 4], Louis et al. [42]	Maximum likelihood estimation of model parameters based on screening data and model assumption	Progressive illness model with preclinical phase classified into states corresponding with prognostic tumor staging schemes, and two "death" states – one corresponding to clinical surfacing and one to death from a competing cause	Percentage reduction due to screening in observed cases of late disease
		Model of screening strategy with probability of positive screen depending on person's age and disease state	Percentage decrease in lost salvageables due to screening
		Applied to breast and cervical cancer screening	
Dubin [25, 26]	Age and stage-specific disease incidence	Aimed at maintaining comparability between the model and observable characteristics of a screened population	Increase in life expectancy
	Survival times in the presence and absence of screening – derived from screening data by assuming particular functional forms for survival distributions	Progressive illness model consisting of disease stages corresponding with prognostic tumor staging schemes	Reduction in probability of dying of breast cancer
		Applied to breast cancer	Reduction in life years lost to women dying of breast cancer
			Mean lead time

Day & Walter [22], Walter & Day [63], Walter & Stitt [64]	Disease incidence derived from screening data	Progressive three-state illness model – a "healthy" state with no detectable disease, the detectable preclinical phase, and the clinical phase	Lead time
	Probability distribution specified for preclinical state sojourn time and survival time	Focus on sojourn time in detectable preclinical phase and survival times after detection	Survival time after detection by screening
		Applied to breast cancer	
Coppleson & Brown [20]	Age-specific clinical incidence data and prevalence data derived from detection rates at first Pap smear	Four-state illness model developed for cervical cancer	Not applicable (model focused on examination of disease natural history)
		Found that observed data could not be explained without allowing for cancer regression in the illness model	
Albert [2]	Transition probability matrix for movement between model states estimated from numbers of cancers detected for each stage in a screening program	Four-state illness model developed for cervical cancer – a healthy state, two preclinical states, and a clinical state.	Not applicable (model focused on examination of disease natural history)
		Cancer regression allowed in the two preclinical states	
Brookmeyer & Day [13]	Parameters of sojourn distribution estimated from screening data and data on interval cancer cases	Extends Day & Walter model	Total preclinical phase sojourn distribution
		Preclinical phase divided into two states – one in which the disease may progress or regress and a second in which the disease always progresses	Screening false negative rate
		Applied to cervical cancer	
van Oortmarssen & Habbema [59]	Parameters of sojourn distribution estimated from screening data and data on interval cancer cases	Similar illness model to Brookmeyer & Day	Not applicable (model focused on examination of disease natural history)
		Applied to cervical cancer

Table 1 (*continued*)

Literature references for model	Model inputs	Key features	Model output/measures of screening benefit
Eddy [27, 29, 30]	Model parameters derived from published results of disease studies and screening programs	Five-stage combined disease and screening model – one healthy state, three preclinical states defined by detectability by screening, and one clinical state	Probability of disease detection
			Probability of death following detection
			Increase of life expectancy due to screening
		Assumes that once a disease is detectable by a screening modality, then any screen using that modality will detect the disease	
		Applied to breast, cervix, lung, bladder, and colon cancer	
Connor et al. [19], Chu & Connor [17]	Stage shifts estimated from analysis of a randomized controlled trial of screening	Multistage progressive disease model	Reduction of deaths at a given stage due to screening
		Focus is on estimation of the shift of the disease at detection to an earlier stage or an earlier point in the same stage as a result of screening	Death prognosis of screen detected cancers
		Applied to breast cancer screening	
Baker et al. [9]	Peak time period for mortality comparison selected from results of a randomized controlled trial of screening.	Focuses analysis on period when screening has maximum effect and hence analysis of screening trial results gives rise to more powerful statistical tests	Ratio of cancer mortality between screened and control groups
		Applied to proportional hazards model for survival analysis	
Day & Duffy [21]	Uses known prognostic factors which are available early in a randomized controlled trial of screening to predict subsequent mortality differentials	Users surrogate endpoints for randomized controlled trial of screening to shorten the duration of the trial and increase its power	Tumor size at cancer detection used as a basis for predicting subsequent mortality differentials
		Applied to breast cancer	

of disease incidence which had been diagnosed earlier due to screening than it would have been in the absence of screening, and used these to derive various measures of screening benefit. Dubin's model is not strictly a deep model as defined above. However, although he makes no explicit hypotheses about the rate of disease progression, such hypotheses are implicit in his model.

Day & Walter [22] developed a variation on the simple three-stage model which has been used extensively. The focus of this model is the sojourn time in the detectable preclinical phase, for which a probability distribution is specified. For example, Walter & Day [63], in applying the model to breast cancer, used several alternate distributions, including the **exponential**, the **Weibull**, and a **nonparametric** step function. Under the model assumptions, one may derive expressions for the anticipated **incidence rates** of clinical disease among groups with particular screening histories and for the anticipated **prevalence** of preclinical disease found at the various screening times. One advantage of this model is that it is relatively simple to obtain approximate **confidence intervals** for parameter values. The model was extended by Walter & Stitt [64] to permit evaluation of survival of cancer cases detected by screening.

A useful synthesis of the analytic models described above applied to breast cancer is presented by O'Neill et al. [46].

All of the above are progressive models, but there are some forms of cancer for which the assumption of progression is not appropriate and for which some form of regression is required. These are cancers, such as large bowel cancer and particularly cervical cancer, where screening detects preinvasive or even precancerous lesions [13].

A number of models have attempted to address this. Coppleson & Brown [20] developed a model for cervical cancer and found that the observed data could not be explained without allowing for regression. Albert [2] developed a variation of his earlier model for cervical cancer which allowed for regression from the carcinoma *in situ* stage back to the healthy state. Brookmeyer & Day [13] and van Oortmarssen & Habbema [59] both developed similar extensions to the Day & Walter model to divide the preclinical phase into two. The first stage allows regression to a healthy state, but once a cancer reaches the second stage only progression is allowed.

The Coppleson & Brown, Albert, and van Oortmarssen & Habbema studies provide an interesting variation on the use of these models, in that the aim of the model was not to study cancer screening directly. Rather, the model was used to study the disease dynamics and, in particular, to examine the epidemiologic evidence for the existence of regression in preinvasive cervical cancer.

The models described above follow a common theme of characterizing the disease as a series of states (corresponding to health, the various disease stages, and death), with people moving between the states with certain transition probabilities and/or certain sojourn times. Screening is then evaluated by superimposing on the disease process a screening process with particular screening regimes and screen sensitivity. This is in contrast to the next model, due to Eddy [27], which uses a different strategy.

Eddy's modeling strategy uses a time varying Markov framework. However, he models the **interaction** between the screen and the disease in his basic model. This is a five-stage model defined in terms of three time points. The first is a reference time point t_p. The way in which this is defined varies with the cancer under discussion but, as an example, for breast cancer it is the point at which the disease can first be detected by physical examination. The *occult interval* is then defined as the time interval between this and the point t_M at which the disease is first detectable by screening (e.g. by mammography). The *patient interval* is defined as the time between t_p and the time t_Π at which the patient would actually seek medical care for the lesion. With Eddy's model, t_Π, t_p, and t_M can occur in any order. The important assumption is that once a disease is detectable by a screening modality (i.e. after t_M), then any screen using that modality will always detect the disease. This assumption replaces the assumption commonly made in models of screening that successive screens are independent.

The other two states are a "healthy" state (which includes any preclinical disease which is still undetectable by screening) and a clinical disease state. Eddy models the probability distributions of the occult and patient intervals and uses these to derive formulas for the probabilities of discovering a malignant lesion by screening and by other methods. Eddy's model has been applied to several breast cancer screening data sets as well as to cervical, gastrointestinal, lung, and bladder cancer. It has also

been extended to the case in which there is more than one type of screening test [31].

Finally, there are three recent analytic models which provide interesting variations on screening modeling.

The first of these is the stage shift model [19]. This assumes that the effect of screening is to shift the diagnosis of a cancer from a higher to a lower stage or within a given stage to an earlier time of diagnosis. Connor et al. develop the theory for a randomized controlled trial with equal sized intervention and control groups, but the equations can be modified to allow for proportional number of cases if unequal groups are used. The method of fitting this model requires a completed trial with follow-up that has reached the point at which comparable sets of cancer cases have accumulated in the study and control groups. For most of the discussion, Connor et al. ignore variability associated with the estimation process and the determination of the point at which comparability is reached in order to emphasize the exploratory nature of the analysis. However, they do present simple variance estimates based on the assumption that their data follow a **Poisson distribution**. The need for a completed trial and long follow-up period limits the model's applicability, but it has been used to analyze breast cancer screening data [17].

The second is the peak analysis model [9]. This uses data from a randomized trial to determine the time period during which screening has the maximum effect on mortality. The results of the trial can then be analyzed restricting attention to that time period, providing more powerful statistical tests. For breast cancer screening, for example, this could mean excluding the mortality experience of the first few years after the initiation of screening. A disadvantage of this model is that the selection of the peak time period for the mortality comparison could be regarded as "data-driven" and subject to the usual problems of a *post hoc* analysis [44].

The third is the use of **surrogate endpoints** for RCTs to shorten the duration of the trial and to increase the **power** [21]. Day & Duffy apply this approach to a study comparing breast cancer screening at three yearly and one yearly intervals. Tumor size is the most important variable in predicting survival from breast cancer in the screening context, so they consider the difference in tumor size distribution between the study groups. They show that using this as an index of benefit and projecting expected mortality allows a result after only five years, compared with the 15–20 years required for a trial based on observed mortality. Furthermore, they demonstrate the rather surprising result that the use of surrogate endpoints leads to an increase in the power of the RCT compared with using the observed mortality. While completed trials remain necessary to establish the primary benefits of screening, this approach allows faster and more efficient resolution of subsidiary issues.

Simulation Models for Cancer

Some of the major simulation models developed for cancer screening are listed in Table 2. Knox [34] developed the earliest and most comprehensive simulation model. As with the analytic models, Knox uses a healthy state, a number of illness states and two death states. However, the model involves considerably more illness states, including classifying the disease as a preclinical, early clinical, or late clinical cancer, and further classifying each of these as treated or not treated and each cancer as high or low grade.

Knox defines a transition matrix containing the estimated transfer rates between the various pathological states, modified according to the age of the individual or the duration of the state. He then simulates the evolution of the disease in a hypothetical cohort of study subjects which has similar characteristics to the population that he wishes to study (which, in this case, is the adult female population of England and Wales) using the transition matrix and a standard **life table** to provide the risks of competing causes of death.

Finally, he adds details of the screening procedures to be considered, specifying the clinico-pathological states to which they apply, and their sensitivities and specificities in relation to each, and the transfers between model states which will occur following detection or nondetection. The screening policies are arranged in incremental series, and the results compared with each other and with the results of providing no screening at all. This allows the appraisal of benefits and costs in both absolute and marginal terms.

This model has been applied to both cervical cancer [34] and breast cancer [35]. It illustrates one

Table 2 Selected simulation models of cancer screening

Literature references for model	Model inputs	Key features	Model output/measures of screening benefit
Knox [34, 35]	Model parameters derived from published results of disease studies and screening programs and from the known characteristics of population under study	Cohort simulation model	Simulated mortality and morbidity in the presence of screening under various screening regimes
		Illness model with 26 defined states	
		Transition matrix defined for movements between these states following detection or nondetection of disease in the presence of specified screening procedures	
		Model applied to a hypothetical cohort of study subjects with similar characteristics to the population under study	
		Model applied to both breast and cervical cancer screening	
Knox [36], Knox & Woodman [37]	Model parameters derived from published results of disease studies and screening programs and from the known characteristics of population under study	Cohort simulation model	Simulated reduction in mortality due to screening
		Illness model with two disease states – one in which the disease is susceptible to early detection and full or partial cure and a second in which the disease is incurable	
		Model applied to subjects who have died from cancer but may have been saved if screening had been offered	
		Applied to breast and cervical cancer screening

Table 2 (*continued*)

Literature references for model	Model inputs	Key features	Model output/measures of screening benefit
Parkin [47]	Model parameters derived from published results of disease studies and screening programs and from the known characteristics of population under study	Microsimulation model developed for cervical cancer screening	Simulated mortality and morbidity in the presence of screening under various screening regimes
		Illness model has nine states – a healthy state, three preclinical states, one clinical state, two death states, and a hysterectomy state (in which a woman is no longer at risk of cervical cancer)	
		Model applied to a hypothetical population with age structure similar to that of the population under study	
Habbema et al. [33], van Oortmarssen et al. [61]	Model parameters derived from published results of disease studies and screening programs and from the known characteristics of population under study	General framework for microsimulation modeling	Simulated mortality and morbidity in the presence of screening under various screening regimes
		Follows similar approach to Parkin	
		Applied to breast and cervical cancer screening	

major difference between the analytic and simulation approaches – the greater complexity of the disease and screening models in the simulation case. However, this extra complexity requires more detailed information on the disease dynamics in order to specify the model and this information is often not readily available. Knox [36] says of his earlier work that

> The chief problem of applying the predictions stemmed from uncertainties about the clinical course of the early stages of cancer.

In this and in all his subsequent analyses, he simplified his model to one with only two illness states. This two-state model is worth discussing in detail because of its different approach to the population under study. Whereas the usual approach is to consider all people at risk of a cancer and to use the model to project mortality with and without screening, Knox's approach is to consider only those who have died from cancer, and to use the model to estimate how many would have been saved if screening had been offered. He refers to it as "tearing down" a graph of age-distributed deaths in successive steps through the insertion of screening procedures at selected ages [37]. This means that Knox does not need to consider variations in the course of the disease, such as lesions which never clinically surface or which regress to a healthy state, because all members of his population have, by definition, a progressive form of the disease.

The two illness states are designated A and B. During state A the disease is susceptible to early detection and full or partial cure. During state B, the disease is incurable. The sojourn time in each state varies around an age-specific mean. The screening procedure has a probability of detecting the lesion which rises linearly during period A, while the probability of curing the disease falls linearly during A.

This model has the advantage of simplicity, which means that it is relatively easy to find plausible parameter values for it. However, this simplicity has disadvantages. The model only considers the situation of a fully established screening program, so that it cannot be used to investigate issues surrounding setting up a new program. Also, because it is focused on mortality reduction, it cannot be used to consider issues relating to costs of screening programs.

Researchers at the Australian Institute of Health and Welfare have extended this approach by combining Knox's disease model with a costs model to evaluate the introduction of breast and cervical cancer screening programs in Australia [6, 7]. They have also combined the disease model with mortality projections to investigate the timing of mortality reductions due to the introduction of a breast cancer screening program [8].

Parkin [47] identifies a number of advantages of the *cohort simulation* approach of transferring year by year specified proportions of a single cohort in a deterministic fashion between model states. These include the model's ability to:

1. demonstrate the relationships between variables;
2. explore the effects of different acceptance rates and test characteristics on outcome measures;
3. examine the net cost-effectiveness of different screening policies by imputing costs to the different outcomes of screening tests (*see* **Health Economics**); and
4. explore the effect of different theoretic natural histories on the outcome of screening.

However, he also identifies some of the disadvantages of this approach. First, services have to be planned, not for a single cohort over an entire lifespan, but for a very heterogenous population over relatively short time periods. When a screening program providing for testing at certain fixed ages is introduced into a community, only people younger than the starting age for the screening policy can possibly receive the full schedule of tests. Thus, benefits from screening will at first be small, but will increase progressively as more of the population receives a series of examinations. Furthermore, many people will have already had previous examinations, so the results of the screening policy will depend on the existing screening status of the population. This cannot be simulated by a single cohort model; nor can differences in the risk of disease in different birth cohorts.

Secondly, it may be desirable to use characteristics other than age to identify subgroups of the population for selective screening. This is less often of practical use, since such subgroups are usually not readily identifiable, but a planning model should be able to explore the effectiveness of policies involving differential screening of such subpopulations. In addition, population subgroups often have different rates of attendance at screening programs which may be correlated with different disease risks.

Finally, screening programs do not exist in isolation from the rest of the health care system. Much screening activity can take place outside a screening program. Most models usually treat this activity as "diagnostic" and ignore it. However, a planning model should take account of all relevant screening activity.

Parkin proposes instead a *microsimulation* approach. Here, the life histories of individual members of a population are simulated. The population in his model has the demographic make-up of that of England and Wales and its size is governed by two considerations: (i) the computer time involved in microsimulation of very large populations; and (ii) the need for reliable results in a stochastic simulation of relatively rare events.

Each individual is characterized by his or her values for a set of variables which will be used in simulating demographic events, the disease natural history, or screening programs. The values of these variables are updated annually using sets of **conditional transition probabilities** (e.g. the probability of childbirth given age, marital status, and initial parity). The occurrence of a transition is decided by comparing the relevant probability against a randomly generated number. There is considerable flexibility in modeling screening programs and, since the model follows individuals, it is possible to simulate contacts with the health care system and the "incidental" screening which occurs on such occasions.

Parkin's microsimulation model was developed specifically for cervical cancer screening, but a group working at Erasmus University in the Netherlands has developed a general modeling framework for microsimulation modeling of cancer screening called MISCAN (MIcrosimulation SCreening ANalysis) [33, 61]. Strictly speaking, MISCAN is not itself a model, but rather a model generator – a package that can generate and calculate a variety of these microsimulation models.

The MISCAN approach, like Parkin's model, is based on the actual structure of a population as it develops in a given country at a particular time. The mass screening program under consideration is taken as starting in a particular year and finishing in a particular year. Standard demographic techniques (*see* **Demography**) are used to project the study population to a year well after the nominated end of the program. This allows for both the introduction of the program to be modeled and the effects, after the end of the program, to be followed up.

The basic structure of the cancer model is similar to Knox's earlier model with a detailed classification of clinical and preclinical cancer states, although it uses a smaller number of states. The interaction between the disease model and the screening program is designed to allow projection of screening and treatment costs as well as cancer mortality and morbidity. MISCAN has been widely used to analyze breast and cervical cancer screening programs.

Model Fitting and Validation

Eddy [28] proposed four levels of validation for mathematical models (*see* **Model Checking**):

1. First-order validation: this requires that the structure of the model makes sense to people who have a good knowledge of the problem.
2. Second-order validation: this involves comparing estimates made by the model with the data that were used to fit the model.
3. Third-order validation: this involves comparing the predictions of the model with data that were available when the model was fitted but that were not used in the estimation of model parameters.
4. Fourth-order validation: this involves comparing the outcomes of the model with observed data when applied to data generated and collected after the model was built (for example, data from a previously unobserved screening program).

In this section we discuss model fitting and validation for cancer screening in the framework of these levels.

First-order validation is generally not difficult to accomplish. The conceptualization of cancer as a series of preclinical and clinical stages is virtually universally accepted as a reasonable characterization of the disease. Problems may arise when the details of the disease stages are specified, but generally a wide variety of model formulations are plausible within the constraints of the limited knowledge of preclinical cancer.

Second-order validation highlights one of the central problems with this sort of deep model. This is the difficulty of directly relating available data to model parameters. The mismatch between the data available, either from screening trials or other sources,

and the model data requirements for parameter estimation has been recognized from the beginning of this type of modeling. Lincoln & Weiss [41, p. 188] note, for example, that

> Here we can do no more than introduce plausible forms for the different functions involved and plausible values for the parameters.

They go on to describe the difficulties in relating available data to the mathematical functions on which their model is based. This is a recurring problem in modeling cancer for screening, and to some extent affects all of the models described in this article.

Some of the analytic models have developed methods of estimating model parameters using standard statistical **estimation** approaches. Dubin [26], for example, structured his model so that it could directly use the data from screening trials, although as a consequence his model relates less to the disease natural history than do the others. Louis et al. [42] derived nonparametric models for the probability distributions specified in their model and proposed the use of **maximum likelihood** methods to fit them. Day & Walter [22] used both parametric and nonparametric functions for their preclinical sojourn time and suggested either maximum likelihood methods or **least squares** criteria to fit them. However, many of the analytic models and all of the simulation models proceed in a more *ad hoc* fashion by varying their disease natural history and model parameters until their models closely reproduce existing data.

Knox [35], pp. 17–18 gives an example of how this *ad hoc* fitting operates, in fitting his earlier model to breast cancer screening data. He describes fitting the natural history data thus:

> A statement of the natural history of the disease process must be provided in the form of a "transition matrix" which gives estimated transfer rates between the various pathological states, modified suitably according to the age of the woman or the duration of the state. This set of values is adjusted iteratively until an output is produced which matches available data on incidence, prevalence and mortality. If, as sometimes happens, more than one natural history statement is capable of mimicking these facts, then the natural history will have to be treated as one of the uncertainties. Subsequent runs will then have to be repeated for a range of natural history alternatives, and each prediction of results will be conditional upon the accuracy of the natural history used.

Parkin [47] provides an example of just such an uncertainty about natural history, with the final model including three different natural histories as alternatives.

This approach to model fitting has the disadvantage that, particularly for models with a large number of unknown parameters, the fit of the predicted values may be close to the observed data whether or not the model is in any sense valid. However, fitting the model to a number of independent data sets simultaneously and validating it against each of these data sets, as was done by van Oortmarssen et al. [61], provides some protection against this possibility.

Third-order validation is usually made difficult by the lack of data. Generally, most available data are used in determining the parameters of the model [56]. Breast cancer models are a good example of this. The only real data sources for fitting models for breast cancer screening are the screening studies, and in particular the RCTs. The first major study was the Health Insurance Plan of New York study (HIP) [53]. This program started screening in 1963. Subsequent studies were not started for another ten years, with the Utrecht Screening Program [18] starting screening in 1974 and the Swedish Two-county Randomized Trial starting in 1977 [58]. This means that many of the models only had access to the HIP data. Screening technology has changed significantly since the HIP program began [61], so when later studies became available they could not be directly compared with the HIP program and, in any case, it is questionable whether models based only on HIP data are directly relevant to modern screening. Because of the long time before mortality benefits from screening are fully apparent, models fitted using solely data from later studies have only appeared relatively recently [61] and, at least in their published form, have generally not addressed the issue of third-order validation. However, as more screening programs are implemented, more data should become available for third-order validation [6].

Eddy [28] recognized that fourth-order validation is only possible in rare cases. However, there are at least two examples of studies which use models in a way that could be called fourth-order validation, coincidentally both using Eddy's own model. Verbeek et al. [62] compare predictions from Eddy's

model for breast cancer to data from a mammography screening program in Nijmegen. The authors note that the comparison does not suggest too good a fit. However, this is only a preliminary study, and further validation work remains to be done. Eddy [29] compares his model for cervical cancer with a later independent analysis of empirical data. In this case the model appears to predict accurately the effect of different cervical cancer screening policies on outcomes that are important for policy decisions.

The best way to see how these models are fitted and used in practice is to examine examples. The following three sections describe an example of fitting a model followed by a description of its application.

An Example of Model Fitting

This section describes the analysis by van Oortmarssen et al. [61] of breast cancer screening based on the MISCAN computer simulation package. This model is designed to reproduce the detection rates and incidence of interval cancers as observed in the screening projects in Utrecht and Nijmegen in the Netherlands.

The basic model structure is shown in Figure 2. The first state is the state of no breast cancer. Women stay in this state until a transition occurs to one of the preclinical states that is detectable by screening (either mammography or clinical examination). The preclinical phase is divided into four states. There is one preinvasive state, intraductal carcinoma *in situ* (dCIS), and three screen detectable invasive states subdivided according to the diameter of the tumor: <10 mm, 10–19 mm, and ≥ 20 mm.

The subdivision applied to the preclinical invasive states is also used for the clinical phase and for screen detected tumors. The state "false positives" refers to women with a positive screening examination in whom no breast cancer is found at further assessment. The two end states of the model are "death from breast cancer" and "death from other causes". Transitions into the "death from other causes" state (not shown in the figure) are possible from every other model state and are governed by the Dutch life table, which is corrected for death from breast cancer. The values of the key parameters of the model are summarized in Table 3.

Parameters relating to clinical breast cancer and survival can usually be taken directly from available data. In this case, the preclinical incidence was estimated from the reported Dutch clinical incidence figures shifted to younger ages according to the model's assumptions about the transitions and durations in the preclinical stages. The distribution of the tumor diameters for clinically diagnosed cancers was obtained directly from data on cancers diagnosed outside the screening program in Utrecht and Nijmegen. Survival is described by a fraction cured and a survival time distribution for women who are at risk of dying from breast cancer. The survival time distribution is based on the **lognormal**, with mean and variance taken from a published analysis of the Swedish Cancer Registry data [52]. The fraction cured was estimated from the Utrecht data on clinically diagnosed cancers and varied with age according to another published analysis of Swedish data on age-specific breast cancer survival [1]. The combination of model assumptions on clinical incidence, stage distribution, and survival result in a good fit for the mortality rate for breast cancer in the Netherlands at all ages.

Parameters relating to the preclinical phase are less easily specified. Parameter estimation was done by comparing simulated results from the model with data from the Utrecht and Nijmegen projects. An initial set of parameter values, partly taken from an earlier analysis of the HIP screening trial [60], resulted in many discrepancies between the simulated and observed data. The model parameters were systematically varied until a set of model specifications was found which gave an adequate overall fit to the Utrecht and Nijmegen data. Finally, the improvement in prognosis due to screen detection was calculated from the results of the Swedish Two-county screening study [58].

This model passes both first- and second-order validation, in that it is consistent with what is known about the natural history of breast cancer and with previous models developed in the literature, and its results are consistent with the Utrecht and Nijmegen data used in its fitting. Third-order validation is more problematic. As noted above, the HIP data are not directly comparable with those considered here and the authors used all the other available data in fitting the model. Similarly, fourth-order validation is not possible in this case, since published results from other breast cancer RCTs were not available at the time this analysis was carried out.

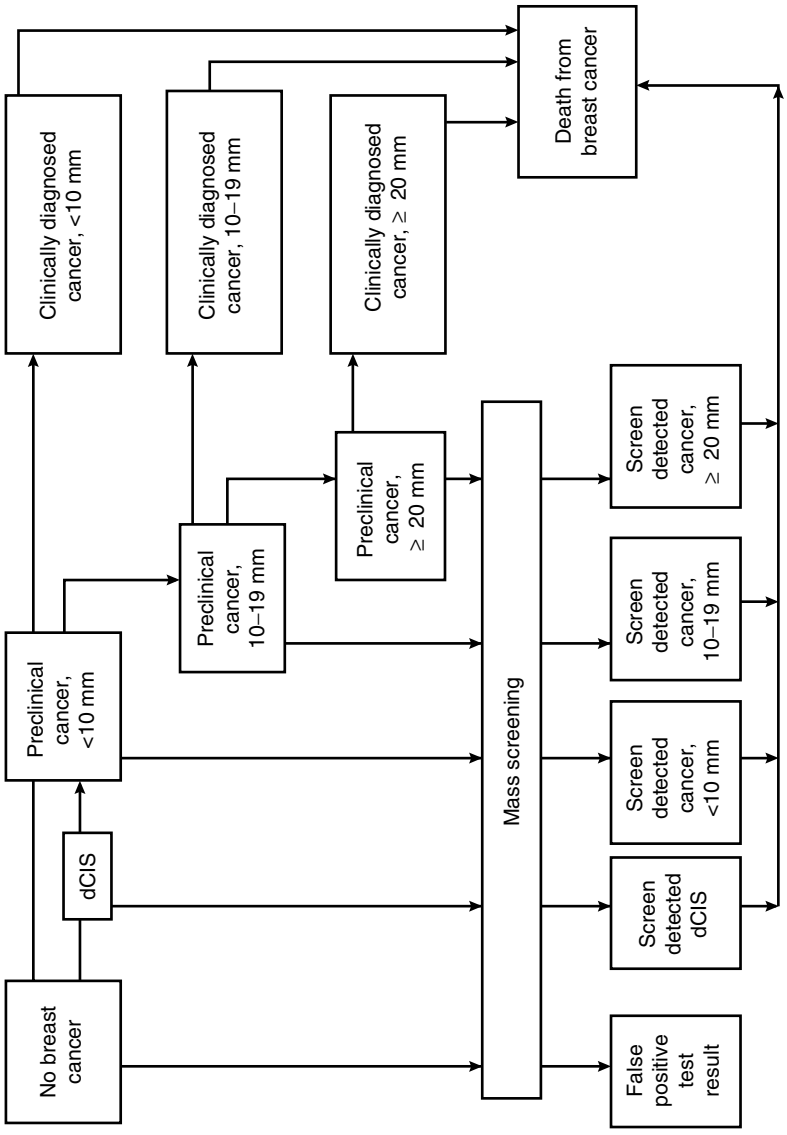

Figure 2 The structure of the disease and screening model for breast cancer developed by van Oortmarssen et al. The state "death from other causes" is not shown. It may be reached from all other states. *Source:* van Oortmarssen et al. [61]

Table 3 Key assumptions of the van Oortmarssen et al. breast cancer screening model

Parameter	Assumption
Preclinical incidence	Based on Dutch clinical incidence, 1977–82
Clinical stage distribution	*Independent of age*
<10 mm	10%
10–19 mm	22%
≥20 mm	68%
20 year survival of clinically diagnosed breast cancer (diagnosis at age 55)	*Age-dependent*
<10 mm	83%
10–19 mm	68%
≥20 mm	51%
Duration of preclinical invasive stages	*Average duration (years)*
Age 40 years	1.6
Age 50 years	2.1
Age 60 years	3.0
Age 70 years	4.7
Sensitivity of mammography	*Independent of age*
dCIS	70%
<10 mm	70%
≥10 mm	95%
Impact of early detection	
Mortality reduction for screen detected cancers	52%

An Application of the Model to Breast Cancer Screening

The breast cancer disease model described above was applied to Australian data by Stevenson et al. [57] to simulate the introduction of a breast cancer screening program. Australian breast cancer data and life table data were used to estimate cancer incidence and population **life expectancies**. Pilot testing of screening programs suggested that a screening participation rate of 70% was a reasonable target [6]. All other model parameters were taken from the van Oortmarssen et al. model.

The model was applied to five different screening options defined in terms of the age group offered screening and the interval between successive screens. These are listed in Table 4. Taking 1990 as the nominal starting year, the analysis simulated the introduction of a screening program phased in over five years and running for a further 25 years. The simulated total life years lost in the absence of a screening program and the life years saved by screening for each of the screening options are listed in Table 5. These results show a clear benefit in including women aged 40–49 in the screening program and of a two year interval over a three year interval. However, they also show that decreasing the interval to one year for women aged 40–49 makes only a marginal improvement.

Table 4 Breast cancer screening options

Option number	Age group screened (years)	Screening interval (years)
1	50–69	2
2	50–69	3
3	40–49	1
	50–69	2
4	40–49	2
	50–69	3
5	40–69	2

An analysis of screening should include consideration of costs as well as benefits. A complete discussion of estimating costs is beyond the scope of this article, but generally they will be based on both current screening experience (with, for example, screening pilot projects in the location under study) and model based projections. These estimates

Table 5 Number and proportion of life years saved among Australian women by mammography screening over a 30 year screening period, as estimated from the van Oortmarssen et al. simulation model

Screening option	Total life years lost in the absence of a screening program ('000s)	Number of life years saved as a result of the screening program ('000s)	Life years saved as a percentage of total life years lost
1	3766.6	250.5	6.7
2	3767.0	202.4	5.4
3	3741.2	324.3	8.7
4	3743.1	258.1	6.9
5	3755.6	309.4	8.2

Source: Stevenson et al. [57].
Note: These results are based on the simulation of individual life histories, with the outcomes for each individual being determined randomly by applying the probabilities of developing the disease and of surviving the disease. This means that the outcome for each individual may vary between simulations. This accounts for the small variation in the simulated total life years lost figures.

Table 6 Relative cost-effectiveness of screening at different screening intervals for women aged 40–69

Screening option	Net present value of costs to service providers and women ($ million)	Net present value of life years saved ('000s)	Average cost per life year saved ($)
3	1917.8	622.2	3082.3
4	1097.5	628.6	1745.9
5	1374.6	620.6	2215.0

Source: Costs data taken from Australian Health Ministers' Advisory Council report on breast cancer screening [6]. Projected life years saved data taken from Stevenson et al. [57].
Note: Net present value calculated by applying an annual discount rate of 5%.

Table 7 Percentage of total life years saved among Australian women by mammography screening as estimated by two simulation models

Screening option	Life years saved as a percentage of total life years lost – van Oortmarssen et al. model	Life years saved as a percentage of total life years lost – Knox two-stage model
1	6.7	12.6
2	5.4	11.1
3	8.7	12.9
4	6.9	11.1
5	8.2	12.8

Source: Stevenson et al. [57].

are usually reported as the present value of the costs. This involves applying an annual discount rate to costs projected for future years. Hence, where costs are compared with benefits, the benefits are usually also presented in present value terms by applying the same annual discount rate.

The estimated total costs and costs per life year saved for the three screening options which include women aged 40–49 are presented in Table 6. This shows that the small increase in life years saved gained by moving to a one year screening interval for women aged 40–49 is offset by a substantial increase in the cost per life year saved.

A Comparison of Two Models for Breast Cancer

Stevenson et al. [57] also simulated the introduction of an Australian breast cancer screening program using Knox's two-state disease model described above. In Table 7 is presented a comparison between the

percentage life years saved for each screening option derived from both this model and the van Oortmarssen et al. model. There are clear differences between the two models, with the Knox model estimates consistently higher for all screening options. Furthermore, the evidence from the Knox model for including women aged 40–49 is more equivocal.

It is tempting to ask which model is right but, while there is some reason for preferring the van Oortmarssen model (because of its more extensive validation), a more relevant question is which model more correctly addresses the issue under study. The Knox model applies to a steady state situation, in which the screening program has been operating for long enough so that no one in the target population is too old to have participated in the full program. The van Oortmarssen et al. model makes allowance for the start of the program excluding some women from fully participating. The effect of this is that the Knox model will overstate the gains in life years saved at the start of the program. The difference in the results for including women aged 40–49 years arise from more realistic assumptions in the van Oortmarssen et al. model about the effect of screening at those ages on subsequent mortality.

Models for Other Diseases

Models for screening can be applied to diseases other than cancer. For example, screening tests exist for diabetes and there is a clear value in its early detection. Undiagnosed diabetes could be considered as a preclinical phase of the disease and modeling techniques applied to investigating its characteristics. Similarly, a disease such as hypertension could be modeled either for its own sake or as a preclinical form of cardiovascular disease.

Some work has been done on simulation modeling for coronary heart disease [38]. This model used **logistic regression** to estimate transition probabilities between risk factor states and heart disease. It focused on the effects of risk factor reduction, but did not address details of screening programs. Hence, it avoided having to model details of the preclinical phase. There have to date been no significant published attempts at modeling the preclinical phase to investigate specific screening programs for chronic diseases other than cancer.

On the other hand, modeling of infectious diseases has a long history in biostatistics (*see* **Communicable Diseases**; **Infectious Disease Models**). Most recently considerable work has been done on disease models of **AIDS and HIV**, although most of this effort has focused on projecting the spread of the disease rather than modeling screening programs (see, for example, Day et al. [23]). However, there has been some work on modeling screening for infectious diseases.

Lee & Pierskalla's model [40] is a good illustration of the similarities and differences in modeling infectious diseases for mass screening. In this model, the preclinical phase equates to the period during which a disease is infectious but without symptoms and the clinical phase to the period during which symptoms develop, the person seeks treatment, and is isolated or removed from the population. The main quantities used in the modeling are:

1. the number of infected people at a given time;
2. the natural incidence rate of the disease;
3. the rate of transmission of the disease from a contagious unit to a susceptible;
4. the rate of infected units ending the infectious period (i.e. clinical surfacing); and
5. the probability that an infected unit will not be detected by a screening test (i.e. the probability of a false negative).

The crucial difference here is that disease is initiated by spread from one unit to another, as well as by its natural incidence rate. Hence, in addition to the lead time, the main index of benefit is the removal of infected units from the population. Indeed, Lee & Pierskalla show that defining the measure of screening benefit as the average lead time across the population under study is equivalent to defining it as the average number of infected units per time period in the population.

Taking treatment as the endpoint of the model, rather than ultimate mortality, has the advantage of avoiding the necessity of modeling survival in the presence of screening. However, these models still have the difficulty of specifying parameters for an unobserved preclinical phase. For example, Lee & Pierskalla note that their model is an oversimplification, because it assumes that the sensitivity of the screening test is constant and independent of how long the person has been infected with the disease.

They also note that varying this assumption is of little practical use, since data on transmission rates at the various disease states are almost nonexistent.

Current State and Future Directions

The problem of model validation and its effect on the credibility of model based results is still a barrier to their wider use. Nevertheless, there are a number of areas in which modeling can make a uniquely important contribution to our current understanding of screening.

In the absence of specific RCTs, modeling remains the only effective way of evaluating different screening regimes. For example, the inclusion of women aged between 40 and 50 in a mammography screening program is still a contentious issue, with no international consensus on the effectiveness of screening at these ages [6]. While it could be argued that decisions on screening these women should not be made in the absence of reliable evidence on the presence or absence of the benefits, in practice, governments are already developing screening programs and modeling plays an important role in guiding policy-makers.

Modeling also has a crucial role to play in assessing the cost-effectiveness of screening programs. Even for cheap and easily available screening technologies, organized mass screening programs are the best way to insure that the benefits of screening are fully realized [7]. Modeling is not only necessary in order to plan these programs, but funding bodies are unlikely to fund such programs without at least initial cost–effectiveness studies, and modeling is the only practical way to derive the necessary estimates of future benefits and costs.

Miller et al. [44], p. 768 best summarize the current situation when, in discussing some recent models, they say

> It is clear that these, and other models already developed or under consideration, may enhance our understanding of the natural history of screen-detected lesions and the process of screening. However, they require validation with the best available data, which is preferably derived from randomized trials, before they could be extrapolated in ways that might guide policy decisions. As such data become available, assumption-based models need to be modified to incorporate this extra information, in order to improve the extrapolations needed to make policy.

While analytic models have a role in investigating specific facets of the disease and screening process (see, for example, [59]), the more comprehensive simulation models, and particularly the microsimulation models, seem best suited to the overall assessment of costs and effectiveness in screening programs and the investigation of different screening regimes. However, the challenge in using the simulation approach is to derive disease and screening models which are sufficiently complex to model all relevant aspects of screening but sufficiently simple to enable interpretable second-order validation.

CHRIS STEVENSON

Screening, Overview

The term "screening" is used to denote a variety of procedures in medicine and epidemiology. "Screening for disease" is mostly used to denote "the examination of asymptomatic people in order to classify them as likely, or unlikely, to have the disease that is the object of screening. People who appear likely to have disease are investigated further to arrive at a final diagnosis. Those people who are found to have the disease are then treated" (Morrison [18]).

This definition describes three distinguishing characteristics of screening for disease. First, screening is targeted at apparently healthy persons who are not aware of symptoms for which medical help would be sought. The **prevalence** of the disease in these persons will in general be (very) low. Secondly, the screening examination will give a crude distinction between persons with a normal test result, who do not receive further special attention, and persons in whom abnormalities are found in the screening test. Different grades of abnormalities may lead to more or less intensive follow-up, ranging from a repeat screening test to immediate treatment. Thirdly, appropriate treatment of disease which is detected early is expected to have a favorable impact on prognosis. The public health goal of screening for disease, "To reduce mortality or morbidity or to improve the quality of life" [12], is achieved by the more favorable outcome of early treatment in the cases identified by the screening test in comparison with similar cases that have been diagnosed on the basis of symptoms.

However, Table 1 shows that this benefit of screening is accrued by a very small proportion (group D+) of the persons screened. Inevitably screening will have a negative impact for other persons (groups C and D−). The small **risks** of some screening tests – for example, the increased risk of miscarriage following amniocentesis as part of antenatal screening, or the **radiation** risk of mammographic screening – cannot be disregarded completely given the very large number of tests performed (groups ABCD). Participation in screening for a serious disease will lead to anxiety, followed by relief when the result appears to be negative (groups A and B). Although this may sometimes be a relatively small effect, it cannot be neglected given the large number of persons involved.

False positive test results (group C) might lead to a (sometimes serious) burden of follow-up diagnostic tests needed to exclude disease. A true positive test result may still turn out to give adverse effects when early treatment does not improve the prognosis (group D−), but the person has been made aware of the disease for a longer period of time. Lack of improvement may occur when the outcome of early treatment remains unfavorable, but also when a person would have had a very good **prognosis** without screening.

Several extensions and modifications to the rather strict definition of Morrison are being used; see, for example, Holland & Stewart [13] or Wald [22]. For example, the term screening is also used to describe identification of people at high *risk* of disease (for example, high cholesterol or blood pressure levels) instead of early detection of the disease itself. The public health goal of screening for a disease may also be achieved indirectly, e.g. by preventing morbidity and mortality in other persons than those being screened. For example, specific groups of individuals, such as employees in the food industry, persons applying for a driving licence, or a circumscribed population in which an outbreak of an infectious disease occurred, may be screened to protect the general population.

Performing screening tests in an asymptomatic population can also have a scientific aim, such as to estimate the population prevalence of certain conditions, for example HIV infection (*see* **Prevalence of Disease, Estimation from Screening Data**). This extended usage of the term screening is reflected in the more general definition of McKeown [17]: "A medical investigation which does not arise from a patient's request for advice for a specific complaint".

In medicine and epidemiology, usage of the term screening is not necessarily related to testing of (asymptomatic) individuals, but is often used as a synonym for "testing". In clinical medicine, screening is used to denote testing of symptomatic patients to establish a diagnosis. It is also used in laboratory testing of donor blood for HIV infections, for example, and in medical research (laboratory, epidemiologic surveillance), the term screening is used to denote testing of chemical agents to identify toxic substances.

Discussion of screening for disease in this Section is confined to screening adhering to the strict definition of Morrison, while admitting that

Table 1 The different outcomes of screening, their usual impact and frequency. Extended version of table given by Morrison [18]

	Outcome	Impact	Proportion of target population
O	Nonparticipation	?	medium–large
A	True negative	anxiety, relief, side-effects of test	large
B	False negative	anxiety, false relief, side-effects of test	very small
C	False positive	moderate adverse effects	(very) small
D−	True positive, serious condition not postponed	adverse	(very) small
D+	True positive, serious condition postponed	large benefit	very small

it is difficult to draw exact boundaries for this definition. Examples will mostly be derived from cancer screening studies. (See the series *Screening Brief* in the *Journal of Medical Screening* for up-to-date information on screening programs for specific diseases.)

A broad distinction can be made between, on the one hand, genetic screening (*see* **Genetic Counseling**; **Genetic Markers**), and most antenatal and neonatal screening procedures which involve a single screening examination and, on the other hand, screening for chronic diseases, including screening for problems during growth of children and screening for cancer in adults, which typically involve repeated screening tests with intervals between several months to years.

Genetic screening can be done at different times throughout life. It can be performed prior to conception to inform persons of a high risk of conceiving a child with a severe disorder, during pregnancy for early detection and elective termination of pregnancy, shortly after birth to detect treatable disorders, or later in life to enable preventive measures which reduce the risk of developing serious disorders. In antenatal and neonatal screening, optimal timing of the test is important because the gestational age or age of the child determine the **sensitivity** and **specificity** of the test(s) and the possibilities for intervention.

In the case of repeated screening examinations for early detection of diseases such as (breast, cervical, or colorectal) cancer, proper timing of tests is even more complicated because of various time-related factors involved: incidence and prevalence of the detectable preclinical phase (DPCP) varies with age, the **sojourn time** of the DPCP varies between persons, and test characteristics and the outcome of early treatment vary during the course of the DPCP. The number of factors involved, and the dynamic interrelations between factors, complicate the design, analysis and evaluation of such screening programs (*see* **Screening Benefit, Evaluation of**; **Screening, Models of**).

Important questions in analysis and evaluation of screening for disease are:

1. Will screening indeed reduce the mortality and/or morbidity in the population and, if so, what is the estimated magnitude of the reduction?
2. What are the favorable and adverse effects and costs of different screening policies, and what will be the impact on existing health care? A policy is characterized by the recommended age(-range) to be screened, the screening test(s) used, the intervals between examinations in the case of repeated screening, and the diagnostic follow-up and subsequent treatment to be applied.
3. What are efficient policies, and is screening worthwhile?
4. Does the screening program, when implemented as part of routine care, perform adequately?

These issues are discussed in turn in the following Sections.

Establishing the Effectiveness of Screening

The effect of a certain screening policy on mortality and morbidity depends on several factors, such as the screening test, the natural history of the disease, the

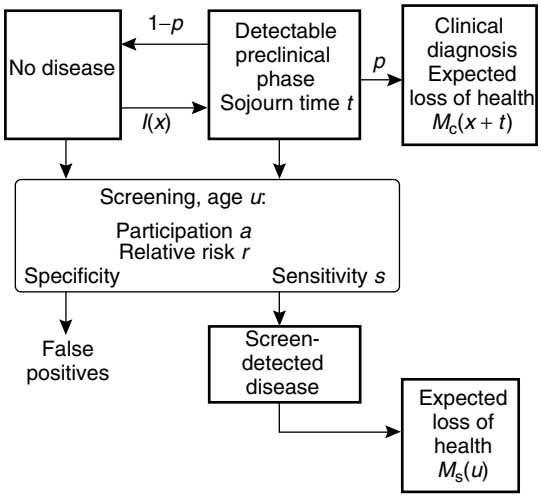

Figure 1 A single screening examination for a disease with a detectable preclinical phase starting at age x. Without screening, the disease will remain unnoticed until progressive cases are diagnosed clinically at age $z = x + t$. Screening at age u will lead to false positive test results, but also to early detection and treatment for part of the prevalent cases at age u, i.e. in participants for which $x < u < x + t$ and the test result is correct. These true positive cases will include persons with nonprogressive disease that would never have been diagnosed in the absence of screening

x = age at onset of the detectable preclinical phase
$I(x)$ = incidence density of the detectable preclinical phase
t = sojourn time in the detectable preclinical phase, probability density $f(t)$
p = proportion with progressive disease among incidence $I(x)$
a = proportion participating in screening at age u
r = relative risk of participants
s = sensitivity of the screening test
$M_s(u)$ = expected loss of health following detection by screening at age u
$M_c(z)$ = expected loss of health following clinical diagnosis at age $z = x + t$

diagnostic and treatment options for the disease, the improvement in prognosis resulting from early treatment, and, at the level of the population, the degree of participation in the screening program, including possible selective participation of high risk groups. Figure 1 shows these factors for a single screening examination, one screening test, and a disease with a fixed duration for the detectable preclinical phase

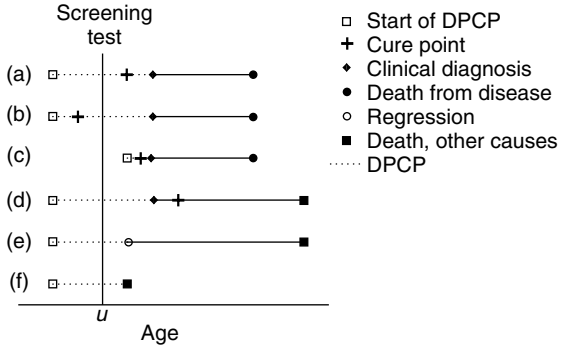

Figure 2 Example disease histories that are missed, diagnosed without benefit, or diagnosed with favorable effect, by a single screening examination at age u. The cure point indicates a hypothetical moment in the disease history where treatment ceases to be effective. The thick line indicates the detectable preclinical phase (DPCP)

(*see* **Decision Analysis in Diagnosis and Treatment Choice**; **Natural History Study of Prognosis**; **Risk Assessment in Clinical Decision Making**).

Together, these factors determine not only the positive health effect of screening, but also its negative effects and its costs. Figure 2 shows examples of disease histories, starting from the onset of the detectable preclinical phase (DPCP), for which screening has favorable or adverse effects. In these examples it is assumed that the main goal of screening is to prevent death from the disease, such as, for example, in cancer screening. A cure point is indicated, denoting a hypothetical point in the history where treatment ceases to be effective [9].

In history (a), the disease is detected by a true positive screening test result, and death from the disease is to be prevented by screening since detection occurs before the cure point. Death from the disease will not be prevented in the case of a **false negative** test result or inadequate follow-up in this history. Screening will also be ineffective and have merely adverse effects when it is too late (history (b)), or when the DPCP has a short sojourn time and is missed by the screen (history (c)). Screening has no impact on mortality and clear negative effects in history (d), where clinical diagnosis would also have occurred before the cure point, in history (e) of regressive disease where the DPCP would never have been detected in the absence of screening, and in history (f) where the person dies from other causes

before the disease would have been diagnosed clinically. The increasing likelihood of the last type of history at older ages should be kept in mind in evaluating screening for diseases such as cancer of the prostate that mainly occur in the elderly.

The lead time is the length of the time interval between the moments of detection by screening and clinical diagnosis without screening. The average lead time is indicative of the potential positive effect of screening, since a longer average lead time means that more cases can be detected before the cure point is reached. But in histories (b) and (d), the lead time only represents a negative effect: the person is merely aware of having serious disease for a longer period of time. Histories (a) and (c) illustrate the **length-biased** sampling phenomenon, which means that screening tends to pick up histories with long sojourn times selectively. Zelen & Feinleib [26] have pointed out the consequences for the **mean** lead time ($\overline{L}$) of screen-detected cases at a single screening examination:

$$\overline{L} = \frac{1}{2}\left(\overline{t} + \frac{\sigma_t^2}{\overline{t}}\right), \qquad (1)$$

indicating that the mean lead time is longer than the mean sojourn time $\overline{t}$ when the **variance** σ_t^2 of the sojourn time distribution exceeds its mean value.

For the simplified situation of Figure 1 with a single screening test at age u, the true prevalence $D(u)$ of preclinical disease is given by

$$D(u) = \int_{x=0}^{u}\int_{t=u-x}^{\infty} I(x)\,f(t)\,\mathrm{d}t\,\mathrm{d}x, \qquad (2)$$

where $I(x)$ denotes the incidence density of the detectable preclinical phase and $f(t)$ the probability density function of the sojourn time t in the detectable preclinical phase.

The expected health effects $G(u)$ for the population in which this single screening examination is taking place accrue to the screen-detected cases. This is a subset of the prevalent cases, including persons who participate in screening and have a certain associated **relative risk**, and for whom the test has a true positive result. The health effect for these cases is obtained by subtracting the loss of health M_c in a situation without screening for the fraction p of progressive cases, which would have been diagnosed clinically at age $x + t$, from the loss of health M_s in all screen-detected cases at age u in the situation with screening:

$$G(u) = \int_{x=0}^{u}\int_{t=u-x}^{\infty} I(x)\,f(t)ars \times [M_s(u) - pM_c(x+t)]\,\mathrm{d}t\,\mathrm{d}x, \qquad (3)$$

where $I(x)$ denotes the **incidence density** of the detectable preclinical phase, $f(t)$ the probability density of the sojourn time t in the detectable preclinical phase, a the proportion participating in screening at age u, r the relative risk of participants, and s the sensitivity of the screening test.

In (3), the lead time for screen-detected progressive cases is $x + t - u$, the time interval between detection at screening and clinical diagnosis in the absence of screening. In the example of a potentially lethal disease as presented in Figure 2, the measures M_c and M_s for the loss of health might be taken to represent the lethality from the disease following diagnosis and treatment. Comparison of M_c and M_s on the individual level is, of course, impossible, because the exact clinically diagnosed counterparts of screen-detected cases will always remain unknown.

In general it will be difficult to obtain direct estimates of the components of (3), except for $M_c(\cdot)$ and $M_s(\cdot)$, which may be based on follow-up registries (*see* **Disease Registers**) of clinically diagnosed and screen-detected patients. Although it is tempting to compare $M_c(\cdot)$ and $M_s(\cdot)$ directly, this will give rise to incorrect conclusions because of four sources of sampling **bias** that all tend to lead to a too favorable estimate for the effect of screening.

If not all preclinical stages progress ($p < 1.0$), then the comparison will yield a too optimistic estimate because of overdiagnosis bias (see history (e) in Figure 2.) Self-selection bias (*see* **Selection Bias**) with respect to survival occurs when participants in screening would have had a better prognosis anyhow, for example because of self-selection of health-conscious persons. Self-selection may also be related to the risk of developing the disease. Participants have been observed to have a higher than average risk in breast cancer screening [23], but the opposite has been observed in cervical cancer screening [1]. Lead time bias occurs when cumulative lethality is compared for equal durations of follow-up after diagnosis, giving screen-detected cases an advantage equal to the duration of the lead time even in the absence

of a real effect of screening. Length-biased sampling will also lead to biased comparisons if the sojourn time and M_c are **correlated**, for example when slowly developing preclinical disease also has a better-than-average prognosis.

Lead time bias and length biased sampling are specific for screening, and different approaches have been proposed to correct these biases [24]. However, these correction methods are always based on assumptions about the sojourn time distribution, and will not lead to unambiguous evidence about the effect of screening.

The four biases can only be avoided by conducting a randomized controlled trial (RCT) (*see* **Clinical Trials, Overview**; **Screening Trials**). In its basic form, a population involved in an RCT is randomly divided (*see* **Randomization**) in a study group in which persons are invited to be screened, and a **control** group in which no screening is offered. The endpoint to be compared between the two groups is the condition that is to be prevented by early detection and treatment, for example mortality in cancer screening (*see* **Outcome Measures in Clinical Trials**). Use of other endpoints – for example, diagnosis of malignancy in cervical cancer screening – might lead to biased estimates of the effect of screening when, on average, screen-detected cases are less severe than clinically diagnosed cases. A huge population will be needed to obtain sufficient **power**, and several design variants have been proposed to limit trial costs [9]. The impact of trials has been considerable, both in diminishing the use of screening for lung cancer, and in speeding up implementation of breast cancer screening program in several countries. Screening for lung cancer did not turn out to be effective according to RCT results, despite clear differences in survival between screen-detected and clinically diagnosed patients [10]. In most RCTs conducted thus far, screening for breast cancer has been found to reduce breast cancer mortality in women above age 50, but results for women below age 50 are still not conclusive [5, 21].

Use of disease-specific outcome measures in an RCT is controversial. Critics state that the beneficial effect should be checked from overall mortality and morbidity. But this would require an enormous trial size. Even the combined results of four Swedish breast cancer trials, with a relative risk for breast cancer death of 0.80 (95% CI 0.70–0.92) did not show a discernable effect on overall mortality in the trial population [20].

Some screening tests that are widely used have never been rigorously tested in an RCT. One example is cervical cancer screening, for which a very large RCT would be required. In such a situation, estimates of the effectiveness of screening can only be obtained from nonexperimental designs, such as **cohort studies, case–control studies**, and **ecologic studies**.

In cohort studies, a comparison of morbidity and mortality is made between persons with different screening experience in the cohort. Case–control studies for testing the effectiveness of screening have become increasingly popular, but the outcomes are highly sensitive to several kinds of bias such as overdiagnosis bias, self-selection bias, and healthy screenee bias (see Morrison [18] or Weiss [25]). This has been demonstrated empirically by performing a case–control study on data from an RCT [11].

In ecologic studies, an investigation is made into the association between the morbidity or mortality and the screening intensity in different populations. Cervical cancer screening is now generally considered to be effective on the basis of the findings of many **observational studies:** cohort studies and case–control studies (IARC Working Group [14]) and ecologic analyses (see, for example, Läärä et al. [16].

The Favorable and Adverse Effects and Costs of Alternative Policies

When screening is being considered in a country or region, usually different screening policies are being considered which might differ in their effects and costs. Only a limited number of policies have been rigorously tested in RCTs, which are typically carried out in countries or regions with marked differences with respect to, for example, incidence or mortality rate, participation in screening, and specific characteristics and quality of the screening procedures. Furthermore, the long follow-up in many screening trials implies that their results typically pertain to screening technology from the past. These observations complicate both combined analysis of trial results, and **extrapolation** of these results to other situations such as the near future in a new

country in which screening is being considered. Also, RCTs tend to focus on the serious health effects to be prevented by screening (category D+ in Table 1), paying less attention to the adverse effects of screening.

Two methods are used to resolve (partially) these problems – modeling and use of **surrogate endpoint** measures.

In building a model, assumptions have to be made about the factors listed in Figure 1. These assumptions can be checked (*see* **Model Checking**) by fitting the model to available data from RCTs and to data from nonexperimental screening studies. For example, outcomes of cancer screening models are compared with observed detection rates at successive screening rounds, incidence of clinical disease in the interval between screening exams, and with the stage-distribution of these different types of cases. Characteristics of, and trends in, background variables can be taken into account explicitly in a model. In this way, known differences between trials can be incorporated in combined analyses of RCT results (see [5]). Models are increasingly being used to make predictions about other screening policies than those tested in trials, and to transfer outcomes from trials to specific characteristics in other areas (see, for example, [6]).

Introducing screening for a disease in a population will change the type and amount of diagnostic and treatment procedures for this disease. In a first screening round, a relatively large pool of prevalent cases will have a positive test result, leading to a temporary increase in demand for assessment and treatment, followed by a decrease in later screening rounds. Models can make quite detailed predictions of these changes, which is useful in planning of equipment, recruitment, and training of personnel, and in anticipation of changes in clinical procedures [4].

The number of assumptions used in screening models may easily become quite large, and some of these assumptions lack a thorough foundation. Use of surrogate outcome measures can be regarded as an attempt to obtain a more direct empirical basis in comparing different policies, without the lengthy follow-up period needed in large RCTs [2]. A surrogate outcome measure is a short-term observed result of a screening program that is known (or suspected) to be closely associated with the long-term impact on morbidity and mortality. Such a relation can be estimated from RCT data. For example, mortality reduction after breast cancer screening has been shown to be closely associated with particular changes in the stage distribution of diagnosed cancer cases.

Surrogate outcome measures can be used to evaluate various small adaptations of policies that have already been proven to be effective. The surrogate outcome measures of the policy variants can be compared directly, and the observed differences can also be translated into predicted differences in reduction of mortality and morbidity.

Efficient Policies

In deciding about screening policies an important criterion is the ratio of the health effects of a screening program and its incremental costs, i.e. the difference in (medical) costs between the situation with and without screening. The incremental costs of a screening policy are directly related to the cost of administering and assessing the screening test, but may also be influenced by the impact of screening on the demand for diagnostic and treatment procedures. For each level of the incremental costs, an optimal screening policy exists which gives the highest effectiveness (net health benefit) or the best cost-effectiveness ratio (*see* **Health Economics**). Figure 3 shows a typical intensity–response relationship which emerges when

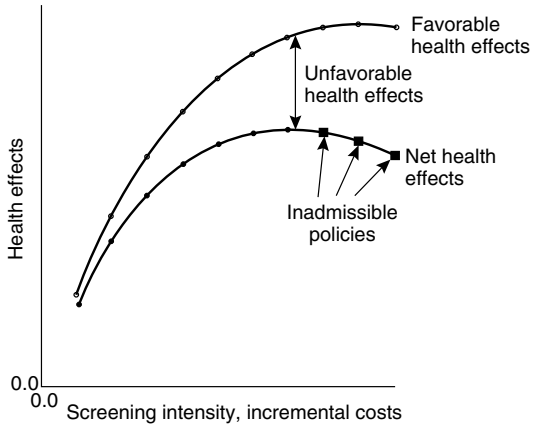

Figure 3 Relation between intensity of screening and its favorable and unfavorable health effects (intensity–response curve) or similarly between the incremental costs of screening and health effects (efficient frontier). The net health benefit summarizes the favorable and adverse effects of screening

different numbers of screenings are compared. The net health benefit is relatively high for a single screening test. The extra benefit decreases for each additional screening examination. When the number of screening tests per person increases, the adverse effects of screening might well become larger than the favorable effects. For example, extending screening to older ages will increasingly lead to detection of cases that would not have been diagnosed in the absence of screening, leading to reduction in **quality of life** that is no longer compensated for by a decrease in mortality.

Although the top of the curve in Figure 3 represents the policy with the maximum effectiveness, the marginal cost-effectiveness of this policy is very poor. If the X-axis of Figure 3 represents costs, the curve can be interpreted as the efficient frontier, i.e. the set of all **Pareto**-optimal screening policies – policies for which no alternative can be found that give both higher health benefits and lower costs [8]. A good policy on this frontier would be the one which still shows an acceptable marginal cost-effectiveness ratio.

Simulation models have been applied to derive the efficient frontier of screening policies [7, 8, 15].

Monitoring of Screening Program

If screening is not conducted properly, effectiveness and cost-effectiveness can easily be impaired. A well-known example is the cervical cancer screening program in the UK, which has not been able to prevent increasing mortality rates in young women [19]. Each of the stages in the screening process could give rise to loss of potential benefits, and sometimes also to excessive negative effects. Sufficient coverage of the population at risk, adequate administration of the test and interpretation of test results, compliance with follow-up in the case of suspicious results, and proper treatment of early stages of the disease are all necessary to achieve the health benefits at a reasonable cost. Quality assurance and monitoring are important in this respect.

Measures of performance can be defined for each component of a screening program – e.g. the participation rate and **predictive value** of a positive test result – and should encompass diagnostic and treatment procedures applied to screen-detected disease. Target values for the short-term results of a screening program (such as detection rates and incidence of interval cases) can be specified on the basis of experience from randomized trials and pilot projects [3]. Regular evaluation of the screening results and of the costs of the screening program may than lead to timely revision of the screening policy.

GERRIT J. VAN OORTMARSSEN

Screening, Sojourn Time

Screening for disease can take place in a variety of contexts, notably the control of transmission of infectious disease, as part of an immunization program or to advance the time of diagnosis to facilitate effective treatment. Central to the potential suitability of a disease for screening is the period during which the disease does not produce symptoms leading to medical consultation and diagnosis, but is detectable by a screening test. This is the time between the point at which a disease case becomes detectable by screening and the point at which it would become clinically apparent in the absence of screening. This period is called the *preclinical phase* and its duration is referred to as the *sojourn time* [4, 18]. One example is the period during which a breast tumor is not palpable and has no symptoms but is detectable by mammography. Another is the period of HIV antibody positivity after seroconversion but before onset of **AIDS**-related illnesses.

The sojourn time is an important parameter of the potential effectiveness of a screening program. It is an upper limit on the lead time, the advance in the time of diagnosis achieved by screen detection. In practice, the parameter estimated is the average sojourn time of all disease cases (average time from becoming screen detectable to becoming clinically apparent in the absence of screening), usually referred to as the mean sojourn time and often abbreviated to MST. A long mean sojourn time will indicate a good potential for screening. The shorter the mean sojourn time, the more frequently screening will have to take place in order to be effective [2]. If mean sojourn time is very short, then it may not be worth screening at all.

In terms of the definition above, the sojourn time seems a relatively simple concept. There are, however, various complexities, due either to the varying effectiveness of the screening tool or the nature of the disease screened for [8, 18]. To take the first problem, suppose that in one breast cancer screening program in women aged 50–69 a mean sojourn time of 2.5 years is observed and that in a neighboring region the breast screening program has a mean sojourn time of 3.3 years. There are two possible explanations for this: (i) that in the second region tumors take longer to come to clinical attention, and (ii) that in the second region the sojourn time begins earlier in tumor development, due to better **sensitivity** (relating to better perceptive skills on the part of screening staff or better image quality of the X-ray films). Thus the sojourn time is closely related to the sensitivity of the screening instrument.

Another complication relates to nomenclature and the disease screened for. In breast cancer screening this problem does not arise. The aim of a breast cancer screening program is to diagnose breast cancers while they are small and before they have spread to the regional lymph nodes, in order to facilitate successful curative therapy and thus prevent death from the disease. In what is nominally a cervical cancer screening program, the main aim is to detect premalignant dysplasia and to take action which will avoid even a diagnosis of invasive cervical cancer in the future. The sojourn time in this case is not that of cervical cancer alone but of both cancer and dysplasia which may or may not progress to cancer if left untreated. The meaning of sojourn time becomes even more nebulous if we consider the use of hepatitis B virus testing in a liver cancer screening program or Epstein–Barr virus testing in screening for nasopharyngeal cancer (*see* **Incubation Period of Infectious Diseases**).

Development and Estimation

Although the above complications may arise, the concept is still a crucial one in screening for many diseases, notably cancers, and considerable research effort has been expended on methodology for its estimation, in conjunction with estimation of screening sensitivity. The seminal work on the theory and modeling is by Zelen & Feinleib [19], Prorok [12], and Walter & Day [18]. Other early research on the subject includes that of Eddy [8], Shapiro et al. [14], and Shwartz [15]. Underlying the work is the basic acknowledgment that the sojourn time varies from individual to individual. In turn, it is clear that the mean sojourn time is fundamentally important to the screening process, and that a postulated distribution of sojourn time which fits with observed disease incidence and screening data is desirable. An **exponential distribution** has many attractive qualities for temporal data, and Day & Walter [4] found it to be a good fit to breast cancer screening data.

Given a mathematical model for the sojourn time, for estimation of the mean sojourn time, it is also

necessary to model the incidence of preclinical disease. Also, because of the relationship with sensitivity mentioned above, it is preferable to take sensitivity into account when estimating mean sojourn time. Data on both screen-detected cancers (with diagnosis taking place by definition before the sojourn time expires) and cancers diagnosed in the interval between screens (with diagnosis at the expiry of the sojourn time) are necessary to estimate both parameters at once. Clearly a high **prevalence** at screening in comparison with expected annual incidence in the absence of screening suggests a long sojourn time, as does a low incidence of disease after a negative screen, although both of these are also affected by the sensitivity of the screening instrument. Early work tended to approximate the incidence of preclinical disease by the **incidence rate** of disease in the absence of screening, estimated from randomized trials (*see* **Clinical Trials, Overview**) or from historical control data [4, 19]. **Estimation** procedures ranged from simple formulae [14, 6] to results from complex models, involving computer-intensive **optimization** [4] or algebraically complicated **moment** calculations [19].

Current Approaches

Advances in computing power in recent years have enabled a wider variety of modeling techniques to be used in the estimation of mean sojourn time. Alexander [1] has adapted the model of Day & Walter [4] to estimation of the sojourn time when two screening techniques are used in the same program. Paci & Duffy [10] have used **generalized linear models** to estimate the mean sojourn time. This has the advantage of being programmable in a few lines of code using generally available statistical software (*see* **Software, Biostatistical**), but has the disadvantage of having to assume a sensitivity of 100% while estimating the MST. Van Oortmarssen et al. [17] have developed powerful computer **simulation** techniques. This approach is very versatile, but careful attention has to be paid to assumptions made in the simulations. More recently, explicit **Markov chain** modeling of both entry to and exit from the preclinical phase has been performed, with **generalized estimating equations** used as the estimation technique [7, 2]. This approach requires laborious computer programming, but has considerable potential for estimation of progression rates with respect to the disease stage as well as from the preclinical to the clinical phase.

In the context of HIV disease, there has been considerable recent activity in estimation of the sojourn time (referred to as the incubation period in this context), as an aid to prediction of the course of the epidemic. Examples abound in the literature, but perhaps the most important models and methods are typified by **back calculation** and use of **Weibull** models [5] and Markov chain models [13].

An interesting example of application is in the evaluation of breast cancer screening by age. It has long been known that screening for breast cancer is less effective in women aged under 50 years than in women aged 50 or more [16]. Breast tissue is denser in premenopausal women, and it is thought that this leads to reduced sensitivity of mammographic screening. Table 1 below shows simultaneous estimates of sensitivity and MST from Markov chain models applied to data from the Swedish Two-County Trial of breast cancer screening [2]. The results indicate that more rapid progression, i.e. shorter sojourn time, is also an important factor in the differential effectiveness of screening by age.

Likely Future Developments

One notable gap in the available methodology is the estimation of mean sojourn time and other screening parameters in the presence of informative attendance (i.e. subjects at greater or lesser risk of disease are more likely to attend for screening). This area seems ripe for future research. Another topic in the modeling field which is likely to be increasingly addressed in the future is the inclusion of attributes of preclinical disease (e.g. tumor size in cancer screening), possibly multidimensional, in models for the sojourn time. Already the simple model of the preclinical phase has been expanded to include some measure of stage of development of disease [17, 16, 3]. It is likely

Table 1 Mean sojourn time and sensitivity by age; Swedish Two-County Trial of breast cancer screening

Parameter	40–49	50–59	60–69
MST (years)	2.35	3.75	4.23
Sensitivity (%)	90	100	100

that more formal and more complex models will be developed in the future.

The increasing complexity of disease progression models may require new methods of estimation. A likely solution is the series of **Markov chain Monte Carlo** techniques, which are becoming increasingly common in biostatistical modeling [9]. One application, in a single model of colorectal cancer screening, has already been published and doubtlessly others will follow [11].

STEPHEN W. DUFFY

Seasonal Time Series

Literally, seasonality is a cyclic variation (*see* **Circadian Variation**) driven by the seasons within the year and, traditionally, seasonal models have been of most importance for economic or business applications, so the methodologies so far favor that direction. In such applications, prediction and seasonal adjustment of mostly univariate series have been the primary objectives. With many biological measurements, daily cycles are probably the most natural, but the methodology of seasonal adjustment would still play a role, so it will be convenient to view periodic time series as being seasonal. However, unlike in economic applications, it will be quite easy in biostatistical applications to get replicated time series from different individuals. In such applications, the analysis objectives of seasonal time series data are likely to be (a) a comparison of different groups of individuals, each having a time series record or (b) a comparison of before-and-after conditions. A general methodology to address these questions is not commonly available in the current literature. More relevant data sets need to be available to encourage methodological development. The rest of the article is a description of the current state of seasonal modeling.

Following the above discussion, to develop a general model of seasonality it is more useful and interesting to include any type of periodic patterns such as a day-and-night or a weekly cycle, or even a periodicity other than that shown by natural cycles. A famous example of the latter is the Canadian lynx time series (the annual number of lynx trapped in the Mackenzie River district of north-west Canada) with a periodicity of around 10 years [7]. Figure 1 shows

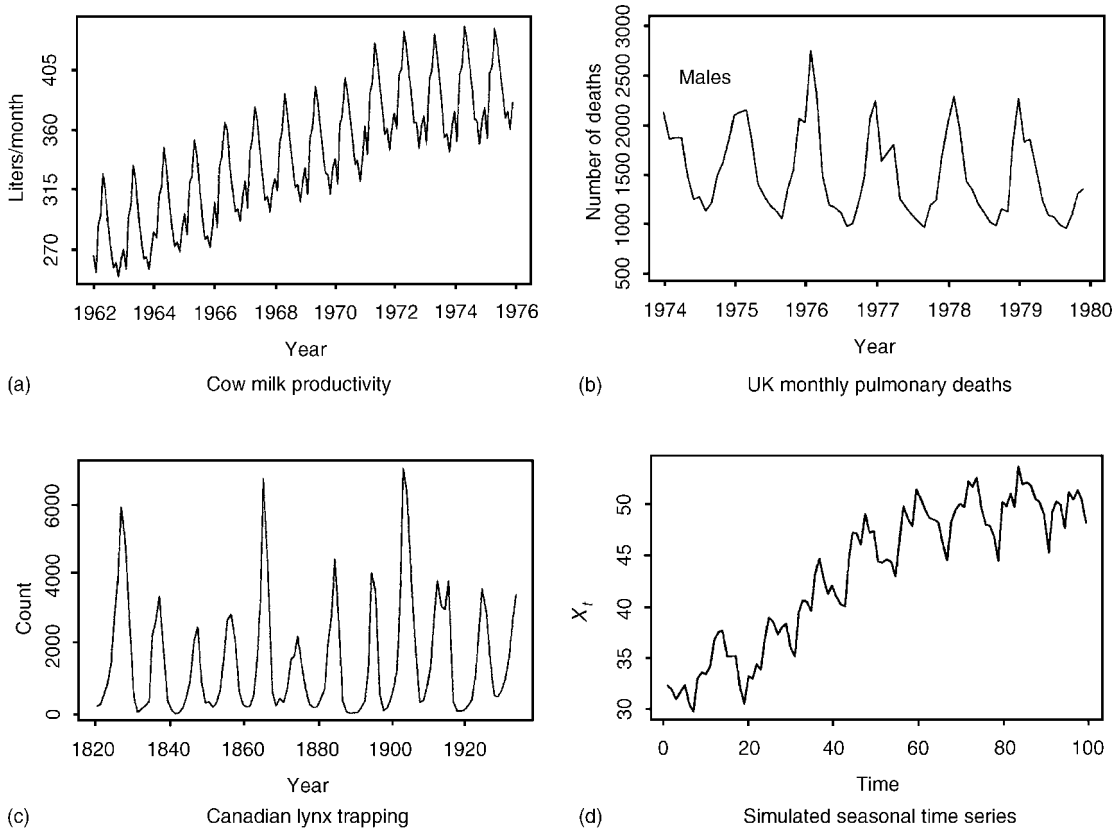

Figure 1 Examples of seasonal time series. In most cases, the seasonality is driven by some natural cycles, except in the Canadian lynx series. See Cryer [4] for the milk production data and Diggle [6] for the UK pulmonary data. The simulated series is ARIMA $(0, 1, 1) \times (0, 1, 1)_{12}$ with Gaussian noise

several examples of time series data that exhibit a common feature of seasonality or periodicity.

The interest in analyzing a seasonal time series may lie in the seasonality itself if it is an indication of some unknown underlying process; this is especially true when the seasonality does not coincide with some natural cycle. Another interest, usually associated with economic time series, is the *removal* of the seasonality. In this case, the cause of the seasonality is typically known and is not of analytical interest. This so-called *seasonal adjustment* allows us to gauge effects other than the known seasonality. For example, we know that the temperature is higher during the summer, so we must remove the general summer effect if we wish to know whether a particular summer has an unusually low or high temperature.

Models for Seasonality: Static

An intuitive and empirical model for a seasonal time series X_t is of the form

$$X_t = T_t + S_t + I_t, \tag{1}$$

where T_t is a long-term trend, S_t a seasonal factor, and I_t an irregular component. The model is static in the sense that it does not specify how the process evolves from one point to the next. In most applications, it is common to model I_t as random noise, and T_t and S_t as nonparametric functions of time. Low-dimensional parametric regression models may also be specified for T_t and S_t: for example, polynomial and trigonometric functions, but generally they are too rigid for most time series data. A simple nonparametric model for S_t may be based on any periodic repetition of a function p_t defined on $t = 1, \ldots, s$, where s is the seasonality. For monthly data, we expect that $s = 12$; for quarterly data, $s = 4$, etc. Then the seasonal component is $S_t = p_{t(\mathrm{mod}\ s)}$, where t (mod s) is the integer remainder of t/s; for example 13 (mod 12) is 1. The function p_t may be estimated from the data by the simple averaging of appropriate times; for example, we can simply compute a January average, a February average, etc.

Figure 2 shows an analysis of the UK pulmonary deaths between 1974 and 1980. In this example, one may be interested in explaining the seasonal variation of the pulmonary deaths, which is high during the winter and low during the summer. If the interest is in prediction, it may be computed simply by extending the periodic component p_t beyond the last measurement. As one might expect, a strongly seasonal series is highly predictable. The residual series is the seasonally adjusted values $X_t - S_t$, centered at the mean number of deaths of each group. These adjusted series show, for example, that (a) the male deaths are decreasing over time, (b) the number of deaths during winter 1976 was unusually high and (c) the pattern is similar for males and females, which suggests a common cause in addition to the seasonal variation.

The periodic repetition model above is generally not satisfactory for many time series data as it does not allow any variation of the function p_t over time. Thus, a straightforward extension is to allow p_t to change slowly over time. One might say that such time series exhibit a stochastic seasonality. This is the basis of many seasonal adjustment procedures currently in use, such as the so-called X-11 program used by the US Bureau of the Census [10]. Instead of computing, say, a January average from the whole time series, the assumption of a slowly varying p_t suggests a local averaging of the nearby January values. In practice, some weights are usually applied when computing the average.

Models for Seasonality: Dynamic

The development of autoregressive and integrated moving-average (ARIMA) modeling by Box & Jenkins [1] (*see* **ARMA and ARIMA Models**) provides a rich class of dynamic linear models that also include stochastic seasonal models. Figure 1(d) shows a simulated ARIMA $(0, 1, 1) \times (0, 1, 1)_{12}$, i.e. a nonstationary seasonal moving-average process of the form

$$(1 - B)(1 - B^{12})X_t = (1 - 0.25B)(1 - 0.5B^{12})a_t, \tag{2}$$

where $BX_t \equiv X_{t-1}$, so the model specifies

$$X_t = X_{t-1} + X_{t-12} - X_{t-13} + a_t - 0.25a_{t-1} - 0.5a_{t-12} + 0.125a_{t-13}, \tag{3}$$

where a_t is an uncorrelated Gaussian series. This is, in fact, a fitted model for the milk production series (with slightly different parameter values). Note that the model generates a stochastic seasonality,

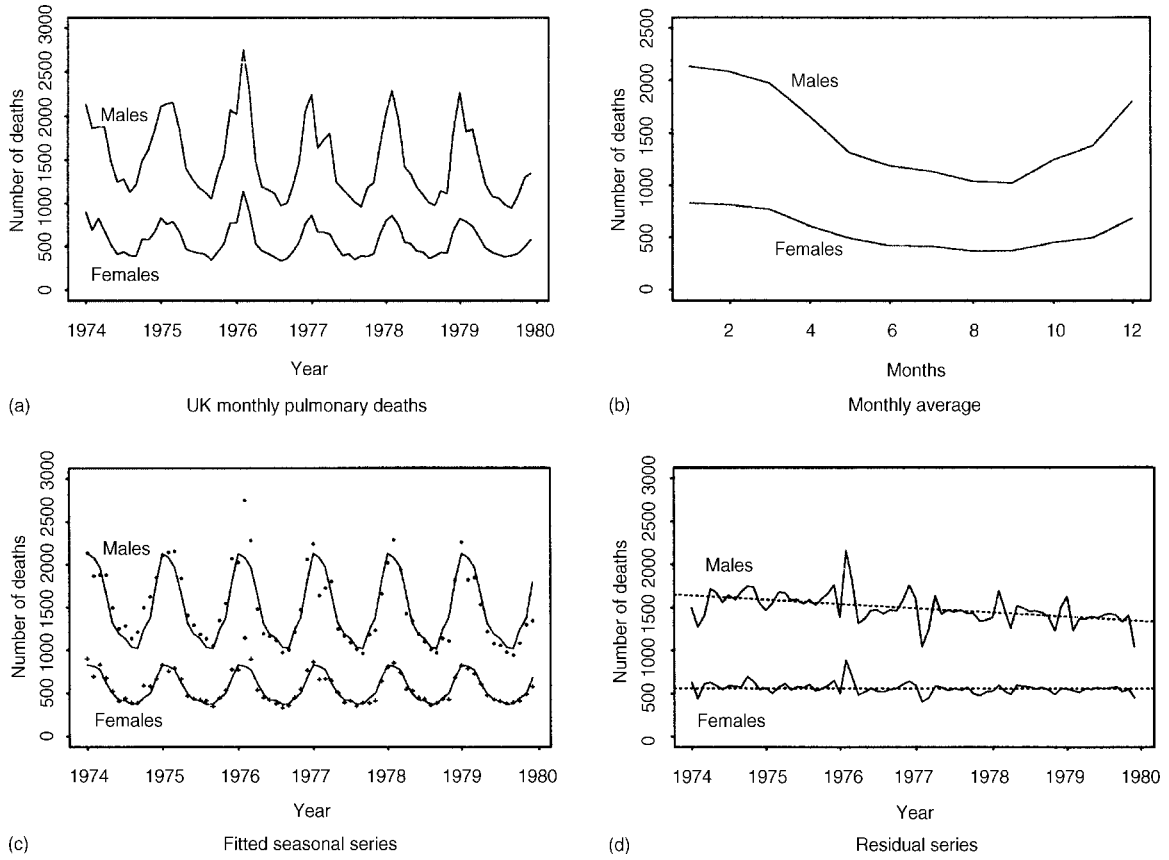

Figure 2 Analysis of UK pulmonary deaths. The seasonal component is computed by simple averaging, e.g. January average, February average, etc. The residual series is the so-called seasonally adjusted series, centered at the mean number of deaths

one where the periodic function p_t changes slowly over time. This has been the basis for a modified X-11 procedure called X-11-ARIMA developed by Statistics Canada. The advantage of the dynamic modeling is apparent for the estimation of S_t at the beginning and ending periods of observations [5]. Another approach is via a separate ARIMA modeling of the trend and seasonal components. Using a linear estimation theory, one can estimate S_t from the time series data X_t; see, for example, [2]. The set of weights generated by this method is, in fact, similar to that used in the X-11 program.

There is currently quite a large literature on seasonal models; a keyword search on "seasonal" in the Current Index of Statistics up to 1992 yields more than 500 records, most of which are related to seasonal modeling and adjustments. A recent reference is Hylleberg [8]. A literature study would indicate that most of the methodology for seasonal adjustment currently in use is either of the nonparametric type described above, or some ARIMA-based modification; a review article by Pierse [9] is still relevant. For a general statistical program, the X-11 procedure in SAS implements the Bureau of the Census X-11 program as well as X-11-ARIMA. The function stl() in **S-PLUS** performs nonparametric seasonal adjustment with some robustness capability as described in Cleveland et al. [3]. (*see* **Software, Biostatistical**).

Recent development of dynamic nonlinear models may also provide another wide class of periodic time series; Tong [11] is the main reference in this area. One of the most important properties of these models is the possible existence of limit cycles, a

phenomena that is absent within the linear models context. For series that exhibit a periodicity other than the natural cycles, a nonlinear model may yield a more satisfactory scientific description of the pattern; see, for example, [11, Chapter 7] for an extensive analysis of the Canadian lynx series.

YUDI PAWITAN

Secondary Attack Rate

The secondary attack rate (SAR) is the probability that infection occurs among susceptible persons within a reasonable **incubation period** following known contact with an infectious person or another infectious source [7]. The SAR is conditional on the contact between an infectious source and a susceptible host, as opposed to the usual unconditional parameters of epidemiology such as the **incidence rate**, **hazard rate**, or **cumulative incidence** [10]. It is a special form of the transmission probability (*see* **Communicable Diseases**; **Infectious Disease Models**).

The term SAR is a misnomer, because it is actually a proportion, not a **rate**. The magnitude of the SAR depends on **covariates** of the infectious person and the susceptible person, the type of contact between the two, and the infectivity of the infectious agent. For given types of susceptibles, infectives, and contacts, it provides an epidemiologic measure of the infectivity of an infectious agent. Measles [1] and chicken pox [24] have relatively high household SARs of 86% or higher, while mumps has a lower household SAR of about 43% [13].

Study Designs to Estimate SAR

The most common study design to estimate the conventional SAR is first to identify infectious persons, and then to identify the susceptible people who make contact with them. The initially identified infectious persons are called the *primary* or *index cases*. The conventional SAR is estimated as the probability of the occurrence of disease among known (or presumed) susceptible persons following contact with a primary case:

$$\mathrm{SAR} = \frac{\begin{array}{c}\text{number of persons exposed}\\ \text{who develop disease}\end{array}}{\begin{array}{c}\text{total number of susceptible}\\ \text{exposed persons}\end{array}}. \qquad (1)$$

A clear definition of what is a contact is important in designing a study. It can vary from study to study for the same infectious agent. A potentially infective contact in a whooping cough study could be defined as being in a school on one day with someone with culture-proven whooping cough. Alternatively, it could be defined as living in the same house during the presumed period of infectiousness of a person with clinically diagnosed whooping cough. In a study of HIV transmission, a potentially infectious contact could be defined as each sex act between two sexual partners in a steady relationship, or as simply being in a partnership with someone who is infectious. The SAR is often defined for exposure to an infective of the susceptibles within some small population unit, such as a household, classroom, or school bus. Within any given unit, mixing and exposure of the susceptible persons to infection are usually assumed to be homogeneous.

Another approach to estimating the secondary attack rate is contact tracing. For example, upon identification of an infectious person with tuberculosis, public health officials locate people who have made contact with the infectious case and test them for whether or not they have become infected. The pooled estimate of the proportion who have become infected is an estimate of the SAR. The SAR can also be estimated in **experimental studies**. In studies of the infectivity of malaria in humans for mosquitoes, groups of 20–30 mosquitoes are fed experimentally on an infectious person. After 2 weeks, the mosquitoes are dissected to see if they have become infected and how many parasites have developed. The proportion of mosquitoes becoming infected is an estimate of the SAR.

The SAR has no explicit time dimension. However, the time interval during which the infected person is presumed to be infectious determines which of the people making contact were potentially exposed. Therefore, the time interval of infectiousness affects the determination of the denominator of the SAR. If infection is the outcome of interest, the minimum and maximum **latent periods** of the infectious agent define the time interval after exposure in which exposed people can develop infection and have been infected by the index case. If disease is the outcome of interest, the minimum and maximum incubation periods determine the time interval after exposure in which exposed people can develop disease and have been infected by the index case. Thus, either the latent period or incubation period enters into the determination of the numerator of the SAR.

Ratios of SARs

The ratio of two SARs can be used to estimate the relative infectivity or susceptibility of two types

of people, different infectious agents, or types of contacts. Let 0 and 1 represent two levels of a risk factor, such as vaccination status, gender, or age. Then there are four possible secondary attack rates for a given infectious agent and definition of contact – SAR_{00}, SAR_{11}, SAR_{10}, and SAR_{01} – where the first subscript represents the infectious person and the second subscript represents the susceptible person. The relative susceptibility of a person with risk factor level 1 compared to risk level 0 conditional on a given exposure to infection is SAR_{01}/SAR_{00} or SAR_{11}/SAR_{10}. The relative infectivity of a person with risk factor level 1 compared to risk factor level 0 is estimated by SAR_{10}/SAR_{00} or SAR_{11}/SAR_{01}. The relative transmissibility between persons of risk factor level 1 compared to that between persons with risk factor level 0 is SAR_{11}/SAR_{00}.

Vaccine efficacy can be estimated using the SAR (*see* **Vaccine Studies**). If 0 and 1 represent the unvaccinated and vaccinated people, respectively, then vaccine efficacy for susceptibility, VE_S, and infectiousness, VE_I, are estimated by

$$VE_S = 1 - \frac{SAR_{01}}{SAR_{00}}$$

and

$$VE_I = 1 - \frac{SAR_{10}}{SAR_{00}}. \quad (2)$$

The relative SAR between two vaccinated people compared to two unvaccinated people, i.e. the ratio SAR_{11}/SAR_{00}, can be thought of as the *naive susceptible equivalent* of a vaccinated compared to an unvaccinated person [11]. It gives the relative contribution of a vaccinated person to the basic **reproduction number**, R_0, compared to that of an unvaccinated person, and thus information about the effect of widespread vaccination on reducing the spread of an infectious agent in a population.

Household Secondary Attack Rate

The *household secondary attack rate* (SAR) is the probability that a susceptible individual living within the same household as an infectious person during their period of infectiousness will become infected. The household SAR is a parameter commonly used for estimating the protective efficacy of a vaccine in directly transmitted infections, such as pertussis, mumps, chicken pox, and measles [6, 22]. It can also be used to estimate the efficacy of a vaccine in reducing infectiousness [9, 10]. The data required are the time of onset of disease for each case in the household, as well as knowledge of who is susceptible. Estimates or assumptions about the minimum and maximum incubation periods, E_1 and E_2, respectively, and the maximum time I that a person remains infectious are also required and are sometimes obtained from other studies. One sometimes assumes that the onset of symptoms coincides with the onset of infectiousness, and that there are no asymptomatic cases.

The first step in assessing SAR is to define for the disease under study the time interval after the index case that would include secondary cases. The presumed beginning of infectiousness of the index case is defined as time 0 for each household. *Secondary cases* are those with time of onset between the end of the minimum incubation period E_1 relative to the beginning of infectiousness of the index case ($t = 0$) and the end of the maximum incubation period E_2 relative to the time of the maximum infectious period of the primary case, $t = I$. Thus, secondary cases are those occurring in the interval $(E_1, I + E_2)$. A case with recorded onset time less than one minimum incubation period, E_1, after that of the index case, was presumably not infected by the index case and is called a *co-primary case*. Tertiary and higher cases are those occurring after the maximum allowable time interval for the secondary cases.

Example

For an early efficacy study of pertussis vaccines, Kendrick & Eldering [12] estimated the infectious period for the bacteria from studies of throat cultures. In those studies, nearly everyone had a positive culture up to 21 days after onset of symptoms. They defined a definite exposure (potentially infective contact) as living in the same house as the index case or being indoors in another house with the index case for at least 30 min within $I_d = 21$ days of onset of symptoms of the index case. The **mean** incubation period of pertussis from two other studies was estimated to be 13 ± 7.6 days and 15.4 ± 1.3 days. Based on this information, Kendrick & Eldering somewhat arbitrarily set the minimum incubation period to $E_1 = 10$ days and the maximum incubation

period to $E_2 = 30$ days. Under the definition of definite exposure, secondary cases were those occurring between $E_1 = 10$ and $I_d + E_2 = 21 + 30 = 51$ days after the onset of symptoms in the index case.

Kendrick & Eldering had a second, less stringent, definition for a potentially infective contact that included outdoor contacts. Based on the observation that between 21 and 35 days after onset of symptoms, throat cultures were less often positive, someone exposed up to $I_i = 35$ days after onset of symptoms in the index case was defined as an indefinite exposure. For indefinite exposures, secondary cases were those occurring between day $E_1 = 10$ and $I_i + E_2 = 35 + 30 = 65$ days after the onset of symptoms of the index case.

The second step in assessing the SAR is to determine for each ascertained case within each household whether it is a co-primary, secondary, tertiary, or higher generation case. The estimated household SAR is the total number of secondary cases in all households divided by the total number of at-risk susceptibles in all households as in (1). Co-primary cases are excluded from the denominator. Tertiary or higher cases are excluded from the numerator but are included in the denominator.

Difficulties in estimating the conventional SAR include determination of the latent, incubation, and infectious periods, ascertainment of onset times of cases, and determining when an exposure to infection has taken place.

Inference

Possible **correlation** of responses among susceptibles exposed to the same infectious source need to be taken into account in making **inferences**. **Generalized estimating equations** (GEES) [15] using a logit model or the nested **bootstrap** [5] can be used for inference when estimating secondary attack rates [4]. The GEE approach is usually the preferred method.

Model-Based Approaches to Estimating SAR

One problem with the conventional SAR is that it does not take into account that susceptibles exposed to the index case could become infected from infectious sources other than the index case. The estimated SAR would be too high if there is a substantial possibility of becoming infected from other sources in the community. An alternative approach is a model for transmission of an infectious disease in a community of households that allows joint estimation of the SAR as well as the probability of becoming infected within the community, CPI, by the end of an outbreak [16]. In this model, the probability that during an outbreak exactly j persons become infected in a household with s susceptibles is

$$\begin{aligned}\pi_{js} &= \binom{s}{j}\pi_{jj}(1-\mathrm{CPI})^{(s-j)} \\ &\quad \times (1-\mathrm{SAR})^{j(s-j)}, \quad 0 \le j < s, \\ \pi_{ss} &= 1 - \sum_{j=0}^{s-1}\pi_{js}, \end{aligned} \tag{3}$$

where the **likelihood** function is the product of the probabilities π_{js}, $j = 0, 1, \ldots, s$, over all the households in the sample. Maximization of the likelihood provides **maximum likelihood** estimates of the SAR as well as the CPI. The advantage of this model over the conventional secondary attack rate method is that it requires only final value data, namely, who is in which household and who becomes infected during the outbreak. Disadvantages include relatively large **standard errors** and strong modeling assumptions.

Similar models have been used by others [2], as well as for estimating the effects of covariates [8, 19], including vaccine efficacy [14, 17, 18]. Another approach to estimation [20] is to use the **EM algorithm** [3] and a **generalized linear model** [21]. A discrete time model has been developed that allows estimation of the SAR from the time of onset data while adjusting for the possibility of infection from outside the household [23]. The disadvantage of the approach is that it requires the user to specify probability distributions for the latent, incubation, and infectious periods. **Chain binomial models** can also be used to estimate the SAR.

Summary

The secondary attack rate is defined as the probability that infection occurs among susceptible persons within a reasonable incubation period following

known contact with an infectious person or other infectious source. It is a key epidemiologic parameter in infectious diseases that are transmitted by contact. It can be estimated using a variety of epidemiologic study designs, models, and methods of estimation. Inference needs to take into account correlation of susceptibles exposed to the same infectious source.

M. ELIZABETH HALLORAN

Segregation Analysis, Classical

To determine the mode of inheritance of a genetic disease (or a trait), dichotomous (affected and unaffected) phenotypic data on members of families are generally collected. Given the phenotypes of parents, the probability of an offspring being affected depends on whether the **gene** responsible for the disease is dominant or recessive. Therefore, inference regarding the mode of inheritance of the disease is possible from an estimate of this probability. Statistical analysis of family data to determine the mode of inheritance is called *segregation analysis*.

The probability of an offspring being affected given parental phenotypes can be estimated from the proportion of affected offspring in a family. Consider, for example, a disease determined by a recessive allele (D) at a single autosomal biallelic locus with alleles D and d. Suppose in a family one parent is affected (**genotype** dd) and the other parent is unaffected (DD or Dd). Let R denote the number of affected offspring and S the total number of offspring in this family. If $R \neq 0$, then the unaffected parent is of genotype Dd. Hence, an estimator of $\theta = \Pr$ (an offspring is affected | parental genotypes) is R/S. θ is called the *segregation probability* or *segregation ratio*. R/S is actually the **maximum likelihood** estimator (MLE) of θ because the likelihood $L_\theta(s, r)$ of the observations $S = s$, $R = r$, conditional on parental genotypes is $\text{bin}(s, \theta)$. If, however, $R = 0$ (a *nonsegregating family*), then the genotype of the unaffected parent cannot be uniquely determined. If the parental mating is d d × DD, then the family is incapable of producing an affected offspring; hence, in this family, $\theta = 0$. Thus, ascertaining a family through the presence of an affected offspring (a *segregating family*) helps uniquely determine the genotypes of both parents for a simple recessive disease. If the disease allele D is dominant, even when the family is ascertained through an affected offspring, the genotypes of both parents cannot be uniquely determined; the affected parent can be of either genotype DD or Dd. If the mating is d d × DD, then the segregation probability is $\theta_1 = 1$. If the mating is d d × Dd, then this probability is $\theta_2 = 1/2$. The **likelihood** for the observations on s offspring of whom $r(\neq 0)$ are affected is a mixture of likelihoods

$$\omega_1 L_{\theta_1}(s, r) + \omega_2 L_{\theta_2}(s, r), \tag{1}$$

where $\omega_1 = \Pr(\text{d d} \times \text{DD} \mid \text{unaffected} \times \text{affected})$ and $\omega_2 = \Pr(\text{d d} \times \text{Dd} \mid \text{unaffected} \times \text{affected})$. ω_1 and ω_2 are functions of the D allele frequency in the population from which the family is drawn.

To avoid the complications arising from a mixture of likelihoods we shall make an assumption that enables unique identification of parental genotypes from parental and offspring phenotypes. *Classical segregation analysis* relates to analysis of such data on offspring for which the likelihood is not a mixture of likelihoods (*see* **Segregation Analysis, Complex**). We shall assume that the probability of the disease-causing allele in the population is low (say, 0.01 or 0.001). Under this assumption, in the example of the autosomal dominant disease given earlier, the parental mating will virtually always be d d × Dd. (For a recessive disease this assumption is not required to identify parental genotypes uniquely.)

For a rare genetic disease, random sampling of families is not a method of choice because all members of most randomly sampled families will be unaffected and hence will provide no information for estimating θ. A commonly used method is to ascertain families through the presence of at least one affected offspring. An affected individual in a family through whom the family can be ascertained is called a *proband*; the *probability of* **ascertainment** of a proband is defined as $\pi = \Pr$ (individual is a proband | individual is affected). Ascertainment can also be made through an affected parent. The dependent nature of familial data and adoption of nonrandom sampling schemes require specialized statistical methodology for analysis of such data. If an appropriate correction for bias of ascertainment (bias due to nonrandom sampling) is not made, the estimate of θ will be positively biased and inference on the mode of inheritance will be incorrect.

Statistical Methodology

Estimation of θ

If R denotes the number of affected offspring in a sibship of size S, then its probability density function

(pdf) is

$$p_\theta(S, r) = \binom{S}{r} \theta^r (1-\theta)^{S-r}, \tag{2}$$

$r = 0, 1, \ldots, S, 0 \le \theta \le 1$. However, if a family is ascertained through an affected offspring, then families with $R = 0$ will be excluded. Let $w(r, \pi)$ denote the probability of ascertaining a family with $R = r$. Hence, the pdf of R in ascertained families will be [10]

$$p^*_\theta(r, \pi, S) = \frac{w(r, \pi) p_\theta(S, r)}{\mathrm{E}[w(R, \pi)]}. \tag{3}$$

In the present case, since each ascertained family has at least one proband [9],

$$w(r, \pi) = 1 - (1-\pi)^r, \tag{4}$$

$$\begin{aligned} \mathrm{E}[w(R, \pi)] &= \sum_{r=1}^{S} w(r, \pi) p_\theta(S, r) \\ &= 1 - (1 - \pi\theta)^S. \end{aligned} \tag{5}$$

If $\pi = 1$, *complete ascertainment*, then $p^*_\theta(r, \pi, S)$ reduces to a truncated bin(S, θ) distribution, truncated at zero. If $\pi \simeq 0$, *single ascertainment*, then $w(r, \pi) \approx r\pi$, and $p^*_\theta(r, \pi, S)$ is a bin$(S-1, \theta)$ distribution.

In practice, ascertained families will have different numbers of offspring, both total and affected. If a_{rs} denotes the observed number of independently ascertained families each with $s(= 1, 2, \ldots, S)$ offspring of whom $r(= 1, 2, \ldots, s)$ are affected, then the joint likelihood for observations on all sibships will be

$$L_s(\theta) = \frac{n_s!}{\prod_{r=1}^{s} a_{rs}!} \prod_{r=1}^{s} [p^*_\theta(r, \pi, s)]^{a_{rs}}, \tag{6}$$

where $n_s = \sum_{r=1}^{s} a_{rs}$. Let $A = \sum_{s=1}^{S} \sum_{r=1}^{s} r a_{rs} =$ observed total number of affected offspring in all families. Then, it is easy to show [4] that the MLE of θ is obtained iteratively from the equation

$$\frac{A}{\theta} = \sum_{s=1}^{S} \frac{[1 - (1-\pi)(1-\pi\theta)^{s-1}] s n_s}{1 - (1 - \pi\theta)^s}, \tag{7}$$

where $\pi \in (0, 1]$ is assumed to be known. For $\pi \simeq 0$, an explicit solution of θ is easily obtained as

$$\hat{\theta} = \frac{A - N}{T - N}, \tag{8}$$

where $N = \sum_{s=1}^{S} n_s =$ total number of ascertained families, and $T = \sum_{s=1}^{S} s n_s =$ total number of offspring in all ascertained families. For $\pi = 1$, (7) reduces to

$$\frac{A}{N} = \sum_{s=1}^{S} \frac{s n_s}{1 - (1-\theta)^s}. \tag{9}$$

We note that the value of π may be unknown and may need to be estimated simultaneously with θ. The maximum likelihood estimation procedure, score vectors and **information matrices** are derived in [2] and [4] for both cases, π known and unknown. (See, however, some corrections in [1].) A simpler and computationally more efficient method of estimating θ (or, θ and π) using the **EM algorithm** is given in [1].

While for a rare recessive disease both parents in most families will be unaffected, for a relatively common disease at least one of the two parents may be affected, and thus families can be ascertained through an affected parent. If the disease is recessive, then to identify the genotype of the unaffected parent uniquely, we restrict ourselves to data on only those families in which there is at least one affected offspring. Then, the pdf of R (= number of affected offspring) in a sibship of size S will be

$$p_\theta(S, r | r > 0) = \frac{\binom{S}{r} \theta^r (1-\theta)^{S-r}}{1 - (1-\theta)^S}, \tag{10}$$

$r = 1, 2, \ldots, S$, which is identical to the pdf [truncated bin(S, θ) distribution] for complete ascertainment through offspring.

If the disease is dominant, then instead of analyzing data on affected persons, we can analyze data on unaffected persons, which is a recessive trait.

Thus, simple segregation analysis for families with at least one recessive offspring ascertained through an affected parent is the same as that for complete ascertainment through offspring.

Hypothesis Testing

In classical segregation analysis, we generally wish to test whether a disease is dominant or recessive. This **null hypothesis** $\mathrm{H}_0 : \theta = \theta_0$ is easily framed, because θ_0 is known for a specific parental genotypic mating under a model. For example, if the disease is

recessive, we know that in Dd × Dd families, $\theta_0 = 1/4$. Thus, from unaffected × unaffected families each ascertained through an affected offspring, we can obtain $\hat{\theta}$ and calculate the test statistic

$$X^2 = \frac{(\hat{\theta} - \theta_0)^2}{V(\theta_0)}, \tag{11}$$

where $V(\theta_0)$ is the variance of θ evaluated at θ_0. X^2 follows a **chi-square distribution** with 1 df.

Efficient Approximate Methods

For complete ascertainment ($\pi = 1$), Li & Mantel [8] suggested a simple method, the *singles method*. The estimator of θ is

$$\hat{\theta}_{\mathrm{LM}} = \frac{A - J_1}{T - J_1}, \tag{12}$$

where J_1 denotes the number of families with only one affected offspring. Gart [6], who independently proposed the method, has shown that $\hat{\theta}_{\mathrm{LM}}$ is almost fully efficient as the MLE for all realistic values of S.

It may be noted that for single ascertainment ($\pi \simeq 0$), Weinberg [11] proposed a method, the *proband method*, and derived the simple estimator given by (8), which was shown to be the MLE by Haldane [7].

For *incomplete ascertainment* ($0 < \pi < 1$), Weinberg [12] had initially suggested an estimator that was modified by Fisher [5]. However, Davie [3] showed that these estimators are not very efficient and proposed another estimator which he showed to be very efficient at all levels of ascertainment. This estimator is

$$\hat{\theta}_{\mathrm{D}} = \frac{R - J}{T - J}, \tag{13}$$

where J denotes the number of families having exactly one proband. Not only does $\hat{\theta}_{\mathrm{D}}$ becomes identical to $\hat{\theta}_{\mathrm{LM}}$ for complete ascertainment and to $\hat{\theta}$ of (8) for single ascertainment, the large sample variance of $\hat{\theta}_{\mathrm{D}}$ also becomes identical to the variances of the corresponding estimates at these two extremes of ascertainment.

PARTHA P. MAJUMDER

Segregation Analysis, Complex

Complex segregation analysis refers to a statistical genetic method that focuses on the detection and characterization of the unobserved **genes** that influence phenotypic variation. It was originally termed "complex" because, unlike **"classical" segregation analysis**, it considers the situation in which more than one mating type is possible for a given sibship, thus requiring summation over mating types in the **likelihood** [19]. The adjective "complex" is equally appropriate because the phenotypes that it considers have multiple determinants (e.g. multiple loci, environmental factors, etc.). Mendel first discovered the transmission laws that bear his name by the examination of continuous characters of pea morphology (*see* **Mendel's Laws**). He was fortunate that the underlying **genotypic** distributions were essentially nonoverlapping and thus could easily be discretized in a biologically meaningful way and that the leading factors determining them were simple two-allele **polymorphisms**. However, for most characters, the form of inheritance is more elaborate. Multiple genes interact to influence most traits of relevance to biomedicine. Additionally, most of the physiological characters that are important in normal and pathological variation are also influenced by the environment. Ultimately, genes and environment interact (*see* **Gene-environment Interaction**) to determine the phenotype.

The primary goal of modern **human genetics** is to disentangle this complex web of interacting variables and to determine the role of genetic variation in health and disease. Most of the genes influencing complex phenotypes exhibit small effects, although in aggregate their joint effect may be large. However, it is clear that some of the genes influencing phenotypic variation have moderate to large effects and that the signal of their Mendelian transmission pattern may be seen in the examination of variation within and between families. It is the goal of segregation analysis to detect these leading genetic factors and to provide statistical descriptions of their essential features. The formal application of complex segregation analysis is used to infer the inheritance model for a trait and to provide estimates of the underlying genetic parameters. Most often, complex segregation analysis is used in an attempt to determine whether the transmission pattern of a phenotype within a family is consistent with Mendelian expectations (*see* **Genetic Transition Probabilities**). The basic strategy of complex segregation analysis is to fit a series of inheritance models, including nongenetic models, to family data, and then to select the model that best explains the observed data.

There are three basic models of genetic inheritance. Their distinctions are largely quantitative, yet inexact. When a phenotype is dominated by the effects of a single locus, and there is no evidence for any residual genetic effects, the inheritance pattern is called monogenic. If the trait in question is influenced by a few loci, then the inheritance is said to be oligogenic. Finally, when the trait is influenced by a large number of loci each with small effects, we have **polygenic inheritance**. In our search to elucidate the genetic architecture of complex phenotypes, we are primarily interested in finding large genetic effects due to specific loci. Therefore, for those traits whose inheritance pattern is monogenic or oligogenic, we hope to be able to characterize the primary loci influencing observed phenotypic variability.

The methods of complex segregation analysis are used to analyze many different types of phenotypes from continuous characters to meristic traits to discrete phenotypic states, although some latent continuous distribution is usually associated with discrete traits. In the following, we primarily focus on the analysis of continuous traits (*see* **Genetic Liability Model** for discrete traits).

The Model

In this Section, the basic model utilized in complex segregation analysis of quantitative traits is described. Table 1 presents the definition of the canonical parameters of quantitative trait segregation analysis to be explicated. The reader should bear in mind that there are many equivalent alternative parameterizations.

Modeling the Genotype

Since the goal of segregation analysis is to determine whether or not there is sufficient evidence for the effects of a specific locus influencing variation in a trait, it is necessary to consider more general alternative models in which mixtures of environmental

Table 1 Basic parameters of complex segregation analysis for a quantitative trait

Parameter	Definition
p_A	Frequency of A allele (factor)
$\mu_{AA}, \mu_{Aa}, \mu_{aa}$	Genotypic (ousiotypic) means
h_r^2	Residual heritability
σ_r	Residual phenotypic standard deviation
$\tau_{AA}, \tau_{Aa}, \tau_{aa}$	Transmission probabilities

origin are allowed. In most applications of complex segregation analysis, the number of components in the mixture distribution is limited to three. These three distributions can be related to unobservable genotypes or, more generally, ousiotypes [13], with or without genetic inheritance.

Ousiotypes are the product of two discrete factors, A or a. Upper case letters (e.g. A) represent factors associated with lower levels of the quantitative trait, and lower case letters represent factors associated with higher levels. The three genotypes can be denoted as AA, Aa, and aa. To simplify computations, the frequencies of the genotypes are usually assumed to follow **Hardy–Weinberg** proportions $\boldsymbol{\psi} = [\psi_{AA}, \psi_{Aa}, \psi_{aa}]' = [p_A^2, 2p_A(1-p_A), (1-p_A)^2]'$, where p_A is the frequency of the A factor (allele); thus only one **admixture** parameter (p_A) is required. The elements of $\boldsymbol{\psi}$ provide the probabilities that an individual in the founding (i.e. parental) population has a particular genotype. As an alternative parameterization, frequencies of genotypes can be directly estimated, requiring two parameters (ψ_{AA}, and ψ_{Aa}, since $\psi_{aa} = 1 - \psi_{AA} - \psi_{Aa}$). This relaxation of the Hardy–Weinberg equilibrium assumption may be more appropriate in populations where we know that random mating does not hold (e.g. small isolated populations). Regardless, it is assumed that the probability of a mating between two individuals with genotypes ij and kl, respectively, is simply $\psi_{ij}\psi_{kl}$ [20].

Modeling Transmission of the Genotype

The focal source of nonindependence among relatives in complex segregation analysis is due to the transmission of factors (alleles) between generations from parents to offspring. Mendelian segregation provides a decidedly nonrandom and systematic form of transmission that is unlikely to be mimicked by environmental agents. Therefore, in the absence of having a directly measurable genotype, the inference that a gene is influencing a particular phenotype is based on testing whether the observed pattern of phenotypic variation within families is consistent with Mendelian transmission. If there is no transmission, then there is no nonindependence due to the genotype and offspring genotypes will not be a function of parental genotypes. All of the essential features of genotype transmission are contained in a set of probabilities that are a function of a vector of arbitrary transmission parameters written as $\boldsymbol{\tau} = (\tau_{AA}, \tau_{Aa}, \tau_{aa})'$, whose elements denote the probability that an individual of a given genotype transmits factor "A" to an offspring [22]. Conversely, the probability of transmitting factor "a" is given by $\mathbf{1} - \boldsymbol{\tau}$. When Mendelian transmission holds, $\boldsymbol{\tau} = (1, 1/2, 0)$. With these three basic parameters, all of the **genetic transition probabilities** for offspring can be obtained. For the $m^2 = 9$ possible mating types, we can obtain the 9×3 matrix of probabilities for offspring genotypes by

$$\mathbf{T} = \begin{bmatrix} \boldsymbol{\tau} \otimes \boldsymbol{\tau} \\ \boldsymbol{\tau} \otimes (\mathbf{1} - \boldsymbol{\tau}) + (\mathbf{1} - \boldsymbol{\tau}) \otimes \boldsymbol{\tau} \\ (\mathbf{1} - \boldsymbol{\tau}) \otimes (\mathbf{1} - \boldsymbol{\tau}) \end{bmatrix}', \qquad (1)$$

where $\otimes$ is a Kronecker product operator.

Modeling the Phenotype

The phenotype of an individual is usually assumed to be a linear function of a set of **fixed effects** and **random effects**. Under the **mixed model**, which includes both a major factor and a residual polygenic component [22, 36, 38], the phenotype of the jth individual with genotype i is

$$(y_j | o_j = i) = \mu_i + g_j + \boldsymbol{\beta}'(\mathbf{x}_j - \mathbf{s}) + e_j, \qquad (2)$$

where o is the genotype, $\mu_i (i = AA, Aa, aa)$ is the mean associated with the ith genotype, and $\mathbf{x}_j$ is the jth individual's vector of **covariates** (i.e. the jth row of $\mathbf{X}$) scaled to some baseline $\mathbf{s}$. In this model, the genotype represents an unobservable discrete random effect and the covariates represent fixed effects. The g and e terms represent random effects, with g being an additive polygenotypic effect and e being a random environmental deviation or random error. Assuming that $E(g) = E(e) = 0$, the expectation of (2) is

$$E(y_j | o_j = i) = \mu_i + \boldsymbol{\beta}'(\mathbf{x}_j - \mathbf{s}). \qquad (3)$$

It is generally assumed that the random effects g and e are **normally distributed** so that the polygenotypic effect can be thought of as the cumulative sum of additive genetic effects at a large number of loci [25]. It is also assumed that the two random factors are independent so that $\text{cov}(g, e) = 0$. Thus, there is no genotype–environment correlation. Following these assumptions, the conditional variance of the y is written as

$$\text{var}(y_j|o_j = i) = \sigma_g^2 + \sigma_e^2. \tag{4}$$

The genetic component (σ_g^2) of the conditional variance given in (4) represents the residual additive genetic variance. This residual polygenic component is useful to absorb genetic effects other than the potential major locus. Residual nonindependence among relatives due to biological kinship is allowed by including this genetic component (*see* **Genetic Correlations and Covariances**), the residual **heritability** parameter (h_r^2) refers to the proportion of phenotypic variance due to additive genetic variance within each genotype's phenotypic distribution, and $\sigma_r = (\sigma_e^2 + \sigma_g^2)^{1/2}$ is the within-genotype standard deviation. Therefore, the proportion of phenotypic variance attributable to random environmental variation within genotypes is given by $1 - h_r^2$.

Since g and e are assumed to be normally distributed and the convolution of two normal densities is again normal, the conditional density of y is normal. This density is also known as the **penetrance** function in genetic terminology. It provides the probability density for having a specific phenotypic value given a specific genotype.

The unconditional variance of y has an additional variance component attributable to the effect of the major factor:

$$\text{var}(y) = \sigma_o^2 + \sigma_g^2 + \sigma_e^2, \tag{5}$$

where $\sigma_o^2 = \sum \psi_i(\mu_i - \sum \psi_i \mu_i)^2$ is the variance due to the major factor (locus), so that the relative proportion of phenotypic variance (after controlling for covariates) that is due to the major factor is $h_o^2 = \sigma_o^2/(\sigma_o^2 + \sigma_g^2 + \sigma_e^2)$. If a gene is the source of this genotypic variation, then h_o^2 is the heritability due to this gene. Generally, if the relative variance due to a locus is approximately 15% or larger, then it is termed a major gene. However, rare alleles with large displacements (i.e. the difference between the means of contrasting genotypes) of several standard deviations (so-called megaphenic effects) may also be called major genes, regardless of their relative importance at the population level.

The Likelihood

The three basic parts of the model outlined above provide the necessary components for developing the likelihood function of a phenotypic vector in a group of relatives. Generally, the term pedigree can be used for any set of biologically related individuals and their mates. Useful pedigrees for segregation analysis may be as simple as nuclear families or as complex as multigenerational extended kindreds. The key relationship in segregation analysis is that of parent–offspring, which is the fount of information regarding Mendelian segregation. As multiple generations are added, segregations can be followed further down the descendent chain, thus improving the ability to detect Mendelian transmission. In this Section, the general form of the likelihood for a pedigree of arbitrary size and complexity is described.

Joint Density Function of Genotypes and Quantitative Phenotypes

Let $\mathbf{O}$ denote the $n \times 3^n$ matrix containing all possible genotypic combinations for a given pedigree of size n. Given a vector of genotypes $\mathbf{o}_j$ (which denotes the jth column of the $\mathbf{O}$ matrix), the joint probability density of genotypes and quantitative phenotypes can be written as

$$f(\mathbf{o}_j, \mathbf{y}) = f(\mathbf{o}_j) f(\mathbf{y}|\mathbf{o}_j). \tag{6}$$

The first factor on the right-hand side of (6) gives the probability of observing the genotypic vector. This probability is a function of the frequency of the major factors (alleles) and the transmission probabilities, and is written

$$f(\mathbf{o}_j) = \prod_{i=1}^{n_F} \psi_{o_{ij}} \prod_{k=n_F+1}^{n} \Pr(o_{kj}|o_{fj}, o_{mj}, \boldsymbol{\tau}). \tag{7}$$

In (7), $\psi_{o_{ij}}$ is the probability of observing the genotype of individual i, which is equal to the population frequency of the genotype. The term $\Pr(o_{kj}|o_{fj}, o_{mj}, \boldsymbol{\tau})$ is the probability of an individual exhibiting genotype k given his father's and mother's genotypes, which is simply the appropriate element

of the **T** matrix obtained in (1). The first product in (7) is over the n_F founders (individuals whose parents are not represented in the pedigree), while the second product is over the $n - n_F$ nonfounders. Eq. (7) shows that the probability of the genotypic vector can be decomposed into a series of univariate densities, one for each individual. This is possible because of the **Markov** pattern of dependence in which the genotype of the individual depends at most on those of his/her parents.

The second factor on the right-hand side of (6) is the conditional density of **y** given the genotypic vector, and is assumed to take the following **multivariate normal** form:

$$f(\mathbf{y}|\mathbf{o}_j) = 2\pi^{-n/2}|\boldsymbol{\Omega}|^{-1/2} \times \exp\left[-\frac{1}{2}(\mathbf{y} - \mathbf{Z}_j\boldsymbol{\mu})'\boldsymbol{\Omega}^{-1}(\mathbf{y} - \mathbf{Z}_j\boldsymbol{\mu})\right], \quad (8)$$

where $\mathbf{Z}_j$ is an $n \times 3$ indicator matrix whose ith row is $[\delta_{AA}, \delta_{Aa}, \delta_{aa}]$, with δ_{kl} equal to 1 only if the ith individual has genotype kl and equal to 0 otherwise. In the above density, the phenotypic **covariance matrix** of **y** conditional on knowledge of $\mathbf{o}_j$ is $\boldsymbol{\Omega}$. For the standard mixed model, this residual phenotypic covariance matrix for the pedigree can be written by

$$\text{var}(\mathbf{y}|\mathbf{o}_j) = \boldsymbol{\Omega}, \quad (9)$$

$$= 2\boldsymbol{\Phi}h_r^2\sigma_r^2 + \mathbf{I}_n(1 - h_r^2)\sigma_r^2, \quad (10)$$

where $\boldsymbol{\Phi}$ is a matrix whose ijth element is twice the coefficient of kinship between members i and j (*see* **Inbreeding**), and $\mathbf{I}_n$ is an $n \times n$ identity matrix.

From the conditional joint density in (6), we can now write the likelihood function for a pedigree as

$$L(\boldsymbol{\mu}, \sigma_r, h_r^2, p_A, \boldsymbol{\tau}|\mathbf{y}, \mathbf{O}) = f(\mathbf{O}, \mathbf{y}) \quad (11)$$

$$= \sum_{j=1}^{3^n} f(\mathbf{o}_j) f(\mathbf{y}|\mathbf{o}_j), \quad (12)$$

where the summation is over all possible genotypic vectors. Eq. (12) shows that the underlying distribution of the quantitative trait is made up of a mixture of multivariate normal distributions. It also shows that the model allows for statistical nonindependence among pedigree members due to both the transmission of the oligogenes and the residual polygenic background. The practical utility of the above exact likelihood formulation is rather limited since it requires repeated inversions of the potentially large $n \times n$ matrix, $\boldsymbol{\Omega}$, and the evaluation of all 3^n possible multivariate conditional likelihoods. For large pedigrees, such a direct approach is likely to be intractable. For example, a moderately sized human pedigree with 20 members requires the evaluation of approximately 3.5 billion genotypic vectors. Therefore, for practical applications, it is necessary to consider some algorithmic improvements and likelihood approximations.

Calculating the Likelihood: Approximations and Alternatives

The model presented above poses formidable computational difficulties. A great deal of research has been oriented towards reducing this burden. A number of recursive algorithms, alternative model and likelihood formulations, and likelihood approximations have been suggested [5, 7–9, 17, 22–24, 26–29, 31, 42] (*see* **Elston–Stewart Algorithm** for a discussion of probability calculations on pedigrees).

Approximating the Mixed Model Likelihood

When there is a residual polygenic component, it is impossible to write the likelihood in a simple form. We can write the density of y given by (11) and (8) as

$$f(\mathbf{O}, Y) = \sum_{o_1}\sum_{o_2}\cdots\sum_{o_n}\prod_{i=1}^{n_F}\psi_{o_{ij}}\prod_{k=n_F+1}^{n}\Pr(o_{kj}|o_{fj}, o_{mj}, \boldsymbol{\tau}) \times 2\pi^{-1/2}|\boldsymbol{\Omega}|^{-1/2}\prod_{i=1}^{n}\exp\left[-\frac{\omega^{ii}}{2}(y_i - \mu_{o_i})^2\right] \times \prod_{i=1}^{n-1}\prod_{j=j+1}^{n}\exp\left[-\omega^{ij}(y_i - \mu_{o_i})(y_j - \mu_{o_j})\right],$$

where ω^{ij} is the ijth element of the inverse of the residual covariance matrix $\boldsymbol{\Omega}$ [24, 28]. The complexity lies in the cross-product terms since there will not be complete knowledge of the genotype for both members of any relative pair, other than parent–offspring and spousal pairs, during the appropriate step in the peeling process. There is no simple solution to this problem. Therefore, in practice, approximation is employed to reduce computations.

While this density can also be written in integral form [5, 22, 23, 27], most approximations implicitly involve weighting the cross-product terms using the current approximate probabilities of genotypes [17, 27, 28].

Alternative Formulations

There are several alternative formulations of the mixed model (if we define the mixed model loosely as any model allowing both focal genotypic and residual genetic effects). One option is to employ residual genotypic effects directly. For example, Morton [35, 37] has argued for absorbing residual genetic variation using an oligogenic model incorporating a second locus with two alleles. Although this is a crude approximation to a residual polygenic component, it will tend to absorb much of the residual genetic variation. Additionally, the likelihood of such a model can be calculated exactly and rapidly. Other available alternatives include the finite polygenic mixed model (*see* **Polygenic Inheritance**) and the **regressive models**.

A disadvantage of all of these alternatives is that they lack the potential generality that is implicit in the **variance component** form of the likelihood. This variance component model can be extended easily to allow additional variance components [23, 28] and complexities such as genotype × environment interaction [3] that can lead to violation of the assumptions regarding conditional independence among relatives given parental genotypes.

Likelihood Corrections for Nonrandom Ascertainment of Pedigrees

The likelihood framework sketched above is only appropriate when pedigrees have been ascertained randomly (i.e. sampled without regard to particular phenotypic configurations). Typically, when dealing with diseases that may be rare, it is necessary to sample pedigrees nonrandomly so that they are enriched for the disease or for higher (or lower) values of a quantitative phenotype that is a concomitant of the disease. In such cases, the sampling mechanism by which the selection of a pedigree has occurred needs to be taken into account by the likelihood model. If nonrandom ascertainment is ignored, then the estimation of some of the parameters may be severely **biased**. This is particularly true for allele frequencies and relative variance components due to genetic factors. Therefore, ascertainment corrections to the likelihood typically require that the selection mechanism be known (*see* **Ascertainment**; **Pedigrees, Sequential Sampling** for a more detailed discussion).

Estimation

Maximum Likelihood Estimation

Given that the likelihood can be calculated exactly or approximately, estimates of the parameters of complex segregation analysis are usually obtained by the standard **maximum likelihood** method. Maximization of such a complicated likelihood represents a considerable numerical problem, with the primary difficulty being the high probability of observing multiple maxima (a problem associated with finite mixture models in general). One approach to this problem is to search the likelihood surface for all existing maxima by using random initial parameter estimates in a **Monte Carlo** procedure [1]. While we are primarily interested in the global maximum, sometimes local maxima appear to supply important additional information about the underlying genetic model [1, 4, 6].

Markov Chain Monte Carlo Estimation

One relatively recent approach to parameter estimation in complex segregation analysis involves the use of **Markov chain Monte Carlo** (MCMC) methods [26]. In this approach, the latent genotypes and polygenotypes are imputed conditional upon the phenotypic information and current parameter values using a Monte Carlo **algorithm**. After this "missing" information is completely filled in for a pedigree, estimation using the augmented data is straightforward since it utilizes closed-form estimators. The process is iterated until convergence. The strength of this method is that it can accommodate models of great complexity in which it would be difficult, if not impossible, to calculate the likelihood directly. The MCMC approach, therefore, opens the door for the application of more realistic models in segregation analysis. Also, this method allows the possibility of performing **Bayesian** estimation and inference, if reasonable functional forms for the **prior distributions** of the parameters can be specified [43]. Using this method, it is also possible either

to estimate **likelihood ratio test** statistics to compare models [44] or alternatively to estimate the likelihood directly [43].

Estimation Using Generalized Estimating Equations

Another recent approach to parameter estimation in complex segregation analysis involves the application of **generalized estimating equations** (GEE) [33, 46–48]. This method of estimation makes fewer assumptions about the distributional form that the mixture of genotypes takes and therefore may be more **robust**. It involves the estimation of parameters using the first few **moments** of the observed distribution by relating observed estimates of moments to those expected under the model. A set of potentially high-dimensional linear equations are solved to obtain estimates of the parameters. It has been shown that evaluation of the first four moments is required to achieve statistical identification of the parameters of the mixed model [48]. Since these moments involve all possible tricovariances and quadricovariances within pedigrees, the dimension of the matrices requiring inversion increases nonlinearly as pedigree size is increased.

Comparing Models of Inheritance

Competing Transmission Models

In practice, complex segregation analysis involves the evaluation of several possible models of inheritance and their comparison with a general model in which transmission of the genotype is allowed to take an arbitrary form (i.e. the transmission probability parameters ($\boldsymbol{\tau}$) are allowed to vary freely). Each of the models to be compared to the general model represents a nested submodel of the general model.

Several classes of restricted models can be tested against the most general model using the unified approach of Lalouel et al. [32]. The simplest models generally considered include sporadic models which allow only random environmental effects. In this type of model, all individual trait values are independent of one another. Therefore, there are no genetic factors acting on the trait.

When multiple distributions are considered, a sporadic model becomes a simple finite mixture (or **commingling**) model. It is obtained by forcing the admixture parameter (p_A) to equal the transmission parameters ($p_A = \tau_{AA} = \tau_{Aa} = \tau_{aa}$). This transmission model preserves the assumption of equilibrium since the expected genotypic frequencies do not change from generation to generation. By allowing p_A to vary independently of the τs, this model permits heterogeneity of mixture proportions between generations.

A closely related class of model, the environmental transmission model, assumes random environmental effects for major factors, but also permits residual polygenic inheritance (i.e. it is a finite mixture model extended to allow nonindependence due to genetic kinship among individuals). Again, two different constraints on the transmission probabilities are possible: $p_A = \tau_{AA} = \tau_{Aa} = \tau_{aa}$ or $p_A \neq (\tau_{AA} = \tau_{Aa} = \tau_{aa})$, depending on whether it is decided to force equilibrium between generations. A model with only one underlying phenotypic distribution allowing for a polygenic component of variation reduces to the classical additive polygenic model of quantitative genetics.

The Mendelian models considered incorporate transmission probabilities fixed at their Mendelian expectations ($\tau_{AA} = 1, \tau_{Aa} = 1/2, \tau_{aa} = 0$). Mixed Mendelian models additionally allow for a residual polygenic background. Subsets of Mendelian models include: (i) additive models in which the allelic effects act additively to determine the mean of a genotype ($\mu_{Aa} = [\mu_{AA} + \mu_{aa}]/2$); (ii) recessive models in which the "a" allele is recessive, leading to $\mu_{AA} = \mu_{Aa}$; and (iii) dominant models in which the "a" allele is dominant so that $\mu_{Aa} = \mu_{aa}$. Analogous constraints on the genotypic means can be made for both the environmental and general models.

One potential problem with the general model is that it does not necessarily preserve the equilibrium between generations [16]. While this provides some flexibility with regard to model fitting, it may not always be biologically relevant. Therefore, if it is desirable to maintain the assumption of equilibrium, then the following nonlinear constraint can be placed on the transmission probability for the heterozygote:

$$\tau_{Aa} = \frac{p_A - p_A^2\tau_{AA} - (1 - p_A)^2\tau_{aa}}{2p_A(1 - p_A)}. \qquad (13)$$

Likelihood Ratio Tests

Depending upon the availability of a sufficient data structure, all parameters can be estimated by

numerical maximization of the likelihood for the data given the assumed transmission model. Model comparison is usually performed using likelihood ratio tests in which the test statistic is defined by

$$\Lambda = 2\left[\text{Sup}\ln L(\hat{\theta}_{H_0+H_A}|\mathbf{y}) - \text{Sup}\ln L(\hat{\theta}_{H_0}|\mathbf{y})\right],$$

where $\hat{\theta}_{H_A+H_0}$ refers to the maximum likelihood parameter estimates under the alternative hypothesis, and $\hat{\theta}_{H_0}$ refers to the estimates under the **null hypothesis**. This test statistic is simply twice the difference between the $\log_e$ likelihoods of the unrestricted and restricted models. In some cases, these test statistics are asymptotically distributed as **chi-square** variates with degrees of freedom equal to the difference in the number of parameters between the two competing models. However, for the main contrast that we are interested in, that of the general transmission model ($\hat{\tau}_{AA}, \hat{\tau}_{Aa}, \hat{\tau}_{aa}$) against the Mendelian mixed model ($\tau_{AA} = 1, \tau_{Aa} = 1/2, \tau_{aa} = 0$), two of the constrained transmission parameters of H_0 fall on a boundary of the parameter space, $\tau_{AA} = 1$ and $\tau_{aa} = 0$. The resulting Λ is not distributed as a χ^2 variable but as a complex mixture of χ^2 distributions [15, 41]. If the comparison involves the equilibrium-constrained general model in which τ_{Aa} is estimated by (13), then $\Lambda \sim \frac{1}{4} + \frac{1}{2}\chi_1^2 + \frac{1}{4}\chi_2^2$ and the ***P* value** can be calculated easily [41].

Inferring the Presence of a Major Gene

The inference that a major gene is influencing a trait requires the sequential elimination of a number of competing hypotheses. When compared against the general transmission model, each of the nested submodels (e.g. the sporadic model, the polygenic model, and the environmental model) should be rejected, while the Mendelian mixed model should not exhibit a significantly worse likelihood than the general transmission model. Rejection of the environmental model is particularly important since such a test effectively guards against simple distributional **skewness** being interpreted as a major gene effect. This conservative testing framework protects against spurious findings of major loci but unfortunately tends to lead to diminished **power** to detect major genes [11, 12].

Comparing Nonnested Inheritance Models

Sometimes it is useful to compare pairs of nonnested models. In this case, there is no asymptotic theory for the distribution of the likelihood ratio test. Generally, when nonnested models must be compared, **Akaike's criterion** (AIC) can be used to choose the most parsimonious model, or the distribution of the likelihood ratio test statistic found empirically using a Monte Carlo procedure such as the parametric **bootstrap** [40].

Extensions of Complex Segregation Analysis

Genotype-Specific Regressions and Genotype × Environment Interaction

The model for the phenotype given in (2) contains a number of simplifying assumptions that can be removed. For example, different genotypes may exhibit different relationships with covariates. A number of authors have used genotype-specific **regressions** on covariates to model genotype–environment interaction [3, 18, 30, 34, 39]. Under the genotype-specific regression model, the phenotype of the jth individual (with genotype $o_j = i$) is given by

$$(y_j|o_j = i) = \mu_i + g_j + \boldsymbol{\beta}_i'(\mathbf{x}_j - \mathbf{s}) + e_j, \qquad (14)$$

where the vector of regression coefficients $\boldsymbol{\beta}_i$ is now a function of the major genotype. The conditional variance of y in this model is the same as that in (4). The unconditional variance has an additional component due to this **interaction** and is given by

$$\text{var}(y) = \sigma_o^2 + \sigma_{o\times c}^2 + \sigma_e^2 + \sigma_g^2, \qquad (15)$$

where $\sigma_{o\times c}^2$ denotes the variance due to major genotype by covariate interaction. Tests of heterogeneity of these effects among genotypes can be performed using likelihood ratio statistics. The test of $\beta_{AA} = \beta_{Aa} = \beta_{aa}$ is a direct test of genotype × environment interaction. Rejecting this null hypothesis leads to the inference that there is a major locus component in the response of the phenotype to the environment [3]. However, to safeguard against falsely inferring the presence of genotype × environment, it is necessary to also consider tests of polygenotype × environment interaction [3]. These latter tests require application of the fully general variance component model. Ignoring genotype × environment interaction may severely compromise the ability to detect major loci [3, 30, 45].

Two-Locus Models

The model can also be extended to allow two latent factors yielding two sets of genotypes/genotypes. If we assume (or have determined statistically) that both factors represent genetic loci, we can also allow these two genotypes to exhibit epistasis (i.e. the two loci need not have additive effects on genotypic means). The phenotype of an individual can be modeled as a function of both loci (o_A and o_B) as

$$(y_j|o_{Aj} = i, o_{Bj} = k) = \mu_{ik} + g_j + \boldsymbol{\beta}'(\mathbf{x}_j - \mathbf{s}) + e_j, \tag{16}$$

where μ is now a function of both loci and $k =$ BB, Bb, bb at the second locus. For two loci, the unconditional variance of y is given by

$$\text{var}(y) = \sigma^2_{oA} + \sigma^2_{oB} + \sigma^2_{oA\times oB} + \sigma^2_g + \sigma^2_e, \tag{17}$$

where $\sigma^2_{oA\times oB}$ is the variance due to the interaction (i.e. epistasis) between the two loci.

A reparameterization of the two-locus means allows direct tests of epistasis [6]. We can classify a number of mean effect models into two categories (epistatic vs. additive) which are based on how the two-locus genotypes map to phenotypes. To simplify interpretation, we define the mean genotypic vector as

$$\begin{bmatrix} \mu_{AABB} \\ \mu_{AABb} \\ \mu_{AAbb} \\ \mu_{AaBB} \\ \mu_{AaBb} \\ \mu_{Aabb} \\ \mu_{aaBB} \\ \mu_{aaBb} \\ \mu_{aabb} \end{bmatrix} = \begin{bmatrix} 1 & -1 & -1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & -1 & 0 & 1 & 0 & 0 \\ 1 & -1 & -1 & 0 & 0 & -1 & 0 & 0 & 0 \\ 1 & 0 & -1 & -1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & -1 & -1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & -1 & 0 & 0 & 0 & -1 & 0 \\ 1 & 1 & -1 & 0 & 0 & -1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & -1 & 0 & -1 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix} \times \begin{bmatrix} m \\ a_A \\ a_B \\ d_A \\ d_B \\ aa_{AB} \\ ad_{AB} \\ ad_{BA} \\ dd_{AB} \end{bmatrix}, \tag{18}$$

or, in matrix notation, as

$$\boldsymbol{\mu} = \mathbf{D}\boldsymbol{\gamma},$$

where $\boldsymbol{\mu}$ is the vector of genotypic means, $\mathbf{D}$ is a design matrix, and $\boldsymbol{\gamma}$ is the vector of two-locus effects. The backtransformation is given by

$$\boldsymbol{\gamma} = \mathbf{D}^{-1}\boldsymbol{\mu}.$$

The components of $\boldsymbol{\gamma}$ have simple interpretations based on gene action. The parameter m represents the unweighted mean of the four double homozygotes and serves as a baseline component of all nine two-locus genotypes. The parameters a_A and a_B represent the additive genetic effects of the A and B loci, respectively. Similarly, d_A and d_B are defined as locus-specific dominance effects. The remaining parameters represent different forms of epistatic interactions. The aa_{AB} term is a digenic additive $\times$ additive interaction, whereas dd_{AB} represents dominance $\times$ dominance interaction. The terms ad_{AB} and ad_{BA} measure the two possible types of additive $\times$ dominance interactions.

This method of defining two-locus effects permits intuitive specification of a number of hypotheses that can be tested using the likelihood ratio. For example, the null hypothesis of no epistasis (i.e. a model in which effects are additive among loci) can be tested by comparing a model in which the four digenic interaction terms are forced to be zero, with the more general model in which the interactions are estimated.

Multivariate Complex Segregation Analysis

The basic model for the phenotype can be extended to the multivariate case [2, 5, 6, 10, 21]. Multivariate segregation analysis can be used to examine the pleiotropic (multivariate) effects of major loci and polygenes. For t phenotypes, the expected conditional covariance matrix for the ith genotype is given by

$$\begin{aligned} \text{var}(\mathbf{y}_j|o_j = i) &= \mathbf{P}_w \\ &= \mathbf{G} + \mathbf{E}, \end{aligned}$$

where $\mathbf{P}_w$ refers to the $t \times t$ within-genotype phenotypic covariance matrix, $\mathbf{G}$ is the residual additive genetic covariance matrix, and $\mathbf{E}$ is the residual environmental covariance matrix.

For the multivariate mixed model, the total phenotypic covariance matrix is

$$\begin{aligned} \text{var}(\mathbf{y}) &= \mathbf{P}_T \\ &= \mathbf{M} + \mathbf{G} + \mathbf{E}, \end{aligned}$$

where **M** is the genetic covariance matrix due to the major locus. There are general matrix formulas for calculating **M**, **G**, **E**, and other decompositions of $\mathbf{P}_T$ [5]. One fast method for multivariate segregation analysis uses the approximate mixed model of Hasstedt [27] and is based on a simplification of the multivariate likelihood via a transformation that simultaneously orthogonalizes $\mathbf{P}_w$, **G**, and **E**. The transformation makes the traits genetically (for the residual polygenic component) and environmentally uncorrelated. Multivariate conditional likelihoods then reduce to the product of t univariate conditional likelihoods. An alternative **bivariate** approach using the Class D regressive model also is available [2, 7].

Given well-known results from finite mixture distribution theory [14] showing that the asymptotic variance of the estimator of the mixing weights always decreases as the number of traits (showing evidence of the mixture) is increased, multivariate segregation analysis is likely to be more powerful than univariate segregation analysis for detecting major genes. The inclusion of multiple traits, that are influenced by the pleiotropic effects of a major locus, provides additional information on the underlying major locus and leads to increased precision in the estimation of the parameters of major locus transmission.

Discrete Phenotypes

All of the above discussion has been oriented around continuous phenotypes. However, much of the research in genetic epidemiology involves dichotomous traits such as affection status or ordered **polytomous** variables such as discrete indicators of disease severity. Such traits are usually assumed to be the outward indicators of some unknown continuous process. The assumption of an underlying continuous liability makes the analysis of these traits completely analogous to that of quantitative phenotypes (*see* **Genetic Liability Model**).

Examples

Genetics of Thyroxine in Baboons

We recently obtained preliminary evidence for a major gene influencing quantitative variation of circulating levels of the thyroid hormone, thyroxine (T_4), in the baboon. Thyroid hormones influence many aspects of physiology, yet little is known regarding the genetic basis of normal quantitative variability. Total T_4 levels were measured by **radioimmunoassay** in the frozen sera of 248 pedigreed baboons (*Papio hamadryas anubis*). After correcting for sex and age effects, we performed complex segregation analysis on these data.

A number of competing transmission hypotheses were evaluated. A series of models of varying complexity were examined, including: (i) a general model that allows arbitrary transmission probabilities (τs); (ii) a finite mixture model in which there is no transmission of the major factor; (iii) a reduced general model (the free τ_{Aa} model) in which the transmission probability of the Aa heterozygote is allowed to take a non-Mendelian value; (iv) a Mendelian recessive model; (v) a polygenic model in which there is no major factor; and (vi) a sporadic model in which there is no resemblance among relatives. Models incorporating a major factor (gene) were also allowed to exhibit a residual polygenic component. Extensive model comparisons revealed that only two component distributions were required to account adequately for observed variation in baboon T_4. Therefore, only two-distribution models are presented in which the heterozygote mean μ_{Aa} is constrained to be equal to that of the low homozygote, μ_{AA}. The best fitting, most parsimonious, model was chosen as the one that was not significantly different from the fully parameterized most general model and which also exhibited the minimum AIC (a measure of both model parsimony and fit). Table 2 shows the results of this analysis.

Table 2 shows that all models are significantly worse than the general model except for the free τ_{Aa} model and the recessive model. Additionally, the recessive model is not significantly worse fitting than the free τ_{Aa} model ($\Lambda_1 = 1.49$, $P = 0.222$) and also exhibits the minimum AIC value (AIC = 13.54). Therefore, the recessive Mendelian model represents the best-fitting, most parsimonious, model for transmission of quantitative T_4 levels. The recessive model exhibits two distributions. Individuals in the lower one comprise both AA homozygotes and Aa heterozygotes and have a mean T_4 level of 4.50 μg/dl, while aa homozygotes exhibit a mean of 6.58 μg/dl. There was no evidence for a residual polygenic effect ($h_r^2 = 0.000$), and the common within-genotype phenotypic standard deviation was estimated as 1.02.

Table 2 Segregation analysis of thyroxine in 248 baboons: maximum likelihood estimates, AICs, and Λ statistics. Parentheses identify noniterated constrained parameters; brackets denote parameters that are constrained as functions of other parameters

Parameter	General	Environmental	Free τ_{Aa}	Recessive	Polygenic	Sporadic

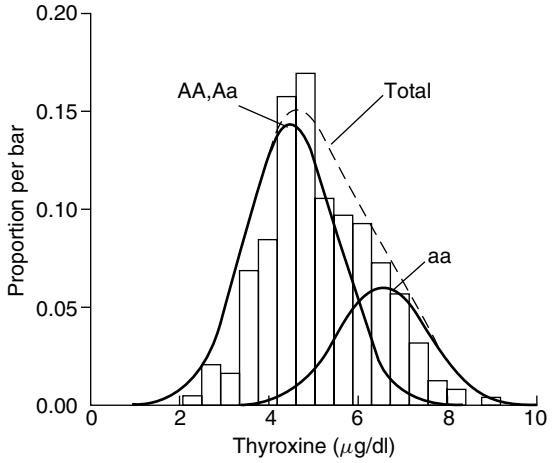

Figure 1 Expected distribution of T_4 given the best fitting major locus model. The bars of the histogram show the observed distribution

The major locus accounted for 47% of the total phenotypic variation in baboon T_4 variation. Figure 1 shows the expected distribution implied by the fitted major locus model against the observed distribution of T_4 concentration.

Analysis of IGF-I in Mexican Americans

The second example of complex segregation analysis involves the analysis of insulin-like growth factor-I (IGF-I) concentrations. IGF-I is an important regulator of cell growth/differentiation and exhibits insulin-like metabolic effects on glucose homeostasis.

Table 3 Segregation analysis of IGF-I in Mexican Americans: model comparisons. Parentheses identify noniterated constrained parameters; brackets denote parameters that are constrained as functions of other parameters

Model	Major factor transmission			Λ	df	P
General	τ_{AA}	$[\tau_{Aa}]$	τ_{aa}	–	–	–
Environmental	$[p_A]$	$[p_A]$	$[p_A]$	7.31	2	0.026
Mendelian	(1)	(1/2)	(0)	0.03	2	0.687
Polygenic	–	–	–	106.23	10	<0.001
Sporadic	–	–	–	113.36	11	<0.001

Serum levels of IGF-I decrease markedly with age and are partly regulated by nutritional factors such as protein intake. To understand better the role of genes and genotype × environment interaction in the determination of normal IGF-I variation, we measured IGF-I serum levels in 422 Mexican Americans distributed in 24 pedigrees. Information on dietary intake was obtained for each individual using a food frequency questionnaire (*see* **Nutritional Exposure Measures**). Using an extension of segregation analysis that allows for genotype × environment interaction [3], we found evidence for the effect of a major gene influencing IGF-I levels. Table 3 shows the results of the comparisons among competing transmission models. For this analysis, the equilibrium-constrained general model was used in which τ_{Aa} is given by (13). All restricted transmission models exhibited significantly worse likelihoods than the general transmission model except for the Mendelian model. The estimated frequency of the A

allele associated with lowered IGF-I levels was 0.54 ± 0.05. The A allele/factor also appeared to be dominant to the a allele/factor in all analyses.

Likelihood ratio tests of the heterogeneity in genotype-specific regression coefficients revealed evidence for genotype × sex, geno-type × age, and genotype × diet interaction. These tests are shown in Table 4. When these interactions were not considered, evidence for a major locus was attenuated.

Figure 2 shows the form of the genotype-specific regressions for two covariates – age and dietary composition. As can be seen in Figure 2(a), individuals with genotypes AA and Aa showed a less marked decline in IGF-I levels with age than that observed for the aa genotype. Similarly, as shown in Figure 2(b), IGF-I concentration exhibited a stronger positive relationship with the relative intake of dietary protein and carbohydrate in aa individuals than that observed in the other genotypes. Because of this genotype × environment interaction, the relative phenotypic variance attributable to the major gene is highly dependent upon age and diet.

Table 4 Tests of MG × E interaction: IGF-I

Interaction	Λ	df	P
Dietary composition	4.70	1	0.030
Sex	6.35	1	0.012
Age	39.93	2	<0.001

Segregation Analysis, Mixed Models

The term "mixed model" is used often in the biostatistical literature and basically refers to statistical models that incorporate parameters that quantify a wide variety of factors thought to influence a specific outcome. For example, extensions of linear and **variance component** models that incorporate parameters that estimate the degree to which *fixed* factors, i.e. directly measured items such as gender or age (*see* **Fixed Effects**), and *random* factors, i.e. unmeasured or hypothetical items whose presence can only be dealt with probabilistically (*see* **Random Effects**), contribute to some outcome are often referred to as mixed models [18]. In parametric pedigree **segregation** and **linkage analysis** contexts the term "mixed model" refers to models that incorporate parameters that quantify the degree to which both a single locus (or few loci) with a large, individually measurable (but as yet unmeasured) effect, i.e. a "major" locus, and collective or aggregated loci with small, individually unmeasurable effects contribute to a particular phenotype [4]. Segregation analysis mixed models may also incorporate parameters that quantify the effects of measured **covariates** such as age, gender, and race, or include parameters that quantify fixed or random environmental factors shared by the pedigree members. Thus, pedigree analysis mixed models often "mix" more than two types of effect. The design of efficient, reliable, and computationally feasible mixed models for segregation and linkage analysis purposes has been notoriously difficult and presents quite a history for students of statistical genetics (*see* **Genetic Epidemiology**), especially as these models relate to the analysis of human quantitative variation. Although mixed models for categorical or discrete traits have been devised [2], they have not received as much attention as models for quantitative trait analysis. In this brief review, mixed models for quantitative traits are given exclusive attention.

Virtually all derivations of pedigree analysis mixed models for quantitative traits have as a foundation a classical single-locus, two-allele, mixture distribution-based segregation analysis model [17]. As with all parametric pedigree analysis models, this single-locus model typically involves two basic modeling components: a **penetrance** function which characterizes the probability that an individual with a certain genotype will have a certain quantitative trait value; and a transmission function. Where various mixed model formulations differ, however, is in the way in which they model and parameterize the aggregate effects of polygenes acting over and above the major locus (see, for example, [1, 3, 5, 7, 9, 10, 13, 14, 16], and [19]). In the following, a formulation of a mixed model originally attributed to Ott [14] is described. A description of this model can offer insight into the modeling and computational issues that make mixed models difficult to implement.

To introduce Ott's segregation analysis mixed model, an overview of how the modeling of the collective action of polygenes that influence the trait over and above a locus with large and measurable effect should be discussed. Consider a pedigree with N members whose trait values can be collected in a vector $\mathbf{Y} = [y_1, \ldots, y_N]$. **Multivariate normality** of the trait values among the pedigree members is assumed (see [12] for a discussion), with an N-dimensional mean vector whose elements consist of a common mean parameter $\boldsymbol{\mu} = [\mu, \ldots, \mu]$ and an $N \times N$ **covariance matrix**, Ψ, which can be partitioned, for example, in the following way:

$$\boldsymbol{\Psi} = 2\mathbf{A}\sigma_{\mathrm{a}}^2 + \mathbf{D}\sigma_{\mathrm{d}}^2 + \mathbf{H}\sigma_{\mathrm{h}}^2 + \mathbf{I}\sigma_{\mathrm{r}}^2, \qquad (1)$$

where σ_{a}^2 is a **variance component** associated with additive genetic factors, σ_{d}^2 is a variance component associated with dominance genetic factors, σ_{h}^2 is variance component associated with (unmeasured) shared household factors, and σ_{r}^2 is a variance component associated with random or individual-specific factors. The coefficient terms in (1) are $N \times N$ matrices that relate the variance components to the individuals in the pedigree: $\mathbf{A}$ is the *kinship coefficient* matrix and characterizes the degree to which related individuals share genes in expectation [11, 20]; $\mathbf{D}$ is Jacquard's Δ_7 matrix and characterizes the degree to which related individuals share both alleles at a locus [11] (*see* **Identity Coefficients**); $\mathbf{H}$ is a matrix that characterizes household sharing, whose ijth element could be either 1 or 0 depending on whether or not persons i and j share the same household; and $\mathbf{I}$ is the identity matrix. The **likelihood** of the parameters can be

written as

$$L(\boldsymbol{\mu}, \sigma_a^2, \sigma_d^2, \sigma_h^2, \sigma_r^2|\mathbf{Y}) = \frac{1}{(2\pi)^{n/2}|\boldsymbol{\Psi}|^{1/2}} \exp\left[\frac{1}{2}(\mathbf{Y}-\boldsymbol{\mu})'\boldsymbol{\Psi}^{-1}(\mathbf{Y}-\boldsymbol{\mu})\right]. \quad (2)$$

The next step in Ott's model is the addition of parameters accommodating a specific major genetic locus effect within the framework of (2). Once this component is added to the model in (2), the variance component parameters characterize "residual" variation, or variation not explained by the major locus. As with a simple monogenic segregation analysis model, Ott's mixed model considers all possible **genotype** configurations at this major locus for the pedigree members. Ott's model assumes that a locus with two alleles (three genotypes) influences a trait, and produces an extended version of (2) whose formulation for a pedigree becomes:

$$L(p_a, \mu_{AA}, \mu_{Aa}, \mu_{aa}, \sigma_a^2, \sigma_d^2, \sigma_h^2, \sigma_r^2|\mathbf{Y}) = \sum_g^{G(n)} \tau(g) \frac{1}{(2\pi)^{n/2}|\boldsymbol{\Psi}|^{1/2}} \times \exp\left[-\frac{1}{2}(\mathbf{Y}-\boldsymbol{\mu}_g)'\boldsymbol{\Psi}^{-1}(\mathbf{Y}-\boldsymbol{\mu}_g)\right], \quad (3)$$

where the sum is over all possible genotype configurations the pedigree members can have and where p_a is a major locus allele frequency (the other allele having frequency $1-p_a$) and μ_{AA}, μ_{Aa}, and μ_{aa} are mean effect parameters for each of the three major locus genotypes. $\tau(g)$ is the probability of the genotype arrangement g and is a function of the allele frequency p_a for persons without parents in the pedigree and is determined by **Mendel's Laws** for those with parents in the pedigree. Consider a nuclear family with five members, where the two parents are identified as individuals 1 and 2 and their three offspring are identified as individuals 3, 4, and 5. One possible genotype configuration for this family is: $g = [AA, Aa, AA, Aa, Aa]$ (where the genotypes are given in pedigree member number order). The probability of this configuration, given a simple allele frequency parameter, p, and Mendel's laws, is $\tau(g) = (1-p)^2 \times 2p(1-p) \times 1/2 \times 1/2 \times 1/2$. During the evaluation of the likelihood, the mean vector will change depending on the genotype configuration assessed for the family. Thus, for the genotype configuration in question, the mean vector would be $\mu_g = [\mu_{AA}, \mu_{Aa}, \mu_{AA}, \mu_{Aa}, \mu_{Aa}]$.

Evaluation of (3) for large pedigrees is extremely difficult computationally. The total number of possible genotype configurations for a family of size N is 3^N. However, not all of these genotype configurations are compatible with Mendelian theory; for example, the configuration $g = [AA, AA, aa, aa, aa]$ is incompatible with Mendelian theory, barring mutation, since it suggests that parents without a alleles transmit them to offspring. Ott [14] has shown that for a nuclear family of size N, there are $4 + 3^{N-2} + 2^N$ Mendelian compatible genotype configurations for a two-allele, three-genotype model. Although this number is considerably less than 3^N for large N, it can still be quite large. As a result, the computational burden associated with segregation analysis of quantitative traits in large pedigrees via Ott's mixed model can be heavy, and this is especially true if one is analyzing a number of pedigrees or families, since in this situation the likelihood is given by the product of the likelihoods associated with each family. In addition, the fact that the evaluation of the residual variation and covariation involves all the pedigree members does not permit the likelihood to be broken up in a way that could accommodate the **Elston–Stewart algorithm**. Schork [16], however, has described a version of Ott's model that allows the use of the Elston–Stewart algorithm, but at the sacrifice of parameters that specify polygenic covariation among distantly related individuals. Other researchers have tried to formulate the mixed model in ways that permit computational ease by eliminating terms in this manner and have met with varying degrees of success [1, 9, 10]. Attempts to incorporate residual parameter terms simply in ways that do not involve variance components as in (2) suffer from enormous computational difficulties for large families [15].

The computational complexity associated with likelihood evaluation is not the only problem plaguing mixed models. For example, one must often estimate a large number of parameters that are highly correlated. Since most mixed model likelihoods are unwieldy analytically, it is often difficult, if not impossible, to obtain analytic derivatives of the likelihood. Thus, maximization of the relevant likelihoods

to obtain parameter estimates often requires numerical methods whose reliability can be hard to gauge in pedigree analysis contexts. In addition, inclusion of covariate and other fixed or random effects information only exacerbates computational and estimation difficulties. Also, since the mixed model (as with the standard major locus segregation model for quantitative traits) often uses a mixture distribution to model the effects of the major locus genotypes, **likelihood ratio tests** of relevant hypotheses suffer a number of problems whose nature is beyond the scope of this review (see [6] and [8]). As a result of these and other problems, the derivation and implementation of reliable and easily implemented mixed models will likely continue to present challenges to statistical geneticists for some time.

NICHOLAS J. SCHORK

Segregation Ratios

When parents with known **genotypes** for a particular trait have children, the expected ratios of the different phenotype classes of offspring are called segregation ratios. If, for example, two parents each have genotype Aa at a particular locus, and the phenotypes corresponding to the three genotypes AA, Aa, and aa are distinct, then these three classes of offspring are produced in the segregation ratios $1:2:1$. However, if the allele A is dominant to the allele a with respect to the observed phenotype, then the two classes of offspring (AA/Aa and aa) are produced in the segregation ratio $3:1$; the same information can also be expressed by saying that for the mating Aa $\times$ Aa the segregation ratio of the recessive phenotype is 1/4.

More generally, the genotypes of the parents may not be known, and the segregation ratios are then quoted conditional on the parent's phenotypes, e.g. affected $\times$ affected, affected $\times$ unaffected, or unaffected $\times$ unaffected mating types. **Segregation analysis** is concerned with determining whether empirical segregation ratios from such mating types are consistent with simple modes of inheritance, such as one-locus dominant or recessive inheritance. Segregation ratios refer to the distribution of offspring phenotype classes, whereas **genetic transition probabilities** refer to the distribution of offspring genotype classes.

ROBERT C. ELSTON

Selection Bias

Selection bias is a **bias** that arises when individuals included in a study are not representative of the **target population** for the study. Selection bias can arise because an inappropriate **sampling frame** is used, because inappropriate sampling methods are applied (*see* **Probability Sampling**), or because some of those sampled refuse to participate in the study (*see* **Bias from Nonresponse**). In studies relying on samples of convenience, such as **hospital-based case–control studies** or **clinical trials** in which patients volunteer for particular treatments, it is difficult to rule out the possibility of selection bias (*see* **Bias in Case–Control Studies**; **Bias in Cohort Studies**; **Bias in Observational Studies**; **Bias, Overview**; **Missing Data in Clinical Trials**; **Missing Data in Epidemiologic Studies**; **Validity and Generalizability in Epidemiologic Studies**).

MITCHELL H. GAIL

Semi-Markov Processes

Semi-Markov processes are useful generalizations of a class of **stochastic processes** commonly referred to as a Markov jump process in continuous time. One of the most famous examples of a Markov jump process in biostatistics is the illness–death process, which has been discussed extensively by Chiang [1] and subsequent editions (*see* **Fix–Neyman Process**). To illustrate the ideas, suppose one takes observations on the histories of patients who visit a clinic from time to time. As time passes, any patient may be in one of a set of states. Among these states are E_1, indicating that a patient has died, and another E_2, indicating that a patient has been lost to follow-up. From the point of view of an observer in the clinic, no further data would be available on patients in states E_1 and E_2, so in this sense the process terminates. In general, such states of termination will be called *absorbing states*.

From the point of view of health care workers in a clinic, two other states would be of compelling interest. One of these states could be labeled E_3, indicating that a patient is ill and undergoing treatment, and another state could be labeled E_4, indicating that the patient is well, or, in the case of cancer, the patient is in remission. Moreover, as time passes, after an episode in state E_3, a patient may move to state E_4; after an episode in state E_4, a patient may move back to state E_3, and so his or her sample path continues until one of the absorbing states, E_1 or E_2, is entered. In general, sets of states such as E_3 and E_4, among which a process may move prior to termination, will be called *transient*.

If an investigator were to formulate a model of the situation just described as a Markov jump process in continuous time with stationary laws of evolution, then from the sample path perspective, a very simple picture for the evolution of the process emerges. Suppose that the process begins in transient state E_3 at time $t = 0$. Then the length of the episode in this state follows an **exponential distribution** with parameter $\theta_3 > 0$, i.e. the probability that the process is still in state E_3 at time $t > 0$ is $\exp(-\theta_3 t)$. Given that an exit from state E_3 occurs, a jump to one of the states E_1, E_2, or E_4 occurs with probabilities p_{31}, p_{32}, or p_{34}, respectively. Similar statements hold for the transient state E_4.

A limitation of the exponential distribution as a model of the waiting time for the occurrence of some biological event is that it has the memoryless or nonaging property. To illustrate this property, suppose it is known that the length of an episode in state E_3 is $s > 0$ time units. Then, given this event, the past is forgotten in the sense that $\exp(-\theta_3 t)$ is the **conditional probability** that the process is still in this state at time $s + t$. Among other things, semi-Markov processes were introduced to remove the restriction that the length of an episode in a state necessarily follows an exponential distribution. As we shall see, formulating a model as a semi-Markov process not only removes this restriction but also provides useful alternatives for viewing Markov jump processes in continuous time. Some authors, such as Cinlar [2], also refer to these generalized models as Markov **renewal processes**.

An Overview of the Structure of Semi-Markov Processes

A first step in formulating a model as a semi-Markov process is to define a state space $\mathfrak{S}$, consisting of two disjoint sets of absorbing and transient states denoted by $\mathfrak{S}_1$ and $\mathfrak{S}_2$, respectively. For the sake of simplicity, attention will be confined to the case where the state space is finite. By way of another illustrative example, suppose an investigator is considering the evolution of a cohort of patients infected with HIV, the causal agent of AIDS (*see* **AIDS and HIV**). Then, in light of the effects of protease inhibitors in controlling HIV reported recently in the literature, it would seem plausible to consider a set $\mathfrak{S}_1$ of three absorbing states E_{11}, E_{12}, and E_{13}, denoting death from a cause other than AIDS, death due to an AIDS defining disease, and a case in which patients are cleared of the virus through treatment, respectively. The elements of the set $\mathfrak{S}_2$ of transient states could be symbolized by E_{2k}, $k = 1, 2, \ldots, 6$, representing classes of $CD4^+$ counts of T-lymphocytes used to define clinical stages of HIV disease.

In general, let $\mathfrak{S}_1$ denote the set of $r_1 \geq 1$ absorbing states and $\mathfrak{S}_2$ the set of $r_2 \geq 1$ transient states so that the state space $\mathfrak{S}$ has $r = r_1 + r_2$ elements. The evolution of the process is defined by two sequences of random variables. Let $X_0 = i \in \mathfrak{S}_2$ denote the initial transient state, and let the random variable X_n denote the state in $\mathfrak{S}$ entered at the nth jump

for $n \geq 1$. The evolution of the process in time is accounted for by the increasing sequence of random variables

$$0 = T_0 \leq T_1 \leq T_2 \leq \cdots \leq T_n \leq \cdots,$$

taking values in $[0, \infty)$ and denoting the random times jumps occur, where, for $n \geq 1$, the random variable T_n is the time that the nth jump occurs. If $X_n = j$, a transient state, then $T_{n+1} - T_n$ is the random length of the episode in state $j \in \mathfrak{S}_2$.

A another basic step in formulating a model as a semi-Markov process is the construction of an $r_2 \times r$ matrix,

$$(a_{ij}(t)|i \in \mathfrak{S}_2, j \in \mathfrak{S}), \tag{1}$$

of continuous one-step density functions defined for $t \in [0, \infty)$. In the next section, methods for constructing such densities will be described, but, for the time being, attention will be focused on the structure of the process. In describing this structure, functions defined by

$$A_{ij}(t) = \int_0^t a_{ij}(s)\,\mathrm{d}s \tag{2}$$

will play a basic role.

The sequence of pairs

$$\{(X_n, T_n)|n = 0, 1, 2, \ldots\}$$

will be said to have the semi-Markov property if the condition

$$\begin{aligned} &\Pr[X_{n+1} = j, T_{n+1} - T_n \leq t|(X_k, T_k), \\ &\qquad k = 0, 1, \ldots, n] \\ &= \Pr[X_{n+1} = j, T_{n+1} - T_n \leq t|X_n] \end{aligned} \tag{3}$$

holds for all $n = 0, 1, 2, \ldots$ and $t > 0$. When $X_n = i \in \mathfrak{S}_2$, the conditional probability on the right will be identified as

$$\Pr[X_{n+1} = j, T_{n+1} - T_n \leq t|X_n = i] = A_{ij}(t). \tag{4}$$

According to this formulation, the laws of evolution of the process are stationary in the sense that the right-hand side of (4) does not depend on n.

By considering marginal distributions in (4), it can be seen that the sequence of random variables $(X_n|n = 0, 1, 2, \ldots)$ is a discrete time **Markov chain** embedded in a continuous time semi-Markov process with a one-step transition matrix determined for all $n \geq 0$ by

$$\Pr[X_{n+1} = j|X_n = i] = \lim_{t \uparrow \infty} A_{ij}(t) = p_{ij}, \tag{5}$$

where $i \in \mathfrak{S}_2$ and $j \in \mathfrak{S}$. Similarly, the distribution function on the random length of time for any episode in state i is given by

$$A_i(t) = \Pr[T_{n+1} - T_n \leq t|X_n = i] = \sum_{j \in \mathfrak{S}} A_{ij}(t) \tag{6}$$

for all $n \geq 0$.

When working with a semi-Markov process, it is often possible to avoid much formidable formalism by focusing on a matrix representation of the basic functions governing the evolution of the process. To this end, one may extend the definition of the one-step density matrix in (1) to the case $i \in \mathfrak{S}_1$, the set of absorbing states. For every $i \in \mathfrak{S}_1$, let $a_{ii}(0) = 1$ and let $a_{ii}(t) = 0$ for $t > 0$, and for $i \neq j \in \mathfrak{S}$, let $a_{ij}(t) = 0$ for all $t \geq 0$ to indicate that any transition from an absorbing state occurs with probability zero. Then, for $t > 0$, the matrix of one-step transition densities may be represented in the partitioned form

$$\mathbf{a}(t) = (a_{ij}(t)) = \begin{bmatrix} \mathbf{0}_{r_1,r_1} & \mathbf{0}_{r_1,r_2} \\ \mathbf{r}_{r_2,r_1}(t) & \mathbf{q}_{r_2,r_2}(t) \end{bmatrix}, \tag{7}$$

corresponding to the sets of r_1 and r_2 absorbing and transient states, respectively. Having identified the dimensions of the submatrices in (7), from now on, to lighten the notation, subscripts on such matrices will be dropped. Briefly, the matrix $\mathbf{r}(t)$ governs one-step transitions from transient states to absorbing states, while the matrix $\mathbf{q}(t)$ governs transitions among transient states.

With the $r \times r$ matrix $\mathbf{a}(t)$ defined as in (7), and the atom at $t = 0$ for absorbing states properly accommodated in the integrals, the matrix of functions in (4) may be represented in the partitioned form

$$\mathbf{A}(t) = \int_0^t \mathbf{a}(s)\,\mathrm{d}s = \begin{bmatrix} \mathbf{I}_{r_1} & \mathbf{0} \\ \mathbf{R}(t) & \mathbf{Q}(t) \end{bmatrix} \tag{8}$$

for $t > 0$, where $\mathbf{I}_{r_1}$ is an identity matrix of order r_1. From this representation it can be seen that the transition matrix for the embedded Markov chain may be represented in the partitioned form

$$\mathbf{P} = \lim_{t \uparrow \infty} \mathbf{A}(t) = \begin{bmatrix} \mathbf{I}_{r_1} & \mathbf{0} \\ \mathbf{R} & \mathbf{Q} \end{bmatrix}. \tag{9}$$

In their pioneering book on finite Markov chains, Kemeny & Snell [3] used this partitioned form extensively. As we shall see, numerical answers to many questions of interest may be expressed in terms of the matrices **R** and **Q**.

On Constructing Transition Densities

As will be shown by illustrative examples, several approaches may be used in constructing matrices of these densities. In one approach, based on the classical theory of **competing risks**, a point of departure could be the specification of a matrix of latent risk, **hazard**, or rate functions. If, for example, an illness–death process were being considered, then a 4×4 matrix of continuous latent risk functions could take the form

$$\mathbf{\Theta}(t) = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \theta_{31}(t) & \theta_{32}(t) & 0 & \theta_{34}(t) \\ \theta_{41}(t) & \theta_{42}(t) & \theta_{43}(t) & 0 \end{bmatrix}, \quad (10)$$

where $t \in (0, \infty)$. Because the states E_1 and E_2 are absorbing, the latent risks governing transitions out of these states are 0. But, if a patient is in state E_3 undergoing treatment, then the function governing his or her rate of entrance into the well state, E_4, is $\theta_{34}(t)$. Analogous interpretations may be attached to the other nonzero risk functions in (10). Also, observe that all diagonal elements of $\mathbf{\Theta}(t)$ corresponding to transient states are zero, because in jump processes a state cannot make a transition into itself.

In general, let $\mathbf{\Theta}(t) = (\theta_{ij}(t))$ be an $r \times r$ matrix of latent risk functions. For any transient state $i \in \mathfrak{S}_2$, the total risk function is

$$\theta_i(t) = \sum_{j \in \mathfrak{S}_2} \theta_{ij}(t). \quad (11)$$

Thus, by appealing to well-known formulas for expressing survival functions in terms of risk functions (*see* **Survival Distributions and Their Characteristics**), it can be seen that if transient state i is entered at time $t = 0$, then

$$S_i(t) = \exp\left[-\int_0^t \theta_i(x)\,\mathrm{d}x\right] \quad (12)$$

is the conditional probability the process is still in state i at time $t > 0$. As in the second section, let $A_{ij}(t)$ be the conditional probability that a transition to state $j \neq i$ occurs sometime during the time interval $(0, t]$, $t > 0$, given that state i was entered at $t = 0$. Then, by appealing to the classical theory of competing risks, it follows that

$$A_{ij}(t) = \int_0^t S_i(x)\theta_{ij}(x)\,\mathrm{d}x = \int_0^t a_{ij}(x)\,\mathrm{d}x. \quad (13)$$

A simple and useful case arises when all nonzero latent risk functions are positive constants. For in this case, (13) takes the form

$$A_{ij}(t) = [1 - \exp(-\theta_i t)]\frac{\theta_{ij}}{\theta_i}. \quad (14)$$

Consequently, when all latent risk functions are constant, the distribution of the length of any episode in transient state i is that of a random variable following an exponential distribution with parameter $\theta_i > 0$.

Because of this property, it can be shown that a model formulated as a semi-Markov process with constant latent risks is an alternative way of viewing a Markov jump process in continuous time. Furthermore, it can be seen from (14) that the transition probabilities for the embedded Markov chain have the form

$$p_{ij} = \lim_{t \uparrow \infty} A_{ij}(t) = \frac{\theta_{ij}}{\theta_i}. \quad (15)$$

If an investigator is inclined to suspect that latent risk functions would not be constant, then among the alternative choices would be **Weibull** risk functions of the form

$$\theta_{ij}(t) = \alpha_{ij}\beta_{ij}t^{\alpha_{ij}-1}, \quad (16)$$

where $t > 0$, $\alpha_{ij} > 0$, and $\beta_{ij} > 0$. If $0 < \alpha_{ij} < 1$, then $\theta_{ij}(t)$ decreases as t increases, but if $\alpha_{ij} > 1$, then $\theta_{ij}(t)$ increases as t increases, indicating, in the latter case, that the longer the episode in state i, the greater is the risk of a transition to state $j \neq i$. As software becomes more user-friendly and as desk-top computers increase in power and speed, the computation of integrals of form (13) become increasingly feasible.

An alternative approach to the classical theory of competing risks is to start with "latent" distribution functions $G_{ij}(t)$ with a finite expectation, μ_{ij}, governing the waiting time for the transition $i \to j$ in the "absence" of other transitions. When there is

"competition" for transitions out of state i, it seems plausible that the larger the value of μ_{ij}, the smaller the conditional probability, p_{ij}, of an eventual transition from state i to j. Hence, it seems reasonable to consider transition probabilities for the embedded Markov chain of the form

$$p_{ij} = \frac{c_i}{\mu_{ij}}, \tag{17}$$

where c_i is a normalizing constant chosen so that

$$\sum_{j \in \mathfrak{S}} p_{ij} = 1. \tag{18}$$

In this formulation the function $A_{ij}(t)$ would be chosen as

$$A_{ij}(t) = p_{ij} G_{ij}(t) \tag{19}$$

so that the distribution function of the length of any episode in state i would be the mixture

$$A_i(t) = \sum_{j \in \mathfrak{S}} p_{ij} G_{ij}(t). \tag{20}$$

The construction just described would be most useful for those families of distributions with nonelementary risk functions. An example of a family of such distributions is the **gamma**, which has simple Laplace transforms that can be useful in the numerical analysis of semi-Markov models with transition densities constructed by this method.

Renewal-Type Integral Equations

Unlike models based on continuous time Markov jump processes, in which some version of the forward Kolmogorov differential equations is the focus of primary attention, renewal-type integral equations play a fundamental role in the analysis of semi-Markov processes. Trains of thought, known as *renewal type arguments*, are used repeatedly in derivations of these equations. For example, suppose, at time $t = 0$, a process starts in some transient state $i \in \mathfrak{S}_2$ and let $f_{ij}(t)$ be the density function of the waiting time for the termination of the process in some absorbing state $j \in \mathfrak{S}_1$. Either the process enters state j on the first step or there is a jump to some other transient state $k \neq j$ at some point $s \in (0, t]$, $t > 0$, with probability $a_{ik}(s)\,\mathrm{d}s$. At time s the process "renews" and $f_{kj}(t - s)$ is then the density of the waiting time to absorption in state j. By integrating and summing over all possibilities, the following renewal-type integral equation arises:

$$f_{ij}(t) = a_{ij}(t) + \sum_{k \in \mathfrak{S}_2} \int_0^t a_{ik}(s) f_{kj}(t - s)\,\mathrm{d}s. \tag{21}$$

As an aid to understanding the structure of the process, it will be helpful to cast (21) in matrix form. Let

$$\mathbf{f}(t) = (f_{ij}(t) | i \in \mathfrak{S}_2, j \in \mathfrak{S}_1) \tag{22}$$

be an $r_2 \times r_1$ matrix of absorption densities. Then, from an inspection of (7), it can be seen that (21) may be written in the compact matrix form

$$\mathbf{f}(t) = \mathbf{r}(t) + \int_0^t \mathbf{q}(s)\mathbf{f}(t - s)\,\mathrm{d}s \tag{23}$$

for $t > 0$.

Laplace transforms can be very useful tools in deducing formulas of interest to understanding semi-Markov processes. Accordingly, let

$$\hat{\mathbf{f}}(s) = \left[\hat{f}_{ij}(s) = \int_0^\infty \exp(-st),\, f_{ij}(t)\,\mathrm{d}t \right], \tag{24}$$

defined for $s \geq 0$, be the $r_2 \times r_1$ matrix of Laplace transforms of the absorption densities, and let the matrices $\hat{\mathbf{r}}(s)$ and $\hat{\mathbf{q}}(s)$ be defined similarly. Then, from (23), it follows that these matrices of Laplace transforms satisfy the following matrix linear equation:

$$\hat{\mathbf{f}}(s) = \hat{\mathbf{r}}(s) + \hat{\mathbf{q}}(s)\hat{\mathbf{f}}(s). \tag{25}$$

Given that the process starts in transient state $i \in \mathfrak{S}_2$ at time $t = 0$, let b_{ij} be the conditional probability that the process eventually terminates in absorbing state $j \in \mathfrak{S}_1$. Then,

$$b_{ij} = \int_0^\infty f_{ij}(t)\,\mathrm{d}t = \lim_{s \downarrow 0} \hat{f}_{ij}(s) \tag{26}$$

connects the elements of the matrix $\mathbf{B} = (b_{ij})$ with the Laplace transforms in (25). But, from (9), it can be seen that

$$\lim_{s \downarrow 0} \hat{\mathbf{r}}(s) = \mathbf{R} \tag{27}$$

and

$$\lim_{s \downarrow 0} \hat{\mathbf{q}}(s) = \mathbf{Q} \tag{28}$$

connect the Laplace transforms with the transition matrix of the embedded Markov chain. Therefore, by letting $s \downarrow 0$ in (25) and solving for the matrix $\mathbf{B}$, it can be seen that

$$\mathbf{B} = (\mathbf{I}_{r_2} - \mathbf{Q})^{-1}\mathbf{R}, \tag{29}$$

provided that the matrix inverse exists.

For many processes it can be shown under rather general conditions that $\mathbf{Q}^n \to \mathbf{0}$, an $r_2 \times r_2$ zero matrix as $n \uparrow \infty$. Therefore, the inverse matrix in (29) is the sum of a matrix geometric series:

$$\mathbf{M} = (m_{ij}) = \mathbf{I}_{r_2} + \mathbf{Q} + \mathbf{Q}^2 + \cdots = (\mathbf{I}_{r_2} - \mathbf{Q})^{-1}. \tag{30}$$

Moreover, m_{ij} is the conditional expectation of the number of episodes in transient state j prior to termination of the process in some absorbing state, given that the process starts in transient state i.

A given row of the matrix $\mathbf{B}$ of absorption probabilities is often of fundamental interest. For example, for the case of a model for the progression of patients with HIV disease, given that a patient is first observed in transient state i with some $CD4^+$ count, the ith row of the matrix $\mathbf{B}$ could be interpreted as the conditional probabilities that a patient eventually dies from a cause other than AIDS, an AIDS-defining disease, or is eventually cleared of the virus by treatment with drugs.

Another useful perspective for viewing the evolution of a semi-Markov process is the state of the process at time $t \in [0, \infty)$. Let the random function $Z(t)$ denote the state of the process at time t. For $i \in \mathfrak{S}_2$, a transient state, the conditional probabilities

$$\Pr[Z(t) = j | Z(0) = i] = P_{ij}(t), \tag{31}$$

which are sometimes referred to as the *current state probabilities*, are often the focus of attention. When working with models formulated on Markov jump processes in continuous time, it is these probabilities that are the desired solution to the forward Kolmogorov differential equations.

If $j \in \mathfrak{S}_1$, an absorbing state, then for $t > 0$, the equation

$$P_{ij}(t) = \int_0^t f_{ij}(s)\,\mathrm{d}s, \tag{32}$$

connecting current state probabilities with absorption densities, is valid. But, if $j \in \mathfrak{S}_2$, then it can be shown that the $r_2 \times r_2$ matrix,

$$\mathbf{P}(t) = (P_{ij}(t)), \tag{33}$$

of current state probabilities for transient states satisfies a renewal-type integral equation.

Let $S_i(t) = 1 - A_i(t)$ be the survival function for transient state i and let $\mathbf{D}(t)$ be the $r_2 \times r_2$ diagonal matrix defined by

$$\mathbf{D}(t) = (\delta_{ij} S_i(t)), \tag{34}$$

where δ_{ij} is the Kronecker delta. Then, by a renewal argument similar to that used in the derivation of (21), it can be seen that the matrix in (33) satisfies the following matrix renewal-type integral equation

$$\mathbf{P}(t) = \mathbf{D}(t) + \int_0^t \mathbf{q}(s)\mathbf{P}(t - s)\,\mathrm{d}s \tag{35}$$

for $t > 0$. If there were no absorbing states, then this integral equation would be a primary focus of attention.

Just as in (23), the passage to Laplace transforms in (35) can yield useful and interesting results. Let the random variable V_j denote the total time spent in transient state $j \in \mathfrak{S}_2$ prior to the termination of the process in some absorbing state. The expected length of any episode in state j is

$$\eta_j = \int_0^\infty S_i(t)\,\mathrm{d}t. \tag{36}$$

By passing to Laplace transforms in (35) it can be shown, after some analysis, that for any initial transient state $i \in \mathfrak{S}_2$

$$E[V_j | Z(0) = i] = \int_0^\infty P_{ij}(t)\,\mathrm{d}t = \lim_{s \downarrow 0} \hat{P}_{ij}(s) = m_{ij}\eta_j. \tag{37}$$

This result has a clear and simple interpretation. If the process starts in transient state i, then m_{ij} is the expected number of episodes in transient state j prior to the termination of the process in some absorbing state, and the expected length of each episode in state j is η_j. Therefore, (37) is valid. If, for example, state j indicates a patient is in a hospital and the cost per unit time is known, then (37) could be used to estimate the expected total cost of an illness.

The ease with which the formulas of this section could be implemented numerically would depend to

some extent on the tractability of the Laplace transforms of the transition densities $a_{ij}(t)$. If all these densities belonged to the gamma family and the construction in (33) were used, then all Laplace transforms would be tractable and all formulas presented in this section could be evaluated numerically with relative ease, provided the state space is not too large. When all latent risks are constant, it is also possible to use the exponential matrix as a solution of the Kolmogorov differential equations, which will require the construction an $r \times r$ rate matrix $\mathbf{Q}$.

To construct this matrix, let $\mathbf{\Theta}$ be a constant matrix of latent risks and let θ_i be the sum of the elements of the ith row of $\mathbf{\Theta}$. Then, the matrix $\mathbf{Q}$ has the form

$$\mathbf{Q} = \mathbf{\Theta} - \text{diag}(\theta_1, \theta_2, \ldots, \theta_r). \tag{38}$$

As is well known, for $t > 0$ the solution of the Kolmogorov differential equations is the exponential matrix

$$\mathbf{P}(t) = \exp(\mathbf{Q}t) \tag{39}$$

Many computer packages have software designed to evaluate an exponential matrix either symbolically or numerically, (*see* **Matrix Computations**).

Further Reading

Whenever a model is formulated as a semi-Markov process, it is usually difficult to use **maximum likelihood** to estimate unknown parameters from data, because the **likelihood** function is difficult to derive and compute. Thompson et al. [6] have proposed an interesting method for estimating parameters on the basis of **simulating** realizations of the process and minimizing a **goodness-of-fit** criterion such as a **chi-square test** statistic. Such well-known computer software packages as MATLAB have built-in programs for computing the exponential matrix, Packages with a capability for doing **computer algebra**, such as MAPLE, may also be used to produce symbolic forms of the exponential matrix. Methods for solving discrete time versions of renewal-type integral equations numerically have been discussed and used extensively in Mode [4]. Tan [5] has presented an extensive array of applications and references to Markov processes with time inhomogeneous laws of evolution in cancer research. Many of these models could also be viewed within a semi-Markov framework with time inhomogeneous laws of evolution. See [4] for applications of related processes in **demography**.

CHARLES J. MODE

Semiparametric Regression

Semiparametric regression models are a compromise between parametric and nonparametric models. The idea is to retain a certain amount of the **parsimony** and structure of a parametric model while gaining some of the flexibility of a nonparametric model.

There is no widely accepted rigorous definition of a semiparametric model. Informally we will call a model semiparametric if it is not fully parametric but has a finite dimensional parameter of interest. The most widely used semiparametric regression model is the proportional hazards (*see* **Proportional Hazards, Overview**) model of Cox [6] (*see* **Cox Regression Model**), in which the conditional hazard at time t, given **explanatory variable z**, is $\lambda_0(t)\exp(\boldsymbol{\beta}'\mathbf{z})$, where λ_0 is an unknown function of t (the nonparametric component) and $\boldsymbol{\beta}$ is an unknown (finite dimensional) vector (the parametric component). It is often helpful to think of λ_0 as an infinite-dimensional parameter rather than as a nonparametric component.

This informal definition of a semiparametric model excludes structured **nonparametric regression** models such as the **generalized additive model**:

$$Y_i = \alpha_0 + \alpha_1(X_{1i}) + \cdots + \alpha_p(X_{pi}) + \varepsilon_i,$$

in which $\alpha_1, \ldots, \alpha_p$ are mean zero smooth functions of the variables $X_1, \ldots, X_p$; ε_i is a mean zero "error term" and $\alpha_0 = \mathrm{E}(Y_i)$ for all i. Although α_0 is a one-dimensional parameter, we assume that it is not of primary interest in the model.

Here we describe a large class of semiparametric regression models and identify some special cases of biostatistical interest. We also discuss the sort of problems posed by semiparametric regression. Details of specific models are discussed elsewhere.

Consider the generic model

$$\psi(Y) = r(\mathbf{X}) + \varepsilon, \tag{1}$$

in which ε is a random element with distribution F. For a full specification we would have to consider the distribution of $\mathbf{X}$, but we prefer to view (1) as a model for Y given X. The model in (1) has three components: the transformation function ψ, the regression function r, and the distribution function F. For the regression model to be termed semiparametric, r must have a finite dimensional component of interest, and at least one of ψ, r, and F must have an infinite-dimensional component.

Example 1. Semiparametric Regression Functions

1. Partly parametric additive model:

$$\psi(Y) = Y, \varepsilon \sim \mathrm{N}(0, \sigma^2), r(\mathbf{X}) = \boldsymbol{\beta}'\mathbf{X}_1 + s(\mathbf{X}_2).$$

2. **Projection pursuit** regression. As in (1) but with $r(\mathbf{X}) = s(\boldsymbol{\beta}'\mathbf{X})$, where $s : \mathcal{R} \to \mathcal{R}$ is an unknown function. Only the direction of $\boldsymbol{\beta}$ is identifiable.

Example 2. Transformation Model

A general transformation model has an arbitrary nondecreasing ψ and $r(\mathbf{X}) = -\boldsymbol{\beta}'\mathbf{X}$. The error distribution F may be parametric or nonparametric. When the distribution of ε is Gaussian, one has a semiparametric extension of the Box–Cox model [3] (*see* **Power Transformations**). The model leads naturally to **rank regression**. Estimation of $\boldsymbol{\beta}$ with **censored data** has been studied by Cheng et al. [4]. Horowitz [8] considers estimation of ψ and F.

1. The Cox model. The Cox model is a special case in which $F(t) = 1 - \exp(-e^t)$, the **extreme value** (minimum) distribution, $\psi(Y) = \log \Lambda_0(Y)$, and $r(\mathbf{X}) = -\boldsymbol{\beta}'\mathbf{X}$. Here Λ_0 is a cumulative hazard function; in particular, it is nonnegative and nondecreasing.
2. The Clayton–Cuzick model. A multivariate generalization of the Cox model proposed by Clayton & Cuzick [5] has received much attention. The model assumes that individuals within the same "cluster" share a common **frailty**. The frailty may be regarded as an unobserved covariate. The hazard for the ith individual is

$$Z_i\lambda_0(t)\exp(\boldsymbol{\beta}'\mathbf{X}_i)$$

where the frailty Z_i is common to all individuals in the cluster, and is assumed to have a **gamma distribution** with mean 1.

Example 3. Accelerated Failure-Time Models

Accelerated failure-time models are simply linear models for the logarithms of survival times. Such a

model will usually permit censored survival times. If the error distribution F is nonparametric, then the model is semiparametric. One has

$$\log Y = \boldsymbol{\beta}'\mathbf{X} + \varepsilon,$$

where the ε has distribution function $F \in \mathcal{F}$, the space of all distribution functions on the real line.

Schick [11] considers efficient estimation in the model in (1) when ψ is the identity function. His approach takes into account the unknown distribution of the covariates $\mathbf{X}$. Not all semiparametric regression models can be described by (1).

Example 4. Partly Parametric Aalen model

McKeague & Sasieni [10] added a parametric component to the model introduced by Aalen [1] (*see* **Aalen's Additive Regression Model**). The model for the hazard function conditional on vectors $\mathbf{x}$ and $\mathbf{z}$ is

$$\lambda(t|\mathbf{x},\mathbf{z}) = \alpha_0(t) + \alpha_1(t)x_1 + \cdots + \alpha_p(t)x_p + \boldsymbol{\beta}'\mathbf{z}.$$

It has $p+1$ infinite-dimensional components $\alpha_0, \alpha_1, \ldots, \alpha_p$ and a finite-dimensional parameter $\boldsymbol{\beta}$.

Example 5. Cox Model with Time-Dependent Coefficients

Cox Model with Time-Dependent Coefficients

A closely related model is a generalization of the Cox model which permits the relative hazards to change over time:

$$\lambda(t|x,z) = \exp[\alpha_0(t) + \alpha_1(t)x_1 + \cdots + \alpha_p(t)x_p + \boldsymbol{\beta}'\mathbf{z}].$$

Here the baseline hazard function is given by $\exp[\alpha_0(t)]$. Whereas no explicit smoothing is required to obtain $n^{1/2}$-consistent estimators of $\boldsymbol{\beta}$ in the partly parametric Aalen model, all estimators for this model require smoothing [13, 7].

Example 6. Conditionally Parametric Models

Severini & Wong [12] studied estimation of the parametric component of a semiparametric model via the **profile likelihood**. The method is particularly useful in conditionally parametric models, in which, conditional on an explanatory variable X, the model is parametric, but the dependence on X is nonparametric. For instance, given $X = x$, the parameters are θ and η_x, but $\eta_x = s(x)$ is a smooth function of x. The model is closely related to the varying coefficient models of [7].

Example 7. Semiparametric Regression Functionals

LeBlanc & Crowley [9] considered semiparametric models in which a certain linear functional T of the conditional distribution function F_X of Y given X is assumed to be linear in X:

$$T[F_X(y)] = \mathbf{X}'\boldsymbol{\beta}.$$

It is further assumed that $F_{X=x}$ is a smooth function of x. Applications include **quantile regression**, for which one would solve the estimating equation

$$\int \psi(y, \mathbf{x}'\boldsymbol{\beta})\, \mathrm{d}\hat{F}_n(y) = 0,$$

where $\hat{F}_n(y)$ is an estimate of the conditional distribution function and $\psi(y,\eta) = -q/(1-q)$ if $y \geq \eta$ and 1 otherwise.

The book by Bickel et al. [2] on semiparametric models concentrates on asymptotic bounds for estimation. It discusses how well, in theory, one can estimate the parameters (both finite- and infinite-dimensional) in a given model. Some consideration is also given to construction of estimators, but different methods seem best for different problems. Of course, all the problems that statisticians have studied on parametric models may be posed for semiparametric models. Most researchers have concentrated on the problem of efficient estimation (*see* **Efficiency and Efficient Estimators**), but more interest is now being given to robust estimation (*see* **Robustness**). Other topics that will doubtless be studied in greater depth include: **Hypothesis testing** – in particular, testing between semiparametric models and parametric submodels (*see* **Model, Choice of**); **bootstrap** and **jackknife methods**, and whether these can be used to perform tests and provide confidence bands; **goodness of fit**, **model checking** and **diagnostics**; computing and finite-sample consideration; **Bayesian methods**. Additionally, several authors have begun to relax the independent and identically distributed assumption common to most papers on semiparametric models.

Sensitivity Analysis

Sensitivity analysis is a reassessment of the model used for data summary that attempts to detect whether changing any of the assumptions used in a model to derive the analysis leads to different interpretations of the outcome.

Sensitivity analysis is commonly used by taking estimates of parameters from models and varying them over possible values to detect whether this variation leads to different interpretation of the response. For example, in a cost–effectiveness analysis (*see* **Health Economics**), the discount rate for the cost of future events may be set at the conventional level of 5%. (The cost of a future event in present-day currency is cheaper than a current unit because the delay of k years could generate compound interest at the rate r, so the value of a unit compounded for k years would be $(1 + r)^k$. Hence, the cost of a future event is said to be discounted at $r\%$ in terms of present currency values. The usual or conventional discount rate is $r = 5\%$.) The sensitivity analysis might be varied over the levels, 0%, 5%, and 10% to decide whether changing the discount rate over these three levels had any impact of final conclusions drawn from the study. If the final conclusion was insensitive to varying of the factor over its multiple levels, the conclusion is said to be insensitive to the choice of discount rate. A sensitivity analysis that varies one factor at a time is called a "one-way" sensitivity analysis, while a sensitivity analysis that simultaneously varies two factors in the model is called a "two-way" sensitivity analysis; these can be extended to "n-way" sensitivity analysis, where n is a positive integer.

A sensitivity analysis can be extended to a **Monte Carlo** sensitivity analysis providing the analyst can get computer-generated samples with random number **algorithms** to select amongst the various factor level combinations (cases) to be used in the sensitivity analysis. A Monte Carlo sensitivity analysis generally takes into account all of the factors that are being varied in the sensitivity analysis. A distribution of results or a set of summary statistics computed from the distribution are then used to convey the results.

Readers who are familiar with **factorial experiments** will recognize that information on multiple factors as well as changes in the structure of the model can be detected by using factorial experimentation rather than "one factor at a time" studies. Indeed, factorial designs have the possibility of detecting whether **interactions** between factors play a role and can detect smaller effects by increasing precision using the hidden replication property of factorial design. (Hidden replication is the term used in the experimental design literature to characterize the efficiency of a factorial design to estimate the effects of multiple factors with a sample size used for a single factor.) However, in the health sciences literature, one does not usually find factorial experiments conducted as sensitivity analyses; these sensitivity analyses tend to deal with one factor at a time.

An explicit definition of sensitivity analysis in equation form is difficult to find in the literature. However, there are many applications of these principles in the health economics literature. For example, a two-way sensitivity analysis showed that the use of the drug Misoprostol to prevent gastric bleeding in rheumatoid arthritis patients who were taking nonsteroidal anti-inflammatory drugs was an economically sound decision, provided the background ulcer complication rate was at least 1.5%. This conclusion was derived from a sensitivity analysis. The authors also show the results of a Monte Carlo sensitivity analysis, without changing the conclusions of the study [4].

Some authors have attempted to provide multiple factor approaches to using the principles of **experimental design** in suggesting how a sensitivity analysis can be helpful to provide conclusions about studies where judgments have to be made about more than one factor. One reference has drawn together examples that use the **general linear model** from a factorial experiment to suggest how this may be used to answer multiple sensitivity questions on the same set of data. They include applications to pneumonoccol vaccination, neonatal intensive care, and prevention of pulmonary emboli [6].

If one examines the references in the health sciences literature, there are many examples of sensitivity analysis applications to clinical and biological problems. In *Current Index to Statistics* [5], there are 13 entries suggesting applications of sensitivity analysis to a variety of problems. These include applications to growth models (*see* **Bacterial Growth, Division, and Mutation**), stochastic flow networks, (*see* **Stochastic Processes**) and **structural equation models**.

Sensitivity analyses tend *not* to challenge: (i) the form of the models; (ii) the underlying distribution of the errors; or (iii) the link between the model and the error distribution that one conventionally finds in **generalized linear models**. Hence, these may be a fruitful areas of research to determine whether improvements can be made in the application of sensitivity analysis to a variety of health care problems by exploiting some of the recent innovations in generalized linear modeling of data [8].

Sensitivity analyses have been used more recently in the field of **meta-analysis**. Meta-analysis is a technique for combining outcomes from multiple studies simultaneously with the hope of increased precision and increased **power** to detect important clinical effects [2, 3]. Sensitivity analysis has been used by systematically dropping studies, performing subgroup analyses (*see* **Treatment-covariate Interaction**) and generally using all the conventional statistical techniques to understand the **robustness** of the analyses [2, 3].

Petitti [9] discusses applications of sensitivity analyses to gallstone surgery and isoniazid prophylaxis in HIV patients, choices of factors for sensitivity analyses, and how sensitivity analysis can be used in meta-analysis.

Bailar & Mosteller [1] also define sensitivity analysis and show various **graphical displays** that can help in the interpretation of the findings from multiway sensitivity analyses, including the use of estrogens to prevent osteoporosis in postmenopausal women.

Sensitivity analysis can be described as a measure and then applied to different **estimation** methods of growth rates of algae, heart catheterization data, and the atomic weight of iodine [10].

Sensitivity analysis can help to understand whether living near a nuclear waste facility relates to childhood leukemia incidence (*see* **Leukemia Clusters**). Here the authors varied the cluster test method, reference rates, time, and age of children [12].

Smith et al. [11] used sensitivity analysis to help describe the similarities and differences between using **fixed effects** and **random effects** models in a meta-analysis.

Hunter [7] applied the principles of sensitivity analysis to product design by employing the principles of experimental design. These principles could be applied to diagnostic test development (*see* **Diagnostic Tests, Evaluation of**), drug and therapy evaluation.

CHARLES H. GOLDSMITH

Sensitivity

In the context of diagnostic testing or disease **screening**, sensitivity refers to the proportion of individuals with the target disease who have a positive test result. In other words, it is the probability that an actual case of disease will be correctly diagnosed by the test. In probability terms, sensitivity is Pr(positive test|disease). Consider Table 1 for the general relationship between the test results and the true disease state. Then, the sensitivity is given by $a/(a+c)$. A synonym is the *true positive rate*, invoking the proportion of positive test results among the denominator of true disease cases.

Achievement of high sensitivity is important when case detection is important, specifically where the implied costs of missing disease cases (i.e. giving **false negative** test results to cases) are high relative to the costs of incorrectly assigning positive test results to individuals without the disease (the so-called **false positive** results). Typically, if the test is designed for high sensitivity, the false positive rate $b/(b+d)$ will also be high and the test **specificity** $d/(b+d)$ will be low.

A test with high sensitivity is useful clinically for the purpose of ruling out possible disease; a negative result from such a test implies a relatively high chance of not having the disease.

Therapeutic decisions are often considered using a **likelihood ratio** calculation. The likelihood ratio, LR, here is

$$LR = \frac{\text{Pr(positive test|disease)}}{\text{Pr(positive test|no disease)}}$$

or, equivalently the ratio of sensitivity to (1 − specificity). The positive and negative **predictive values** are also relevant.

In simple formulations, sensitivity and specificity are often assumed to be independent of the **prevalence** of disease in the population. In practice, these test characteristics may actually depend on prevalence, for a variety of reasons. For instance, if testing is carried out in a population in which the prevalence is higher because of a greater proportion of mild disease, one would expect sensitivity to be lower. Such effects may occur artifactually on occasion; for instance, because of different clinical definitions of disease operative in various populations.

Table 1

	Disease present	Disease absent
Test positive	a	b
Test negative	c	d

A second meaning of sensitivity is used in the context of describing the measurement properties of a device. The sensitivity here refers to the smallest stimulus that the device can detect, or the smallest input required so that the device can provide an appropriate output. This idea is commonly used to describe electronic components, but is also used to characterize the lowest concentration or amount of a substance that is detectable by the device, such as in clinical chemistry testing. A similar interpretation pertains to the sensitivity of an individual, organism or biological system, depending on the context.

In the context of data analysis, sensitivity may refer to the degree of dependence of the results to assumptions invoked by the particular techniques employed (e.g. an assumption of **normality** in a **regression** calculation), or to features in the data (e.g. the presence and position of an outlier observation). Lack of sensitivity to such characteristics is known as **robustness**. For further details of methods to examine sensitivity (in this sense), see **sensitivity analysis**.

STEPHEN D. WALTER

Separate Families of Hypotheses

A fundamental problem in statistical analysis is that of the choice between alternate statistical models. In this context, the following questions may arise.

1. Is there any evidence that different models give significantly different fits to the data?
2. If it is assumed that one model is true, what is the evidence provided by the data as to which is the true one? (This question is often the basis of a **Bayesian** formulation of model choice.)
3. If one model represents the currently maintained hypothesis, is there any evidence of a departure from it in the direction of another model?

To compare models, the Neyman–Pearson theory of **hypothesis testing** may be used if the models belong to the same family of distributions and the relevant comparisons involve **hierarchical** (or nested) models. However, special procedures are needed if the models belong to families that are separate, in the sense that an arbitrary member of one family cannot be obtained as a limit of members of the other.

A considerable amount of research on separate families of hypothesis has been done since the fundamental work of Cox [7, 8], who first dealt with the problem. For previous reviews and references, see [11, 15–18, 21, 24].

This article first presents the results of Cox and some alternatives. Then the Bayesian approach is introduced. Finally, some references to applications of this work are given.

Cox Procedure and Alternatives

Let $\mathbf{y} = (y_1, \ldots, y_n)$ be independent observations from some unknown distribution. Suppose that there are **null** and **alternative hypotheses** H_f and H_g specifying parametric densities $f(\mathbf{y}, \boldsymbol{\alpha})$ and $g(\mathbf{y}, \boldsymbol{\beta})$ for the random vector $\mathbf{y}$. Hence $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are unknown vector parameters and it is assumed that the families are separate in the sense defined above. Formal definitions of separate or nonnested hypotheses are given in [10] and [27].

The asymptotic tests (*see* **Large-sample Theory**) developed by Cox [7, 8] were based on a modification of the Neyman–Pearson maximum **likelihood ratio**. If H_f is the null hypothesis and H_g the alternative hypothesis, the test statistic considered was

$$T_{fg} = lr_{fg}\left(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}}\right) - \mathrm{E}_{\hat{\boldsymbol{\alpha}}}\{lr_{fg}(\boldsymbol{\alpha}, \boldsymbol{\beta}_{\boldsymbol{\alpha}})\},$$

where for a random sample of size n, $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{\beta}}$ denote the maximum likelihood estimators of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ respectively, $lr_{fg}(\boldsymbol{\alpha}, \boldsymbol{\beta}) = l_f(\boldsymbol{\alpha}) - l_g(\boldsymbol{\beta})$ is the log-likelihood ratio, $\boldsymbol{\beta}_{\boldsymbol{\alpha}}$ is the probability limit, as $n \to \infty$, of $\hat{\boldsymbol{\beta}}$ under H_f, and the subscript $\boldsymbol{\alpha}$ means that expectations and so on are calculated under H_f.

Cox showed that, asymptotically, under the alternative hypothesis T_{fg} has a negative mean and that under the null hypothesis T_{fg} is normally distributed with mean zero and variance

$$V_{\boldsymbol{\alpha}}(T_{fg}) = V_{\boldsymbol{\alpha}}\{lr_{fg}(\boldsymbol{\alpha}, \boldsymbol{\beta}_{\boldsymbol{\alpha}})\} - \mathbf{C}'_{\boldsymbol{\alpha}}\mathbf{I}^{-1}\mathbf{C}_{\boldsymbol{\alpha}},$$

where $\mathbf{C}_{\boldsymbol{\alpha}} = \partial \mathrm{E}_{\boldsymbol{\alpha}}\{lr_{fg}(\boldsymbol{\alpha}, \boldsymbol{\beta}_{\boldsymbol{\alpha}})\}/\partial\boldsymbol{\alpha}$, and $\mathbf{I}_{\boldsymbol{\alpha}}$ is the **information matrix** of $\boldsymbol{\alpha}$.

When H_g is the null hypothesis and H_f is the alternative hypothesis, analogous results are obtained for a statistic T_{gf}. Therefore $T^*_{fg} = T_{fg}\{V_{\boldsymbol{\alpha}}(T_{fg})\}^{-1/2}$ and $T^*_{gf} = T_{gf}\{V_{\boldsymbol{\beta}}(T_{gf})\}^{-1/2}$, under H_f and H_g respectively, can be considered as approximately standard normal variates, and two-tailed tests can be performed. For example, if T^*_{fg} is significantly negative, there is evidence of a departure from H_f in the direction of H_g. If T^*_{fg} is significantly positive, there is evidence of a departure from H_f in the opposite direction to H_g. The possible outcomes when both tests are undertaken are shown in Table 1. The decision-related terms of accept and reject are used for simplicity. Rejection of both hypotheses suggests that it is necessary to look elsewhere for an appropriate model. Acceptance of both implies that there is no evidence with which to choose between the models. Possible acceptance suggests that further testing is required, since while one model is not rejected, the other is rejected in favor of alternatives in a direction opposite to that of the model which is not rejected.

As an illustration suppose that H_f specifies that the distribution is **lognormal** and H_g specifies that it is **Weibull**; that is,

$$\mathrm{H}_f : \frac{1}{y_i(2\pi\alpha_2)^{1/2}} \exp\left\{\frac{-(\log y_i - \alpha_1)^2}{2\alpha_2}\right\}$$

Table 1 Possible outcomes from a pair of separate family significance tests

		T_{fg}		
		Significantly negative	Not significant	Significantly positive
T_{gf}	Significantly negative	Reject both	Accept H_f	Reject both
	Not significant	Accept H_g	Accept both	Possible acceptance of H_g
	Significantly positive	Reject both	Possible acceptance of H_f	Reject both

and

$$H_g : \left(\frac{\beta_2}{y_i}\right)\left(\frac{y_i}{\beta_1}\right)^{\beta_2} \exp\left\{-\left(\frac{y_i}{\beta_1}\right)^{\beta_2}\right\}.$$

We then have [23]

$$T_{fg} = n\{\hat{\beta_2}\log\hat{\beta_1} - \beta_{2\hat{\alpha}}\log\beta_{1\hat{\alpha}} - \log\hat{\beta_2} + \log\beta_{2\hat{\alpha}} - \hat{\alpha_1}(\hat{\beta_2} - \beta_{2\hat{\alpha}})\}$$

and

$$V_\alpha\{T_{fg}\} = 0.2183\ n,$$

where

$$\beta_{1\hat{\alpha}} = \exp\left\{\hat{\alpha_1} + \frac{1}{2}(\alpha_2)^{1/2}\right\} \text{ and } \beta_{2\hat{\alpha}} = \frac{1}{(\hat{\alpha_2})^{1/2}}.$$

Also,

$$T_{gf} = n\left\{\hat{\beta_2}(\hat{\alpha_1} - \alpha_{1\hat{\beta}}) + \frac{1}{2}\log\frac{\hat{\alpha_2}}{\alpha_{2\hat{\beta}}}\right\}$$

and

$$V_\beta\{T_{gf}\} = 0.2834\ n,$$

where

$$\alpha_{1\hat{\beta}} = \frac{-0.5772}{\hat{\beta_2}} + \log\hat{\beta_1} \text{ and } \alpha_{2\hat{\beta}} = \frac{1.6449}{\hat{\beta}_2^2}.$$

As an alternative to this approach, Cox [7] suggested the combination of the two models in a general model of which they would be both special cases. The density could be taken to be proportional to the exponential mixture [3]

$$\{f(\mathbf{y}, \boldsymbol{\alpha})\}^\lambda\{g(\mathbf{y}, \boldsymbol{\beta})\}^{1-\lambda},$$

or a linear mixture distribution [28]

$$\lambda f(\mathbf{y}, \boldsymbol{\alpha}) + (1-\lambda)g(\mathbf{y}, \boldsymbol{\beta}),$$

and inferences concerning λ are possible. These mixtures can be generalized for testing more than two models. The exponential mixture is the base of much of the econometric work. Cox also outlined a general formulation from the point of view of Bayesian decision theory.

Likelihood inference was used by Lindsey [13, 14] to compare models. His approach is based on the relative likelihoods

$$R_f(\tilde{P}_f) = \prod_j \left(\frac{\tilde{P}_{fj}}{\hat{P}_j}\right)^{n_j}$$

and

$$R_g(\tilde{P}_g) = \prod_j \left(\frac{\tilde{P}_{gj}}{\hat{P}_j}\right)^{n_j},$$

where $\tilde{P}_{fj} = \int_\delta^\gamma f(y_j,\ \hat{\boldsymbol{\alpha}})\ \mathrm{d}y_j$, $\tilde{P}_{gj} = \int_\delta^\gamma g(y_j,\ \hat{\boldsymbol{\beta}})\ \mathrm{d}y_j$, and $\hat{P}_j = n_j \big/ \sum_i n_i$, in which $\hat{P}_j$ is the **maximum likelihood** estimator obtained from a **multinomial** with endpoints of the jth interval defined by $\delta = y_j - 1/2\Delta_j$ and $\gamma = y_j + 1/2\Delta y_j$ and where Δy_j is the width of the jth interval. The higher the relative likelihood, the higher is the plausibility of that model.

An **information** criterion was used by Sawyer [29], who proposed the alternative to Cox statistics,

$$S_{fg}(\hat{\boldsymbol{\alpha}}) = \mathrm{E}_{\hat{\boldsymbol{\beta}}}\{lr_{fg}(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})\} - E_{\hat{\boldsymbol{\alpha}}}\{E_{\hat{\boldsymbol{\beta}}}[lr_{fg}(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\beta}})]\},$$

with the analogous definition for a statistic $S_{gf}(\boldsymbol{\beta})$. These statistics are asymptotically normally distributed.

Shen [34], also using **Kullback–Liebler** measure of direct divergence of a density function $g(\mathbf{y}, \boldsymbol{\beta})$ from a target density function $f(\mathbf{y}, \boldsymbol{\alpha})$, proposed a test of H_f against H_g based on a classical chi-square result for the likelihood ratio (*see* **Likelihood Ratio Tests**) by testing $g(\mathbf{y}, \boldsymbol{\beta}_{\boldsymbol{\alpha}})$ against $g(\mathbf{y}, \boldsymbol{\beta})$ since $g(\mathbf{y}, \boldsymbol{\beta}_{\boldsymbol{\alpha}})$ is the closest member to $f(\mathbf{y}, \boldsymbol{\alpha})$.

A test based on the empirical **moment generating function** was studied by Epps et al. [9]. The statistic is based on the asymptotically normal distribution of

$$G_{fg} = M(t) - M_f(t, \hat{\boldsymbol{\alpha}}),$$

where $M(t) = n^{-1} \sum \exp(ty_j)$ and $M_f(t, \boldsymbol{\alpha}) = \mathrm{E}_{\boldsymbol{\alpha}}\{\exp(ty)\}$, are, respectively, the empirical moment generating function and the moment generating function of $f(y, \boldsymbol{\alpha})$.

Sawyer [30], using the distributional results in [8], proposed a multiple test applied when K alternate models are under consideration. Let $f_i(y, \boldsymbol{\alpha}_i), i = 1, \ldots, K$, be the densities considered, and T_{ij}, the $K - 1$ Cox statistics for testing the null hypothesis H_i against each alternative hypothesis H_j, $j \neq i$, and let $\mathbf{T}'_i = (T_{i1}, \ldots, T_{i,i-1}, T_{i,i+1}, \ldots, T_{ik})$. The statistics for testing H_i against all others H_j, $j \neq i$, is

$$\mathbf{T}'_i \boldsymbol{\Sigma}^{-1} \mathbf{T}_i,$$

which is asymptotically χ^2_{k-1} under H_i. Here $\boldsymbol{\Sigma}$ is the covariance matrix $\mathbf{C}_i(T_{ij}, T_{i1})$ which is obtained from the results of Cox. An analogous test can be obtained from the exponential mixture as a Lagrange multiplier test.

Comparison among these alternative statistics does not suggest any general preferences.

Finally, other alternative tests for separate families are based on most powerful invariant statistics [20], the generalized **method of moments** [2] and **bootstrap** methods [31–33, 36].

Bayesian Analysis

Another general approach suggested by Cox [7] used Bayesian inference. The posterior odds for H_f vs. H_g are

$$\frac{\pi_f \int f(\mathbf{y}, \boldsymbol{\alpha}) \pi_f(\boldsymbol{\alpha}) \, \mathrm{d}\boldsymbol{\alpha}}{\pi_g \int g(\mathbf{y}, \boldsymbol{\beta}) \pi_g(\boldsymbol{\beta}) \, \mathrm{d}\boldsymbol{\beta}} = \frac{\pi_f}{\pi_g} B_{fg}(y),$$

where π_f and π_g are the **prior probabilities** of H_f and H_g, respectively, and $\pi_f(\boldsymbol{\alpha})$ and $\pi_g(\boldsymbol{\beta})$ are the prior probabilities for the parameters conditional on H_f and H_g. $B_{fg}(y)$ is the Bayes factor and represents the weight of evidence in the data for H_f over H_g. Cox also gives a general expression when **loss functions** are involved, and a large-sample approximation.

One difficulty with this approach lies in the fact that the prior knowledge expressed by π_f and $\pi_f(\boldsymbol{\alpha})$ must be coherent with that of π_g and $\pi_g(\boldsymbol{\beta})$. If the parameter spaces have different dimensions and there is no simple relation between the parameters, the problems are not simple. When prior information is weak and improper priors are used there are also difficulties and paradoxes with the use of Bayes factors which are unspecified (see [1, 19]). To overcome these difficulties due to improper priors the following alternatives have been proposed recently.

Posterior Bayes Factor [1]

The posterior density $\pi_f(\boldsymbol{\alpha}|y)$ under H_f is, by **Bayes' theorem**,

$$\pi_f(\boldsymbol{\alpha}|\mathbf{y}) = \frac{f(\mathbf{y}, \boldsymbol{\alpha}) \pi_f(\boldsymbol{\alpha})}{\int f(\mathbf{y}, \boldsymbol{\alpha}) \pi_f(\boldsymbol{\alpha}) \, \mathrm{d}\boldsymbol{\alpha}}.$$

Let

$$\bar{l}_f(\boldsymbol{\alpha}) = \int f(\mathbf{y}|\boldsymbol{\alpha}) \pi(\boldsymbol{\alpha}|\mathbf{y}) \, \mathrm{d}\boldsymbol{\alpha}$$

be the posterior mean of the likelihood function under H_f. Define $\bar{l}_g(\boldsymbol{\beta})$ similarly. The ratio of the posterior means $PB_{fg} = \bar{l}_f(\boldsymbol{\alpha}) / \bar{l}_g(\boldsymbol{\beta})$ is called the posterior Bayes factor.

Partial Bayes Factor [19]

Here, the sample is divided in two parts $(y, \ldots, y_i)$ $(y_{i+1}, \ldots, y_n) = (\mathbf{x}, \mathbf{z})$. The first part is used as a training sample to obtain a proper posterior $\pi_f(\boldsymbol{\alpha}|\mathbf{x})$ which is taken as a prior distribution to be used with the second part $\mathbf{z}$ of the data. Similarly, $\pi_g(\boldsymbol{\beta}|\mathbf{x})$ is obtained. The partial Bayes factor is defined as

$$PB_{fg}(\mathbf{z}|\mathbf{x}) = \frac{\int f(\mathbf{z}, \boldsymbol{\alpha}) \pi_f(\boldsymbol{\alpha}|\mathbf{x}) \, \mathrm{d}\boldsymbol{\alpha}}{\int g(\mathbf{z}, \boldsymbol{\beta}) \pi_g(\boldsymbol{\beta}|\mathbf{x}) \, \mathrm{d}\boldsymbol{\beta}}$$

Intrinsic Bayes Factor [5]

Suppose that $y = (\mathbf{x}, \mathbf{z})$ and that $\mathbf{x}$ is a minimal training sample for the comparison of H_f and H_g if the posteriors for $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are proper and no subset of $\mathbf{x}$ gives a proper posterior. There are usually many training samples. Let N be the number of training

samples $\mathbf{x}$. The idea of an intrinsic Bayes factor is to use the median or average of all the partial Bayes factors obtained for the N training samples. If N is too large the suggestion is to take a random sample from the collection of possible training samples.

The geometric intrinsic Bayes factor is

$$IB_{fg}^{G}(\mathbf{y}) = \left\{ \prod_{i=1}^{N} PB_{fg}(\mathbf{z}_i|\mathbf{x}_i) \right\}^{1/N},$$

the arithmetic Bayes factor is

$$IB_{fg}^{A}(\mathbf{y}) = \frac{1}{N} \sum_{i=1}^{N} PB_{fg}(\mathbf{z}_i|\mathbf{x}_i),$$

and the median Bayes factor is $IB_{fg}^{M}(\mathbf{y}) = \text{med}\{PB_{fg}(\mathbf{z}_i|\mathbf{x}_i)/i = 1, \ldots, N\}$. Other measures of location could also be defined.

Fractional Bayes Factor [19]

The Fractional Bayes Factor with training fraction b is defined by

$$B_{fg}^{b}(\mathbf{y}) = \frac{q_f(\mathbf{y})}{q_g(\mathbf{y})},$$

where

$$q_f(\mathbf{y}) = \frac{\int f(\mathbf{y}, \boldsymbol{\alpha}) \pi_f(\boldsymbol{\alpha}) \, \mathrm{d}\boldsymbol{\alpha}}{\int f^b(\mathbf{y}, \boldsymbol{\alpha}) \pi_f(\boldsymbol{\alpha}) \, \mathrm{d}\boldsymbol{\alpha}}$$

and there is an analogous expression for $q_g(\mathbf{y})$.

These different Bayes factors can be interpreted using Jeffreys' rule, but their properties are still under investigation.

Applications

Applications of the procedures of this article are reviewed in [21, 24], and [17], where the focus is primarily on econometric research. In econometrics the emphasis is on testing, $\mathrm{H}_0 : \mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}_0\lambda \sim \mathrm{N}(\mathbf{0}, \mathbf{I}\sigma_0^2)$ against $\mathrm{H}_i : \mathbf{y}_i = \mathbf{Z}_i\boldsymbol{\gamma}_i + \boldsymbol{\varepsilon}_i, \boldsymbol{\varepsilon}_i \sim \mathrm{N}(\mathbf{0}, \mathbf{I}\sigma_i^2)$, $i = 1, \ldots, m$, where $\mathbf{X}$ and $\mathbf{Z}_i$ represent separate explanatory variables. Pereira [26] tests H_0 vs. H_1, when the $\boldsymbol{\varepsilon}_i$ follow a Weibull distribution. He shows that the results of [22] hold also when the alternative hypotheses specify alternative regressors with alternative error distributions. McAller's paper [17] also reviews the linear $\times$ loglinear and the **time series** hypotheses.

Some biostatistical applications can be found in [4, 6, 8, 12–14, 25, 32, 33, 35], and [36].

Sequence Analysis

Owing to the abundant and rapidly increasing availability of genomic sequence data, we are confronted with many new methodologic problems, most of which are statistical in nature. Statistical significance estimates play a critical role in biologic sequence comparisons, or, more specifically, in pairwise alignment. The most basic sequence analysis task is to ask if two genomic or protein sequences are homologous. That is, are they derived from the same evolutionary ancestor (*see* **Cladistic Analysis**)? This can be achieved by first aligning the sequences to measure the sequence similarity by using some scoring function, and then using a test for statistical significance of the similarity measures to infer whether alignment is due to chance alone.

We assume an evolutionary model where the two sequences have diverged from a common ancestor by the process of **mutation** and selection (*see* **Population Genetics**). Mutations can be classified by the type of changes caused by substitution, which changes one nucleotide to another in a **DNA sequence** or changes one amino acid to another in a protein. Natural selection works as a screening process to weed out certain deleterious mutations and favors neutral or advantageous mutations. Comparisons of two sequences usually cannot determine whether a deletion has occurred in one sequence or an insertion has occurred in the other. Insertions and deletions are together referred to as *gaps*. When scoring the alignment, the gaps are penalized by assigning a cost to a gap by a function of a gap length. There is a well-established theory for generating a substitution matrix for every pair of nucleotides or pair of amino acids.

Let $x = x_1, x_2, \ldots, x_n$ and $y = y_1, y_2, \ldots, y_m$ be two sequences of length n and m, respectively, where x_i and y_j represent the elements of the set {A, G, C, T} in the case of a DNA sequence, and they assume values from the set of 20 amino acids in the case of proteins. For simplicity, suppose we are given two aligned sequences of equal length, i.e. $n = m$. How do we test for a significantly good match? The null hypothesis is that x and y do not diverge from the common ancestor. So, the hypothesis assumes an underlying random model R where x_i in x and y_j in y occur independently and hence the probability of two sequences is just the product of the probabilities of each letter in the sequences:

$$\Pr(x, y|\mathrm{R}) = \prod p_{x_i} \prod p_{y_j}. \tag{1}$$

The alternative hypothesis A is that x and y have diverged from same ancestor, i.e. x and y have each independently been derived from some unknown ancestor sequence z. Let $p_{x_i y_j}$ be the probability that x_i and y_j are derived from z_k. So, the probability for the whole alignment is

$$\Pr(x, y|\mathrm{A}) = \prod p_{x_i y_j}. \tag{2}$$

The ratio of these two **likelihoods** gives a reasonable score for the alignment, since it compares the alternative hypothesis that is based on evolution with the **null hypothesis** of the random model. To achieve an additive scoring system, we take the logarithm of this ratio by defining the entries of the substitution score matrix by

$$s(x_i, y_j) = \log\left(\frac{p_{x_i y_j}}{p_{x_i} p_{y_j}}\right). \tag{3}$$

For proteins, we have a 20×20 matrix, with $s(x_i, y_j)$ in the position i, j in the matrix, where x_i and y_j correspond to ith and jth residues. The most commonly used scoring matrices are PAM matrices [2] and BLOSUM matrices [6].

Now, given the scoring system, we need to have an algorithm to find an optimal alignment for a pair of sequences. There are several methods for finding alignment, depending on whether interest focuses on global alignment, i.e. involving entire sequences, or on local alignment, i.e. involving just some part of the sequences. One approach would be to find all the alignments and then pick the best one. However, the number of alignments between two sequences is exponential, and such an approach would result in an extremely slow algorithm. To find the global alignment of protein sequences, Needleman & Wunch [9] developed a dynamic programming algorithm, and there are a number of extensions to the original algorithm, most notably by Gotoh [4].

The basic idea of the Needleman & Wunch algorithm is to build up the optimal alignment recursively from the previously aligned subsequences. We construct a matrix M indexed by i and j corresponding to x_i and y_j in the sequences x and y, respectively. Let d_{ij} be the score of the optimal alignment between the subsequence of x up to x_i and

subsequence of y up to y_j. If $d_{i-1,j-1}$, $d_{i-1,j}$, and $d_{i,j-1}$ are known, then it is possible to calculate d_{ij}. There are three possible ways that the d_{ij} could be obtained. The x_i could be aligned to y_j, in this case, $d_{ij} = d_{i-1,j-1} + s(x_i, y_j)$; or x_i is aligned to a gap, in this case $d_{ij} = d_{i-1,j}$ + gap penalty; or y_j is aligned to a gap, in this case $d_{ij} = d_{i,j-1}$ + gap penalty. The optimal score will be the largest of these three values, therefore

$$d_{ij} = \max \begin{cases} d_{i-1,j-1} + s(x_i, y_j), \\ d_{i-1,j} + \text{gap penalty}, \\ d_{i,j-1} + \text{gap penalty}. \end{cases} \tag{4}$$

We fill the entries of the matrix M recursively, and keep a pointer in each cell back to the cell from which it was derived. The value in the final cell is, by definition, the best score for an alignment of x and y. To find the alignment itself, we trace back through the matrix M in the usual manner, setting our pointer back from the final cell, and retracing back through the cell from which it was derived. At the end, we will reach the start of the matrix, $i = j = 0$.

Local alignment algorithms are very similar to the preceding method, except that the goal is different. Instead of trying to find similarity between the sequences, we are now trying to find the best alignment between subsequences of x and y. The highest scoring alignment of subsequences of x and y is called the best local alignment. The algorithm by Smith & Waterman [11] is commonly used, and is

$$d_{ij} = \max \begin{cases} 0, \\ d_{i-1,j-1} + s(x_i, y_j), \\ d_{i-1,j} + \text{gap penalty}, \\ d_{i,j-1} + \text{gap penalty}. \end{cases} \tag{5}$$

The only difference between this and the global optimal score (4) given above is that d_{ij} can take on the value 0 if all other options are negative. Because of the 0 values in the matrix, the score can never become negative, and hence we will obtain areas of similarity even if there are long mismatches or gaps in between them.

Suppose we have optimal alignment. How do we assess the significance of this alignment statistically? The statistical theory has been well developed by Karlin & Altschul [7, 8] and Dembo & Karlin [3] and is implemented in the basic local alignment search tool (BLAST) [1]. BLAST returns a list of high-scoring matched subsequences between the query sequence and sequences in the database. We can determine the distribution of the maximum of N match scores compared with independent random sequences. The score of a match to a random sequence is the sum of many similar random variables, so can be approximated by a normal distribution, and the limiting distribution of the maximum of N identical independent normal variables is known to be the extreme value distribution (EVD) [5]. So, we can use the EVD to calculate the probability that the optimal match from the search of a large number of unrelated sequences has a score greater than our observed maximal score. If this is less than some small value, then the observation is considered significant. FASTA [10] is another heuristic sequence searching package widely used for sequence database search.

HEMANT K. TIWARI

Sequential Analysis

The subject of sequential analysis was initiated by **Abraham Wald** [39, 40] in response to demands for more efficient sampling inspection procedures during World War II.

Sequential Tests of Hypotheses

Wald introduced the sequential probability test (SPRT) of a simple **null hypothesis** $H_0 : f = f_0$ vs. a simple **alternative hypothesis** $H_1 : f = f_1$ based on independent observations $X_1, X_2, \ldots$ having a common density function f (*see* **Hypothesis Testing**). The test stops sampling at stage

$$N = \text{first } n \geq 1 \text{ such that } r_n \leq A \text{ or } r_n \geq B,$$

where $0 < A < 1 < B$, $r_n = \prod_{i=1}^{n} [f_1(X_i)/f_0(X_i)]$ and N is defined to be ∞ if $A < r_n < B$ for all n. The SPRT rejects H_0 if $r_N \leq A$ and rejects H_1 if $r_N \geq B$. Wald & Wolfowitz [41] showed that it has the following optimality property: among all tests whose expected sample sizes under H_0 and H_1 are finite and whose type I and type II error probabilities (*see* **Level of a Test**) are less than or equal to those of the SPRT, denoted by α and β, respectively, the SPRT minimizes the expected sample sizes under H_0 and H_1. Moreover, Wald [39] showed that

$$\alpha \leq \frac{(1-\beta)}{B}, \qquad \beta \leq A(1-\alpha),$$

and that these inequalities become equalities if r_N does not "overshoot" the boundary B or A. Ignoring overshoots, Wald treated these inequalities as equalities and arrived at the approximation $A \simeq \beta/(1-\alpha)$, $B \simeq (1-\beta)/\alpha$ to determine the boundaries of the SPRT from prescribed error probabilities α and β.

Within a few years after Wald's introduction of the subject, it was recognized that sequential hypothesis testing might provide a useful tool in biomedical studies. In particular, making use of Wald's theory of the SPRT, Morton [26] developed a standard for proving genetic linkage (*see* **Linkage Analysis, Model-based**). A number of papers appeared during the 1950s on modifications of the SPRT for the design of sequential clinical trials, and an overview of these developments was given in the first edition of Armitage's book [3] in 1960. Subsequently, Armitage et al. [4] proposed a new alternative to the SPRT and its variants. This is the "repeated significance test" (RST), a detailed treatment of which appeared in the second edition of Armitage's book in 1975. The underlying motivation is that, since the strength of evidence in favor of a treatment from a clinical trial is conveniently indicated by the results of a conventional significance test, it is appealing to apply such a test, with nominal significance level α, repeatedly during the trial. However, the overall significance level α^*, which is the probability that the nominal significance level is attained at some stage, may be substantially larger than α.

For example, suppose that $X_1, X_2, \ldots$ are independent normal with unknown mean μ and known variance σ^2. Let $S_n = X_1 + \cdots + X_n$. The conventional significance test of $H_0 : \mu = 0$ based on $X_1, \ldots, X_n$ rejects H_0 if $|S_n| \geq a\sigma\sqrt{n}$, where $1 - \Phi(a) = \alpha/2$. The RST, with a maximum sample size M, stops sampling and rejects H_0 at stage

$$T = \text{first } n \geq 1 \text{ with } n \leq M \text{ such that } |S_n| \geq a\sigma\sqrt{n}.$$

If $|S_n| < a\sigma\sqrt{n}$ for all $1 \leq n \leq M$, then the RST does not reject H_0. The overall significance level of the test is

$$\alpha^* = \Pr_{\mu=0}(|S_n| \geq a\sigma\sqrt{n} \text{ for some } 1 \leq n \leq M)$$

$$= 1 - \Phi(a) + \sum_{n=2}^{M} p_n(a),$$

where $p_n(a) = \Pr_{\mu=0}(|S_n| \geq a\sigma\sqrt{n}$ and $|S_j| < a\sigma\sqrt{j}$ for $1 \leq j < n)$. Armitage et al. [4] developed a recursive numerical integration algorithm to evaluate $p_n(a)$. The choice of a is such that the overall significance level α^* (instead of the nominal significance level) is equal to some prescribed number. For example, for $\alpha^* = 0.05$ and $M = 71$, Table 5.5 of [3] gives $a = 2.84$, which corresponds to a nominal significance level of $\alpha = 0.005 = \alpha^*/10$. Note that $a = 2.84$ is considerably larger than the value 1.96 associated with a 5% level significance test with fixed sample size M. The price of the smaller expected sample size of the RST is, therefore, a loss of power compared to a fixed sample size test with the same significance level and the same M.

Haybittle [17], Peto et al. [28], and Siegmund [33] proposed the following modification of the RST to increase its power. The stopping rule has the same

form as the preceding RST but the rejection region is modified to

$$T \leq M-1 \quad \text{or} \quad |S_M| \geq c\sigma\sqrt{M},$$

where $a \geq c$ are so chosen that the overall significance level is equal to some prescribed number. In particular, $a = \infty$ gives the fixed sample size test and $a = c$ gives the RST.

Pocock [29] introduced another modification of the RST. Noting that in practice it is difficult to arrange for continuous examination of the data as they accumulate to perform the RST, he considered a "group sequential" (*see* **Data and Safety Monitoring**) version in which X_n above represents an approximately normally distributed statistic of the data in the nth group (instead of the nth observation) and M represents the maximum number of groups. Instead of the square-root boundary $a\sigma\sqrt{n}$ for $|S_n|$ in the group sequential RST, O'Brien & Fleming [27] proposed to use a constant stopping boundary b that does not change with n. Siegmund [34] gives an extensive treatment of the theory of truncated sequential tests, and in particular of the RST and its modifications.

The problem of group sequential testing for the mean of a normal distribution with known variance discussed above serves as a prototype for more complex situations. Note that a group sequential test for a normal mean, assuming M equally sized groups, involves a stopping rule for $(S_1, \ldots, S_M)$ which has a **multivariate normal distribution** with $\text{var}(S_n) = n\sigma^2 = \text{cov}(S_i, S_n)$ for $i \geq n$. For more complicated statistics U_n in more general situations, one has an asymptotically normal distribution for $(U_1, \ldots, U_M)$ whose covariance matrix is not known in advance and has to be estimated from the data. Flexible methods to construct stopping boundaries of group sequential tests in these situations have been proposed by Slud & Wei [35], Lan & DeMets [25], Fleming et al. [13], and Jennison & Turnbull [18] (*see* **Data and Safety Monitoring**).

For example, consider a **clinical trial** whose primary objective is to compare survival times (times to failure) between two treatment groups. Patients enter the trial serially and are randomized to either treatment and then followed until they fail or withdraw from the study, or until the trial is terminated. The trial is scheduled to end by a certain time t_M and there are also $M-1$ periodic reviews at calendar times $t_1, \ldots, t_{M-1}$ prior to t_M (*see* **Data and Safety Monitoring**). Let U_i be the **logrank** statistic calculated at calendar time t_i. Then under the null hypothesis that the two treatment groups have the same survival distribution $(U_1, \ldots, U_M)$ is asymptotically normal, as shown by Tsiatis [38], who considered more general **rank** statistics including the logrank statistics as a special case. It is also shown in [38] how the asymptotic covariances of the U_i can be estimated to perform group sequential testing. For the logrank and many other rank statistics, U_i and $U_j - U_i$ are asymptotically independent for $j > i$, so one needs only estimate $\text{var}(U_i)$ in this case.

Whitehead [42] gives a comprehensive overview of these and other methods for sequential hypothesis testing in clinical trials. He considers the case where $(U_1, \ldots, U_M)$ is asymptotically normal under the null hypothesis, with $U_j - U_i$ asymptotically independent of U_i for $j > i$. Letting V_i denote a consistent estimate of the null variance of U_i for $i = 1, \ldots, M$, he advocates the use of certain triangular stopping boundaries in the (V_i, U_i) plane and has developed a computer package, PEST, for their implementation (*see* **Software, Biostatistical**). These triangular boundaries are associated with the problem of minimizing the maximum expected sample size of sequential tests for the mean μ of a normal distribution subject to constraints on the type I error at $\mu = 0$ and type II error at some $\mu \neq 0$, as shown by Lai [20].

Sequential Estimation

Analysis of the data at the conclusion of a clinical study typically not only permits testing of the null hypothesis but also provides **estimates** of parameters associated with the primary and secondary end points. The use of a stopping rule whose distribution depends on these parameters introduces substantial difficulties in constructing valid **confidence intervals** for the parameters at the conclusion of the study. For example, consider the simple example of independent normal X_i with unknown mean μ and known variance σ^2. For a sample of fixed size n, the sample mean $\overline{X}_n$ is an **unbiased** estimate of μ and has a normal distribution with variance σ^2/n, yielding the classical confidence interval $\overline{X}_n \pm z_{1-\alpha}\sigma/\sqrt{n}$ with coverage probability $1-2\alpha$ for μ, where z_α is the α-**quantile** of the standard normal distribution. If n is replaced by a stopping rule T whose distribution depends on μ, then $\overline{X}_T$ is typically biased and

$\sqrt{T}(\overline{X}_T - \mu)/\sigma$ is no longer standard normal but has a distribution that depends on μ.

Rosner & Tsiatis [31] proposed the following method to construct a $1 - 2\alpha$ confidence interval for μ. For every value of μ, find the quantiles $u_\alpha(\mu)$ and $u_{1-\alpha}(\mu)$ of $\sqrt{T}(\overline{X}_T - \mu)$, i.e.

$$\Pr_\mu[\sqrt{T}(\overline{X}_T - \mu) < u_\alpha(\mu)] = \alpha$$
$$= \Pr_\mu[\sqrt{T}(\overline{X}_T - \mu) > u_{1-\alpha}(\mu)].$$

These probabilities can be computed by the recursive numerical integration algorithm of Armitage et al. [4] when T is bounded by M. Hence the confidence region $\{\mu : u_\alpha(\mu) \le \sqrt{T}(\overline{X}_T - \mu) \le u_{1-\alpha}(\mu)\}$ has coverage probability $1 - 2\alpha$. Note that this confidence region reduces to an interval whose end points are found by intersecting the line $\sqrt{T}(\overline{X}_T - \mu)$ with the curves $u_\alpha(\mu)$ and $u_{1-\alpha}(\mu)$ if there is only one intersection with each curve, which is the case commonly encountered in practice.

Siegmund [33] proposed another approach based on ordering the sample space in a certain way, following an earlier proposal of Armitage [2]. Chapter 5 of Whitehead's monograph [42] gives a comprehensive treatment of this ordering approach. It also discusses the construction and properties of bias-adjusted estimates following sequential tests. Emerson & Fleming [12] proposed an alternative ordering and used it to construct bias-adjusted estimates and confidence intervals.

A considerably simpler class of sequential estimation problems deals with estimation of a parameter θ with prescribed accuracy using a randomly stopped statistic $\hat{\theta}_N$, whose stopping rule N is targeted towards achieving the prescribed accuracy. In these problems, Anscombe's [1] **central limit theorem** for randomly stopped sums typically yields adequate normal approximations for the distribution of $\sqrt{N}(\hat{\theta}_N - \theta)$, which can be used to construct fixed-width confidence intervals for θ. For example, let $X_1, X_2, \ldots$ be independent random variables from a population with mean μ and variance σ^2. The variance of the estimate $\overline{X}_n$ of μ is σ^2/n and an approximate $1 - 2\alpha$ confidence interval for μ is $\overline{X}_n \pm z_{1-\alpha}\sigma/\sqrt{n}$, which can be made to have width $2d$ by choosing n to be the smallest integer $\ge (z_{1-\alpha}\sigma/d)^2$, assuming σ to be known. When σ is unknown, Chow & Robbins [7] proposed to replace it by the sample variances at successive stages, leading to the stopping rule

$$N = \text{first } n \ge m \text{ such that } nd^2/z_{1-\alpha}^2 \ge (n-1)^{-1}\sum_{i=1}^{n}(X_i - \overline{X}_n)^2 + n^{-1}.$$

The confidence interval is taken to be $\overline{X}_N \pm d$. This has approximate coverage probability $1 - 2\alpha$ when d is small, since $\sqrt{N}(\overline{X}_N - \mu)/\sigma$ has a limiting standard normal distribution as $d \to 0$ by Anscombe's theorem. Schmidt et al. [32] used this procedure to construct fixed-width confidence intervals for the concentrations of enzymes in the normal human pancreas. Two-stage and three-stage analogs of this fully sequential procedure were developed by Stein [37] and Hall [16].

Adaptive Allocation, Sequential Design, and Decision Theory

Other topics in the field of sequential analysis of interest to biomedical studies are adaptive treatment allocation (*see* **Adaptive and Dynamic Methods of Treatment Assignment**) and sequential design of experiments. The "**up-and-down**" (staircase) method in bioassay and dosage determination is an example of sequential experimentation. A traditional nonsequential method for performing a **bioassay** experiment is to test a prescribed number of animals at each of several fixed dose levels. In the up-and-down method, one chooses a series of test levels with equal spacing (on an appropriate scale, usually log dose) between doses, and carries out a series of trials using the following rule: use the next higher dose following a negative response and use the next lower dose following a positive response. Details of implementation of the design and applications to estimation of the LD_{50} ("lethal dose 50" – the dose producing response on 50% of the subjects) are given by Dixon & Moood [10] and Dixon [9].

Stochastic approximation, introduced by Robbins & Monro [30], is another example of sequential experimentation. In the context of quantal bioassay, Cochran & Davis [8] considered the following version of the Robbins–Monro scheme. To start the experiment, an initial guess x_1 of LD_{50} is made and m animals are given dose x_1. Let $c > 0$. For $n \ge 1$, let $\hat{p}_n$ be the observed proportion of deaths

in the group of m animals assigned dose x_n, and define

$$x_{n+1} = x_n - cn^{-1}\left(\hat{p}_n - \tfrac{1}{2}\right)$$

to be the dose level at which another group of m animals are tested. The basic idea behind stochastic approximation is to use the recursive scheme $x_{n+1} = x_n - a_n(Y_n - h)$ to find the solution θ of the equation $M(\theta) = h$, in which $M(x)$ is not observable and all that can be observed for each x is a random variable $Y(x)$ with $\mathrm{E}[Y(x)] = M(x)$ and in which $Y_n = Y(x_n)$. Thus, in the quantal bioassay application above, $h = \frac{1}{2}$ and $Y_n = \hat{p}_n$. Under certain regularity conditions, the best choice of a_n is $(\beta n)^{-1}$, where β is the derivative of M at θ. Adaptive stochastic approximation schemes that replace the unknown β in the optimal choice $a_n = (\beta n)^{-1}$ by simple recursive estimates b_n have been proposed and analyzed by Lai & Robbins [24] and Frees & Ruppert [14].

In classical fixed-sample **decision theory**, one has a parameter space containing all possible values of the unknown parameter θ, an action space consisting of all possible actions a, and a **loss function** $L(\theta, a)$ representing the loss when the true parameter is θ and action a is taken. In sequential decision theory, one has a sequence of actions $a_1, a_2, \ldots$ and loss $L_n(\theta, a_n)$ at stage n. For sequential experimental design problems of the type described above, a_n is the choice of the design level x_n at stage n. For sequential hypothesis testing (or estimation) problems, a_n represents whether stopping occurs at stage n and also acceptance of the null or alternative hypothesis (or the estimate of the unknown parameter) when stopping indeed occurs at stage n. In this case, it is more convenient to represent the action sequence $(a_1, a_2, \ldots)$ by a stopping rule denoting when stopping occurs and a terminal decision rule denoting the action taken upon stopping. Given successive observations $Z_1, Z_2, \ldots$, whose joint distribution depends on θ, a finite-horizon sequential decision problem, with horizon M, is to choose action $d_n = d_n(Z_1, \ldots, Z_n)$ at stage n on the basis of the current and past observations, for $1 \le n \le M$ (*see* **Adaptive and Dynamic Methods of Treatment Assignment**). The overall risk of $(d_1, \ldots, d_M)$ is $R(\theta) = \mathrm{E}_\theta[\sum_{n=1}^{M} L_n(\theta, d_n)]$. In particular, putting a **prior distribution** G on the parameter space, one can consider the Bayes rule that minimizes $\int R(\theta)\,\mathrm{d}G(\theta)$ (*see* **Bayesian Methods**). The solution can be found by the backward induction algorithm of dynamic programming. Applications of the algorithm to determine optimal stopping boundaries of group sequential tests have been given by Berry & Ho [5] and Eales & Jennison [11]. Chernoff's monograph [6] gives a comprehensive treatment of optimal stopping problems in sequential analysis. Spiegelhalter et al. [36] discuss Bayesian approaches to monitoring clinical trials.

The handbook edited by Ghosh & Sen [15] gives extensive references and survey articles on a wide variety of topics in sequential analysis including those covered in the present brief review which is oriented towards biomedical applications. The monograph by Jennison & Turnbull [19] on group sequential tests and the review articles by Lai [21, 22, 23] describe important developments in stochastic approximation, interim and terminal analyses of clinical trials with failure-time endpoints, and other areas of sequential analysis following the publication of the First Edition and provide updated lists of references.

Sequential Linkage Analysis

The term "sequential **linkage analysis**" has several possible meanings to genetic epidemiologists. One arises from extending an already sampled pedigree, by sequentially adding additional contiguous segments to it based upon the presence of the phenotype (*see* **Genotype**) of interest. This sequential extension procedure was originally developed for **segregation analysis**, but is now sometimes used in linkage analysis (e.g. [12]). A second meaning arises from serially adding linked loci, as in the *variance component linkage method* implemented in the program Sequential Oligogenic Linkage Analysis Routines (SOLAR), which is actually closer to a stepwise analysis procedure, rather than a sequential sampling one (e.g. [2]). But the primary meaning (and the one we discuss here) arises from the classical development of the lod score by Morton [8], in which sequential sampling of independent family units is performed until prespecified levels for or against linkage are reached. A very good overview of the history of sequential designs in genetic linkage studies can be found in Böddeker & Ziegler [3].

Sequential Probability Ratio Test (SPRT) and the Lod Score

The roots of the lod score method, like all sequential ones, go back to Wald's Sequential Probability Ratio Test (SPRT) [13]. Wald developed this theory during the Second World War as a way to minimize measurement costs when testing meant destruction of expensive samples (e.g. firing high-tech proximity-fused antiaircraft ammunition). Morton recognized that an analogy existed in genetic linkage, when genotyping was both limited and expensive, being confined to a small number of blood **markers**, with relatively few **genetic epidemiology** groups working on any given problem. He derived the lod score method for *post hoc* combining of linkage results across investigations which, if invented today, might be termed a **meta-analysis** or "retrospective collaboration" [7]. Each pedigree is added one at a time, followed by formal analyses to see if we continue sampling or have reached a conclusion in favor or against linkage, in which case pedigree sampling stops.

The SPRT approach starts from the recognition that a hypothesis test depends upon four interconnected quantities:

1. type I error (α) = the probability of concluding for H_1 if H_0 is true;
2. type II error (β) = (1 − power) = the probability of concluding for H_0 if H_1 is true;
3. effect size (D) = a measure of how far H_1 is from H_0; and
4. sample size (N).

In traditional (fixed sampling) theory, we hold both α and N constant, and take whatever relationship we find in the data between the other two factors (β, D) [usually, N is chosen to achieve a target (β, D) relationship]. By contrast, the SPRT a priori fixes the first three quantities (α, β and D), allowing N to vary with the experiment. It therefore automatically accounts for sampling fluctuations, as they occur at every stage of the process, requiring just the right amount of additional samples to achieve the target precision in type I and II errors for the target effect size, D. However, the "price" we pay for being able to fix these three factors is that N could theoretically extend indefinitely. Fortunately, sequential theory demonstrates that:

- The sequential process *will* terminate at a finite N with probability "1" (almost surely).
- On average, the N required under sequential sampling will be smaller than that for the "best" fixed sample test that gives the same power [13].

For the SPRT applied to the linkage problem, if θ is the recombination fraction and $f(x_n|\theta)$ is the **likelihood** function of the cumulative pedigree data x_n, up to the nth family unit, then to test the simple hypothesis H_0: $\theta = \frac{1}{2}$ (no linkage) against any simple alternative H_1: $\theta = \theta_1 \neq \frac{1}{2}$ (such as $\theta_1 = 0$, tight linkage, for instance), the SPRT procedure defines the ratio of the probabilities:

$$Z_n = \ln \frac{f(x_n|\theta = \theta_1)}{f\left(x_n|\theta = \frac{1}{2}\right)} \quad \text{for } n = 1, 2, \ldots.$$

By the **maximum likelihood** principle, when data are more compatible with H_1, then this ratio will tend to grow larger with increasing n, while, if the data are more compatible with H_0, then Z_n will tend to become more negative. Before sampling, prespecified

limits are defined, $a^* < 0 < b^*$, which are functions of the target α, and β. Analysis of additional data stops when the first Z_n falls outside these limits, with a decision for the corresponding hypothesis.

For convenience, Morton used the base 10 log instead of the natural log in defining his lod score, but this just applies a scalar multiplier to the SPRT statistic. An important theoretical result is that very simple bounds exist on a^* and b^* which can be used to define slightly wider (more liberal) stopping criteria, but that are much easier to compute, namely

$$A = \frac{1-\beta}{\alpha} \leq a^* \quad \text{and} \quad b^* \leq B = \frac{\beta}{1-\alpha}.$$

If we take type I error $= \alpha = 0.001$ and power $= (1-\beta) = 0.99$, we have $\log(A) = +3$ and $\log(B) = -2$, the values proposed by Morton [8].

Beyond the Lod Score

The SPRT method can be readily extended to both one-sided as well as two-sided compound hypothesis tests in many statistical frameworks (e.g. [5, 11, 15], and [16]). In linkage, sequential adaptations have been extended beyond strongly model-based linkage tests in pedigrees to model-free linkage tests, and to smaller sampling units (e.g. [14]) as well as to joint linkage/association tests of disequilibrium (*see* **Linkage Disequilibrium**) using group sequential designs [6]. The sequential sampling philosophy has also been advocated as an approach to reduce genotyping costs in linkage. Boehnke & Moll [4] demonstrated via simulation that considerable savings can be produced by ranking pedigrees by the evidence for segregation at a locus and sequentially genotyping for linkage accordingly.

Sequential Sampling vs. Sequential Analysis

While sequential testing methods have been widely available for the past 50 years, they are still relegated to a relatively small universe of devoted followers, and are largely ignored by the "fixed sampling" world of investigators. This is partly due to the analytic difficulty of obtaining some of the solutions, and partly to the practical difficulty of conducting a truly sequentially sampled study. Genotyping in small family or relative pair units is not very cost efficient, and the prospect of having quickly to clean, transform, and reanalyze data at every sampling point is daunting. Even the more practical block sequential designs [16] require a higher degree of organization and immediate response to data than most investigators are willing or able to commit, although there is increasing enthusiasm for the promise of such approaches [6]. But perhaps the most unappealing aspect of true sequential sampling is the idea that sample size for a given study should be so completely dictated by the test of any single hypothesis. Usually, there are many phenotypic outcomes and many hypotheses to be tested. This is particularly true in the context of a genome scan, when one may want to use the same family data to search for genes for many phenotypes using a large spanning set of linkage markers. The requirement of true sequential sampling would be prespecifying exactly one primary hypothesis on which to make sampling decisions to the exclusion of all others, and could very easily leave one with an inadequate sample for all other hypotheses of interest. While actual sequential *sampling* may not be very practicable, sequential *analysis* of fixed-sample data is not only practicable but can be quite efficient, at least in the special case of genome-wide linkage or **association** scans. The theory of sequential sampling predicts that the same power can be achieved at a substantially lower average sample number using sequential analysis. Fixed sample advocates usually argue that this "saving" is meaningless if one has already decided to use a fixed sampling scheme, since it is too late to make use of the savings. But in the special case of genome-wide scans, we can gain a lot if we envision a genome scan as a two-step process, an initial hypothesis-generation or "training" phase, in which promising regions are suggested, followed by a confirmatory hypothesis testing phase in which only those few regions are formally tested in independent samples. A special class of sequential procedures, called sequential multiple decision procedures (SMDPs), allow us to formalize and optimize this concept.

SMDPs

SMDPs [1] provide a powerful generalization of the traditional two-hypothesis paradigm to allow U mutually exclusive and exhaustive hypotheses, H_i, where $i = 1, 2, \ldots, U \geq 2$, of which we want to

select one. In the particular case of a genome-wide scan [9, 10], we form every possible subset of markers, (U total) and try to select the one subset that contains only the truly linked (or associated) ones. In traditional hypothesis testing, we have only two hypotheses, H_0 and H_1, two corresponding decisions, D_0 and D_1, and two types of errors, α and β, with relationship for any test procedure, $\wp$:

- $(1-\alpha) = \Pr_{\wp}[\text{make decision } D_0 | H_0 \text{ is true}]$.
- $(1-\beta) = \Pr_{\wp}[\text{make decision } D_1 | H_1 \text{ is true}]$.

But in the SMDP framework, we have U types of errors, α_i, where

- $(1-\alpha_i) = \Pr_{\wp}[\text{make decision } D_i | H_i \text{ is true}]$ for $i = 1, 2, \ldots, U$.

We wish to minimize the probability of any incorrect decision, or conversely maximize the probability of a correct decision (PCD), denoted by P^*, on condition that the "distance" between hypotheses (using an appropriately defined metric) is at least at a certain prespecified "effect size". In the case of a genome-wide scan [9, 10], we compare the *relative* evidence for linkage (or association) among the markers, instead of looking for *absolute* evidence at each marker. As evidence accumulates with each successive data point, the few "signal" markers will eventually separate from the more prevalent background "noise" markers as a distinct subgroup, thus terminating the sequential analysis and identifying the hypothesis to select. For example, using one of the variations on the Haseman–Elston (H–E) method (*see* **Linkage Analysis, Model-free**) on a large number of markers, M, we first *rank* the linkage evidence, $\theta_{[1]} \leq \theta_{[2]} \leq \cdots \leq \theta_{[M]}$, where the $[i]$ denotes index of the ith ranked marker, using the (sequential estimate of the) error **variance** from the H–E regression, $\sigma^2_{e[1]} \leq \sigma^2_{e[2]} \leq \cdots \leq \sigma^2_{e[M]}$. Intuitively, this makes sense, as the regressions showing the smallest error variances will be the most significant ones, while the nonsignificant "noise" markers should have error variances nearly equal to the total variance of the response variable. Next we try to divide the markers into two subsets: those highest t showing "nonsignificant" linkage and the lowest $(M-t)$ "significant" ones, by splitting between rank $[M-t]$ and rank $[M-t+1]$. This is equivalent to choosing the one partition that correctly separates the $(M-t)$ truly linked ones from the t unlinked out of all possible ways (U) to select t from M populations, [$U = M!/(t!M-t)!$) hypotheses]. The sufficient statistics for this procedure, $\wp_B$, at sib pair $h+1$, will be the (transformed) sequential sums of squared residuals, using the prediction (H–E) equation for all the *previous* sib pairs. Then, the target effect size, D^*, will be characterized in terms of a minimum "distance" between two adjacently ranked error variances at the critical juncture between $[M-t]$, and $[M-t+1]$, using the distance metric

$$D_{ij} = \left| \frac{1}{2\sigma_i^2} - \frac{1}{2\sigma_j^2} \right|.$$

Using these definitions, the SMDP theory guarantees that:

$$\Pr_{\wp_B}\{\text{correct selection}\} > P^*, \quad \text{whenever } D > D^*.$$

Since it is sequential, the SMDP zeros in on the hit regions with predefined, analyst-specified type I and type II errors, using (on average) a smaller sample than the corresponding fixed sampling test. Also, since it is a single test for all regions simultaneously, questions about the differences between the locus-wise and genome-wise type I and type II errors do not arise (as they do when one conducts multiple fixed sampling marker by marker tests) (*see* **Genome-wide Significance**). Because of these very compelling advantages, the sequential analysis research continues to be of interest as a method to dissect the genetic nature of complex traits.

M.A. PROVINCE

Sequential Methods for Clinical Trials

For the purpose of this article, a "sequential method" is any approach to the conduct of a clinical trial in which:

(i) there is the potential to perform a series of analyses on the accumulating data at different times during the conduct of the trial;
(ii) each analysis includes a comparison of the treatments featuring in the trial; and
(iii) each analysis has the potential to lead to stopping the trial.

In (i), the word "potential" is included because the very first analysis might lead to stopping, the point being that the number of analyses actually performed is not fixed in advance. Sample size reviews, also known as "internal pilot studies" [10, 25, 26, 69] are excluded from this definition as no treatment comparison is involved. The number of potential analyses may be just two, or may be one after every new patient response. Thus, the definition is intended to encompass the use of a single interim analysis or of group sequential methods (*see* **Data and Safety Monitoring**), as well as earlier approaches such as the sequential probability ratio test.

Part (iii) of the definition excludes purely administrative looks at the data with no potential for stopping. However, it is questionable whether comparisons of the treatments can be made which do not have the potential to lead to stopping.

Each of the series of analyses will be referred to as an "interim analysis". Here only the treatment comparison and its use in deciding whether to stop the trial will be considered, although other calculations might be performed at the same time. Once the trial has stopped, a "final analysis" will be performed in which the significance level of the test of treatment effect will be calculated together with a point estimate and confidence limits for its magnitude.

In most of what follows it will be assumed that a Phase III clinical trial (*see* **Clinical Trials, Overview**) is being conducted to establish whether a single experimental treatment is more efficacious than some control treatment in respect of a single primary endpoint (*see* **Outcome Measures in Clinical Trials**). The extension of sequential methods to other forms of trial will be considered briefly at the end of the article. The exposition will be frequentist throughout: equivalent **Bayesian** procedures have been described in [50].

The Past

Traditional statistical approaches to scientific investigations separate out the phases of design, conduct and analysis. During the design phase, the sample size is fixed, and the method for allocating treatments to experimental units determined. Once the data have been collected, the analysis is conducted. In agricultural applications, which were so influential in the early development of statistical methods, the seasonal nature of farming makes this approach both natural and perfectly satisfactory.

It was in the context of quality control inspections that the above statistical pattern was first broken. Manufactured items are inspected, one at a time, with a view to accepting or rejecting a batch in terms of its quality. Double sampling, in our terms the use of a single interim analysis, was introduced to quality control by Dodge & Romig [16]. The Second World War provided the impetus for the development of the sequential probability ratio test, by Wald [60] in the US and by Barnard [5] in the UK. In this procedure, an "interim analysis" is conducted after the inspection of every individual item.

In quality control, a single sequence of observations is made, modeled as independent, identically distributed random variables from some parametric distribution. The way in which sequential methods could be applied far more generally, by plotting against Fisher's information rather than sample size, was indicated early in the development of the subject by Bartlett [6].

The advantages of sequential methods for clinical trials were also soon noticed. In the medical context the benefits of stopping early can be ethical as well as purely economic. Bross [11] introduced sequential medical plans for comparing two sets of binary responses, and Kilpatrick & Oldham [32] applied the sequential t-test to a comparison of bronchial dilators. The latter design was perhaps too effective: the study was stopped after only four responses. By 1960 there was already enough accumulated theory and practice to guarantee an audience for the first edition of Armitage's book on *Sequential Medical Trials* [3].

The principal limitation of the early theory of sequential analysis for implementation in clinical trials was the need to perform an interim analysis after every patient response. To be more precise, a plot of a comparative sample statistic against sample size had to be approximated as a continuous Brownian motion, and its final position after crossing a stopping boundary had to be treated as being on the boundary. This "no overshoot" assumption could be justified if interim analyses were conducted after every response, or in larger trials, at frequent intervals. Even after decades of talk of immediate on-line computer data entry, the reality of such continuous data monitoring in clinical trials appears to be as far away as ever.

The no overshoot assumption was eventually overcome in two differing ways, one involving computing power, the other relying on mathematical sophistication. The method of recursive numerical integration introduced by Armitage et al. [4] utilizes the independent increments of a Brownian motion to compare the distribution of the final position of a sequential sample path, given a series of upper and lower stopping limits. This allows a more precise evaluation of the properties of designs such as the sequential probability ratio test applied with infrequent looks as well as the specification of alternative designs based on different criteria. The method requires considerable computing input, which even today can be prohibitive if there are to be very large numbers of interim analyses.

The stopping criteria, which became popular during the 1970s, involved considering each interim analysis as a miniature fixed sample analysis, conducted with a type I error rate referred to as a "nominal significance level". It was well known that for the procedure as a whole to comply with an overall type I error rate of (say) 0.05, each of these nominal significance levels had to be less than 0.05. Various schemes were devised for setting the nominal significance levels. Pocock [42] suggested constant values, and then in 1982 recommended certain varying sequences [43]. O'Brien & Fleming [38] considered an increasing sequence of levels for which early stopping was extremely unlikely, so that the final nominal level would be close to 0.05 (or some other chosen overall value). These methods were referred to as "group sequential methods", a title which unfortunately has led to a false distinction from the wider family of sequential methods of which they are a part.

The mathematical answer to the overshoot problem was developed from renewal theory by Siegmund [47]. Earlier theory assumed that the final position of the sample path was on the boundary. Siegmund evaluated the expected overshoot of the boundary. This allows the boundary to be moved inwards by an amount equal to the expected overshoot. Now the expected final position of the sample path is on the original boundary. The boundary is changed, and the "no overshoot" theory is left intact and now more accurate. Whitehead & Stratton [68] and Whitehead [65] explain how this device can be used to allow "group sequential methods" to be based on straight-line boundaries such as the sequential probability ratio test and its modifications due to Anderson [1]. The resulting "Christmas tree correction" is extremely accurate in the case of the triangular test [51], but it can be less successful for other straight-line boundaries if interim analyses are few.

The Christmas tree correction offers complete flexibility over the frequency and timing of interim analyses while guaranteeing that when they occur they are conducted according to preordained rules. By contrast, the early "group sequential methods" relied on tabulations of critical values which were accurate only if a prespecified schedule of looks was followed. The α-spending function method of Lan & DeMets [34] brought that same flexibility into "group sequential methods".

The timing of the interim analysis no longer had to be prespecified or, more importantly, the amount of information available at each interim did not have to be anticipated. Instead, when an interim analysis was conducted, the amount of information available could be calculated, and the stopping criteria deduced in order to ensure that the total null probability of stopping up to and including the current look achieved some desired value, $\alpha(t)$. Here t is the ratio of the information accumulated to date and the maximum possible amount of information. The function $\alpha(t)$ is defined in advance for all t, and is called the α-spending function. When $t = 1$ (information is at its maximum value), $\alpha(1)$ is equal to the overall type I error rate (perhaps 0.05). Various α-spending functions have been devised, by Lan & DeMets [34], Kim & DeMets [33] and Hwang et al. [28] amongst others. Some are similar in spirit to older rules, such as those of Pocock and O'Brien and Fleming.

During the 1980s research attention focused on how to analyze a sequential clinical trial once it had stopped. Unfortunately, some of the language used to describe sequential methods obscured the main task. Interim analyses are not interpretations of the data in the way that conventional statistical analyses are; they serve only to determine whether the trial should stop. The term "nominal significance level" is potentially misleading, as it relates to the significance level appropriate to a design which was not in fact used. "Adjusting P values" or "paying a penalty on α" suggest rather *ad hoc* procedures, whereas appropriate analysis methods can be quite precise.

The monitoring of a sequential clinical trial is in fact best viewed as part of the design phase rather than being part of the analysis. It is a flexible **sample size computation** that avoids unnecessary sampling while guaranteeing the desired power. Once this sample size has been reached, and the trial has been stopped, the analysis phase begins. Frequentist analyses require consideration of those study outcomes *supporting the alternative hypothesis as strongly or more strongly than was observed*. For ease of interpretation it is best to restrict attention to one-sided alternatives of the form "experimental treatment is better than control", and to perform the appropriate multiplication by 2 to obtain two-sided P values. In a fixed sample study, evidence concerning treatment difference is usually expressed in terms of a one-dimensional test statistic, and the phrase above in italics is taken to refer to test statistics as large or larger than that observed. The frequentist analysis of a sequential design necessitates contemplation of repeated runs of the same design, and identification of which outcomes support experimental superiority more than others.

Armitage [2] and Siegmund [46] addressed the ordering of outcomes by degree of support for the alternative hypothesis in the case of continuous monitoring. In that situation the sample path will end on the boundary, and an anticlockwise ordering, from sample paths plunging down to the lower boundary (least support for superiority), via lengthy horizontal sample paths, through to sample paths shooting up to the upper boundary (most support), is natural. This leads to P values being defined for trials ending positively on the upper boundary, as the null probability of earlier stopping on the upper boundary.

Although the anticlockwise ordering will serve to provide a good approximation when interim analyses are frequent, it is incomplete in the more common case in which only a few looks at the data are planned. Here, a two-dimensional set of possible outcomes comprising the value of the final test statistic and the identity of the look at which it was observed have somehow to be resolved into a single ordering. The original, and most successful form of ordering in this case was introduced by Fairbanks & Madsen [20] and explored further by Tsiatis et al. [59]. For trials stopping on the upper boundary, in favor of the experimental treatment, the earlier the stopping, the stronger the support for superiority. Outcomes with the same final look are ordered in terms of the value of the test statistic. On the lower boundary, the later the final look, the better the support for experimental superiority (or at least, the less bad). This retains an anticlockwise element, in common with the ordering of Armitage and Siegmund.

The ordering of Fairbanks & Madsen [20] is *truncation adaptable*, to use a phrase later introduced by Liu & Hall [35]. Computations of analyses are made conditionally on how much information turned out to be available at each look, up to the final one. However, they require no knowledge of whether, when and how any future interim analyses would have been conducted, had the trial not been stopped. This means that analyses based on two designs that share the same criteria for (say) the first three looks, and then diverge, will be identical if stopping occurs at one of the first three looks. In particular, if a sequential trial is stopped at the first look, then the Fairbanks & Madsen [20] ordering leads to an analysis which is identical to the conventional fixed sample analysis. This is not to be confused with the type I error rates of the two procedures which, being properties of the whole design, are definitely different.

Once an ordering of possible outcomes has been identified, a full frequentist analysis becomes possible. Let θ denote the advantage of the experimental treatment over control. Define the P value function $P(\theta)$ as the probability of obtaining evidence supporting experimental superiority as strongly or more strongly than observed, according to the ordering, when the treatment advantage is θ. Then the P value against the one-sided alternative of experimental superiority will be $P(0)$, and against the one-sided alternative of experimental inferiority it will be $1 - P(0)$. Taking the smaller of these two and doubling it will give the P value against the two-sided alternative. A 95% confidence interval for

θ is given by (θ_L, θ_U), where $P(\theta_L) = 0.025$ and $P(\theta_U) = 0.975$, and a median unbiased estimator of θ by θ_M, where $P(\theta_M) = 0.05$

Other orderings of the sample space have been suggested by Rosner & Tsiatis [45], Chang [12] and Emerson & Fleming [18]. The last of these, for example, consists of ordering by the magnitude of the final maximum likelihood estimate $\hat{\theta}$ of θ. These orderings are not truncation adaptable. For example, if stopping occurs at the second look, it might have been possible for a later look to yield a higher value of $\hat{\theta}$. Thus, computations of P values and estimates have to take into account what might have happened later. Worse still, certain of the orderings of Rosner & Tsiatis [45] lead to confidence regions which are not intervals, but instead consist of disjointed separate intervals. Such flaws would appear to render them unsuitable for practical use.

Alternative methods for post-trial analysis include bias-adjusted maximum likelihood estimates [62] and Woodroofe confidence intervals [58, 70]. These methods modify certain conventional analysis procedures (maximum likelihood estimation and pivot-based confidence intervals) for use after a sequential trial. The former estimates are, to quite an accurate extent, unbiased in the conventional expectation sense. These methods also share the need to integrate over all possible final outcomes in order to compare expectations of various combinations of test statistic and information measure. Unfortunately, this need prevents them from being truncation adaptable. In practice, various scenarios for the inspection schedule that would have taken place after stopping can be imposed, and they make little difference to the numerical results. All the same, the mere need to speculate about what might have been is a drawback to these methods.

Emerson [17] has devised a truncation adaptable method of computing an unbiased estimate of treatment effect using the method, due to Rao [44] and Blackwell [8], of taking the expected value of a simple unbiased estimate conditional on a sufficient statistic. The simple unbiased estimate used is the maximum likelihood estimate of θ computed at the first look, and the sufficient statistic is the bivariate combination of the test statistic and the information measure at termination. The mathematics of the method were explored by Ferebee [21], and the resulting estimate has been shown to give the uniformly minimum variance unbiased estimate within the class of truncation adaptable estimates by Liu & Hall [35].

Sequential methods are now widely used in practice, especially in large-scale studies in serious and life-threatening diseases. The book edited by Peace [41] provides a collection of case studies, and Whitehead [67] provides references to several more.

The Present

Investigators planning a clinical trial today have a wide range of sequential methods available to choose from, with **software** packages such as PEST 4 [37], EaSt 2000 [15] and the S-PLUS module S + SeqTrial [36] to facilitate calculations. If the trial is to be a comparison of two treatments in respect of a single primary endpoint, with the objective of discovering whether one treatment is superior to the other, then it is extremely likely that a suitable method already exists. This means that infeasibility or unfamiliarity are no longer excuses for avoiding interim analyses and stopping rules in such trials, when ethical or economic purposes would be served by them.

Sample size determination in any trial begins with specification of a power requirement. If a certain treatment advantage ($\theta = \theta_R$) is present, then significance at level α should be achieved with power $1 - \beta$. In a fixed sample study there will inevitably be an interplay between resource limitations and the setting of θ_R and $1 - \beta$, although it is unwise to proceed with a sample size that is underpowered for credible and worthwhile treatment advantages.

Sequential designs offer more scope, first in the power requirements available, and second in how these are to be attained. In a fixed sample design, assuming a suitable measure θ of treatment difference, its power is set at $1 - \beta$ for $\theta = \theta_R$; it will also be $1 - \beta$ for $\theta = -\theta_R$. This need not be so in sequential studies. It is possible to set the power to be $1 - \beta$ for $\theta = \theta_R$ while accepting a much lower power at $\theta = -\theta_R$. This is entirely appropriate if the investigator has no need to distinguish the experimental treatment as being inferior to the control from the case of no effect. If the experimental treatment is novel and expensive, then either of these situations will lead to its development being abandoned, and so it would not be proper to recruit patients merely to determine which is true. This sort of specification is called

Power Requirement I by Whitehead [65], and it leads to asymmetric designs such as the triangular test. The opposite situation of requiring a power of $1 - \beta$ for $\theta = -\theta_R$, but not needing to distinguish between superiority and **equivalence**, arises in a noninferiority comparison of a cheaper and safer alternative with an established active control. (Sequential equivalence and noninferiority designs are discussed by Whitehead [64].) Sequential methods can be devised, of course, for the same symmetric power requirement as the fixed sample design (known as Power Requirement II).

Having chosen a power requirement, the shape of the plot of the expected terminal sample size against θ should be considered. This is known as the average sample number (ASN), within quality control applications. For a fixed sample size trial the ASN is a horizontal line. For a triangular test, it rises from low values over $\theta < 0$, to a maximum around $0.5\ \theta_R$ and then falls again. A truncated sequential probability ratio test has lower expected sample sizes for $\theta < 0$ and $\theta > \theta_R$ than the triangular test, but rises to a higher maximum in between. This then is the design question: For the power requirement set, for what values of θ should the expected sample size be large, and for what values should it be small?

Generally speaking, sample sizes should be small when θ is distant from zero, as in those situations when one group of patients is being seriously disadvantaged relative to the other. For designs constructed from Power Requirement I, the ASN will be asymmetric, with low values whenever $\theta < 0$. When Power Requirement II is specified, the main choice concerns whether expected sample sizes should be small for $\theta = 0$. They can be made so by choosing a design such as the double triangular test in PEST or opting for "Early rejection of H_0" in EaSt. Such designs will generally reduce sample size, and may be suitable for establishing equivalence. In some trials it is desirable to allow larger sample sizes when $\theta = 0$. There are seldom ethical concerns about continuation under H_0, and the larger sample size allows scope for eventual investigation of secondary endpoints and subgroup effects (*see* **Treatment-covariate Interaction**). This option may also provide insurance against concerns over model fit. Designs such as the restricted procedure within PEST or methods for two-sided alternatives and without early rejection of H_0 in EaSt satisfy these objectives. Within the desired class of procedures, fine tuning can be achieved by varying parameters such as the slope in PEST or Δ in EaSt and investigating the effect on the ASN. Other properties of final sample size, such as the median or 90th percentile, can also be used to facilitate choice.

The conduct of a sequential clinical trial is often within the context of a **Data and Safety Monitoring Board** (DSMB). The timings of the interim analyses are usually fixed in advance, and the plots of the test statistic against information measure form part of the report to the DSMB. As far as the mathematical model of the trial is concerned, it is the prespecified sequential plan that controls the stopping of the trial; there is no deviation from the prespecified protocol. The analysis computations developed over the years all rely on this being true, and any lack of adherence to plan will lead to inaccuracy in the computation of significance levels, point estimates and confidence limits. However, this is a clinical trial involving human subjects, and so the mathematical model of the trial cannot be the whole story. The DSMB will be presented with data other than the formal sequential plot, and these data may lead to stopping the trial earlier than the formal sequential rule or continuing it for longer. The mathematical modeling may involve formal interim analyses starting some time after the trial began, becoming more frequent thereafter. The DSMB, however, may receive safety data that lead to stopping even before the first formal interim analysis has taken place. Part of the art of designing sequential studies is to make the formal rule as close as possible to the likely actions of the DSMB. This involves careful choice of the primary efficacy endpoint, a detailed presentation of the sequential plan to the DSMB before the trial begins and, if necessary, pretrial revision of the plan to make it fit more closely to the DSMB's view of safety issues. An account of the role of the statistician in the DSMB, with particular reference to sequential studies, is given by Whitehead [66].

The most likely direction of discrepancy between a formal sequential plan and the actions of the DSMB is towards stopping for safety. The Board may see problems sooner than they are picked up by the sequential analysis, or concerning patient outcomes that are not part of the formal procedure. It is far less likely that the Board will wish to stop the study earlier than the plan allows in order to claim increased efficacy. This is because they know that a positive finding has to be accepted as valid, either by drug regulatory authorities (*see* **Drug Approval**

and Regulation) or by clinical opinion, before the new treatment receives widespread use. Departure from the plan might weaken the authority of the trial findings and result in delay in their acceptance. Having set in place a formal plan which does react to early strong positive evidence, it is most likely that the DSMB will respect it. The DSMB is also likely to respect rules governing stopping because the null hypothesis appears to be true: sometimes this is called stopping for futility. As scientists, they may wish to see the accrual of large and informative data sets, but this is not a safety issue, and in this instance they are acting to conserve the sponsor's resources.

The only result of unplanned stopping for safety can be the negative one of not claiming advantage and so its only consequence for trials seeking to demonstrate superior efficacy which do stop positively is to cause their P values to be conservative and their point estimates to be biased downwards. This is because, potentially, true claims of efficacy might be lost due to these "unofficial" stopping rules. The effect of such unofficial stopping does, however, have more serious consequences for equivalence and noninferiority trials. It is possible to formulate additional safety monitoring rules to be used in addition to efficacy sequential plans or within a fixed sample trial; for examples see Bolland & Whitehead [9].

The final analysis, including computation of the P value, point estimate and confidence interval, must be done in a way that is consistent with the sequential designs used. This need is now being recognized by regulators [19]. Sometimes a design has been chosen deliberately to ensure that a conventional analysis is essentially valid, and an argument to that effect may be acceptable. However, a numerical demonstration of the adequacy of the conventional analysis removes any residual doubt, and it is unwise anyway to constrain the choice of design in order to avoid the need to conduct an appropriate analysis.

Between the termination of the study and the final analysis, extra data may become available that did not feature in the last interim analysis. These data may be the result of inevitable delays in reporting, or they might be responses taken after some weeks or months of follow-up that could not have been available any earlier. Provided that these observations are collected under **protocol** conditions they should form part of the final analysis. The inclusion of such results in an "overrunning analysis" is discussed by Whitehead [63].

The Future

Current methodological research in sequential analysis is being directed towards extending its utility beyond comparisons of two treatments in respect of a single endpoint.

The multiple treatment problem has long been of interest, with the general methodology going back to the elimination procedures of Paulson [39, 40]. Sequential χ^2 and F tests have been developed by Siegmund [48] and Jennison & Turnbull [29]. These procedures are of limited utility in clinical applications. Elimination procedures allow treatments to be dropped at each of a series of interim analyses, and aim to select the best. However, although the treatment remaining at the end is indeed likely to be the best, evidence of significant superiority over any competitor is not guaranteed. Sequential χ^2 and F tests stop when it is evident that the treatments under comparison differ, but this may not mean that any individual treatment has yet demonstrated superiority over others.

More recent work has concerned allowing inferior treatments to be eliminated at interim analyses while preserving the error rates associated with recommending effective treatments. Follmann et al. [23] present a general procedure based on pairwise comparisons of k treatments with conservative preservation of error rates. Thall et al. [55, 56] present two-stage procedures for binary outcomes in which one of several experimental treatments is selected at the end of the first stage, and its comparison with a control is completed during the second. Data from both stages feature in the final analysis, and the overall type I error is controlled. Stallard & Todd [52, 53] take a similar approach, considering general responses rather than just the binary case, incorporating extra looks into the second pairwise comparison stage, and allowing the selection to be based on a **surrogate** rather than the primary response.

Methods that allow for the simultaneous monitoring of more than one endpoint are also being developed. Jennison & Turnbull [30], Cook & Farewell [13] and Thall & Cheng [54] have devised procedures in which both efficacy and safety endpoints are considered at each interim analysis. Todd [57] has looked at more general bivariate procedures, considering cases in which superiority has to be demonstrated in each of two efficacy endpoints

and also cases in which superiority in either will be sufficient.

A special case of multiple endpoints arises when subjects are assessed repeatedly in terms of the same response during the course of follow-up. The inclusion of such longitudinal data in interim analyses has been considered by Gange & DeMets [24] and Cook & Lawless [14] amongst others. In each case it is necessary to make modeling assumptions that allow the predominantly early follow-up data available at the first one or two interim analyses to be used to decide whether to stop a study intended to investigate longer-term follow-up. This dependence on extrapolated model assumptions is shared with long follow-up survival studies, in which context it is discussed by Gregory et al. [27] and Sooriyarachchi & Whitehead [49].

The theoretical developments cited above are ongoing, and have as yet received little implementation. However, within the pharmaceutical industry a desire to reduce drug development time and a need to satisfy regulatory conditions concerning multiple aspects of treatment safety and effectiveness are likely to lead to practical exploitation of this work. The selection procedures can be viewed as ways of combining Phases II and III, and the multiple endpoint designs may ensure that stopping does not occur until all trial objectives have been realized. On-line model checking is an important issue, especially for long-term survival or longitudinal studies, and the new methods may be able to address the problems of making repeated goodness-of-fit assessments alongside the repeated treatment comparisons.

Another current area of research concerns "adaptive designs". These allow greater freedom of action as a result of the findings of interim analyses. Examples include the methods of Bauer & Köhne [7] and Wassmer [61] as well as the "self-designing clinical trials" of Fisher [22]. Such approaches have the potential to introduce a great amount of freedom into the conduct of clinical trials, allowing them to follow more closely the instinctive learning processes of scientific enquiry, without losing control over error rates. However, two dangers are present. The first is that the new found freedom leads to a progressive reduction of the targeted "clinically relevant difference" as a trial reveals less and less promise of a new treatment. This can result in the greatest resources being devoted to the least important treatments, being the counterpart of scientific desperation rather than self-critical enquiry. The second danger lies in the conflict between the need to limit access to the results of interim analyses and the desire to act upon them. Confidentiality of interim results is a necessary precaution to avoid operational bias; that is, the conduct of the trial being a result of its findings rather than the other way round. If actions affecting the trial or the development of the drug involved are taken as a result of interim findings, then inferences about the nature of those findings will be drawn. It may be that mathematical preservation of error rates is the easy part of developing adaptive procedures.

The future of sequential methods in clinical trials appears to be assured. The recent appearance of two up-to-date texts on the subject [31, 65] and the simultaneous release of three new software packages for their implementation [15, 36, 37] ensures that the procedures developed in the past can be routinely and accurately implemented. The flourishing interest in methodological research will serve to ensure that the remit of sequential methods continues to widen.

Serial Correlation

Many biostatistical investigations involve longitudinal data in which subjects, possibly in naturally occurring or experimentally determined groups, are observed on several different occasions over some particular period of time (*see* **Longitudinal Data Analysis, Overview**). A characteristic of this type of data is a correlation between pairs of measurements on the same subject, the magnitude of which usually depends on the time separation of the measurements – typically, the correlation becomes weaker as the time separation increases. This *serial correlation* needs to be properly accounted for in the analysis of such data if appropriate inferences are to be made.

(*See also* **Analysis of Variance for Longitudinal Data**; **Durbin–Watson Test**; **Generalized Linear Models for Longitudinal Data**)

BRIAN S. EVERITT

Serial Dilution Assay

Serial dilution assays were originally developed to estimate the concentration of viable bacteria in liquid suspension, from observations of the presence or absence of the organism in samples at different dilutions (*see* **Dilution Method for Bacterial Density Estimation**). Let λ denote the concentration of bacteria per unit volume; this is the parameter of interest. A key assumption is that the bacteria are distributed at random throughout the suspension, with no tendency to aggregate. This implies that the number of bacteria in a sample of volume v follows a **Poisson distribution** with mean λv. In particular, the probability that the sample contains one or more bacteria is $1 - \exp(-\lambda v)$.

The original suspension is diluted m times and, at the ith dilution, n_i samples are taken from the diluted suspension, each sample containing a volume v_i of the original suspension. The samples are deposited in tubes containing a suitable culture medium. Following incubation, Y_i, the number of samples that show evidence of bacterial growth, is recorded. The second key assumption is that observable growth will result from any sample that contains at least one viable organism, implying that the data indicate reliably the presence or absence of bacteria in each sample.

The probability of observing bacterial growth at the ith dilution is therefore

$$\pi_i = 1 - \exp(-\lambda v_i) \tag{1}$$

and, provided that samples can be assumed to be independent, Y_i will have the **binomial distribution** $\text{bin}(n_i, \pi_i)$. This model forms the basis of the statistical analysis.

Bacterial concentrations can also be estimated by culturing samples on petri dishes and counting the number of colonies that grow. Colony counting clearly gives more precision per sample than simply recording presence or absence of the organism in the sample. However, the gain in precision per sample must be balanced against the increased time needed for counting. Moreover, if the sample is not sufficiently diluted, then the bacterial colonies will coalesce and counting becomes impossible.

Serial dilution assays are used routinely to estimate concentrations of micro-organisms in, for example, foods, water, and soils. Experimental procedures differ in detail, but the key assumptions remain that the number of particles in a sample has a Poisson distribution and that the observed positive or negative responses indicate reliably the presence or absence of the organism in the sample.

Dilution assays are also used to estimate the proportion of individuals in a population that have some characteristic, when it is not feasible, for economic or other reasons, to test individuals and estimate the proportion directly. Such assays are often called *limiting dilution assays*. For example, in immunology, limiting dilution assays are used to estimate the proportion of cells, θ say, that are immunocompetent. The procedure is to test *random* samples consisting of different numbers of cells to ascertain whether each sample does or does not contain immunocompetent cells. As in bacterial estimation, it is assumed that the presence/absence test is completely reliable. It follows that the probability that a sample of r_i cells contains at least one immunocompetent cell is

$$\pi_i = 1 - (1 - \theta)^{r_i}, \tag{2}$$

which is equivalent to (1) with $v_i = r_i$ and $\lambda = -\log(1 - \theta)$. In practice, however, at least in immunology, limiting dilution assays are often analyzed on the basis of (1) with $v_i = r_i$ and $\lambda = \theta$. There are two slightly different justifications for this. First, if θ is small, as it often is in immunologic applications, then $-\log(1 - \theta) \approx \theta$. More importantly, in immunologic applications, the number of cells tested, r_i, is not usually known exactly. Instead, the number is assumed to be a Poisson variable with mean r_i. The unconditional probability that the sample contains immunocompetent cells is then given exactly by (1) with $v_i = r_i$ and $\lambda = \theta$.

This method of estimating a proportion is also known as *group testing* [6], although this term is also used to describe a method of *repeatedly* testing individuals in groups to determine precisely which individuals have the attribute of interest [12].

Point Estimation of λ

Since the observations Y_i are binomially distributed, the log-likelihood for the data, ignoring some terms that do not depend on λ, is

$$l(\lambda) = \sum_{i=1}^{m} Y_i \log[1 - \exp(-\lambda v_i)] - (n_i - Y_i)\lambda v_i.$$

From this one can obtain the **maximum likelihood** estimator of λ, $\hat{\lambda}$ say, which is often known as the *most probable number* (MPN), a terminology introduced by McCrady [24]. Except in special cases, iterative methods, such as the Newton–Raphson method (*see* **Optimization and Nonlinear Equations**), are needed for the calculation of $\hat{\lambda}$, and various special-purpose computer programs are available, e.g. [22]. Alternatively, the maximum likelihood estimator of $\log\lambda$ can be obtained as the constant term in a binomial **generalized linear model** with complementary–log–log link function and with $\log(v_i)$ as an offset variable [25, Section 1.2.4]. Thus, estimation is possible in any package that caters for generalized linear models, though ill-fitting data sets can cause problems occasionally in packages that estimate parameters by Fisher's method of scoring [29].

When all samples are positive, $\hat{\lambda} = \infty$ and the best that can be done is to estimate a lower confidence limit for λ. Sometimes this may be sufficient, e.g. in food safety testing where it is sufficient to know that the bacterium is present in large numbers. Alternatively, if it is important to have a more precise estimate of concentration, then it will be necessary to do further dilutions until some samples give a negative result. Conversely, when all samples are negative, $\hat{\lambda} = 0$. In all other circumstances the likelihood function is unimodal with a finite, nonzero maximum.

Fisher [15] used the serial dilution assay as one of the examples in his original paper on maximum likelihood estimation. However, for practical application he suggested a computationally simpler method in which the observed number of negative results is equated to the expected number. He showed that this method, fully described by Fisher & Yates [17], has an **asymptotic relative efficiency** of 88% compared with maximum likelihood estimation, although Best & Raynor [3] found the estimators to be very similar for sample sizes typically used in practice. Historically, various other methods of estimation have been proposed, but maximum likelihood estimation remains the method most commonly used in practice.

Bias Correction

The maximum likelihood estimator of λ is, however, positively biased, i.e. it tends to *overestimate* the true value of λ (*see* **Unbiasedness**). The magnitude of the bias depends on the value of λ, on the dilutions used, and on the number of replicates at the different dilutions, but can exceed 10% in small assays.

Several authors have therefore considered bias corrections. Gart [18] derives a bias-corrected estimator as a particular instance of the general asymptotic theory given in [8, Section 9.2]. Mehrabi & Matthews [26] note that this is equivalent to an estimator derived, using a different method, by Salama et al. [32]. Mehrabi & Matthews [26] also derive an alternative bias-corrected estimator, based on the approach of Firth [14].

Strijbosch & Does [34] compare various jackknife and bootstrap estimators intended to improve bias. They show in particular that a jackknife estimator based on omitting each individual sample in turn succeeds in reducing bias. However, Mehrabi & Matthews [26] prefer the likelihood-based estimators because their variance can be estimated reliably, whereas the variance of the jackknife estimator cannot.

Garthright [19] has derived a bias-corrected estimator of $\log\lambda$, arguing that, for many purposes, it is more important to have an unbiased estimator of $\log\lambda$ than of λ itself.

Interval Estimation of λ

The distribution of $\hat{\lambda}$ is often quite skewed, particularly in small assays, and **confidence intervals** based on the standard error of $\hat{\lambda}$ are unreliable. However, the distribution of $\log\hat{\lambda}$ is more nearly symmetrical [7], and approximate $100(1-\alpha)\%$ confidence intervals for $\log\lambda$ can be calculated as

$$\log\hat{\lambda} \pm z_{\alpha/2}\ \text{se}\ [\log(\hat{\lambda})],$$

where $z_{\alpha/2}$ is the upper $\alpha/2$ point of the standard **normal distribution**. These limits can then be back-transformed to give limits for λ itself.

Other "large-sample" methods of forming confidence intervals, based on the score statistic (*see* **Likelihood**) or the **likelihood ratio** statistic, are discussed by Gart [18] and Ridout [30]. Cyr et al. [11] give some alternative large sample methods. For all of these methods the coverage (the probability that the interval contains λ) fluctuates around the nominal confidence level, and depends on λ.

Alternatively, "exact" confidence intervals can be constructed. "Exact" here signifies that the intervals are based on the exact binomial probabilities that determine the outcome of the assay. The intervals themselves are *conservative*, i.e. their coverage is never below, and generally exceeds, the nominal level, though this conservatism can be reduced by the use of mid-P values [21]. The various methods are well described by Loyer & Hamilton [23]. Roughly speaking their preferred method chooses the confidence interval as those values of λ for which the observed outcome of the assay is not "improbable". A complication is that some assay outcomes are improbable, whatever the value of λ, and so the method can lead to empty confidence intervals. It can also occasionally lead to disjoint intervals. Hepworth [21] gives an alternative method for which these complications do not arise. It is based on ordering outcomes according to their associated maximum likelihood estimates, and was proposed originally by Woodward [36]. Myers et al. [28] describe a third method based on an exact likelihood ratio test.

Exact intervals can require large amounts of computation and are perhaps best suited to small assays with a standard design, so that confidence intervals can be tabulated for all possible outcomes. Ridout [30] compares exact intervals with large sample intervals for some small assays and recommends intervals based on the large sample distribution of the likelihood ratio statistic.

Basu et al. [2] describe a bootstrap method of constructing confidence intervals for λ. Their method tends to give shorter intervals than the likelihood ratio method, but the coverage is often below the nominal level.

Testing the Validity of the Assumptions

Goodness of fit is often assessed in practice by comparing observed and fitted values using the standard χ^2 statistic for binomial data. However, because this is a general purpose test statistic it tends to have low power against specific alternatives [4].

An idealized assay involving an infinite number of dilutions with constant dilution factor and five replicates at each dilution might yield the following results:

$$\ldots 5\ 5\ 5\ 3\ 0\ 0\ 2\ 0\ 0\ 0 \ldots$$

The transition from all positive to all negative results spans four dilutions (with outcomes 3,0,0,2). Stevens [33] suggested using the length of the transition as a goodness-of-fit statistic, calling it the *range*. Large values of the range indicate a poor fit. The same test statistic was proposed independently by Moran [27]. Haas & Heller [20] develop the test for short series involving only three or four distinct dilutions (*see* **Infectivity Titration**).

When micro-organisms are not distributed randomly this is almost always because they are aggregated or clustered. Consequently, the distribution of micro-organisms in a sample is overdispersed relative to the Poisson distribution. Suppose, for example, that for a sample of volume v the distribution is not Poisson with mean λv but a **negative binomial distribution** with the same mean and with variance $\lambda v + \tau \lambda v^2$. Then the probability that the sample contains one or more micro-organisms is

$$1 - (1 + \tau \lambda v)^{-1/\tau},$$

which approaches the standard model in the limit as $\tau \to 0$. Testing for this particular departure from randomness is therefore equivalent to testing the null hypothesis that $\tau = 0$. A likelihood ratio test could be used, but this would involve fitting the alternative model. Cyr & Singh [9] suggest instead a score test for which it is only necessary to fit the standard model. This score test is robust insofar as the same test statistic results from some other distributions that are overdispersed relative to the Poisson.

However, some types of overdispersion are not detectable. For example, if the number of micro-organisms in a sample of volume v again has a negative binomial distribution with mean λv, but now with variance $(1 + \phi)\lambda v$ (where $\phi > 0$), then it can be shown that the standard analysis will incorrectly estimate $\lambda' = \lambda \log(1 + \phi)/\phi$ instead of λ, but there will be no apparent lack of fit.

The other principal assumption is that the presence of at least one bacterium in a sample is sufficient to produce an observable response. Any departures from this assumption will result in underestimation of λ. Particular types of departure that might arise depend on the specific application. Cyr & Singh [10] develop score tests for several alternatives that are important in immunology.

Planning a Serial Dilution Assay

Fisher [16] showed that to minimize the asymptotic variance of the maximum likelihood estimator $\hat{\lambda}$, the volume of the original suspension present in every sample should be $v = 1.59/\lambda$. This volume is such that each sample has a probability of 0.80 of giving a positive response. This result is not of much practical use unless a good prior estimate of λ is available.

Most work on planning of serial dilution assays has assumed instead that the experimenter can indicate an interval (λ_L, λ_U) within which the true value of λ is believed to lie. Finney [13, Section 20.8], for example, suggests choosing a range of dilutions such that the expected number of organisms per sample (λv) is at least 2 at the first dilution and at most 0.5 at the last dilution. Cochran [7] suggests slightly different limits. Dilutions are then made with a constant dilution factor, d, to cover the required range of volumes. The usual recommendation is that d should be as small as is practicable. For example, two-fold dilutions would be preferred to five- or 10-fold. This is because the smaller the value of d, the more nearly constant is the standard error of $\log \lambda$, when the same number of samples are tested in total [7]. One disadvantage of a small dilution factor is that there will be a greater cumulative effect of any pipetting errors. The results of Chase & Hoel [5] suggest that small errors of dilution can increase the variance of $\hat{\lambda}$ substantially.

For $d \leq 5$, Cochran [7] notes that the standard error of $\log_{10}(\hat{\lambda})$ is approximately independent of λ over the interval (λ_L, λ_U) and is given by

$$0.55 \left(\frac{\log_{10} d}{n} \right)^{1/2},$$

where n is the number of samples at each dilution (assumed equal). For $d \geq 10$ the approximation is better if the constant 0.55 is increased to 0.58. This approximate formula is useful in choosing a suitable value of n.

Strijbosch et al. [35] give an alternative procedure which ensures that, for any value of λ in the interval (λ_L, λ_U), there are some dilutions that are "informative", in the sense that the probability of a positive result is not too close to zero or one.

Another approach is to construct Bayesian optimal designs, based on a prior distribution for λ. Zacks [37] and Ridout [31] have given designs based on a gamma prior for λ and a uniform prior for $\log \lambda$ respectively. These authors also discuss two- and three-stage Bayesian designs.

Multistage designs are also considered by Abdelbasit & Plackett [1]. Given an initial estimate of λ, λ_0 say, the first stage tests samples with volume $v_1 = 1.59/\lambda_0$. The second stage tests samples with volume $v_2 = 1.59/\hat{\lambda}_1$, where $\hat{\lambda}_1$ is the maximum likelihood estimator of λ based on data from the first stage. At subsequent stages the volume is determined by the maximum likelihood estimator of λ based on data from all previous stages. Abdelbasit & Plackett present results on efficiency of designs with up to five stages. The optimal number of stages depends on how good the initial estimate λ_0 is and on how many samples are to be tested in total.

MARTIN RIDOUT

Serial-sacrifice Experiments

In simple survival experiments with animals to study the development of one or more particular disease(s), one observes the age at death along with the presence or absence of the disease(s) and also, in studies with **competing risks**, the cause of death for each animal. At the end of the experiment (which may be prefixed by design), there may be a provision for killing all the animals surviving at that time point, which is called *terminal sacrifice*. Such data give little information on the progress of disease(s), if they can be detected only at death, and possible interaction between different disease(s). For example, in many animal carcinogenicity experiments, development of cancer (occurrence of tumor) is of particular interest along with its contribution to the final death and possible interaction with other causes of death. But simple survival experiments give insufficient information to study this aspect, although with the introduction of *conceptual* survival times due to different causes of death and strong assumption such as independence between incidence of tumor and subsequent death and death from other causes, some analyses have been carried out [16, 20, 23, 27, 42, 52] to estimate the distribution of time to tumor incidence. One can also circumvent this problem by assuming strong parametric models ([10, 14, 26] (*see* **Parametric Models in Survival Analysis**); see also Borgan et al. [7], who consider piecewise-constant intensity parameters to demonstrate that serial-sacrifice experiments are moderately efficient with respect to complete observation, whereas simple survival experiments have very low efficiency). There is also a semiparametric approach wherein parametric assumptions are made for a part (tumor incidence rate) of the model, thereby requiring few or only one (terminal) sacrifices [2, 15, 30, 44, 46, 47]. In general also, data from simple survival experiments are analyzed by introducing conceptual survival times due to different causes of death (assumed mutually exclusive and exhaustive) which are then assumed independent using parametric or nonparametric methods [19, 22, 40].

Tsiatis [50] has shown that, with data only from simple survival experiment, **identifiability** problems may arise for the distribution of the conceptual survival times; it is impossible to distinguish the independent model from some dependence models. However, the point is that a simple survival experiment is not an appropriate one to study development of different diseases and possible interactions between them (leading to dependence between the conceptual survival times).

Serial-sacrifice experiments are an improvement over simple survival experiment toward achieving this goal, as indicated above, by allowing interim observation on some individuals before death occurs. Intuitively, this will allow one to probe the disease process and the complex interrelationships between different diseases before death occurs. Ideally, in serial-sacrifice experiments, individual animals are randomly selected and killed (sacrificed) at fixed or adaptively selected time points, allowing the examination of presence or absence of different diseases (which is done also for naturally dying animals); cause of death for each case may or may not be recorded [4, 9, 38, 42, 51].

The above serial-sacrifice experiment, in principle, permits one to test if the different diseases are independent and to determine the nature of interaction if it exists, as considered in a complicated illness–death model by Berlin et al. [4] assuming Markov transition rates (*see* **Fix–Neyman Process**). In animal carcinogenicity experiments, as mentioned earlier, serial sacrifice allows the estimation of tumor occurrence time distribution under very general conditions (see the next section for more clarification).

Identifiability and Analysis

Clearly, a serial-sacrifice experiment, as described above, embodies two sampling mechanisms in operation – one corresponding to death of an animal and the other to sacrifice. The latter is unbiased in the sense that all the animals alive at time t have equal chance of being sacrificed, thus providing an estimate for $p_{\mathcal{A}}(t)$, probability of being alive and having a particular disease combination $\mathcal{A}$ at time t. On the other hand, death is a biased sampling mechanism, the probability of death at any time depending on the illness state history of the animal. This will, thus, provide an estimate of probability of death with the particular disease combination $\mathcal{A}$, given by $\mu_{\mathcal{A}}(t)p_{\mathcal{A}}(t)$, where $\mu_{\mathcal{A}}(t)$ denotes the mortality rate from disease combination $\mathcal{A}$. Note that $S(t)$, the probability of

being alive at time t, can be estimated either in the **Kaplan–Meier** style [24] using both death and sacrifice information, or simply summing estimates of $p_{\mathcal{A}}(t)$ over all possible $\mathcal{A}$s. Hence, the prevalence of disease combination $\mathcal{A}$ (probability of having disease combination A given alive) at time t, $p_A(t)/S(t)$, can also be estimated. The **likelihood** function of the observable quantities is, therefore, a product of terms such as $p_A(t)$ and $\mu_A(t)p_A(t)$ for different disease combinations and different sacrifice and death times, respectively. Thus, only terms such as the above two and functions thereof will be estimable (identifiable) from serial-sacrifice experiments. Clearly, this is more than one can do from a simple survival experiment with different diseases. However, as pointed out by Clifford [9], assuming a progressive Markov illness–death model, quantities related to transition from one illness state (alive with a particular disease combination) to another, and hence quantities related to events subsequent to an illness state (e.g. mean residual life after being in an illness state), are not identifiable even from a serial sacrifice experiment; that is, these quantities are not expressible in terms of the above two quantities.

Berlin et al. [4] formulate different cases of independence between different diseases leading to relationships between different μs and ps from relationships between different transition rates. For example, if disease a is independent of disease b, then, besides many others, we should have the relationship $\mu_{(a,b)} = \mu_a + \mu_b$ (notation having the usual meaning). These relationships allow identifiability to some extent. Thus, hypotheses of disease independence, in some cases, can be rejected when they are false. One has to take note of the number of estimable independent parameters while calculating **degrees of freedom** for an asymptotic **likelihood ratio test**. However, failure to reject the hypotheses when they are false may be due not only to a type II error (*see* **Level of a Test**), but also to the nonidentifiability of the model parameters (i.e. the fact that relationships implied by hypotheses of independence may not necessarily imply independence).

In this context, two papers by Turnbull and Mitchell (see [38, 51]) also merit mention. Here, the authors write the likelihood function in terms of the estimable parameters of the type $p_{\mathcal{A}}$s and $\mu_{\mathcal{A}}$s, and then suggest estimation of these parameters using the **EM algorithm** [11]. They also parameterize the model in **loglinear** form by taking *treatment, time*, and *illness states* as different factors for reparameterizing the "prevalence" and "lethality" parameters corresponding to observations from sacrificed and dead animals, respectively. A generalized EM algorithm is used, by making use of the **iterative proportional fitting** algorithm [6] in the M-step, to obtain maximum likelihood estimates of the parameters for a broad class of unsaturated models. Tests based on relative likelihoods are proposed to investigate the effects of treatment, time, and the presence of other diseases on the prevalence and lethality of a particular disease of interest. Mitchell & Turnbull [39] develop a computer program for this analysis.

In animal carcinogenicity experiments with serial sacrifice, the tumor occurrence time distribution can be expressed, at least approximately, in terms of the estimable quantities as mentioned above ([12, 33, 37]; see [36] for a review). Thus, the tumor occurrence time distribution becomes estimable under very general conditions without assuming independence between different event times (tumor occurrence, death with tumor present, and death with no tumor) and having no cause of death information. McKnight & Crowley [37] give a closed form estimator for a function which approximates the tumor incidence rate; this, however, may take a negative value. A test for differences in tumor incidence rates in two groups is suggested, by comparing estimates of the approximate tumor incidence rates. Dewanji & Kalbfleisch [12] develop an EM algorithm for estimating the tumor incidence rates in a discrete framework. A score test (*see* **Likelihood**) is developed for comparison of two groups with respect to tumor incidence, assuming a polychotomous logistic model for the tumor incidence rate and death rate with no tumor. Malani & Van Ryzin [33] give closed form estimates of the tumor incidence rates, also in a discrete framework, but these may fail to satisfy the nonnegativity condition in some cases. Malani & Van Ryzin [34] extend this work to the problem of comparing two treatment groups.

Design Issues

In designing serial-sacrifice experiments, optimal sacrifice schedules have received some attention. The choice of an **optimal design** depends on the specific criterion to be optimized. Thus, a design which is optimal for one criterion may not be so for a different

one. Sometimes procedural simplicity dictates selection of a specific criterion.

Berry [5] considers the determination of an optimal time to terminate an experiment by sacrificing all surviving animals in terms of maximum Fisher's **information** per unit cost, assuming a **Weibull distribution** for tumor incidence. It turns out that the optimum strategy is to allow all animals to live out their lives. Portier [43] addresses the question of finding optimal fixed sacrifice times for small carcinogenesis experiments using different optimal criteria including optimal **goodness of fit**. The study is very limited, as it considers only four underlying tumor incidence distributions and six designs.

It is argued [3] that when no prior knowledge on tumor incidence is available, information on an optimum sacrifice schedule should be obtained only from the data. Otherwise, if sacrifices are carried out too early there will be few animals with tumor and if sacrifices are too late nearly all animals will have tumor, leading to very little information on tumor incidence in either case. Such consideration led to modification of serial sacrifice schedule in the ED01 study [21, 49] when too few tumors were found at the beginning of the study. Also, in the FD & C Red No. 40 mouse experiment [28], unexpected findings of early reticulo-endothelial (RE) tumors led to an acceleration of the sacrifice rate. All this suggests consideration of sequential or adaptive approach for choosing an optimal design although that requires a quick histopathological examination of all the sacrificed/dead animals.

Bergman & Turnbull [3] consider this problem for nonlethal tumors assuming an **exponential distribution** for tumor incidence. For a fixed sequence of times $t_1 < \cdots < t_M$, at which one or more sacrifice could be made, their procedure suggests how many to sacrifice at each time point so that estimation of the exponential parameter is asymptotically efficient in the sense that the Fisher information approaches that as obtained by using the true value of the parameter, as the total number of animals increases. At time t_i, animals are selected one by one at random and sacrificed until either a stopping rule $\mathcal{R}_i$ is satisfied or there are no animals left for sacrifice, whichever occurs first. If there are still more animals left after $\mathcal{R}_i$ is satisfied, the next sacrifice is made at time t_{i+1}, and so on. At the last time t_M, all the remaining animals are sacrificed and the experiment is terminated. The stopping rule they suggest for achieving asymptotic efficiency stops sacrificing at time t_i, when the ratio of the number of animals with tumor *plus* a specified constant to the number of animals without tumor, found at time t_i, is sufficiently small.

In order to find optimum sacrifice times, for experimenting with nonlethal tumors, Bergman & Turnbull [3] (see also [8] and [18] in a different context) note, assuming exponential distribution with mean $1/\theta$ for tumor incidence, that Fisher's information is maximized by choosing only one sacrifice time at $1.5936 \times \theta^{-1}$. This result is of no immediate use as the optimal design depends on unknown θ. Chernoff [8] suggests a sequential procedure by which the ith sacrifice will be at time $1.5936 \times \hat{\theta}_i^{-1}$, where $\hat{\theta}_i$ is the current best estimate of θ based on observation from the $i-1$ animals sacrificed so far (see also [1]). However, this optimal design does not ensure that the ith sacrifice time will always be later than the $(i-1)$th sacrifice time. Louis [31] proposes an asymptotically efficient suboptimal rule for time-ordered sequential design which has favorable small sample properties (see also [32] and [41]).

Portier [45] gives a brief review of the different design issues discussed here.

Examples

The earliest example (found in the literature) of serial-sacrifice experiment is that of Upton et al. [53], conducted at the Oak Ridge National Laboratory. Groups of RFM female mice were given various doses of γ-radiation. Each group included about 4000 mice, of which about 300 were sacrificed at different times ranging from 150 to 800 days. For all animals, postmortem examination records presence or absence of up to eight diseases. Berlin et al. [4] consider two groups (control and irradiated to $300R$) with three disease categories from the eight for their analysis. Parts of these data have been considered for analysis by many other authors [12, 38, 44, 51].

The ED01 study with 2-acetylamino-fluorene (2-AAF) conducted by the US National Center for Toxicological Research (NCTR) ([49]; see also a series of 19 papers in a special issue of *Journal of Environmental Pathology and Toxicology* [21] – Littlefield et al., pp. 17–34, in this series may be mentioned as one example) is probably the largest serial-sacrifice experiment so far. This study involved

over 24 000 mice exposed to one of eight different doses varying from 0 to 150 ppm in the diet. Serial sacrifices were carried out at 9, 12, 14, 15, 16, 17, 18, and 24 months, with a terminal sacrifice at 33 months. In addition to presence/absence of tumor at different sites, cause of death was also ascertained. The data from this study have been extensively analyzed by many authors [2, 13–15, 30, 35].

Another experiment by NCTR with benzidine dihydrochloride in mice has been considered for analysis by many authors [16, 26, 27, 30, 34, 46, 55, 56]. Information on cause of death and presence/absence of liver tumor was available. Sacrifices were designed at specific time points (280, 420, and 560 days).

Red 40 data [28] considered the incidence of RE tumors due to dosing of Red 40. The experiment used three treated groups and a control in both sexes of CD-1 HAM/ICR mice with about 50 animals in each group. A single interim sacrifice of between 14 and 20 animals per group was done at 42 weeks and a terminal sacrifice at 104 weeks.

There are few other examples of serial-sacrifice experiments found in the literature. Levitt et al. [29] studied morphogenesis of pancreatic adenocarcinoma in Syrian golden hamster induced by *N*-nitroso-*bis*(2-hydroxypropyl)amine. Kennedy et al. [25] considered ^{210}Po-induced tumor in the peripheral lung of Syrian golden hamster. Borgan et al. [7] mentioned an experiment for studying lymphatic leukemia in mice (see also [17]). Schuller et al. [48] studied pulmonary toxicity induced by the anticancer drug 1,3-*bis*(2-chloroethyl)-1-nitrosourea (BCNU), in F344 rats. Van Nesselrooij et al. [54] considered blood-filled cavities in estrogen-induced anterior pituitary tumors in male Sprague–Dawley rats with two treated and two control animals sacrificed at each of 15 time points ranging from 7 to 272 days.

Sex Ratio at Birth

Most human populations contain approximately equal numbers of males and females. This apparent equality can clearly be only approximate, since the mortality and migration rates of the two sexes vary in different ways with age and with time. In most communities, the males slightly outnumber the females at birth, a ratio of about 1.05 being typical, but are subject to higher mortality rates, so that females are in excess at higher ages and have the higher expectations of life. Studies of the variation in the sex ratio are predominantly concerned with the sex ratio at birth, conventionally expressed as the ratio of males to females (sometimes multiplied by 100 or 1000). In some research studies, it is more convenient to use the proportion of males, denoted here by p. More formally, the ratio at birth is the *secondary sex ratio*, the *primary sex ratio* being the ratio at conception. Reference is sometimes made to the less well-defined *tertiary sex ratio*, the ratio of males to females at an age at which children become independent of their parents, or perhaps at the onset of reproductive capacity.

The primary sex ratio is especially difficult to estimate, since many early spontaneous abortions are not observed. Some workers have suggested that the ratio is very high, the sperm bearing the Y chromosome perhaps being more successful in achieving fertilization. However, Hytten [20] argues that in spontaneous abortions during the first trimester, females considerably outnumber males, suggesting that the primary sex ratio is quite low. Later in pregnancy, there are more male than female fetuses, but more males than females miscarry or are stillborn. McKeown & Lowe [30] reported that sex ratios in early stillbirths (after 28 weeks' gestation) were not greatly in excess of unity, but that they increased slightly with **gestational age**.

The secondary sex ratio (for which we shall use merely the term "sex ratio") has been a topic of statistical interest for over 200 years. Statisticians and probabilists in the eighteenth and nineteenth centuries seized on the data emerging from birth registers to exemplify the developing theory of **binary** events; we summarize their work below. During the twentieth century, most studies have been motivated by **demographic**, **epidemiologic**, or **genetic** considerations. From the demographic point of view, the sex ratio contributes to an understanding of the age–sex composition of a population, although its effect is very limited because it varies between populations to such a small extent. The epidemiologist is interested in even small differences in the sex ratio between population groups, or in trends over time, because they may point to the possible effects of environmental agents or differing lifestyles.

Much interest has been focused on surveys of the sex distributions in families of various sizes. These studies are interesting from a general point of view and in relation to the effects of family limitation. Perhaps a more important purpose is to examine the evidence for variability in the sex ratio, in order to shed light on the **heritability** of the sex ratio [9]. If the tendency to produce an excess of offspring of one or the other sex is genetically determined, it will be subject to natural selection. Fisher [13] and others [21, 22] have offered theories as to how such a mechanism might act. It is therefore of some interest to see whether distributions of the sex composition in different families provide any evidence for such variation. As we shall note later, such evidence is hard to find.

Early Studies

The following summaries rely heavily on the much fuller accounts given by Hald [18, 19]. The earliest statistical study appears to be that of **Graunt** [17], who noted the slight excess of males at both christenings and burials, in both London and Romsey. Graunt regarded the near equality as a justification for the practice of monogamy rather than polygamy.

Arbuthnot's study [1] is celebrated as the first recorded example of a statistical significance test (*see* **Hypothesis Testing**). Arbuthnot noted that for each of the 82 years between 1629 and 1710, there were more male than female christenings in London. A sign test gives a ***P*** **value** of $(1/2)^{82}$. Arbuthnot regarded the excess of male christenings (and hence, presumably, of births) as evidence of divine providence in compensating for the higher mortality risks encountered by males. The calculations of Nicholas **Bernoulli** [3] showed that the 82 proportions of males are **overdispersed** relative to the **binomial distribution**, although Bernoulli himself appears to have accepted the hypothesis of homogeneity, the mean proportion of males being 0.516.

Daniel Bernoulli [2] used the **normal** approximation to the binomial to study a related data set of christenings in London between 1664 and 1758. He noted that the overall estimate of p was 0.513, but that the value fell to 0.510 during the decade 1721 to 1730. Taking the 10 values during that decade, he showed that they agreed with normal variation for $p = 0.510$ (as judged by the number of years for which the value fell within probable error limits), but less satisfactorily for $p = 0.513$. The demographers Struyck (1687–1769) and Süssmilch (1707–1767), in the meantime, had extended Graunt's descriptive work to cover data sets from various regions, but avoiding any probabilistic analyses.

Laplace [25] used the numbers of male and female births in Paris during 1745 to 1770 to illustrate the calculation of a posterior probability using the normal approximation to the binomial, finding, of course, that the probability of a ratio favoring females was extremely low. Cournot [4] used a similar approach to compare sex ratios in different subgroups, showing an awareness of the danger of **multiple comparisons**. **Poisson** [32] examined births in France from 1817 to 1826, again using the normal approximation and found no evidence for overdispersion between these 10 values. He then examined the yearly figures for different administrative areas, and found too high a frequency of instances where female births were in excess, suggesting that variation between years and between areas had been obscured in the overall picture.

Recent Epidemiologic Work

Although the eighteenth- and nineteenth-century workers were mainly concerned about illustrating theoretical results by using conveniently extensive sets of binary data, many of them were interested in variations in p between different population groups. Explanations of these differences were less easy to find.

Modern workers have access to even more extensive data sets, and publications exploring group differences abound. Yet, explanations remain contentious, and different studies often seem contradictory.

Time trends in national data sets are easily established. Between 1838 and 1997, the sex ratio for live births in England and Wales showed a roughly sinusoidal curve, with smoothed values falling from about 1.05 to 1.04 around 1895, rising to about 1.06 between 1945 and 1975, and falling to a little over 1.05 in 1995 [28, Figure 6.5]. A similar trend in Japan between 1900 and 1995, with a peak at about 1.07 around 1970, and a subsequent fall to about 1.05 in 1995, is reported by Ohmi et al. [31]. Similar recent falls have been reported for other countries [5].

Many other associations have been reported. Black populations have frequently been shown to have low ratios, but extensive ethnic comparisons are hampered by the lack of reliable data in many developing countries. The sex ratio tends to decline with maternal age [27]. A negative relationship with the sex ratio has been reported for a very wide range of factors, including maternal smoking, maternal schizophrenia, fathers who fly extensively, births in late autumn and winter, and multiple births, with a complex effect of parents' hormonal levels and time of conception during the menstrual cycle [20, 28]. The sex ratio tends to decline with increases in the stillbirth rate, a natural consequence of the higher ratio for stillbirths.

Claims for associations need to be replicated with sufficiently large studies to eliminate random variation and serendipitous selection. However, there seems to be a general finding that low sex ratios are associated with deprivation of some sort. Unexpected changes in the sex ratio may therefore provide a form of monitoring to detect adverse environmental effects. This must, however, be a rather blunt instrument, as the change in sex ratio may not become evident for some time after the causative event, and the effect will be nonspecific. In 1978, the sex ratio in Northern Ireland (and in three adjacent counties of the Republic of Ireland) was unusually low (about 1.01), but no explanation has been found.

Family Studies

Geissler [14] published data on the distributions of boys and girls in families of various sizes for about four million births in Saxony from 1876 to 1885. The data have various deficiencies, being derived from statements by parents at the time of birth registration, recording the numbers of previous children of each sex. They have, nevertheless, been the subject of extensive analyses by, among others, Gini [15, 16], Fisher [12], Lancaster [23] and Edwards [6]. Much of the research has been concerned with possible deviations from the binomial distributions to be

expected from purely random sampling with constant p. One difficulty here is that parents may be less likely to stop having children if the current sex distribution is unbalanced; so the sex distributions of completed families of any given size above two might be expected to show excess frequencies for the extreme categories. However, this effect of family limitation may have been less pronounced in Geissler's data than in some later data sets of this type.

Lancaster's [23] doubts about the reliability of Geissler's data were dismissed by Gini [16] and Edwards [6], but were reiterated by Lancaster [24]. Edwards [6] concluded that the data showed excess variability of p between families, which they represented by the **beta-binomial distribution**, and Lindsey and Altham [26] fitted a variety of models for overdispersion, suggesting that the effect increased with family size.

Edwards and Fraccaro have analyzed several later data sets in which the sequence of boys and girls in each family is recorded: 14 230 French families [7], 5477 Swedish families [10, 11], and 60 334 Finnish families [8]. The Swedish data show no evidence of any form of heterogeneity. The French and Finnish data support the hypothesis of a positive **correlation** between the sexes of adjacent births as distinct from the fixed correlation between *all* members of the family that would be expected if there were merely a between-family variance component.

The possible effect of family limitation on these data sets is unclear. As Edwards & Fraccaro observe, the effect may be mitigated by considering the frequencies of different ordered sex combinations in the first N children in families with N births or more, but this is not a complete solution to the problem. An alternative approach is to estimate p directly from observations of the Nth birth, separately for each ordered combination of outcomes for the first $N-1$. Maconochie & Roman [29] examined in this way a large collection of 549 048 singleton births in Scotland from 1975 to 1988, derived from linked records of maternity discharges. They found no evidence of heterogeneity between families, or for the effect of birth order, maternal age, maternal height, paternal or maternal social class, year of delivery, or season of birth, the estimated sex ratio being 1.06.

The evidence for heterogeneity between families is thus, at best, equivocal. If heterogeneity were to be clearly established, it would remain to be shown that this was genetic rather than environmental. As Edwards [9] remarks, "... if genetic variability exists, it is of a very low order of magnitude".

PETER ARMITAGE

Shape Analysis

Shape is an essential ingredient of biology and medicine. The geometrical description of an object can be separated into two parts: (a) the registration information and (b) the "shape" (which is invariant under registration transformations). By registration, we mean a basic geometrical transformation of an object, for example, translation, rotation, and rescaling. Objects can be registered into a standard reference frame or with respect to each other. Equivalent names for registration include superimposition, superposition, transformation, pose, and matching.

Shape has been studied for centuries in medicine and biology, for example, Galileo's [16] study of bone shape (see Figure 1). Most studies have relied on the location of anatomical landmarks, and then **multivariate analysis** is carried out on collections of angles and ratios of lengths [14, pp. 6–7].

Geometrical shape analysis began with the independent work of Kendall [28, 30], Bookstein [4, 5] and Ziezold [51]. Subsequent developments have led to a deep differential geometric theory of shape spaces [31], as well as practical statistical approaches to analyzing objects using probability distributions of shape and **likelihood**-based inference. Summaries of the field are given by Bookstein [7], Goodall [20], Small [46], Dryden and Mardia [14], Kendall et al. [31], and Lele and Richtsmeier [37], and the main emphasis is on the shapes of labeled point set configurations.

Shape and Shape Space

General Shape

Shape is defined to be all the geometrical information that is invariant under registration transformations. Depending on the application at hand, the registration transformations may be of little interest (e.g. in comparing the shapes of bones); the registration and shape may be equally important (e.g. in object recognition (*see* **Pattern Recognition**) in **image analysis**); or the registration parameters are the primary interest (e.g. in medical image registration).

There are several common types of registration invariance that are encountered in shape analysis. The most common examples include the Euclidean similarity transformations (translation, rotation, and scale), the rigid body transformations (translation and rotation) and affine transformations (translation, rotation, and shears).

The types of objects under study are either point sets of landmarks, curves, surfaces, or solid objects. The study of shape is particularly well developed for the study of *landmarks*, which are points of meaningful biological or geometrical correspondence.

Two-dimensional Point Sets

When landmarks are available in two dimensions, the shape space and statistical analysis of shapes are relatively straightforward (e.g. [5, 14, 30]). Consider $k \geq 3$ points in a plane and use complex notation: $z_j \in \mathbb{C},\ j = 1, \ldots, k$. We remove location (by centering) $z_j - \overline{z}$, $j = 1, \ldots, k$, where $\overline{z} = \sum_{j=1}^{k} z_j / k$ is the centroid. We then identify scaled and rotated versions as an equivalence class, which is the shape of z:

$$[z] = \{\lambda(z_j - \overline{z}),\ j = 1, \ldots, k, : \\ \lambda = re^{i\theta} \in \mathbb{C} \setminus \{0\}\}. \qquad (1)$$

The shape space is, therefore, the complex projective space $\mathbb{C}P^{k-2}$ [30], which is the space of complex lines through the origin (but not including it). So, the challenge from the statistical point of view is to provide models and inferential procedures, which are appropriate for the non-Euclidean shape space.

There are several choices of shape distance that could be used and a natural choice is the Riemannian shape distance between two landmark configurations $z = (z_1, \ldots, z_k)^T$, $w = (w_1, \ldots, w_k)^T$:

$$\rho = \arccos \frac{\sum (z_j - \overline{z})^* (w_j - \overline{w})}{(\sum |z_j - \overline{z}|^2 \sum |w_j - \overline{w}|^2)^{1/2}}, \qquad (2)$$

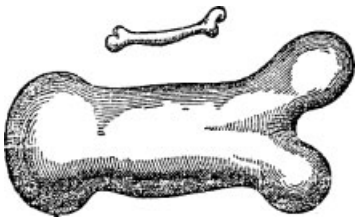

Figure 1 From Galileo (1638), illustrating the differences in shapes of the bones of small and large animals. Reproduced from [14]

where z^* is the complex conjugate of z^T. The triangle case is special since $\mathbb{C}P^1 \equiv S^2$ [29]. The shapes of triangles are represented by points on a sphere of radius $\frac{1}{2}$ and in this case, ρ is the great circle distance.

The size of a configuration is often taken to be the centroid size:

$$S(z) = \sqrt{\sum_{j=1}^{k} |z_j - \overline{z}|^2} = \|Cz\|, \tag{3}$$

where $C = I_k - 1_k 1_k{}^T/k$ is the $k \times k$ centering **matrix**, with I_k the $k \times k$ identity matrix and 1_k the column k-vector of ones. Other choices such as square root of area could be used, but are not so convenient to work with statistically. In order to represent shape, it is often convenient to specify suitable shape coordinates, for example, Bookstein shape coordinates

$$u_j^B = \frac{z_j - z_1}{z_2 - z_1} - \frac{1}{2}, \quad j = 3, \ldots, k, \tag{4}$$

where u_j^B are the complex coordinates of the landmarks after translating, rotating, and rescaling so that point 1 is sent to $-1/2 + 0i$ and point 2 is sent to $1/2 + 0i$. When shape variability is small, one can work in a tangent space to shape space, and hence use tangent space coordinates (see [14, p. 71]). For small variations, Bookstein coordinates and tangent space coordinates are approximately linearly related, and hence **multivariate normal**–based inference is approximately equivalent using either shape coordinate system [32].

Higher-dimensional Point Sets

For higher than two-dimensional point sets, the geometry is not so straightforward. Kendall et al. [31] discuss the differential geometry of shape spaces in detail, and one particular problem with the higher-dimensional shape spaces is that the spaces are not homogeneous and there are singularities. Nevertheless, we can obtain distances and work with care with such higher-dimensional spaces.

Let X be a $k \times m$ matrix of the Cartesian coordinates of the k points in m real dimensions ($k \geq m + 1$). We can consider three steps to obtaining the shape:

1. Remove location (center)
$$X_C = CX \tag{5}$$
2. Remove size (rescale)
$$Z = \frac{X_C}{S(X)} = \frac{CX}{\|CX\|}, \tag{6}$$
which is the preshape that lies on a sphere ($Z \in S^{(k-1)m-1}$).
3. Finally, the shape is obtained by identifying all rotated versions as an equivalence class, that is,
$$[X] = \{Z\Gamma : \Gamma \in SO(m)\}, \tag{7}$$
is the shape of X, where $SO(m)$ denotes the special orthogonal group of rotation matrices (i.e. orthogonal matrices with determinant 1).

Statistical analysis of shapes can be carried out on the preshape sphere subject to invariance under rotations.

Shape Distances

There are a variety of choices of shape distances for shape analysis. Some possible choices are Procrustes distances, Riemannian distance, and **Mahalanobis distance** in the Procrustes tangent space. For the m-dimensional case, some specific shape distances are:

Partial Procrustes distance:

$$\mathrm{d}_P(X_1, X_2) = \inf_{\Gamma \in SO(m)} \|Z_2 - Z_1\Gamma\|, \quad (0 \leq \mathrm{d}_P \leq \sqrt{2}). \tag{8}$$

Riemannian distance:

$$\rho(X_1, X_2) = 2 \arcsin\left(\frac{\mathrm{d}_P}{2}\right), \quad (0 \leq \rho \leq \pi/2). \tag{9}$$

Full Procrustes distance:

$$\mathrm{d}_F(X_1, X_2) = \inf_{r>0, \Gamma} \|Z_2 - rZ_1\Gamma\| = \sin\rho(X_1, X_2), \quad (0 \leq \mathrm{d}_F \leq 1). \tag{10}$$

Note that ρ reduces to equation (2) in the two-dimensional case. These distances are all quite similar for shapes, which are close together, in particular, $\mathrm{d}_F = \rho + O(\rho^3) = \mathrm{d}_P + O(\mathrm{d}_P^3)$ for small ρ, d_P.

Sometimes we may have registration transformations G, which are not a group: for example, a smoothing **spline** deformation. We can still obtain a discrepancy measure in such cases, for example, a shape discrepancy measure between Y and T:

$$D(Y, T) = \inf_{g \in G} dist(Y, g(T)), \qquad (11)$$

which is not symmetric in T and Y if g is a smoothing thin-plate spline for example.

Shape Variability

Shape Distributions

There are various approaches for modeling shape variability in biomedical objects, for example, (1) marginal/offset shape distributions, (2) distributions in preshape space with rotational symmetry, (3) distributions in shape space, and (4) distributions in a tangent space. Specifying distributions of shapes is also an important component of high-level **Bayesian** image analysis, where the shape distributions form part of the prior model.

Marginal/offset Distributions

We first consider a model for a configuration in the original space of the landmarks. In particular, we take the mean configuration μ with independent isotropic zero mean normal perturbations with variance σ^2. The marginal or offset normal model is the marginal distribution of shape after integrating out the location, rotation, and scale information (see Figure 2).

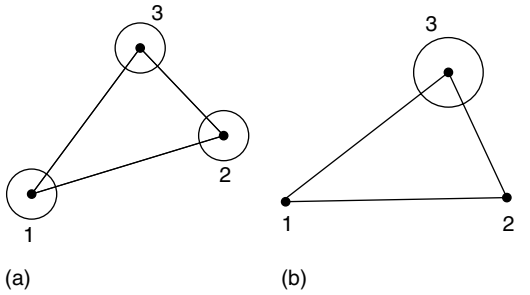

Figure 2 The offset normal shape model involves independent circular Gaussian perturbations about the mean landmarks (a), and then transforming to the shape variables such as Bookstein shape variables where the shape variability is transformed to the third vertex after fixing points 1 and 2 (b)

The offset normal shape density (with respect to uniform measure) is [12, 13, 42, 43]

$$\mathcal{L}_{k-2}(-2\kappa \cos^2 \rho(X, \mu))\exp(-2\kappa \sin^2 \rho(X, \mu))$$

where $\kappa = S(\mu)^2/(4\sigma^2)$, $S(\mu)$ is the centroid size of μ and $\mathcal{L}_j(-x) = \sum_{i=1}^{k-2} \binom{j}{i} \frac{x^i}{i!}$ is the Laguerre polynomial. The parameters are the Shape(μ): $2k-4$ mean shape parameters and κ: concentration parameter. For triangles ($k = 3$), the shape density is

$$\{1 + 2\kappa \cos^2 \rho(x, \mu)\} \exp\{-2\kappa \sin^2 \rho(x, \mu)\}.$$

General covariance matrices and higher dimensions have also be considered by Dryden and Mardia [12] and Goodall and Mardia [21].

Inference with marginal shape models can be carried out, such as testing for mean shape difference between two groups (see [14, p. 144]), although inference is not straightforward for general **covariance** structures due to overparameterization. We consider a particular test in the section "Hypothesis Testing", which assumes an isotropic covariance structure.

Distributions in Preshape and Shape Space

Other shape distributions include the complex Watson distribution [44] with density $f(z)$ proportional to

$$\exp\{-2\kappa \sin^2 \rho\}$$

and the complex Bingham distribution [32] with density $f(z)$ proportional to

$$\exp(z^* A z), \ \in \mathbb{C}S^{k-1},$$

where A is Hermitian. Both distributions are specified on the preshape sphere and have rotational symmetry, that is, $f(z) = f(e^{i\theta}z)$, and hence, they are suitable for shape modeling. The complex Watson distribution is a special case of the complex Bingham distribution, where A has just two distinct eigenvalues. The models on the preshape sphere have the advantage of being simple and tractable, but they do impose rather restrictive symmetries–isotropy for the complex Watson and complex symmetry for the complex Bingham distribution.

If the rotational information is integrated out, then the complex Watson and complex Bingham distributions can be regarded as distributions in the shape space. In the $k = 3$ triangle case, both distributions

reduce to the Fisher–von-Mises distribution on the shape sphere [39].

Procrustes Tangent Space Models

Another practical approach to specifying shape variability is to examine **principal components** from **least squares** matching of geometrical objects. Consider n objects of k landmarks in m real dimensions, that is, $T_1, \ldots, T_n$ are $k \times m$ matrices and $T_i \in \mathbb{R}^{km}$. **Procrustes** matching involves least squares matching to give $\hat{T}_j$:

$$\hat{\mu} = \arg \inf_{\mu: S(\mu)=1} \inf_{r_j>0, \Gamma_j \in SO(m), b_j} \sum_j \|\mu - r_j T_j \Gamma_j - 1_{kb_j}^T\|^2, \tag{12}$$

where the fitted configurations are $\hat{T}_j = \hat{r}_j T_j \hat{\Gamma}_j + 1_k \hat{b}_j^T$. Note that if variations are small, the shapes lie approximately in a linear space (a tangent space to shape space). Kent and Mardia [35] give a thorough description of Procrustes tangent space.

After the matching procedure is carried out, the Procrustes mean is $\hat{\mu} = \sum \hat{T}_i / n$ and the estimated covariance matrix is

$$\hat{\Sigma} = \frac{1}{n} \sum V(\hat{T}_i - \hat{\mu}) \{V(\hat{T}_i - \hat{\mu})\}^T, \tag{13}$$

where $V(T) = \text{vec}(T)$ is the stacked column vector of the columns of T. For two-dimensional objects, the Procrustes matching can be carried out using a complex eigendecomposition [32], but for higher-dimensional cases an iterative procedure such as Generalized Procrustes Analysis [22] must be carried out.

The structure of variability in the objects can be examined through the principal components of the Procrustes matched configurations, that is, through the eigendecomposition of $\hat{\Sigma}$. We can formulate the point distribution model for a two-dimensional configuration matrix $X(2k \times 1)$ of k landmarks in $\mathbb{R}^2$ based on the first p PCs as [40]

$$X = \mu + \sum_{j=1}^{p} y_j \gamma_j + \varepsilon, \tag{14}$$

where $y_j \sim N(0, \lambda_j)$, $\varepsilon \sim N_{2k}(0, \sigma^2 I)$, independently and the vectors γ_i satisfy

$$\mu^{\mathrm{T}} \gamma_j = 0, \gamma_j^{\mathrm{T}} \gamma_j = 1, \gamma_i^{\mathrm{T}} \gamma_j = 0, \quad i \neq j, \tag{15}$$

and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_p$. In addition, for invariance under rotation and for translation, the vectors γ_i satisfy respectively

$$\gamma_j^{\mathrm{T}} \nu = 0 \text{ and } \gamma_j^{\mathrm{T}}(1, \ldots, 1, 0, \ldots, 0)^{\mathrm{T}} = 0,$$
$$\gamma_j^{\mathrm{T}}(0, \ldots, 0, 1, \ldots, 1)^{\mathrm{T}} = 0, \tag{16}$$

where $\nu = (-\beta_1, \ldots, -\beta_k, \alpha_1, \ldots, \alpha_k)^{\mathrm{T}}$ with $\mu = (\alpha_1, \ldots, \alpha_k, \beta_1, \ldots, \beta_k)^{\mathrm{T}}$. Here $p \leq \min(n-1, 2k-4)$ and p is preferably taken to be quite small, for a **parsimonious** model.

This method of shape modeling has been used to great success by Cootes et al. [10, 11] and Kent [32]. Effectively, models are specified in the tangent space to the estimated mean, and hence, they are appropriate for small variations.

Example: T2 vertebrae In Figure 3, we see an example dataset of 60 landmarks on the outline of T2 mouse vertebrae, which have been matched together using Procrustes analysis. The first two principal components of the T2 vertebrae are given in Figure 4. PC1 and PC2 explain 65% and 9% of the shape variability, and PC1 includes the effect of protrusion at the topmost part of the bone, and PC2 includes the effect of asymmetry in this part of the bone. Although the interpretation is relatively straightforward here, the PCs can be difficult to interpret in some applications and may consist of multiple effects.

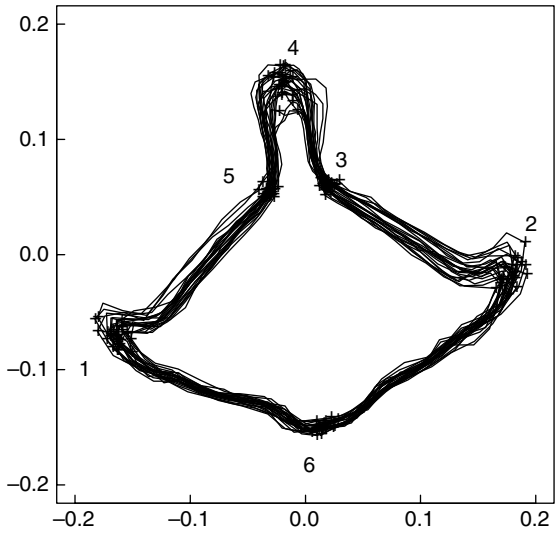

Figure 3 A dataset of 23 second thoracic mouse vertebrae that have been matched using Procrustes registration

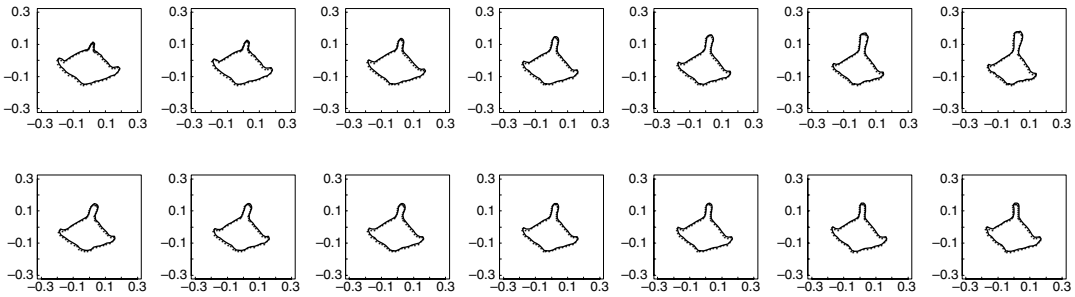

Figure 4 The first two principal components of the mouse vertebrae data. The jth row shows PCj, with the ith column displaying $\hat{\mu} + (i-4)\hat{\lambda}_j^{1/2}\hat{\gamma}_j$ where $\hat{\mu}$ is the Procrustes mean, $\hat{\gamma}_j$ is the jth PC and $\hat{\lambda}_j$ is the j eigenvalue of the tangent space covariance matrix

Hypothesis Testing

Hypothesis tests can be constructed using Procrustes methods, for example, testing for equal mean shapes in two independent groups. Consider an isotropic normal model with mean μ and transformed by an additional location, rotation and scale, that is,

$$X = \beta(\mu + E)\Gamma + 1_k\gamma^{\mathrm{T}}, \quad \mathrm{vec}(E) \sim N(0, \sigma^2 I_{km}), \tag{17}$$

where $\beta > 0$ (scale), $\Gamma \in SO(m)$ (rotation) and $\gamma \in \mathbb{R}^m$ (translation), and σ is small. We take two independent random samples $X_1, \ldots, X_{n_1}$ and $Y_1, \ldots, Y_{n_2}$ from Model (17) with means μ_1 and μ_2 respectively, and arbitrary transformation parameters for each observation. Both populations are assumed to have a common variance for each coordinate σ^2. We wish to test H_0 : Shape(μ_1) = Shape(μ_2){= Shape(μ_0)}, say, against H_1 : Shape(μ_1) $\neq$ Shape(μ_2). Let $\hat{\mu}_1$ and $\hat{\mu}_2$ be the full Procrustes means of each sample. Under H_0, with σ small, the Procrustes distances are approximately distributed as

$$\sum_{i=1}^{n_1} \mathrm{d}_F^2(X_i, \hat{\mu}_1) \sim \tau_0^2 \chi^2_{(n_1-1)M},$$

$$\sum_{i=1}^{n_2} \mathrm{d}_F^2(Y_i, \hat{\mu}_2) \sim \tau_0^2 \chi^2_{(n_2-1)M},$$

$$\mathrm{d}_F^2(\hat{\mu}_1, \hat{\mu}_2) \sim \tau_0^2 \left(\frac{1}{n_1} + \frac{1}{n_2}\right) \chi^2_M,$$

where $\tau_0 = \sigma/\delta_0$ and $\delta_0 = S(\mu_0)$ (*see* **Chi-square Distribution**). Proofs of the results can be obtained using Taylor series expansions. In addition, these statistics are approximately mutually independent (exactly in the case of the first two expressions). Hence, under H_0, we have the approximate distribution

$$F = \frac{n_1 + n_2 - 2}{{n_1}^{-1} + {n_2}^{-1}} \times \frac{\mathrm{d}_F^2(\hat{\mu}_1, \hat{\mu}_2)}{\sum_{i=1}^{n_1} \mathrm{d}_F^2(X_i, \hat{\mu}_1) + \sum_{i=1}^{n_2} \mathrm{d}_F^2(Y_i, \hat{\mu}_2)} \sim F_{M,(n_1+n_2-2)M}, \tag{18}$$

and this result is valid for small σ (*see* ***F*** **Distributions**). We reject H_0 for large values of this test statistic. This test is the two independent sample Goodall's [20] test. An alternative test is a **Hotelling's T^2** test in the tangent space to a pooled mean shape estimator, which can have general (but equal) covariance matrices for each group. Dryden and Mardia [14], Chapter 7 provide more examples of hypothesis testing using tangent space approximations.

Shape and Images

Registration and Matching

In many applications, it is important to match images or objects. An early example was D'Arcy Thompson's [48] work on describing differences between species using simple geometrical transformations. (see Figure 5)

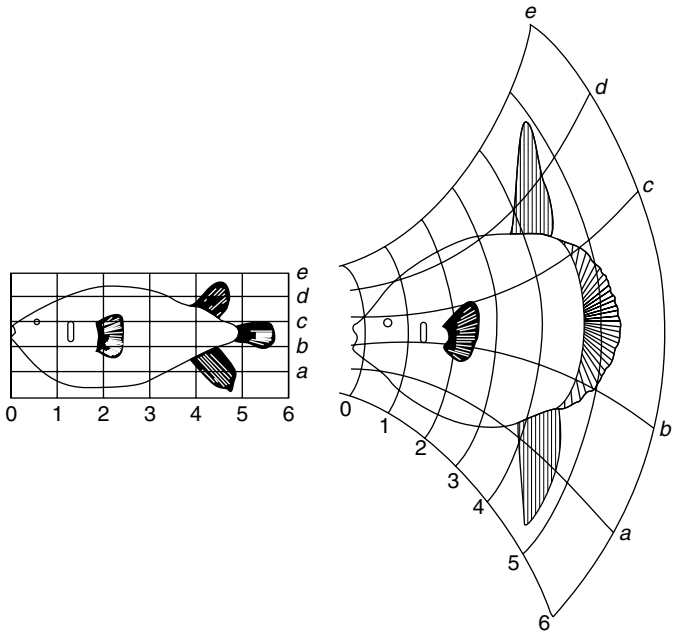

Figure 5 D'Arcy Thompson's [47] famous example of a species of fish *Diodon* being geometrically transformed into another species *Orthagoriscus*

Recent examples include the matching of electrophoresis gel images (e.g. [15]) to assess for differences between species, and the registration of a medical image to an atlas [25]. An algebraically simple but effective method for matching is the use of thin-plate splines [6, 8]. Bookstein's thin-plate spline transformations are also used in an alternative to Procrustes PCA called *relative warps*, where different aspects of bending (large and small scale) can be emphasized (e.g. see [14, Chapter 10]). More sophisticated approaches to image warping include Christensen et al. ([9]).

High-level Image Analysis

An appropriate method for high-level Bayesian image analysis is the use of deformable templates, pioneered by Grenander and colleagues [23, 24]. In many applications one has prior knowledge on the composition of the scene, and we can formulate parsimonious geometric descriptions for objects in the images. For example, in medical imaging, we can expect to know *a priori* the main subject of the image, for example, a heart or a brain. Consider our prior knowledge about the objects under study to be represented by a template S_0. Note that S_0 could be a template of a single object or many objects in a scene. A probability distribution is assigned to the parameters with density (or probability function) $\pi(S)$, which models the allowed variations S of S_0. Hence, S is a random vector representing all possible templates with associated density $\pi(S)$. Here S is a function of a finite number of parameters, say $\theta_1, \ldots, \theta_p$.

In addition to the prior model, we require an image model. Let the observed image I be the matrix of gray levels and the image model (or likelihood) be the joint probability density function of the gray levels given the parameterized objects S, written as $L(I|S)$. The likelihood expresses the dependence of the observed image on the deformed template.

By **Bayes' Theorem**, the posterior density $\pi(S|I)$ of the deformed template S given the observed image I is

$$\pi(S|I) \propto L(I|S)\pi(S). \tag{19}$$

An estimate of the true scene can be obtained from the posterior mode (the maximum *a posteriori* or MAP estimate) or the posterior mean. The posterior mode is found either by a global search, gradient descent (which is often impracticable due to the

large number of parameters) or by techniques such as simulated annealing (*see* **Computer-intensive Methods**) [17] or iterative conditional modes (ICM) [1]. Alternatively, **Markov chain Monte Carlo** (MCMC) algorithms (see, for example, [2, 18]) provide techniques for simulating from the posterior density.

There is a wide variety of possible template parameterizations that we could consider, including geometrical parameter templates, landmarks/point distribution models, graphical templates, continuous outline templates, and continuous deformation models (e.g. see [14, Chapter 11]).

Some possibilities for the image model include (i) a scientific model based on the mode of image capture (e.g. [26]), (ii) a model based on spatial smoothness (e.g. Gaussian Markov random field), (iii) a model based on measurement noise assumptions, (iv) a feature density, where particular weight is given to certain features in the image (e.g. [45]) or (v) combinations of the above. It is often convenient to also include a blurring term in the model.

The use of image analysis in various branches of medicine and biology is becoming increasingly common. Applications include the analysis of cell shapes to detect malignant versus benign tumors, the assessment of tumor volume in an MR image, and the analysis of MRI signals to relate brain activity with a repeated performed task (see [19], and the **Image Analysis and Tomography** entry in this Encyclopedia).

Discussion

An alternative but complementary approach to the use of shape space–based methods is to use methods based on Euclidean distance matrices (*see* **Similarity, Dissimilarity, and Distance Measure**) and **Multidimensional Scaling**. Visualization is more problematic with this approach, but estimation and testing procedures can be carried out with similar results for small shape variability situations (as often encountered in biology and medicine); see [37] for a review of this work.

There are many other examples of the use of shape in high-level image analysis but we have described the main ingredients of landmark or point set models; see, for example, [38, 49] for general reviews of shape measures in pattern recognition.

There is also a wide variety of work on nonlandmark shape models, such as snakes [27], continuous outline models such as the circular Gaussian Markov random field model [33], and Younes' [50] approach to continuous shape analysis with applications in high-level image analysis.

Although we have mainly concentrated on scale invariance, there are many situations in which the relationship between size and shape is of major importance, for example, in the study of **growth**. **Allometry** involves the study of the relationships between shape and size, and, in particular, in the manner in which shape depends on size. Sprent [47] provides a summary of traditional applications, and Dryden and Mardia [14, Chapter 8] provide discussion of the joint modeling and analysis of shape and size.

The notion of symmetry and bilateral symmetry in particular is very important in biology. Mardia et al. [41] and Kent and Mardia [35] explore decompositions of shape variability, which are useful for investigating bilateral symmetry.

There has been much recent discussion about the properties of shape estimators and statistical inference on shape spaces. Consistency issues for Procrustes estimators have been addressed by Kent and Mardia [34] following work by Lele [36]. Also, statistical properties of estimators of intrinsic and extrinsic mean shapes have been investigated by Bhattacharya and Patrangenaru [3], and these estimators are consistent under a very general class of models.

Finally, we conclude with remarks about the future opportunities for shape and registration methodology to be used in many applications. Geometrical invariances and registration are increasingly commonly found in medicine and biology, such as in the analysis of functions (EEG traces, mass spectrometry; *see* **Clinical Signals**), the analysis and prediction of protein structures, the analysis of electrophoretic gel images, and the analysis of medical image sequences. One of the key difficulties with many applications is that the labeling and correspondence between points/curves/surfaces is unknown. The future development of shape and registration analysis in medicine and biology for the effective analysis of these and other geometrical data is of great importance.

IAN L. DRYDEN

Sheppard's Corrections

Suppose that the discrete variable Y is a continuous variable X rounded to the nearest multiple of some positive h. Generally, the sample **moments** of Y are biased estimates of the population moments of X. Sheppard's corrections [2] are simple formulas, valid for small h, that eliminate this bias (*see* **Unbiasedness**).

For example, suppose that X is normal with mean μ and variance σ^2. If the sample average and variance of Y are $\overline{y}$ and s^2, then the Sheppard-corrected estimates are $\hat{\mu}_{\mathrm{SC}} = \overline{y}$ and $\hat{\sigma}^2_{\mathrm{SC}} = s^2 - h^2/12$. That is, the rounding has negligible effect on the mean but causes a positive bias in the variance.

One derivation of Sheppard's corrections relates the moments of Y to the moments of X. Letting $\mu_k = \mathrm{E}[X^k]$ and $\nu_k = \mathrm{E}[Y^k]$, the Euler–Maclaurin quadrature theorem implies

$$\nu_k = \sum_{m=0}^{[k/2]} \left(\frac{h}{2}\right)^{2m} \binom{k}{2m} \frac{\mu_{k-2m}}{2m+1} + R,$$

where $[\cdot]$ is the greatest integer function. The remainder R becomes small as $h \to 0$ if the density and several of its derivatives go to zero at the limits of the range of X, or at some pseudo-limits that contain most of the probability. The normal distribution is one special case.

The corrected mean and variance are also approximate **maximum likelihood** estimators. The **likelihood** based on Y has a series representation in terms of the density of X (and its derivatives) evaluated at the observed y. Starting from $\mu = \overline{y}$ and $\sigma^2 = s^2$, executing one Newton–Raphson or **EM** step leads again to Sheppard's corrections (*see* **Optimization and Nonlinear Equations**). This result holds specifically for normal X, but also for other distributions satisfying certain regularity conditions.

Although the uncorrected s^2 overestimates the variance of X, the sampling variance of $\hat{\mu}_{\mathrm{SC}}$ is not $\hat{\sigma}^2_{\mathrm{SC}}/n$ but s^2/n. Thus the corrected variance is of little value unless one specifically wants to estimate σ^2. The basic formulas are valid for the normal but possibly not for other distributions. For example, with **uniform** data, the proper correction to s^2 is to *add* $h^2/12$.

For further details and a historical review, see [1].

DANIEL F. HEITJAN

Shrinkage Estimation

Starting from the work of Stein [32] (*see* **James–Stein Estimator**), the topic of shrinkage estimation has received an enormous amount of attention in the statistical literature. The original shrinkage estimators were developed for the case of estimating the mean of a **multivariate normal distribution** under squared error loss, based on observing $\mathbf{X} = \mathbf{x}$, with $\mathbf{X} \sim \mathrm{N}(\boldsymbol{\theta}, \mathbf{I})$, a p-dimensional normal random variable. However, results on shrinkage have been generalized to the extent that these estimators can now be applied routinely to actual problems.

In terms of practical applicability, the direction pointed out by Lindley [29] has proved quite fruitful. Lindley showed that one could shrink toward a point chosen by the data, and demonstrated, for $p \geq 4$, the minimaxity of the estimator

$$\mathbf{d}^{\mathrm{L}}(\mathbf{x}) = \overline{x}\mathbf{1} + \left(1 - \frac{p-3}{|\mathbf{x} - \overline{x}\mathbf{1}|^2}\right)(\mathbf{x} - \overline{x}\mathbf{1}),$$

where $\mathbf{1}$ is a column vector of 1s and $|\mathbf{x} - \overline{x}\mathbf{1}|^2 = \sum(x_i - \overline{x})^2$. A fourth dimension is needed here, rather than the three dimensions needed for the minimaxity of the James–Stein estimator, because we are now shrinking to a one-dimensional subspace, rather than the zero-dimensional point toward which the James–Stein estimator shrinks. The idea of shrinking toward a subspace has enhanced the applicability of shrinkage estimators, and has connected them with **empirical Bayes** estimation. Much of this topic was developed in a sequence of papers by Efron & Morris [13–15], where the connection with **minimax** estimation is explored thoroughly. A comprehensive treatment of theory and applications of empirical Bayes methods is given by Morris [30], and less technical introductions are given by Casella [9, 10].

On the more theoretical side, in the normal case, Strawderman [34] was the first to exhibit *proper Bayes minimax* estimators – estimators that not only dominated $\mathbf{X}$, but were themselves proper Bayes and admissible (*see* **Bayesian Methods**). These estimators have the form of Baranchik's estimators (*see* **James–Stein Estimator**), and a particular one is given by

$$\mathbf{d}^{\mathrm{S}}(\mathbf{x}) = \left(1 - \frac{c(|\mathbf{x}|)}{|\mathbf{x}|^2}\right)\mathbf{x}, \tag{1}$$

where

$$c(|\mathbf{x}|) = p + 2 - \frac{2\exp\left(-\frac{1}{2}|\mathbf{x}|^2\right)}{\int_0^1 \lambda^{p/2}\exp(-\lambda|\mathbf{x}|^2/2)\,\mathrm{d}\lambda}.$$

The estimator (1) can be derived from the Bayes model

$$\begin{aligned}
&\mathbf{X} \sim \mathrm{N}_p(\boldsymbol{\theta}, \mathbf{I}),\\
&\boldsymbol{\theta} \sim \mathrm{N}_p[\mathbf{0}, \lambda^{-1}(1-\lambda)\mathbf{I}],\\
&\lambda \sim \textbf{uniform}\ (0, 1),
\end{aligned}$$

which is a proper Bayes model if $p \geq 5$.

Thus far we have discussed only the normal distribution; however, domination of the usual estimator by a shrinkage estimator occurs in many other situations, even in discrete families. For example, if $X_i \sim \textbf{Poisson}(\lambda_i)$, $i = 1, \ldots, p$, $p \geq 2$, are independent, and the **loss function** is given by

$$L(\boldsymbol{\lambda}, \mathbf{d}) = \sum_{i=1}^{r} \frac{(\lambda_i - d_i)^2}{\lambda_i},$$

then, as Clevensen & Zidek have shown [12], the estimator

$$\mathbf{d}^{\mathrm{CZ}}(\mathbf{x}) = \left[1 - \frac{c\left(\sum x_i\right)}{\sum x_i + b}\right]\mathbf{x}$$

is minimax if

1. $c(\cdot)$ is nondecreasing,
2. $0 \leq c(\cdot) \leq 2(p-1)$, and
3. $b \geq p - 1$.

This result highlights two differences between the normal and Poisson cases. First, domination only requires $p \geq 2$, and the loss is now scaled squared error, instead of ordinary squared error. (The fact that we only now require $p \geq 2$ is discussed by Brown [6], who described it as a "dimension doubling" phenomenon; see also [27].) Shrinkage estimators continue to dominate in many other discrete families. Using a different method of proof from that of Clevensen & Zidek [12], Hwang [24] (see also [19]) demonstrated dominance of shrinkage estimators in many discrete families.

An interesting exception is the **binomial distribution**, where Johnson [26] demonstrated that no

shrinkage estimator will dominate the usual estimator. This result was extended by Brown [8], and later Guttmann [21, 22] established the somewhat surprising result that shrinkage estimators can never dominate in any problem with a finite sample space. (Domination by shrinkage is often referred to as *the Stein effect*, so there is no Stein effect in problems with finite sample spaces.)

Even with this limitation from finite sample spaces, shrinkage estimation has played a large role in developments in both theory and practice. On the practical side, the previously mentioned connection with empirical Bayes methods (and also hierarchical Bayes methods) has allowed the application of shrinkage estimators in a wide variety of problems. The theoretical developments have also been numerous, and have sometimes been accompanied by advances in the mathematical attack on the problem.

In the normal case all restrictions on the **covariance matrix** can be removed (see, for example, [20]). Outside the normal case, shrinkage estimators exist for spherically symmetric distributions [11, 4], and some results apply to the entire **exponential family** [23]. For the case of estimating a **gamma** scale parameter, Berger [2] obtained some interesting domination results, including domination by some "expanders" rather than shrinkers. The implications of this are further discussed by Brown [7].

The theory of *superharmonic functions*, a type of multivariate concave function, which was originally applied to minimax estimation by Stein [33], has also been valuable in extending shrinkage domination. George [17, 18] used it to establish dominion by *multiple shrinkage* estimators – estimators that can shrink to more than one target. More recently, Fourdrinier et al. [16] applied it to construct new families of proper Bayes minimax estimators based on **Cauchy** prior distributions.

Although the use of squared error loss is analytically convenient, shrinkage domination extends to other losses as well. For example, variations on squared error loss that allow weight matrices can easily be accommodated. Domination under an entire class of weighted squared error loss functions can be achieved [5, 31], as well as more general universal domination [25]. Other results include those of Brandwein & Strawderman [3], who established domination results for concave losses, and Berger [1], who derived necessary conditions for dominance under a wide variety of losses. A more complete discussion of this, and many other aspects of shrinkage estimation, can be found in [28].

GEORGE CASELLA

Shrinkage

The problem of estimating the mean of a **normal distribution** is central to the practice of statistics. This simple problem is at the heart of many of the most common procedures used today, such as the **analysis of variance** or **regression.** If we have a **random sample** $X_1, \ldots, X_n$ from a normal population with mean μ and variance σ^2, then the natural estimator of μ is the sample mean $\overline{X} = (1/n)\sum_i X_i$. A question of interest is whether this estimator is the *best* estimator of the parameter μ.

When assessing the performance of an estimator; in particular, whether it is best, it is necessary to have a criterion against which to measure it. A most popular measure is *squared error loss*, where we measure the performance of an estimator d of a parameter θ by the function

$$L(\theta, d) = (\theta - d)^2, \tag{1}$$

which is called a **loss function**.

Under the loss function (1), $\overline{X}$ has many optimality properties. For example, it is a **minimax** *estimator* of μ, meaning that of all estimators of μ, its loss has the smallest maximum value. There are other properties that $\overline{X}$ enjoys, including the property of *admissibility*. An estimator d of a parameter θ is an *admissible estimator* of θ under the loss $L(\theta, d)$ if there is no other estimator d' that satisfies

$$\mathrm{E}_\theta[L(\theta, d)] \geq \mathrm{E}_\theta[L(\theta, d')], \quad \text{for all } \theta,$$

with strict inequality for some values of θ.

Is $\overline{X}$ an admissible estimator of θ? Hodges & Lehmann [3] and Blyth [1] showed that it was. That is, there is no estimator that is uniformly better. However, if the problem is made slightly more complex, then an interesting result unfolds. Suppose that, instead of estimating the mean of one normal population, we are interested in estimating the mean of many normal populations; that is, we observe $\overline{X}_k$, $k = 1, \ldots, p$, where $\overline{X}_k$ is the mean of n observations from a normal population with mean μ_k and variance σ^2, and we want to estimate $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_p)$. The loss of an estimator $\mathbf{d} = (d_1, \ldots, d_p)$ is measured by the sum of squared errors, that is

$$L(\boldsymbol{\mu}, \mathbf{d}) = \sum_{k=1}^{p} (\mu_k - d_k)^2, \tag{2}$$

and we ask if $\overline{\mathbf{X}} = (\overline{X}_1, \ldots, \overline{X}_p)$ is still an admissible estimator of $\boldsymbol{\mu}$. For $p = 2$, Stein [6] showed that the answer is Yes, but he also showed that, if $p > 2$, then the answer is No. Using arguments based on the idea that, for estimating more than 2 means, $\overline{\mathbf{X}}$ tends to be "too long", Stein demonstrated the existence of a better estimator – a *shrinkage* estimator. Such an estimator shrinks the vector $(\overline{X}_1, \ldots, \overline{X}_p)$ toward a specific point in the parameter space. In [4], it was shown that the estimator

$$\mathbf{d}^{\mathrm{JS}}(\overline{\mathbf{X}}) = \left[1 - \frac{(p-2)\sigma^2}{|\overline{\mathbf{X}}|^2}\right]\overline{\mathbf{X}},$$

which shrinks $\overline{\mathbf{X}}$ toward $\mathbf{0}$, uniformly dominates $\overline{\mathbf{X}}$ as an estimator of $\boldsymbol{\mu}$ under the loss (2), so $\overline{\mathbf{X}}$ is not an admissible estimator.

This extremely surprising result has resulted in an enormous amount of research in areas such as **decision theory** and **empirical Bayes** analysis. Many superior procedures have been derived since. See the review article by Brandwein & Strawderman [2], or the book by Lehmann & Casella [5].

Sign Tests

The sign test is a simple distribution-free test (*see* **Nonparametric Methods**) that can be applied easily in a variety of situations. Observations, which may be difference scores, are replaced by their positive or negative signs and analyzed using a binomial test. The specific applications discussed here are a location test for the median, the Cox–Stuart test for trend, and the McNemar test for correlated proportions. Bradley [2] provides a survey of these and other sign tests. These tests are also discussed in more detail in many books on nonparametric statistics, including [1, 3, 5, 7–10, 13–15].

Binomial Test

Consider data consisting of n independent dichotomous (**binary**) trials, where the outcome of each trial is classified as a success or a failure. If the probability of success, p, remains constant from trial to trial, then B, the total number of successes, has the **binomial distribution** with parameters n and p:

$$\Pr(B = b) = \binom{n}{b} p^b (1-p)^{n-b}, \quad b = 0, \ldots, n. \tag{1}$$

In the sign test, we test the **null hypothesis** $H_0 : p = 0.5$ against one- or two-sided **alternatives**. For $H_a : p > 0.5$, the ***P* value** of the test is $\Pr(B \geq b)$ for the observed value b. For $H_a : p < 0.5$, the P value is $\Pr(B \leq b)$; for $H_a : p \neq 0.5$, we double the smaller of the tail probabilities corresponding to the observed b.

For large n, the P value can be approximated using the fact that the null distribution of $Z = (B - n/2)/[(n/4)]^{1/2}$ is approximately standard normal. The approximation can be improved by incorporating a continuity correction of ± 0.5 in the numerator of Z; the sign of the correction is chosen to increase the probability being calculated.

Location Test for the Median

Let $Z_1, \ldots, Z_n$ be independent observations from a distribution with **median** θ. Assume that the distribution is continuous at θ, so that $\Pr(Z_i = \theta) = 0$. Then, $\Pr(Z_i > \theta) = \Pr(Z_i < \theta) = 0.5$. The Z_is may be either a single sample or differences of paired data, $Z_i = Y_i - X_i$.

To test $H_0 : \theta = \theta_0$, define a success as $Z_i > \theta_0$ and a failure as $Z_i < \theta_0$. Under H_0, the number of successes has a binomial distribution with parameters n and $p = 0.5$. The sign test for the median consists of a binomial test of $p = 0.5$ based on the signs of the $Z_i - \theta_0$. The alternative hypothesis $H_a : \theta > \theta_0$ corresponds to $H_a : p > 0.5$, and $H_a : \theta < \theta_0$ corresponds to $H_a : p < 0.5$.

Although continuity at the median implies that $\Pr(Z_i - \theta = 0) = 0$, in practice, $Z_i - \theta = 0$ can occur. A commonly recommended solution is to discard the zero values and reduce n accordingly [9]. This and other methods of handling zeros are discussed by Bradley [1, 2] and Emerson & Simon [6].

The exact **power** of the sign test can be computed using the binomial distribution with parameters n and $p = \Pr(Z_i > \theta_0)$. Randles & Wolfe [14] present results of a Monte Carlo study comparing the small-sample power of the sign test, **Wilcoxon signed-rank test**, and **Student's *t* test** for the **uniform**, **normal**, **logistic**, double **exponential**, and **Cauchy** distributions. The sign test is the most powerful of the three tests for the Cauchy distribution and is superior to the t test for the double exponential. Otherwise, the sign test has the poorest performance in the situations studied.

Noether [12] gives a formula for determining the sample size required to obtain the desired power against specified alternatives (*see* **Sample Size Determination**). The **asymptotic relative efficiency** of the sign test relative to Student's t test is 0.637 for the normal distribution, 0.333 for the uniform, 0.822 for the logistic, 2.0 for the double exponential, and at least 1/3 for any continuous, unimodal symmetric distribution [14, p. 168].

The sign test can be inverted to construct a **confidence interval** for the median θ. The lower and upper limits of the confidence interval are appropriately chosen **order statistics** of the Z_is [9].

Other Sign Tests

Sign Test for Trend

Cox & Stuart [4] proposed a sign test for upward or downward trend in a sequence $X_1, \ldots, X_{n'}$

of continuous observations. The observations are grouped into pairs $(X_1, X_{1+c}), (X_2, X_{2+c}), \ldots, (X_{n'-c}, X_{n'})$, where $c = n'/2$ if n' is even, and $c = (n'+1)/2$ if n' is odd. (If n' is odd, then the middle observation is discarded.) A pair (X_i, X_{i+c}) with $X_i < X_{i+c}$ is a success; a pair with $X_i > X_{i+c}$ is a failure. A preponderance of successes suggests an upward trend, and a preponderance of failures, a downward trend. Under the null hypothesis of no trend, the number of successes is binomial with parameters n and $p = 0.5$, where n is the number of pairs formed.

A modification of the Cox–Stuart test can be used to test for **correlation** between continuous variables X and Y. The bivariate observations (X, Y) are ordered with respect to increasing values of X (or Y), and the trend test is applied to the corresponding values of Y (or X).

McNemar Test

The **McNemar** [11] **test** for correlated proportions is usually considered a sign test, although no signs are actually involved. The test is used to analyze paired dichotomous data (*see* **Matched Pairs With Categorical Data**). For example, subjects and matched controls might be classified according to the presence or absence of a symptom, or subjects might be asked a Yes/No question both before and after an intervention. In the latter example, those subjects who answer Yes at both times and those who answer No at both times contribute no information about the direction of any change caused by the intervention. Thus, the test is based on only those n subjects who change their answers. Under the null hypothesis of no effect, the number of subjects who change from No to Yes is binomial with parameters n and $p = 0.5$.

E. JACQUELIN DIETZ

Signed-rank Statistics

Signed-rank statistics are commonly employed for the analysis of a single sample of data, or for the analysis of matched pairs. Procedures based on signed-rank statistics are nonparametric as they permit valid statistical inferences for data from broad families of probability distributions, such as all continuous, symmetric distributions.

The most typical biostatistical setting in which signed-rank statistics are constructed is for the matched-pairs study. In this instance intrapair differences are calculated, and these differences are **ranked** according to their absolute (unsigned) values using the integers $1, 2, \ldots, N$. Here, 1 is assigned to the smallest absolute difference, 2 is assigned to the next largest absolute difference, and so forth, until the largest absolute difference is assigned the rank of N. After such ranking of the absolute differences, the sign of the difference is restored to the rank. Statistics calculated from these signed-ranks are termed signed-rank statistics. A well-known statistic in this class is the Wilcoxon signed-rank statistic, on which the corresponding **Wilcoxon signed-rank test** procedure is based. This test procedure was introduced by Wilcoxon [4], and is a simple and powerful competitor to the **paired *t* test**.

To illustrate the calculation of signed rank, consider the following study in which resting heart rates are recorded for nine healthy persons. Measurements are made both before and six months after initiation of an aerobic exercise program. The data are displayed in Table 1. Each heart rate in the Table is the mean of five resting heart rates for each person at each time period. The effectiveness of the exercise program in reducing the resting heart rate can be assessed by examination of the direction and the magnitude of the intrapair differences. The positive signed ranks are those associated with the positive differences which occur for all subjects, except subjects 3 and 5. Both of these persons have negative signed ranks.

Two problems can arise in constructing signed ranks; these are zero differences and differences equal to one another in absolute value. It is customary in signed-rank analyses to discard the zero differences prior to ranking, and then reduce the sample size accordingly by the number of such zero differences; see [3] and [1] for further discussion of the effects of this convention. Tied absolute differences are usually resolved by midranking, wherein the tied values each receive the mean value of the ranks they would have been assigned had they been slightly different from one another. For example, suppose the data for subject 2 in Table 1 had been 76 and 72 for the baseline and six-month heart rates, respectively. The difference would then be $+4$, which would be tied in absolute value with the -4 difference calculated for subject 3. In midranking, the rank of 2.5, i.e. $(2 + 3)/2$, would be assigned to each of these absolute differences. The rank of 4 would be assigned to the next largest absolute difference, etc. Data with many such ties require special treatment and adjustments in the analyses; standard text books on nonparametric methods, such as Hollander & Wolfe [2], detail the specifics of these adjustments.

A most common distributional assumption in the construction of signed-rank statistics is that the

Table 1 Resting heart rate of nine people before and after initiation of an exercise regimen

Subject	Heart rate at baseline (y_i)	Heart rate at six months (x_i)	Difference $d_i = y_i - x_i$	Absolute value of difference $\lvert d_i \rvert$	Rank of absolute difference (sign)
1	80	72	+8	8	5(+)
2	76	70	+6	6	3(+)
3	78	82	−4	4	2(−)
4	90	76	+14	14	9(+)
5	84	86	−2	2	1(−)
6	86	76	+10	10	7(+)
7	81	74	+7	7	4(+)
8	84	75	+9	9	6(+)
9	88	76	+12	12	8(+)

differences (such as those calculated in Table 1) arise from a continuous, symmetric distribution. The null hypothesis in settings like Table 1 is that the distribution of these differences is centered at zero (although one can specify any constant, and apply signed ranking to those quantities). Under the null hypothesis, each assignment of signs (+ or −) to each of the N ranks is equally likely, and this fact is utilized to construct formal **hypothesis testing** procedures from these signed-rank statistics. The most common of these tests is the Wilcoxon signed-rank test [4], described in a separate article.

Similarity, Dissimilarity, and Distance Measure

Statisticians are familiar with the concept of the **correlation**, or other measures of **association**, between two variables, but the concept of the similarity between two samples seems to have originated outside mainstream statistics, in ecology, taxonomy, psychology, and entomology (see, for example, Sneath & Sokal [6]) (*see* **Numerical Taxonomy**). Because of the taxonomic origins, **binary** variables are often termed characters or features; similar terms drawn from other fields of application are often encountered. Similarly, the term "sample" used here may be replaced by case, object, subject, OTU (Operational Taxonomic Unit), or unit. The most simple measures of similarity are concerned with binary variables denoting the presence or absence of characteristics, or perhaps two forms of a character, such as red and white. We shall see that the logical difference between these different types of binary variable affects the algebraic forms of acceptable coefficients. With two samples labeled i and j, say, we can count the number of agreements and disagreements among p binary variables to give Table 1, in which the two values of a binary variable are denoted by 1 and 0; thus 0/1 may refer to absence/presence or to red/black.

Thus, Table 1 shows that there are a agreements among form 1 of the p variables and d agreements among form 0. There are b (c) cases in which sample i has form 1 (0) and sample j has form 0 (1). Many similarity coefficients are simple functions of a, b, c, and d, where $p = a + b + c + d$; Hubálek [4] lists 43 similarity coefficients of this type. Two of the most common are the Simple Matching coefficient, defined by

$$S_{\mathrm{SM}} = \frac{a+d}{a+b+c+d} = \frac{a+d}{p}, \qquad (1)$$

and the Jaccard coefficient, defined by

$$S_{\mathrm{J}} = \frac{a}{a+b+c} = \frac{a}{p-d}. \qquad (2)$$

When $a = b = c = 0$, we define $S_{\mathrm{J}} = 0$. Note that S_{SM} and S_{J} typify the two major classes of similarity coefficients, those which include "negative matches" given by d and those which do not. By a negative match we mean that both samples lack a character and a shared missing character may be deemed no useful evidence of agreement. Thus, that two people both speak French as a mother tongue is an indication of a shared characteristic; but two people, neither of whom speaks French, is no such indication – there is a lack of symmetry between what is meant by a score of 1 (presence or +) and a score of 0 (absence or −). However, two samples that are both black or both white would, unless there is evidence to support differential weighting (see below), usually be deemed of equal similarity in respect of color; note however, that in genetics "white" may indicate the lack of a gene controlling the black state. Clearly, there can be major problems in deciding what is and what is not a negative match. These introductory remarks have touched on some of the issues associated with similarity coefficients, and we shall expand on these below (*see* **Agreement, Measurement of**).

Table 1 Numbers of agreements and disagreements between binary variables for two samples

		Sample j	
		1	0
Sample i	1	a	b
	0	c	d

The important problem of matching nucleic or amino acid sequences is related to that of constructing general purpose similarity coefficients, but because **DNA sequences** require alignment, there are special problems, with a large literature.

General Properties of Similarity Coefficients

We have discussed the similarity between samples i and j, and so, strictly speaking, the entries in Table 1 should be written a_{ij}, b_{ij}, c_{ij}, and d_{ij}, with a corresponding similarity coefficient; for simplicity, and when there is no ambiguity, it is customary to drop the suffices i and j. As for the Simple Matching and Jaccard coefficients, most similarity coefficients S_{ij} are positive, symmetric, and bounded by zero and unity. A value of zero indicates no matches ($a_{ij} = 0$, and where necessary also $d_{ij} = 0$). A value of unity implies a complete

match ($a_{ij} = p$, and where necessary, $a_{ij} + d_{ij} = p$). The property of symmetry implies that $a_{ij} = a_{ji}$, $d_{ij} = d_{ji}$ and $b_{ij} = c_{ji}$. A few coefficients of inter-sample correlational form satisfy $-1 \leq S_{ij} \leq 1$, and then the above comments need corresponding changes. With n samples, the $\binom{n}{2}$ pairs of similarity coefficients may be assembled into a nonnegative symmetric matrix $\mathbf{S}$ with unit diagonal elements. $\mathbf{S}$ is termed a similarity matrix and may be analyzed directly (*see* **Classification, Overview**; **Cluster Analysis of Subjects, Hierarchical Methods**) or may be converted into a dissimilarity matrix $\mathbf{D} = \mathbf{11}' - \mathbf{S}$, which has a zero diagonal and values $1 - S_{ij}$ off the diagonal. The obvious question to ask is to what extent do dissimilarities have the same properties as distances, usually Euclidean distances? Gower & Legendre [3] examine the following questions:

1. Do the dissimilarities satisfy the metric (triangle) inequality?
2. Are the dissimilarities Euclidean embeddable for an explanation, (*see* **Principal Coordinates Analysis**)?
3. As above, but for the square root of dissimilarity.

They also provide tools to help answer these questions, and answers for many specific similarity coefficients. The metric property is important because if it is not true, then the dissimilarity between samples i and j can be greater than the sum of the dissimilarities between i and k and j and k, which does not satisfy intuitive ideas of similarity. Euclidean embeddability is of interest in **multidimensional scaling** and, writing $\mathbf{N}$ for the matrix all of the values of which are $1/n$, we have (see (3) in the article on **Principal Coordinates Analysis**) that necessary and sufficient conditions for $(1 - S_{ij})^{1/2}$ to be embeddable is that the centred matrix $(\mathbf{I} - \mathbf{N})\mathbf{S}(\mathbf{I} - \mathbf{N})$ be positive semi-definite; it is sufficient for $\mathbf{S}$ itself to be positive semi-definite, which is usually more easily established than for the centred form. Thus, answers to question 3 relate directly to the properties of $\mathbf{S}$ and, it turns out, are easier to provide than those to question 2. We know that if $\mathbf{S}$ is positive semi-definite then so is the Hadamard (or element by element) product $\mathbf{S} * \mathbf{S}$, which would imply that $(1 - S_{ij}^2)^{1/2}$ is embeddable, but the answer to question 2 requires an investigation of the definiteness of the centred form of the similarity matrix with elements $1 - (1 - S_{ij})^2$. Gower & Legendre [3] answer some of these questions, and the results of special interest – shown in Table 2 – pertain to the following generalizations of the Simple Matching coefficient, defined by

$$S_{\mathrm{SM}}(\theta) = \frac{a + d}{a + d + \theta(b + c)}, \quad \theta > 0, \tag{3}$$

and of the Jaccard coefficient,

$$S_{\mathrm{J}}(\theta) = \frac{a}{a + \theta(b + c)} \quad \theta > 0. \tag{4}$$

Table 2 How the metric and Euclidean properties of the families $S_{\mathrm{J}}(\theta)$ and $S_{\mathrm{SM}}(\theta)$ change with positive values of θ

Family	Coefficient	Nonmetric	Metric	Euclidean
$S_{\mathrm{J}}(\theta)$	$1 - S_{ij}$	$0 < \theta < 1$	$\theta \geq 1$	*
	$(1 - S_{ij}^2)^{1/2}$	$0 < \theta < \frac{1}{3}$	$\frac{1}{3} \leq \theta < \frac{1}{2}$	$\frac{1}{2} \leq \theta$
$S_{\mathrm{SM}}(\theta)$	$1 - S_{ij}$	$0 < \theta < 1$	$\theta \geq 1$	*
	$(1 - S_{ij}^2)^{1/2}$	$0 < \theta < \frac{1}{3}$	$\frac{1}{3} \leq \theta < 1$	$1 \leq \theta$

The entries in Table 2 are worst-case scenarios. Thus, "Nonmetric" means that for the values of θ shown, nonmetric configurations can always be found, although some configurations may be metric or even Euclidean. "Metric" means that all configurations for the indicated values of θ are metric, although Euclidean representations will exist for some sets of data. "Euclidean" means that all configurations for the indicated values of θ are Euclidean. The asterisk indicates that, for these settings, data which generate non-Euclidean representations exist for all values of θ. Note that the case $\theta = 0$ represents a degenerate set of points coincident at the origin, and is not of interest.

The families $S_{\mathrm{J}}(\theta)$ and $S_{\mathrm{SM}}(\theta)$ include many popular similarity coefficients, and the results of Table 2 give some guidance on choices. For both families, we may note that if $S_{ij}(\theta) > S_{pq}(\theta)$, then $S_{ij}(\phi) > S_{pq}(\phi)$ for arbitrary θ and ϕ; that is, the coefficients in each family are monotonically related. It follows that if they are analyzed by any monotonically invariant method, such as nonmetric multidimensional scaling or single-linkage cluster analysis (*see* **Classification, Overview**), then the results do not depend on θ.

Multilevel qualitative variables may be dealt with similarly to binary variables. The simplest method is

to give a score $0 \le s_{ijk} \le 1$ for the match between the ith and jth samples for the kth variable. Then we may define similarity by

$$S_{ij} = \frac{1}{p}\sum_{k=1}^{p} s_{ijk}. \tag{5}$$

When $s_{ijk} = 1$ for a match, otherwise $s_{ijk} = 0$, (5) is termed the Extended Matching Coefficient S_{ESM}, and becomes S_{SM} when all variables are binary. If there are a positive matches and a total of L levels over all p variables, then $S_{\mathrm{ESM}} = a/L$. An alternative approach for handling multilevel qualitative variables is to code each qualitative state as a separate binary variable and then use one of the binary coefficients, now based on L binary variables. Assuming that every character must occur in one of its states, then there are $p - a$ mismatches, each occurring twice, so that $b + c = 2(p - a)$ and $d = L + a - 2p$. Then $S_{\mathrm{SM}} = (L + 2a - 2p)/[(L + 2a - 2p + 2\theta(p - a)]$ and $S_{\mathrm{J}} = a/[a + 2\theta(p - a)]$, both of which are monotonically related to S_{ESM}. Thus, for many purposes, S_{ESM} is equivalent to all members of both families.

Similarity coefficients may also be defined for quantitative variables. Denoting the ith value of the kth variable by x_{ik}, most similarity coefficients of this type have the general form

$$S_{ij} = \frac{1}{p}\sum_{k=1}^{p} s_k(x_{ik}, x_{jk}), \tag{6}$$

in which each variable contributes independently to overall similarity. Here $s_k(x_{ik}, x_{jk})$ denotes a function that may differ for each variable but, in practice, is nearly always the same function in any one study. Typical choices are based on one of the Minkowski metrics to give for positive values of t:

$$s_k(x_{ik}, x_{jk}) = 1 - \left\{\frac{|x_{ik} - x_{jk}|t}{r_k^t}\right\}^{1/t}$$

where r_k is a normalizer that eliminates the effects of scales of measurement and is chosen to ensure that $0 \le s_k(x_{ik}, x_{jk}) \le 1$. The usual choice is $t = 1, 2$ giving, respectively, similarities based on absolute differences and Euclidean distance. Note that for ratio scales, a logarithmic transform eliminates scale effects in differences. A simple choice is to set r_k equal to the range of the kth variable, possibly after transformation, in the sample. Other choices of similarity coefficients for quantitative variables and of normalizers and their metric and Euclidean properties are discussed by Gower [2] and Gower & Legendre [3].

The different choices of θ in (3) and (4) may be regarded as simple examples of character-weighting. In the field of classification, there has been much controversy over the desirability or otherwise of weighting, but if one decides to do so, it is simply done. A general coefficient that includes much of the above as special cases is to define (see Gower [1])

$$S_{ij} = \frac{\sum_{k=1}^{p} w_k(x_{ik}, x_{jk}) s_k(x_{ik}, x_{jk})}{\sum_{k=1}^{p} w_k(x_{ik}, x_{jk})}, \tag{7}$$

where $w_k(x_{ik}, x_{jk})$ is a weighting function. We may obtain $S_{\mathrm{SM}}(\theta)$ by setting $w_k(x_{ik}, x_{jk}) = 1$ when x_{ik} and x_{jk} match, and $w_k(x_{ik}, x_{jk}) = \theta$ when x_{ik} and x_{jk} do not match. Similarly, we obtain $S_j(\theta)$ by setting $w_k(x_{ik}, x_{jk}) = 1$ when x_{ik} and x_{jk} match positively, $w_k(x_{ik}, x_{jk}) = 0$ when x_{ik} and x_{jk} match negatively, and $w_k(x_{ik}, x_{jk}) = \theta$ when x_{ik} and x_{jk} do not match. We may also set $w_k(x_{ik}, x_{jk}) = 0$ when at least one of x_{ik} and x_{jk} is missing. Among other coefficients included are recursive similarity coefficients, where a hierarchy of primary, secondary, tertiary and so on, characters is recognized. Then the similarity among the secondary characters may be used to weight the primary characters, and similarly for characters at higher levels.

Metrics on Graphs

The Overview of Classification mentions minimal link trees, leading to ultrametrics, and additive distances that may be associated with hierarchical representations. More generally, distances may be defined on any connected network: the shortest route between two nodes, the minimal or maximal link on the route between two nodes, or measures that have physical interpretations. For example, one may associate unit resistance with every link and use Kirchoff's law to determine have found applications in molecular chemistry (see [5]).

Similarity Between Populations

In the above, we have referred to the similarity between pairs of samples. In taxonomy, samples typically refer to whole biological populations and characters are chosen that have little or no variation within the populations. This is often acceptable for qualitative characters – for example, all cats have claws and all dandelions are yellow – but quantitative variables will nearly always have a distribution within populations. Taxonomists try to find quantitative characters with little overlap between biological populations, which may be represented by their average or some other typical value. Then, each population may continue to be represented by a single sample, and similarity computed as discussed above. In applications that study closely related populations, the overlap cannot be ignored and inter-population distances, or other measures of inter-population overlap, rather than similarities must be used. These are discussed elsewhere (*see* **Discriminant Analysis, Linear**; **Mahalanobis Distance**). When, perhaps as a **null hypothesis**, the samples can be viewed as random drawn from a single population, the usual statistical questions arise concerning the distribution and joint distribution of the S_{ij}. Because of the nature of the variables, theoretical results are few (see, for example, Snijders et al. [7]) and therefore applications tend to use **jackknife** and other data-resampling techniques.

Simple Structure

In **factor analysis**, a simple structure is the "ideal" structure, in which each factor is defined by a subset of the original variables with as little overlap as possible. In other words, ideally, we want to find a final **factor loading matrix** such that each column has a considerable number of near-zero loadings and a small number of large loadings, and each row has only one or a very small number of large entries. While orthogonal transformations (*see* **Orthogonal Rotation**) are often used, **oblique rotations** are generally better for finding a matrix that exhibits a simple structure. In general, the reference-vector structure matrix, **V**, is used to determine simple structure (*see* **Factor Loading Matrix**; **Primary Factors**). This matrix usually has at least as many near-zero loadings on each factor as the number of factors. Also, this reference structure matrix, which contains the correlations between the variables and the reference-vector factors, is often used for interpretation of the factors. The five criteria of simple structure proposed by Thurstone [4] are often too rigid to be applied to the real data. We prefer the following two criteria, discussed in Cureton & D'Agostino [2].

The first condition of simple structure is given as a criterion of overdetermination. The condition states that:

> There should be at least m near-zero loadings and usually several more than m in each column of the reference-vector structure matrix, where m is the number of the retained factors (i.e. the column of the matrix).

This first condition is used to overdetermine the location of a **primary factor** by at least m variables, and usually more than m. This is to make sure the locations of the primary factors are well determined. This first condition allows a few variables with nonzero loadings on all factors as long as there are enough variables that have near-zero loadings to determine the locations of the primary factors.

The second condition is based on the idea that the factors should be maximally distinct from one another, and that the factorial structure should be unique. The condition is given as follows:

> Among the subset of m or more rows of the reference-vector structure matrix having near-zero loadings in any one column, there is at least one and usually more than one nonzero loading in every other column. Every one of these rows must have at least one nonzero loading, and these nonzero loadings are distributed over all the other columns. Also in every column of the reference structure matrix, the number of negative nonzero loadings should be a minimum.

Alternative to the criteria of simple structure, a procedure based on a criterion of simplicity has been proposed by Bentler [1]. The results given by his procedure are not very different from those based on simple structure.

Since the conditions of the simple structure are given in qualitative terms, it is evident that subjective judgments are required to determine terms such as "near-zero" or "large" loadings, and "subset" of variables. Consequently, various analytic procedures have been developed for computing a simple structure. A review of this development can be found in Harman [3].

Simplex Models

Simplex models are employed for the analysis of relationships among variables that can be arranged according to a logical ordering. In some situations the ordering is known beforehand. For example, the ordering can reflect the sequence of trials in a learning experiment, the age of subjects in a longitudinal study, or the length of preparatory intervals in a stimulus response task. In other situations, the ordering refers to some unobservable property of the variable and has to be inferred from the data. For example, in the original formulation of the simplex model due to Guttman [5], the ordering was according to the complexity of ability tests. A simplex analysis is applicable only when all intercorrelations are positive. The primary aim of the analysis is to investigate the degree of similarity or closeness between successive variables.

Relationships of the simplex model with Markov and Wiener stochastic processes were discussed by Anderson [1]. Jöreskog [6] presented a comprehensive review of different types of simplex models and showed how these models can be fitted by **maximum likelihood**. Most methods for fitting the simplex require a prior knowledge of the ordering of variables, although two-stage procedures in which the ordering of variables is estimated in the first stage have been suggested by Kaiser [8] and by Cureton & D'Agostino [4, Chapter 15]. A reformulation of the simplex model that does not require a prior specification of the ordering of variables was suggested by Schönemann [10]. He also provided a procedure for fitting the order free simplex model using an approach based on **multidimensional scaling**. The method of maximum likelihood can also be used for fitting the order-free formulation of the simplex model [2, p. 132].

The Perfect Simplex

A classic example of a **correlation** matrix exhibiting a simplex pattern, originally presented by Guttman [5, Table 5] and frequently used since, is given in Table 1 (*see* **Guttman Scale**).

This shows correlations between six verbal ability tests applied to 1046 Bucknell sophomores. A correlation matrix is considered, since different tests are on different scales so that variances and covariances would not be meaningful. All tests are from the same domain and all intercorrelations are positive. There is a noticeable inequality pattern in the correlation coefficients. Those next to the diagonal are largest and they taper off as the lower left-hand corner is approached. This pattern is characteristic of the simplex. It is dependent on the ordering of the tests but not on direction. A similar pattern will occur if tests are listed in reverse order, with Test 6 listed first and Test 1 listed last. In Guttman's original work, the fundamental ordering represented complexity, but other fundamental orderings, such as time, may be considered.

Table 1 Six verbal ability tests: Bucknell College sophomores, $N = 1046$

Spelling	1	1.000					
Punctuation	2	0.621	1.000				
Grammar	3	0.564	0.742	1.000			
Vocabulary	4	0.476	0.503	0.577	1.000		
Literature	5	0.394	0.461	0.472	0.688	1.000	
Foreign literature	6	0.389	0.411	0.429	0.548	0.639	1.000

We distinguish between two types of simplex; a perfect simplex where no allowance is made for error of measurement in observing variables, and a quasi-simplex where measurement error is taken into account.

Guttman's Conceptualization of the Perfect Simplex

Let **P** represent the correlation matrix of the variates, $X_1, X_2, \ldots, X_p$. The basic assumption in Guttman's conceptualization is that if **P** satisfies a perfect simplex, all partial correlations between pairs of nonadjacent variables given any variable that is intermediate in the fundamental ordering will be zero:

$$\rho_{ik \cdot j} = 0, \quad 1 \leq i < j < k \leq p. \tag{1}$$

A consequence of the assumption in (1) is that a typical element of **P** may be expressed as

$$\rho_{ij} = \frac{\alpha_i}{\alpha_j}, \quad i < j, \tag{2}$$

where α_i is a parameter that may be interpreted as a measure of the degree of complexity of X_i. Guttman named the α_i "complexity loadings" and regarded them as correlation coefficients of the X_i with a

hypothetical endpoint of the fundamental continuum. They are defined only up to a constant of proportionality, so that an identification condition should be imposed. A suitable identification condition is

$$\alpha_p = 1. \tag{3}$$

If (3) is imposed, α_i may be interpreted as the correlation coefficient of X_i with the most complex available variable, X_p.

The basic assumption (1) also implies (cf. [1, p. 209]) that the regression equation of any variable on the remaining $p-1$ variables will have nonzero partial regression weights only on the adjacent variables in the fundamental ordering (*see* **Multiple Linear Regression**). Consequently, if $p = 5$ for example, the array of row vectors of regression weights of each variable on the remaining variables will have the pattern

$$\begin{bmatrix} - & \beta_{1.2} & 0 & 0 & 0 \\ \beta_{2.1} & - & \beta_{2.3} & 0 & 0 \\ 0 & \beta_{3.2} & - & \beta_{3.4} & 0 \\ 0 & 0 & \beta_{4.3} & - & \beta_{4.5} \\ 0 & 0 & 0 & \beta_{5.4} & - \end{bmatrix},$$

where $\beta_{i \cdot j}$ denotes the partial regression weight of the ith variable on the jth variable.

Since the density of a sample correlation matrix cannot be expressed in closed form, it is common practice to treat a correlation structure as a covariance structure,

$$\mathbf{\Sigma}_X = \mathbf{D}_\sigma \mathbf{P} \mathbf{D}_\sigma, \tag{4}$$

where the diagonal elements, $\sigma_1, \ldots, \sigma_p$, of $\mathbf{D}_\sigma$ represent standard deviations regarded as **nuisance parameters**, and $\mathbf{P}$ is a function of the parameters of interest. Estimates are then obtained by maximizing the Wishart likelihood function (*see* **Wishart Distribution**).

The covariance structure for a perfect simplex model involves $2p-1$ parameters. Maximum Wishart likelihood estimates may be expressed in closed form [9, Section 8.11; 6, Section 2.3]. Let $\mathbf{S}$ represent a sample covariance matrix, with typical element s_{ij}, based on a sample of size N, and let $\mathbf{R}$ be the corresponding correlation matrix, with typical element r_{ij}. **Maximum likelihood** estimates, subject to the identification conditions (3), are given by

$$\hat{\sigma}_i = (s_{ii})^{1/2}, \quad i = 1, \ldots, p$$
$$\hat{\alpha}_i = r_{i,i+1}\hat{\alpha}_{i+1}, \quad i = 1, \ldots, p, \ \hat{\alpha}_{p-1} = 1, \tag{5}$$

and the corresponding -2 log **likelihood ratio test** statistic is [6, Section 2.4]

$$G = (N-1)\left[\sum_{i=1}^{p-1} \ln(1 - r_{i,i+1}^2) - \ln|\mathbf{R}|\right].$$

Under the null hypothesis that the perfect simplex model holds, the asymptotic distribution of G is **chi-square** with $\frac{1}{2}p(p-3)+1$ **degrees of freedom**.

The maximum likelihood estimates (5) are particularly easy to calculate and only make use of the $p-1$ correlation coefficients adjacent to the main diagonal. These estimates are, however, dependent on the ordering of variables. This is generally not known in advance.

Schönemann [10] suggested that the (2) for the elements of a perfect simplex be expressed in the alternative order-free form

$$\rho_{ij} = \frac{\min(\alpha_i, \alpha_j)}{\max(\alpha_i, \alpha_j)}. \tag{6}$$

The direction of complexity in (6) is indeterminate, as $\alpha_1^{-1}, \ldots, \alpha_p^{-1}$ may be regarded as points on an equivalent fundamental continuum, since

$$\frac{\min(\alpha_i^{-1}, \alpha_j^{-1})}{\max(\alpha_i^{-1}, \alpha_j^{-1})} = \frac{\min(\alpha_i, \alpha_j)}{\max(\alpha_i, \alpha_j)}.$$

Schönemann [10] pointed out that the elements of the symmetric matrix $\mathbf{P}^*$, with typical element

$$\rho_{ij}^* = -\ln \rho_{ij} = |\ln \alpha_i - \ln \alpha_j|,$$

s represent Euclidean distances between points $\alpha_i^* = \ln \alpha_i, i = 1, \ldots, p$, on the real line and showed how classical **multidimensional scaling** can be applied to the corresponding matrix of distance estimates to obtain estimates, $\hat{\alpha}_i^*$, of these points. Estimates of the α_i are then obtained by taking antilogarithms: $\hat{\alpha}_i = \exp(\hat{\alpha}_i^*)$. The classical scaling procedure involves the extraction of the largest **eigenvalue** and corresponding **eigenvector** of a symmetric matrix, and the resulting estimates are invariant under reordering of the variables.

Stochastic Process Interpretation

A **stochastic process** is a family of **random variables** $X(t)$ indexed by a continuous parameter $t, 0 \leq t < \infty$, often regarded as a time parameter. Variables

are considered to be observations of the process at the points $t_1, \ldots, t_p$. Correlation coefficients between variables, $X(t_i)$ and $X(t_j)$, are defined by a function of t_i and t_j known as a correlation function.

Anderson [1] considered the simplex from the viewpoint of the Markov and Wiener stochastic processes and pointed out that the partial correlation property in (1) underlying the simplex is a known property of a **Markov process**. The correlation function of a Markov process is

$$\rho_{ij} = \rho(X(t_i), X(t_j)) = \rho^{|t_i - t_j|}, \quad \text{for all } i, j. \quad (7)$$

where ρ is a correlation parameter. This correlation function may be shown to be equivalent to expression (6) for the elements of a perfect simplex by means of the substitution

$$\alpha_i = \rho^{-t_i}. \quad (8)$$

Thus (7) may be regarded as a reparameterization of (6) involving $p + 1$ parameters, $\rho, t_1, \ldots, t_p$ instead of the p parameters $\alpha_1, \ldots, \alpha_p$.

In some situations the time points are known in advance and ρ is estimable. Here, the t_i are not known in advance and the correlation parameter is indeterminate. Two identification conditions must be imposed. Suitable identification conditions are

$$t_1 = 1, \qquad t_p = p. \quad (9)$$

If an order-free approach is employed, t_1 and t_p denote the smallest and largest points respectively, and need not be the first and last points.

These identification conditions fix the endpoints of the time scale and serve to identify ρ and the remaining "time" points, which need not assume integral values. The t_i may be regarded as alternate parameters to be interpreted instead of the complexity loadings, α_i, and values satisfying the identification conditions in (9) may be calculated from

$$t_i = 1 + (p-1)\frac{\ln \alpha_i - \ln \alpha_1}{\ln \alpha_p - \ln \alpha_1}$$

where, again, α_1 and α_p refer to the smallest and largest complexity loadings if they are not given in increasing order. The correlation parameter then is given by

$$\rho = \exp\left[-\left(\frac{\ln \alpha_p - \ln \alpha_1}{p-1}\right)\right].$$

An *equally spaced* simplex [5] is one where the time points, t_i, are equally spaced on the real line.

A data model (cf. [6, Section 5.6; 7, Section 4.1]) that generates a Markov process is the first order autoregressive (AR1) time series (*see* **ARMA and ARIMA Models**) with nonhomogeneous autoregression weights, β_i, and nonhomogeneous white noise variances, ψ_{ii}:

$$(X_{i+1} - \mu_{i+1}) = \beta_i(X_i - \mu_i) + Z_{i+1}, \quad i = 1, \ldots, p-1,$$

where $\mathcal{E}(X_i) = \mu_i$ and the Z_i are mutually independently distributed white noise terms with variances $\psi_{ii}, i \geq 2$. We define $\psi_{11} = \text{var}(X_1)$. This data model generates the covariance structure

$$\mathbf{\Sigma}_X = (\mathbf{I} - \mathbf{B})^{-1}\mathbf{D}_\psi(\mathbf{I} - \mathbf{B}')^{-1}, \quad (10)$$

where $\mathbf{D}_\psi$ is a diagonal matrix with typical diagonal element ψ_{ii} and $\mathbf{B}$ is a matrix with zero elements except for those just below the main diagonal. When $p = 5$ for example,

$$\mathbf{B} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ \beta_1 & 0 & 0 & 0 & 0 \\ 0 & \beta_2 & 0 & 0 & 0 \\ 0 & 0 & \beta_3 & 0 & 0 \\ 0 & 0 & 0 & \beta_4 & 0 \end{bmatrix}.$$

The model of (10) is equivalent (cf. [6, section 5.6]) to the perfect simplex given by (4) and (2). There are $2p - 1$ parameters: $\beta_1, \ldots, \beta_{p-1}, \psi_{11}, \ldots, \psi_{pp}$. In order to see the relationship between the autoregression weights and the complexity loadings, we define the standardized autoregression weight

$$\beta_i^* = \left(\frac{\sigma_{ii}}{\sigma_{i+1,i+1}}\right)^{1/2}\beta_i,$$

where σ_{ii} denotes the ith diagonal element of $\mathbf{\Sigma}_X$ in (10). Thus $\beta_i^* = \beta_i$ if the X_i have been standardized to have unit variances so that $\mathbf{\Sigma}_X$ in (10) has unit diagonals and is therefore a correlation matrix. The relationship between the complexity loadings and the standardized autoregression weights then is

$$\alpha_i = \prod_{j=i}^{p-1}\beta_j^*, \quad i = 1, \ldots, p-1$$

Prior knowledge of the ordering of variables is necessary for use of the formulation of the simplex model in (10).

A Wiener stochastic process has structured variances (*see* **Brownian Motion and Diffusion Processes**). Its indexing parameter will be referred to as $s, 0 \leq s < \infty$, with scale points $s_1, \ldots, s_p$. The Wiener process has the covariance function

$$\sigma_{ji} = \sigma_{ij} = \text{cov}[X(s_i), X(s_j)] = s_i, \quad s_i \leq s_j, \tag{11}$$

so that the variances $\sigma_{ii} = s_i$ are constrained. It can be shown that the correlations obtained from the variances and covariances of (11) have the simplex structure (2) (cf. [1, pp. 207–208; 6, Section 3.1; 9, Section 8.11]) but the relationship between the complexity loading, α_i, and scale point, s_i, is

$$\alpha_i = (s_i)^{1/2}$$

and differs from the corresponding relationship (8) between the complexity loading and the scale point, t_i, of a Markov process. A matrix expression for the covariance matrix with typical element given by (11) is [6, Section 3.1]

$$\boldsymbol{\Sigma}_X = \mathbf{T}\mathbf{D}_\varphi\mathbf{T}', \tag{12}$$

where $\mathbf{D}_\varphi$ is a diagonal matrix with diagonal elements $\varphi_{11} = s_1$ and $\varphi_{ii} = s_i - s_{i-1}, i = 2, \ldots, p$, and $\mathbf{T}$ is a lower triangular matrix with elements on and below the diagonal equal to 1. If $p = 5$, for example,

$$\mathbf{T} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 & 1 \end{bmatrix}.$$

Jöreskog [6] referred to the covariance structure of (12) as a Wiener simplex and to the covariance structure defined equivalently by (4) with (6) or (7) or by (10) as a Markov simplex. The Wiener simplex is more restrictive than the Markov simplex as it has p parameters, instead of $2p - 1$, and imposes a structure on variances. Unlike the Markov simplex, the Wiener simplex is scale dependent.

Maximum likelihood estimates in closed form of the φ_{ii} of the Wiener simplex are provided in Jöreskog [6, Section 3.2]. Since the Wiener simplex is both scale-dependent and order-dependent, it is applicable mainly in situations in which repeated measurements are taken over time on a number of subjects. An example is provided in Jöreskog [6, Section 4.8].

A data model that generates the Wiener simplex has been suggested by Guttman [5, p. 310]. If

$$X_i = \mu_i + \sum_{j=1}^{i} V_j,$$

where the V_j are mutually independently distributed with $\mathcal{E}(V_j) = 0$ and $\text{var}(V_j) = \varphi_{jj}$, then $\boldsymbol{\Sigma}_X$ is given by (12). Each V_j is interpreted as representing the increase in complexity between X_{j-1} and X_j.

An alternate parameterization of the Markov simplex may be obtained by applying a scaling transformation to the Wiener simplex to allow variances to be arbitrary [6]:

$$\boldsymbol{\Sigma}_X = \mathbf{D}_\gamma\mathbf{T}\mathbf{D}_\varphi\mathbf{T}'\mathbf{D}_\gamma, \tag{13}$$

where $\mathbf{D}_\gamma$ is a diagonal matrix with scaling factors, γ_i, as diagonal elements. A single identification condition is required; for example,

$$\varphi_{11} = 1.$$

The relationship between the complexity loadings, α_i, and incremental variances, φ_{jj}, is then given by

$$\alpha_i = \left(\frac{\sum_{j=1}^{i} \varphi_{jj}}{\sum_{j=1}^{p} \varphi_{jj}} \right)^{1/2}.$$

We thus have four alternate but equivalent parameterizations of the covariance structure of a perfect Markov simplex involving parameters with different interpretations. In (4) with (6), the complexity parameters, α_i, represent correlation coefficients with the last variable on the complexity scale; in (4) with (7), the parameters, t_i, are analogous to time points; in (10), the parameters, β_i, are regression weights on the preceding variable; and in (13) the parameters, φ_{ii}, represent incremental variances. Maximum likelihood estimates of the parameters of each of these parameterizations of the simplex applied to the data of Table 1 are shown in Table 2. Since the maximum likelihood estimates

[a]Parameter value fixed for identification purposes

reported are invariant under scale changes, analysis of a correlation matrix instead of a covariance matrix is in order.

Since the four parameterizations of the perfect simplex model are equivalent they yield the same **goodness of fit**, provided that the same ordering is employed in each. This is the case in the present example, since the order-free parameterizations of the model in (6) or (7) with (4) yield the same ordering of variables as Guttman's original ordering in Table 1, used for the parameterizations of (10) and (13). Fit of the perfect simplex to the data of Table 1 is not satisfactory. The largest absolute residual between a sample correlation coefficient and the corresponding correlation coefficient reproduced from the model is 0.27 and the value of the likelihood ratio goodness of fit test statistic is 202.6 with associated degrees of freedom equal to 10.

The Quasi-Simplex

The perfect simplex model is quite restrictive and seldom fits well in practice. Guttman [5] suggested several possible modifications that allow for error and referred to them as quasi-simplex models. One, Guttman's δ-simplex, has become generally accepted as the quasi-simplex.

Suppose now that the variates $X_1, \ldots, X_p$, that have a correlation matrix $\mathbf{P}$ satisfying the condition (1) for a perfect simplex, are unobservable and that, instead, variates $Y_1, \ldots, Y_p$ may be observed with

$$Y_i = X_i + E_i,$$

where the E_i are errors, distributed mutually independently and independently of the X_i with diagonal covariance matrix $\mathbf{D}_\theta$. It follows that the covariance matrix, $\mathbf{\Sigma}_Y$, of the observable variables, $Y_1, \ldots, Y_p$, is related to the covariance matrix, $\mathbf{\Sigma}_X$, of the simplex variables, $X_1, \ldots, X_p$, by

$$\mathbf{\Sigma}_Y = \mathbf{\Sigma}_X + \mathbf{D}_\theta, \tag{14}$$

where $\mathbf{\Sigma}_X$ is defined by any one of the four parameterizations for a perfect Markov simplex considered earlier, or by the perfect Wiener simplex (12).

The introduction of $\mathbf{D}_\theta$ is accompanied by additional indeterminacy in the model. In the case of the quasi-Wiener simplex, defined by (12) with (14), there is a single indeterminacy involving φ_{11} and θ_{11} [6, Section 4.2]. A suitable identification condition is $\varphi_{11} = \theta_{11}$. Two additional identification conditions are required when $\mathbf{D}_\theta$ is introduced in the quasi-Markov simplex: one involves the error variance, θ_{11} for the least complex variable and the other, the error variance, θ_{pp}, for the most complex variable [1; 6, Section 5.1]. Suitable identification conditions (IC) are as follows:

$$\text{IC1:} \quad \theta_{11} = \theta_{22}, \quad \theta_{pp} = \theta_{p-1,p-1} \tag{15a}$$

or

$$\text{IC2:} \quad \theta_{11} = 0, \quad \theta_{pp} = 0. \tag{15b}$$

The choice of identification conditions does not affect the values of $\theta_{22}, \ldots, \theta_{p-1,p-1}$, but does affect other parameters in the model that define the structure of the simplex correlation matrix $\mathbf{P}$ in (4). If variables are ordered according to complexity, the first row (column) and last row (column) of $\mathbf{P}$ are affected. This implies that hypotheses concerning relationships of the least complex simplex variable, X_1, and most complex simplex variable, X_p, to the other simplex variables are not testable.

Maximum likelihood estimates of parameters in the quasi-simplex model cannot be expressed in closed form and an iterative computational procedure is required. When the order-dependent parameterizations, (10), (13) and (12) of $\mathbf{\Sigma}_X$ are incorporated in (14), standard **structural equation modeling** computer programs may be employed (see e.g., [6, 7]). If the order-free formulations of (6) or (7) are employed, a computer program that allows a flexible specification of the model (see e.g., [3]) is necessary.

In Table 3 are shown maximum likelihood estimates of the error variances and complexity loadings when a quasi-Markov simplex, using (6), is fitted to the data of Table 1 under both identification conditions IC1 and IC2 in (15). It is apparent that the

	1	2	3	4	5	6
1	1	*0.79*	*0.74*	*0.53*	*0.47*	*0.38*
2	*0.70*	1	0.93	0.68	0.59	*0.48*
3	*0.65*	0.93	1	0.73	0.63	*0.52*
4	*0.47*	0.68	0.73	1	0.87	*0.71*
5	*0.41*	0.59	0.63	0.87	1	*0.82*
6	*0.30*	*0.43*	*0.46*	*0.63*	*0.72*	1

IC 1 above diagonal; IC 2 below diagonal

choice of identification conditions affects the estimates of complexity loadings. The transition between the two sets of complexity loadings is accomplished by multiplying $\hat{\alpha}_2, \ldots, \hat{\alpha}_5$ by the same constant and $\hat{\alpha}_1$ by a different constant. Consequently, simplex variable correlations that involve the first simplex variable or last simplex variable are dependent on the identification conditions employed. This is apparent in Table 4, in which simplex variate intercorrelation estimates under IC1 are shown above the main diagonal and those under IC2 below. Correlations affected by the identification conditions are shown in italics. While the choice of identification conditions is arbitrary in the sense that the fit of the model is not affected, it seems that IC1 are more plausible because of the closeness of $\hat{\theta}_{22}, \ldots, \hat{\theta}_{55}$ in Table 3.

The fit of the quasi-simplex model is reasonably satisfactory. The largest absolute residual is now 0.09 and the likelihood ratio test statistic is 43.81 with six degrees of freedom.

MICHAEL W. BROWNE

Simpson's Paradox

Simpson's paradox can be illustrated with an example, as Simpson did in his 1951 paper [8]. In that example, 40 patients are treated for a certain disease, whereas the control group consisted of 12 people. The results are given in the following $2 \times 2 \times 2$ **contingency table**, which shows the relationship between treatment and response (whether alive or dead) separately for males and females. Table 1 also shows the marginal table obtained by collapsing over the sex variable.

The odds ratios (*see* **Odds Ratio**) for the first two 2×2 tables (male/female) are both 5/6, which implies that the treatment is effective for both males and females. However, the odds ratio of the combined table is 1.0, which means the treatment is not effective. This phenomenon is called Simpson's paradox, which states that the direction of association between variables X (untreated/treated) and Y (alive/dead) may reverse after pooling over a covariate Z (male/female). The paradox can occur because pooling can lead to inappropriate weighting of the different subgroups [2].

Yule [11] first discovered this phenomenon, and it is also called the Yule–Simpson paradox. Numerous real-life examples of Simpson's paradox have been reported in many areas, including epidemiology, physics, social science, psychology, and sports. For example, Cohen et al. [3] compared tuberculosis deaths in New York City and Richmond, Virginia, in 1910. If the population was divided into racial groups, then Richmond had a lower death rate in both white and nonwhite categories, but the overall death rate was lower in New York.

In the context of contingency tables, Simpson's paradox is restricted neither to one association measure – the odds ratio, nor to $2 \times 2 \times 2$ tables. Let $[a_i, b_i; c_i, d_i]$, $i = 1, \ldots, K$, denote cell counts in a $2 \times 2 \times K$ table, and let $[a = \sum a_i, b = \sum b_i; c = \sum c_i, d = \sum d_i]$ be the corresponding marginal table. Let $\alpha(a_i, b_i; c_i, d_i)$ represent a measure of the association, such as the odds ratio $\alpha(a_i, b_i; c_i, d_i) = (a_i d_i)/(b_i c_i)$. *Simpson's paradox* occurs if $(a_i d_i)/(b_i c_i) > 1 (< 1)$ for all i, and $(ad)/(bc) \leq 1 (\geq 1)$. The paradox is also called *association reversal* by Samuels [7]. Good et al. [6] extended Simpson's paradox to an *amalgamation paradox*, which is defined as follows:

$$\alpha(a, b; c, d) > \max \alpha(a_i, b_i; c_i, d_i) \quad \text{or}$$

$$\alpha(a, b; c, d) < \min \alpha(a_i, b_i; c_i, d_i),$$

where the measure of association α can be the odds ratio or some other measure, such as the relative risk.

It is frequently helpful to collapse high-dimensional contingency tables, since the collapsed table has larger cell frequencies, fewer parameters, and is easier to interpret (*see* **Collapsibility**). It is then of interest to know when a table can be safely collapsed, avoiding the paradox. Let $X \perp Y$ and $X \perp Y|Z$ denote the independence and conditional independence of X and Y, respectively. Wermuth [9] showed that for a $2 \times 2 \times 2$ table we can meaningfully pool over a covariate Z and expect to find the same odds ratio in the marginal table and the partial tables (*strict collapsibility*) if and only if $X \perp Z|Y$ or $Y \perp Z|X$ (see also Bishop et al. [1]). Strict collapsibility implies that Simpson's paradox does not occur. A similar result was obtained for the relative risk [9]. Whittemore [10] showed that an $I \times J \times 2$ table is strictly collapsible if and only if at least one of the two-factor interactions of Z with X or Y in a loglinear model is zero. A table is called *strongly collapsible* (Ducharme et al. [5]) if it remains strictly collapsible no matter how it is partially collapsed (the definition was generalized to n-dimensional contingency tables by Whittemore). In this case, the odds ratio is totally independent of the level of the covariate. Ducharme et al. [5] provided a necessary and sufficient condition for a table to be strongly collapsible.

The paradox can also be avoided by a carefully designed experiment. For a $2 \times 2 \times K$ table, if the ratio of the sums of the two rows of each of the 2×2 partial tables remains constant, the design is called *row-uniform*. A *column-uniform* design can be similarly defined. If a design is both row-uniform and column-uniform, then the odds ratio of the combined table falls between the maximum and minimum of that of the individual tables [6], so the amalgamation paradox is avoided. Samuels [7] gave a necessary and sufficient condition to avoid association reversal, and also obtained a similar result in a regression setting.

When Simpson's paradox does occur in practice, what will the appropriate conclusion be? For example, if a disease is unrelated to a **genotype** for both whites and nonwhites but they are related when the two racial groups are combined, one is interested

Table 1 Survival by treatment among males and among females

	Male		Female		Combined	
	Untreated	Treated	Untreated	Treated	Untreated	Treated
Alive	4	8	2	12	6	20
Dead	3	5	3	15	6	20

in knowing whether the disease is related to the genotype. Suppose X takes value G (genotype A) or $\overline{G}$ (other than genotype A), Y takes value D (disease) or $\overline{D}$ (no disease), and Z is a covariate indexing race. If $X \perp Y|Z$ without $X \perp Y$, Simpson's paradox occurs. Dawid [4] defined Z as a sufficient set of covariates if $Y \perp I|(X, Z)$, where I contains the labels of individual units of the population. In the above example, race is a sufficient covariate if given a person's race and genotype; whether the disease occurs does not depend on an individual person. If Z is sufficient and $X \perp Y|Z$, then the disease is unrelated to the genotype even though they look related when the tables are collapsed over Z.

Simulation

To check his derivation of **Student's *t* distribution**, W.S. **Gossett** ("Student") conducted a simulation experiment:

> The material used was a ... table containing the height and left middle finger measurements of 3000 criminals ... The measurements were written out on 3000 pieces of cardboard, which were then very thoroughly shuffled and drawn at random ..., each consecutive set of 4 was taken as a sample ... and the mean [and] standard deviation of each sample determined ... This provides us with two sets of ... 750 [values] on which to test the theoretical results arrived at. The height and left middle finger ... table was chosen because the distribution of both was approximately normal ...

The pieces of cardboard of 1908 are redundant in the computer era. The result of Figure 1 is readily obtained by the MATLAB code of Figure 2 (*see* **Software, Biostatistical**). Computers have effectively made available easily obtained streams of **random variables** from any distribution. This has revolutionized the whole of statistics, and in particular **Bayesian methods**. Gossett's use of simulation to verify a theoretical result has now become standard practice. The fitting of nonlinear models to data, for example by **maximum likelihood**, usually requires numerical iteration procedures, carried out by computer (*see* **Optimization and Nonlinear Equations**). The correct operation of these procedures should be checked by first applying them to data simulated from the model, using known parameter values.

Classical numerical optimization employs deterministic search **algorithms**. Stochastic search methods, which allow random excursions over the surface to be optimized, can be achieved using simulated annealing techniques – see for example Brooks & Morgan [6] – which are less likely to be trapped in local optima. This is just one of the many ways in which simulation has greatly increased the tools available to statisticians. Note also for instance the use of genetic algorithms [34], the requirements of **randomization tests** and permutation tests [15, 28], the use of the **bootstrap** [11, 16, 21, 41], and **Markov chain Monte Carlo methods** (MCMC) [4, 37]. To demonstrate the wide-ranging influence of simulation on statistics, we outline later **Monte Carlo** inference and Monte Carlo testing. We start with a description of how computers produce the random number streams required.

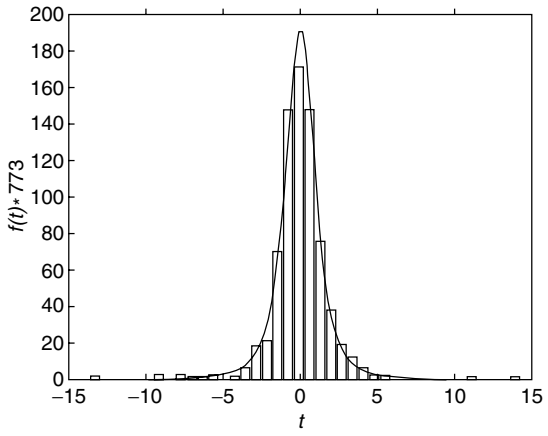

Figure 1 Histogram of 750 realizations of $2\overline{x}/s$, where $\overline{x}$ and s are respectively the mean and standard deviation of a sample of size 4 from a normal distribution of mean zero and variance unity. Also plotted is the underlying probability density function, of a t_3 random variable, given by

$$f(t) = \frac{2}{\pi\sqrt{3}(1 + t^2/3)^2}, \quad -\infty < t < \infty$$

Pseudo-Random Numbers

Computers generate streams of **pseudo-random numbers**, rather than strictly random ones, and they do this by means of recursion formulae. One which is frequently adopted is the congruential generator:

$$x_{n+1} = ax_n + b (\text{mod } m), \quad \text{for } n \geq 0. \qquad (1)$$

Here a, b and m are suitably chosen fixed integer constants, and the stream of numbers is initiated from a seed, x_0.

The integers resulting from (1) all lie in the range 0 to $(m-1)$, and approximations to random variables which are **uniformly distributed** over (0, 1) are obtained from setting $u_i = x_i/m$. Care is needed in how the fixed integers are chosen (see [33]). The MATLAB uniform random number generator, for example, uses $a = 7^5, b = 0$, and $m = 2^{31} - 1$. In particular, it is important to obtain a long sequence before x_0 reappears and the previous sequence cycles again and again. Cycling is not what we expect from random sequences. To put this in perspective, Wichmann & Hill [39] produced a generator that would take more than 800 years to cycle if 1000 of the numbers were used each second. The connection of the sequence of (1) with **chaos** is shown by Bartlett [2] and Lawrance [27]. However MCMC methods, for example, make intensive use of random variables, and it is advisable to exhibit a degree of caution when using pseudo-random numbers. A wide range of tests are available to check that pseudo-random numbers satisfy many necessary requirements of random variables. These range from graphical procedures (we can check Figure 1 by eye for obvious discrepancies between the histogram and the probability density function), through other empirical tests carried out on generated numbers, to theoretical tests such as the spectral test [17, 26] (*see* **Spectral Analysis**).

Alternative methods have been devised to improve on the performance of congruential generators. Generalized Feedback Shift Register (GFSR) methods provide examples that are widely used. These are described by Fishman [17], who also emphasizes that generators need to be easy to implement and portable, in that they produce the same results in different computing environments.

Generating Nonuniform Random Variables

The random variable $X = -\log_e U$, where U is uniformly distributed over the range 0–1, has an **exponential distribution**. If U_1 and U_2 are two independent such uniform random variables, then the pair of random variables given by

$$N_1 = (-2\log_e U_1)^{1/2}\cos(2\pi U_2),$$
$$N_2 = (-2\log_e U_1)^{1/2}\sin(2\pi U_2) \qquad (2),$$

are independent standard normal variables.

In simulations, such as that producing Figure 1, we need to be able to generate realizations of any random variables. The starting point is a stream of pseudo-random uniform random variables. Random variable simulation can be done using particular relationships, as in the Box–Müller [5] method of (2), or through one of a range of general procedures, such as the inversion method, the rejection method, and the composition method, all of which are described in [32]. For discrete random variables, the analog of the inversion method is the "table look-up" method. To take the inversion method as an illustration, if U is a U (0, 1) random variable and we wish to simulate a continuous random variable with cumulative distribution function $F(x)$, then it suffices to set

$$X = F^{-1}(U),$$

and this demonstrates immediately why $X = -\log_e U$ has an exponential distribution.

The use of trigonometric functions in (2) can be avoided by setting

$$N_1 = V_1\left(\frac{-2\log_e W}{W}\right)^{1/2},$$
$$N_2 = V_2\left(\frac{-2\log_e W}{W}\right)^{1/2}, \qquad (3)$$

subject to $W = V_1^2 + V_2^2 \leq 1$, where V_1 and V_2 are independent uniform random variables over the range -1 to 1. If $W > 1$ then the pair of values (V_1, V_2) is rejected and a new pair selected. Thus rejection occurs for a proportion $(1 - \pi/4)$ of the pairs, but results in the computational efficiency gain of using (3), rather than (2). We can see from (3) that the ratio V_1/V_2 has a **Cauchy distribution**. A general simulation method based on a ratio of uniformly distributed random variables has been proposed by Kinderman & Monahan [24]. It is well suited to adaptation to simulate from a probability density function which is specified only up to proportionality, and is therefore very useful in **Bayesian** computations (see [38]).

The general rejection method for any continuous random variable requires a uniform scatter of points over the area underneath the probability density function, $f(x)$, of the random variable. The abscissae of the points then provide realizations of the random variable. The required scatter is obtained by simulating from a density function $h(x)$, chosen both for

its similarity to $f(x)$, and relative ease of variate simulation. The density $f(x)$ is then enveloped by $g(x) = kh(x)$ for a suitable constant $k \geq 1$. The rejection probability is $(1 - k^{-1})$. Typically, selecting k involves solving an optimization problem. Examples are given by Morgan [32].

Random variables may be simulated in many different ways. It is important to use efficient methods, especially in cases of intensive use, as in MCMC work and **bootstrap** sampling. Detailed descriptions of alternative methods for many univariate and **multivariate distributions** are to be found in [10, 12, 17], and [35]. Efficiency can often be increased by the use of variance reduction methods such as importance sampling (*see* **Numerical Integration**), **stratification**, and using **antithetic** or control variates (see [32]).

Monte Carlo Inference

When a likelihood is difficult to construct, simulation techniques may be used to produce an approximation to the **likelihood**. As a simple illustration, suppose the random variable Y is given by the convolution:

$$Y = X_1 + X_2, \tag{4}$$

where X_1 has a **gamma distribution** and X_2 has an independent normal distribution. It is easy to simulate from both X_1 and X_2, and hence from Y, but it is generally not straightforward to write down the density function of Y, and hence the likelihood function. Many examples of this nature occur in statistics – for example in the theory of **queues** (see [20]).

Suppose we observe a **random sample** $\{y_i, 1 \leq i \leq n\}$, from a model with probability density function $f(y_i; \boldsymbol{\theta})$. To obtain the maximum likelihood estimates $\hat{\boldsymbol{\theta}}$, we need to form,

$$l(\boldsymbol{\theta}; y) = \sum_{i=1}^{n} \log f(y_i; \boldsymbol{\theta}),$$

and then maximize this with respect to θ.

In Monte Carlo inference we use

$$l^*(\boldsymbol{\theta}; y) = \sum_{i=1}^{n} \log \hat{f}(y_i; \boldsymbol{\theta}),$$

where simulation has been used to form the density estimate $\hat{f}$.

Diggle & Gratton [13] used a kernel approach (*see* **Density Estimation**), resulting in:

$$\hat{f}(y) = \frac{1}{(sh)} \sum_{k=1}^{s} K\left(\frac{y - x_k}{h}\right), \tag{5}$$

where $\{x_k, 1 \leq k \leq s\}$ is a simulated sample from $f(y; \boldsymbol{\theta})$, $K(u)$ is a kernel function, given by

$$K(u) = \begin{cases} 0.75(1 - u^2), & -1 \leq u \leq 1, \\ 0, & \text{otherwise}, \end{cases} \tag{6}$$

and h determines the smoothness of the approximation.

Diggle & Gratton [13] discuss the choice of s, h, and K. For other applications, see [9] and [19]. In the latter case, in the context of dependent data, MCMC methods are used.

Monte Carlo Testing

After a model has been fitted to a data set, multiple samples can be obtained by simulating from the fitted model, and the model may be fitted in turn to each of these samples. The resulting sets of parameter estimates may be used for inference. For example, **confidence intervals** may be obtained using the percentile method, which selects parameter cutoff points with a percentage, such as 5%, of simulated values lying outside the resulting interval. This general approach is called the parametric bootstrap, as replicate samples are obtained from a fitted model.

The **goodness of fit** of a model to data may be measured in a variety of ways – for example by means of a deviance (*see* **Generalized Linear Model**) or a Pearson chi-square statistic (*see* **Chi-square Tests**). Whatever goodness-of-fit statistic is selected, it may also be calculated for each of the samples simulated from the model fitted to the original data in the parametric bootstrap. In these cases we know that the model is correct, as we simulate from it. The values of the statistic from the simulated samples therefore provide a benchmark set against which to compare the value obtained from the original data. Due to Barnard [1], this approach is considered further by Hope [22] and Marriott [29], who discuss **power**. It may also be used to compare nonnested models, [7, 40] (*see* **Separate Families of Hypotheses**). Monte Carlo tests have been especially useful in spatial analysis (*see* **Epidemic Models, Spatial**).

An extension to dependent data is considered by Besag & Clifford [3]. Monte Carlo exact tests are derived by Forster et al. [18] using Gibbs sampling (*see* **Markov Chain Monte Carlo**).

Computing and Analysis

Computer simulation is widely utilized to mimic the rules of complex systems. The resulting simulation models may then be used to study the effect of changes to those systems. Usually sensitivity studies (*see* **Sensitivity Analysis**) also need to be carried out, in which predictions are investigated for perturbations of the parameter values adopted in the model. Two examples are provided by Duncan & Curnow [14] and Byrom & Gettinby [8]. Such models may be programmed in languages such as C, FORTRAN, and MATLAB. However the simulations regularly require standard bookkeeping operations, and specialized languages exist to simplify such tasks, such as GPSS, SIMSCRIPT, and SIMULA (see [30]). Simulated sequences need examination in order to decide whether they have reached equilibrium, and this is also a problem in MCMC work (see [23]). Analysis is frequently complicated by the presence of **serial correlation**. Moran [31] investigated the use of "batching", in which a sequence is divided into batches, and analysis then proceeds using batch means. Overviews are provided by Fishman [17] and Kleijnen & Groenendaal [25]. Simulation experiments allow statisticians to make use of their design skills (see, for example, [36]).

Simultaneous Confidence Intervals

The terminology *simultaneous confidence intervals* (SCI) refers to a **confidence** region for a multivariate parameter $\boldsymbol{\phi}$, comprised of individual confidence intervals for the components of $\boldsymbol{\phi}$. For example, in a medical application whose objective is to compare k treatment means with a control from $\mathrm{N}(\mu_i, \sigma^2)$, $1 \leq i \leq k$, and $\mathrm{N}(\mu_0, \sigma^2)$ populations respectively, $\boldsymbol{\theta}$ is given by $\boldsymbol{\theta} = (\mu_0, \mu_1, \ldots, \mu_k, \sigma)$, while $\phi_i = \mu_i - \mu_0$, $1 \leq i \leq k$. SCI provide an overall assurance at a specified confidence level of the simultaneous correctness of all the statements concerning the differences ϕ_i, $1 \leq i \leq k$. Typically, $\boldsymbol{\phi}$ has a finite number of components $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_k)$ but sometimes an infinite number as in a confidence band for a **regression** curve.

Denote by $\mathbf{x}$ the data collected in an experiment. A parametric model $P_{\boldsymbol{\theta}}$ is a family of distributions describing a random vector $\mathbf{X}$ which models the data collection process. For a fixed $0 < \alpha < 1$, a $(1-\alpha)100\%$ confidence region $D(\mathbf{X})$ for $\boldsymbol{\phi}$ is a random region satisfying

$$P_{\boldsymbol{\theta}}[D(\mathbf{X}) \ni \boldsymbol{\phi}] \geq 1 - \alpha, \tag{1}$$

no matter what the value of $\boldsymbol{\theta}$. Some authors use equality in (1). An SCI for $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_k)$ is a special case of (1) of the form

$$P_{\boldsymbol{\theta}}[l_i(\mathbf{X}) \leq \phi_i \leq u_i(\mathbf{X}), \text{ for all } 1 \leq i \leq k] \geq 1 - \alpha. \tag{2}$$

The left and right endpoints in (2) provide interval estimates for $\boldsymbol{\phi}$ endowed with the frequentist interpretation that in replicated experiments, in the long run, these intervals, constructed from the data, will cover every corresponding parameter simultaneously $(1-\alpha)100\%$ of the time.

The most universally valid (and "ancient" to quote Miller [5, p. 67]) approach relies on Boole's inequality (or the first **Bonferroni inequality**),

$$P\left(\bigcap_{i=1}^{k} A_i\right) = 1 - P\left(\bigcup_{i=1}^{k} \overline{A}_i\right) \geq 1 - \sum_{i=1}^{k} P(\overline{A}_i) \geq 1 - \alpha,$$

applied to a set of univariate $(1-\alpha/k)100\%$ confidence intervals

$$P_{\boldsymbol{\theta}}[l_i(\mathbf{X}) \leq \phi_i \leq u_i(\mathbf{X})] \geq \frac{1-\alpha}{k},$$

which yields (2) from the choice $A_i = \{l_i(\mathbf{X}) \leq \phi_i \leq u_i(\mathbf{X})\}$ and $\overline{A}_i$, the complement of A_i.

Perhaps the most widely studied SCI are those for **multiple comparisons** of treatment means for which there are three (among others) well-known competitors to the Boole–Bonferroni approach, each having their own advantages depending on the context. Scheffé's [6, 7] method as an SCI valid for all contrasts in an **analysis of variance** (ANOVA) was originally proposed as a follow-up to provide insight when the ***F*-test** rejects the null hypothesis (*see* **Multiple Comparisons**). Tukey's [8] approach, based on the **studentized range** distribution, was derived for comparing the special contrasts of pairwise treatment mean differences. Dunnett's [1] elegant method used the **multivariate *t* distribution** for the further special case of comparing treatments with a control, rather than all differences in means. The natural question of which method provides the shortest intervals has been studied, for instance, by Ury [9] and Einot & Gabriel [2] (*see also* **Multiple Comparisons**, for reference to Duncan's multiple range test).

As a numerical illustration, we present an example adapted from Dunnett [1] of blood count measurements on three groups of animals (see Table 1). The sample standard deviation is $s = 1.175$ and the corresponding multivariate t critical value with 12 df is 2.50. Based on Dunnett's method, the 95% SCI for $\mu_{\mathrm{A}} - \mu_{\mathrm{C}}$ and $\mu_{\mathrm{B}} - \mu_{\mathrm{C}}$ are $(-1.25, 2.55)$ and $(0.85, 4.41)$ respectively, while the Boole–Bonferroni intervals are $(-1.30, 2.60)$ and $(0.80, 4.46)$, which are

Table 1 Blood counts (millions of cells per cubic millimeter)

	Control	Drug A	Drug B
	7.40	9.76	12.80
	8.50	8.80	9.68
	7.20	7.68	12.16
	8.24	9.36	9.20
	9.84		10.55
	8.32		
Means	8.25	8.90	10.88

a little wider. Thus, with 95% confidence we may conclude that drug A raises the blood count by an amount between -1.25 and 2.55 million cells per cubic millimeter, while drug B raises the blood count by an amount between 0.85 and 4.41 million cells. For comparison, Scheffé's intervals, $(-1.47, 2.77)$ and (0.64, 4.62), are wider, but have higher confidence than 95% since we are dealing only with two contrasts, not all possible contrasts.

Applications of SCI have been developed in many other settings, including ANOVA, **multivariate analysis of variance** (MANOVA), **analysis of covariance, Hotelling's T^2** test, regression coefficients (*see* **Multiple Linear Regression**), growth curve analysis (*see* **Nonlinear Growth Curve**), and **variance components**. References may be found in the extensive bibliographies in the books by Miller [5], Hochberg & Tamhane [3], and Hoppe [4].

Simultaneous Inference

In a broad sense, *simultaneous inference* or *the multiplicity problem* includes statistical procedures that assess either more than one parameter in the course of an experiment or one parameter repeatedly in the course of an experiment. The problems studied include **multiple comparisons** (several parameters, one for each treatment group), multiple endpoints (several parameters for each treatment group), **sequential** methods or group sequential methods (one parameter assessed as the data accumulate during the experiment), and **longitudinal data analysis** (one parameter assessed at different time points). Recent work has focused on hypothesis testing problems in combination; for example, group sequential methods for multiple comparisons or multiple endpoints. Simultaneous inference includes point and interval estimation (*see* **Estimation**) as well as **hypothesis testing** and other methods of inference, such as ranking and selection. We give examples of hypothesis testing for multiple comparisons and multiple endpoints, simultaneous confidence intervals, as well as a more complex example involving group sequential hypothesis testing with multiple comparisons. For more detailed information we refer the reader to a number of related articles in this Encyclopedia: **Multiplicity in Clinical Trials; Multiple Comparisons; Multiple Endpoints, Multivariate Global Tests; Multiple Endpoints, *P* Level Procedures; Data and Safety Monitoring;** and **Longitudinal Data Analysis, Overview**.

Philosophies of Simultaneous Inference

When is it appropriate to consider several parameters simultaneously? In his classic book, Miller [12] considered a family to be those statements about parameters resulting from an individual experiment of a single researcher in a majority of instances. He went on to say: "There are no hard and fast rules for where family lines should be drawn, and the statistician must rely on his own judgment for the problem at hand." Hochberg & Tamhane [6] defined a family as any collection of inferences for which it is meaningful to take into account some combined measure of errors. This definition still leaves it to the judgment of the investigators which inferences should be taken as a family.

For a family F of inferences about a set of parameters, let $N(F)$ denote its cardinality and let P be the set of statistical procedures used to decide if each statement in F is true. In undertaking P, we want some protection against falsely rejecting statements in F when they are, indeed, true. Let M (a function of both F and P and the data) be the (random) number of false positives. The familywise (experimentwise) error rate is the probability of making at least one false positive conclusion, i.e. $P\{M > 0\}$. The per-family (per-experiment) error rate is the expected number of false inferences, i.e. $E\{M\}$. The per-comparison (comparisonwise, per-statement) error rate is the expected number of false inferences divided by the number of inferences, i.e. $E\{M\}/N(F)$. [The per-comparison error rate cannot be defined in many cases when $N(F)$ is infinite.] Using elementary probability, it is clear that

$$\frac{E\{M\}}{N(F)} \leq P\{M > 0\} \leq E\{M\},$$

so that control over the per-family error rate is stronger than control over the familywise error rate, which is, in turn, stronger than control over the per-comparison error rate. The three error rates depend on the true configuration of the parameters.

In hypothesis testing, the family of inferences, F, is taken to be the set of statements included in the **null hypothesis**. Procedures that control the familywise error rate for F and all subsets of F are said to provide *strong control*. Procedures that control the familywise error rate for F alone are said to provide *weak control*.

The difference between weak and strong control of the familywise error rate may be illustrated by one-way **analysis of variance** (ANOVA) with $A(> 3)$ groups. Suppose the first $A - 1$ means are equal and the Ath mean is far different. Then a procedure that provides weak control of the familywise error would protect against the rejection of the global hypothesis that all of the means are equal, but would provide no protection against false rejection of the equality of the first $A - 1$ means. Strong protection would protect against both.

While many authors argue that control over the familywise error rate is appropriate [6, 12, 23], others support controlling the per-family error rate for

finite families [18] or even the per-comparison error rate [2, 13, 17]. The relative value of each type of error rate control will depend on what the investigators are trying to accomplish. By way of illustration, suppose four experimenters could have collected exactly the same data in a one-way ANOVA but be interested in different error rates because they are pursuing different goals. The first investigator might have several prespecified hypotheses in mind involving pairwise comparisons and may want to address each one individually. This investigator might be primarily interested in controlling the per-comparison error rate and test each comparison at level α. The second investigator might be searching for effective drugs in a pilot development program (e.g. a **Phase II trial**). In this case a significant initial F test (*see* **Analysis of Variance**) might lead to a larger **clinical trial**, whereas a nonsignificant F test and a significant result on a single drug using a per-comparison error rate might lead to another pilot study on that drug, and no significant per-comparison tests would lead to a negative conclusion. In this situation the investigator is interested in *both* the familywise and per-comparison error rates. The third investigator might test the global hypothesis of the equality of all of the means (controlling the familywise error rate), but having done that, perform pairwise treatment comparisons controlling the per-comparison error rate. The fourth investigator might be performing a definitive trial comparing several treatments and consider it important to control the type I error rate on both the entire family of null hypotheses and on every subset of that family.

The first and second investigators above required per-comparison control of the type I error rate, although with differing families of inferences. The third investigator required weak control of the familywise error and the fourth required strong control of the familywise error rate. Thus, depending on the situation at hand, different degrees of type I error rate control will be considered appropriate. When seeking new drug approval, a manufacturer may conduct a trial of several doses vs. a placebo and argue that the per-comparison error rate with a placebo is of interest, but those with the power to approve the new drug may well disagree.

Prior to data analysis, careful specification of the medical question(s) that the analysis is intended to answer will help investigators focus on what their family of inferences should be and what kind of error control is appropriate in a given situation. Hypotheses that are data driven (i.e. that are tested without prior specification) require tentative conclusions which need further, definitive test no matter what ***P* value** results. Tukey [24] says, "these give us *hints*".

Examples of Simultaneous Inference

Henceforth we assume that investigators have agreed that certain inferences constitute a family. Many procedures have been proposed for various simultaneous inference situations. Here we give three examples and outline several procedures which might be used.

Example 1. Simultaneous Confidence Intervals for all Treatment Versus a Control

Suppose we have a clinical trial with A treatment arms. Let $X_{ij}, i = 1, \ldots, A, j = 1, \ldots, M$ be the jth observation of the ith treatment arm. Assume X_{ij} has mean μ_i and unknown variance σ^2. Suppose that μ_1 is a control treatment and we are interested in simultaneous, two-sided $100(1-\alpha)\%$ confidence intervals for

$$\mu_j - \mu_1, \quad j = 2, 3, \ldots, A. \tag{1}$$

F is a set of $N(F) = A - 1$ confidence intervals of the pairwise comparisons with μ_1. If we assume that the underlying data have a normal distribution, then we may use the procedure of Dunnett [3]. The **simultaneous** two-sided $100(1-\alpha)\%$ confidence intervals for treatment minus control differences, $\mu_j - \mu_1$, are given by

$$(\mu_j - \mu_1) \in \left[\overline{Y}_j - \overline{Y}_1 \pm |T|^{(\alpha)}_{A-1,\nu,1/2} S \left(\frac{2}{M} \right)^{1/2} \right], \quad j = 2, 3, \ldots, A, \tag{2}$$

where S^2 is the mean squared error estimate and $|T|^{(\alpha)}_{A-1,\nu,1/2}$ is the upper α point of the maximum of the absolute value of an A-variate **multivariate *t* distribution** with $\nu = A(M-1)$ **degrees of freedom** and **correlation** coefficients 1/2. The critical values of $|T^{(\alpha)}|_{A-1,\nu,1/2}$ are tabulated, c.f. [[6],

Table 5]. When the sample sizes are not equal, the correlations between the $\overline{Y}_j - \overline{Y}_1$ are no longer 1/2 so that calculations of the critical values are difficult and approximations must be used. The joint confidence intervals have the property that when many experiments are undertaken, in $100(1-\alpha)\%$ of them, *all* of the confidence intervals will contain the true parameters.

Example 2. Hypothesis Testing for all Pairwise Comparisons

A classic example of simultaneous statistical inference considers the A-sample multiple comparisons problem. Suppose we have a clinical trial with A treatment arms. Let $X_{ij}, i = 1, \ldots, A, j = 1, \ldots, M$, be the jth observation of the ith treatment arm. Assume X_{ij} has mean μ_i and unknown variance σ^2. Suppose we are interested in testing

$$\mathrm{H}_0 : \mu_i = \mu_j, \quad i \neq j, i, j = 1, 2, \ldots, A, \quad (3)$$

vs.

$$\mathrm{H}_1 : \mu_i \neq \mu_j, \quad \text{for some } i \neq j, \quad i, j = 1, 2, \ldots, A.$$

Then F is a set of $N(F) = A(A-1)/2$ statements of inferences on all of the pairwise comparisons.

If we assume that the underlying data have a normal distribution, then we may first perform a one-way ANOVA F test to test (3). If $A = 3$, then strong control and weak control coincide, so assume $A > 3$. If the F test rejects H_0 at level α, we may follow with pairwise t tests each at level α, using the pooled estimate of σ^2, a procedure known as Fisher's Least Significant Difference (LSD) for weak control of the familywise error rate [4].

If we wished strong control of the familywise error rate, then we would have to enlarge the family F and consider all statements of equality of means of all subsets in the null hypothesis. That is, we would need to consider the null hypothesis

$$\mathrm{H}_0 : \mu_1 = \cdots = \mu_A \quad (3')$$

and all alternatives, beginning with $A-1$ means equal and one mean different, $A-2$ means equal and the other two means equal but different from the first $A-2$ means, $A-2$ means equal and the other two means each different, etc. We could then use the closed F procedure or the closed Newman–Keuls procedure of Begun & Gabriel [1]. In these procedures, if the hypothesis $(3')$ is not rejected at level α, then we stop and say there are no treatment differences at level α. If $(3')$ is rejected, then we consider all subsets of the null hypothesis in $(3')$ in a particular stepdown manner. If there is no significant difference at level α when testing the null hypothesis of equality of $p(= A-1, A-2, \ldots, 3, 2)$ of the means, then we say the p treatments are homogeneous and do not test further subsets of these. Strong control of α is obtained by simultaneously testing, in addition, disjoint subsets of the null hypothesis in a particular manner. For example, if $A = 4$, then the simultaneous test of $\{\mu_1 = \mu_2$ and $\mu_3 = \mu_4\}$ is undertaken by testing each pair of hypotheses at level $1-(1-\alpha)^{1/2}$. If one of the hypotheses in the intersection set is not rejected at level $1-(1-\alpha)^{1/2}$, then *neither* is rejected. This implies that in determining whether there are pairwise differences based on this procedure, the homogeneity of certain means depends on the homogeneity of other means. In the case $A = 4$, if we do not find a difference between μ_1 and μ_2 at level $1-(1-\alpha)^{1/2}$, then we would also not find μ_3 and μ_4 to differ. While this initially seems strange, it is the price that this procedure pays for strong control of α within the family of hypotheses. For A arms, the tests on the disjoint subsets are performed at level $1-(1-\alpha)^{p/A}$, where p is the number of hypotheses undergoing test.

Example 3. Hypothesis Testing for Multiple Endpoints in a Clinical Trial

Suppose we have a two-armed clinical trial comparing the efficacy of an experimental and a standard treatment and efficacy is reflected by multiple patient characteristics. A statistical formulation of this problem is

$$\mathrm{H}_0 : \boldsymbol{\mu}_\mathrm{E} = \boldsymbol{\mu}_\mathrm{S} \quad (4)$$

vs.

$$\mathrm{H}_1 : \boldsymbol{\mu}_\mathrm{E} - \boldsymbol{\mu}_\mathrm{S} = \boldsymbol{\delta}(> \mathbf{0}),$$

where $\boldsymbol{\mu}_\mathrm{E}$ is the mean of the vector-valued observations of the experimental group, $\boldsymbol{\mu}_\mathrm{S}$ is the mean of the vector-valued observations of the standard treatment, and $\boldsymbol{\delta}$ is a fixed vector of relative treatment differences. The formulation of H_1 is specific to clinical

trials, for which we are interested in the **alternative hypothesis** that one treatment is better than the other with respect to k multiple endpoints. F is a set of statements about the equality of the components of the vectors $\boldsymbol{\mu}_i$ and has cardinality $N(F) = k$.

The rationale for the formulation of H_0 in (4) is that we will control the type I error when there is no difference between the experimental and standard treatments. The formulation of H_1 serves to direct power to an alternative of particular interest, where all endpoints derive a meaningful benefit, a situation in which high power would be desired. In this context, testing efficacy with multiple endpoints need not be viewed as a simultaneous inference problem; the test statistic may be viewed as a univariate measure of efficacy. (For further discussion, see [15].) However, a family of hypotheses becomes of interest when we attempt to identify the individual endpoints that benefit from treatment.

If we assume that the underlying data have a normal distribution, we may test (4) using one of the linear combination test statistics proposed by O'Brien [14] and Tang et al. [20]. Following rejection of the global null hypothesis (4), we may make inferences on the individual endpoints by considering the family F. Lehmacher et al. [10] proposed a stepdown procedure which maintains strong control of α. Following rejection of the global null hypothesis (4), proceed by testing all subsets of size $A - 1$ endpoints, with each test performed at the α level using the same procedure P as used on the A endpoints. If a subset of $A - 1$ endpoints does not differ (at the α level), then conclude that the treatments do not differ with respect to each of those $A - 1$ endpoints. If, however, the test on $A - 1$ endpoints is significant at level α, continue with all subsets of $A - 2$ endpoints. Once a set of endpoints does not differ, no further tests are done on those endpoints and this avoids contradictions. The procedure is continued until it is determined whether the treatments differ with respect to each endpoint. An alternative approach, conferring only weak protection of α, is to follow a significant global test by tests only on the individual endpoints, each conducted at the same α level as used for the global test.

It is worth noting that obtaining strong control in the multiple endpoint problem in clinical trials (Example 3) is easier than obtaining it in the multiple comparisons problem (Example 2) because there is no need to simultaneously test disjoint sets of subset hypotheses in the multiple endpoint case.

An alternative approach which does not require the normality assumption, is the rank sum statistic proposed by O'Brien [14] and the stepdown procedures are analogous. The rank procedure does not consider the correlation between endpoints. This may or may not be desirable, but it should be noted that weighting endpoints according to the correlation structure produces a different measure of overall efficacy.

Other procedures for multiple endpoints have been proposed by Westfall & Young [25], Lefkopoulou & Ryan [9], and Tang et al. [21]. O'Brien & Geller [15] discuss the importance of the specific question being asked when choosing a procedure.

An Example of a More Complex Multiplicity Problem

Recent developments in simultaneous inference entail theoretical results combining classical multiple comparison problems, multiple endpoints, or longitudinal data analysis along with group sequential monitoring (cf. [8, 11, 19], and [22]). We give one conceptual example.

The following trial design was initially proposed for a Raynaud's treatment study. Raynaud's disease is characterized by episodes or "attacks" in cold weather of decreases in blood flow through the veins in the extremities, resulting in extreme cold and pain (and possible loss of function) in the fingers. Patients would be randomized to receive a pharmacologic agent (a long-acting calcium channel blocker), a thermal biofeedback treatment, or a placebo pill. The primary outcome would be change from baseline in the number of Raynaud's episodes per day. Baseline incidence would be assessed over a month period in winter and outcome incidence would be assessed over the same month, a year later. The trial would be undertaken on two cohorts of patients during two successive winters and would be monitored for efficacy at the end of the first season so that if there were a strong treatment effect, early stopping could be considered (*see* **Data and Safety Monitoring**).

The major question of the trial may be formulated in several ways; depending on the formulation, an appropriate statistical procedure could be applied. The global null hypothesis of no difference in the treatment effects overall could be tested using a

group sequential F test [7, 16]. The question of whether either of the active treatments differs from the placebo requires group sequential monitoring of treatments vs. a control. The question of whether any of the pairwise treatment comparisons differ requires group sequential methods for all pairwise comparisons (cf. [5]). The relevant error rate to be controlled would need to be specified in the study protocol.

Simple Random Sampling

The following definition of *simple random sampling* implies that a sample of n enumeration units is selected from a population of N enumeration units *without replacement* (*see* **Sampling With and Without Replacement**).

A simple random sample of n enumeration units from a population of N enumeration units is one in which each of the $\binom{N}{n}$ possible samples has the same probability of selection; namely, $1/\binom{N}{n}$ (cf. [1]).

For example, if a particular population consists of 15 households and we wish to take a simple random sample of 10 households, then there are $\binom{15}{10} = 15!/(10!5!) = 3003$ possible samples, with each having a probability of being selected of $1/3003 = 0.000333$. The above definition is much more restrictive than the term **random sampling**, which can have many different meanings depending on the specific context in which it is being used.

In simple random sampling, no prior knowledge concerning characteristics of the enumeration units other than their labels or identification numbers is used in selecting the sample. Thus, other sampling designs such as **stratified sampling** which do make use of such knowledge generally yield estimates that have lower sampling variability than those obtained from a simple random sample of the same number of enumeration units. Likewise, sampling designs such as **cluster sampling** and **multistage sampling** can be accomplished at lower field costs than simple random sampling. Thus, sample surveys, especially those involving sampling of human populations over large geographic areas, are rarely based on simple random sampling.

Table 1

Population characteristic	Estimate	Standard error of estimate
Mean	$\overline{x} = \dfrac{\sum_{i=1}^{n} x_i}{n}$	$\mathrm{se}(\overline{x}) = \dfrac{\sigma_x}{\sqrt{n}}\left(\dfrac{N-n}{N-1}\right)^{1/2}$
Total	$x' = N\overline{x}$	$\mathrm{se}(x') = \dfrac{N\sigma_x}{\sqrt{n}}\left(\dfrac{N-n}{N-1}\right)^{1/2}$

Estimates of population totals and **means** are shown in Table 1 along with their **standard errors**. These are appropriate for simple random sampling when the **unit of analysis** is the enumeration unit. In Table 1, the term σ_x is the **standard deviation** of the distribution of the variable x in the population. Also, the term $[(N-n)/(N-1)]^{1/2}$ is known as the **finite population correction** and is close to unity when n is considerably smaller than N.

SIR Epidemic Models

SIR epidemic models describe the spread of infectious diseases that follow the scheme Susceptible $\rightarrow$ Infected $\rightarrow$ Removed. This scheme means that a susceptible, if ever "adequately" contacted by an infective, becomes infected for some period of time (the infectious period) after which it recovers and is immune to the disease (other removal states are possible after adjustment).

Our review is only concerned with the stochastic approach, which is more realistic, but also more complex, than the deterministic approach (*see* **Epidemic Models, Stochastic**; **Epidemic Models, Deterministic**). Standard and recent treatises on the subject are [1, 3, 11, 12, 16, 31] (see also [32]). For deterministic models, the reader is referred to [2, 18].

The central situation is when the population is closed (there is neither birth/death nor immigration/emigration), homogeneous (all S, I, or R individuals have similar behaviors), and independently mixing (meetings between any pair of individuals occur independently of each other). In the course of time, the population state is represented by the random vector giving the numbers S_t of susceptibles, I_t of infectives, and Z_t of removed cases present at time $t \geq 0$. Initially, $S_0 = n$, $I_0 = m$, $Z_0 = 0$ say, and the population being closed, $S_t + I_t + Z_t = n + m$ for all t (thus, any two of these variables specify the epidemic process). The epidemic ceases as soon as there are no more infectives in the population, which arises with probability one after a finite time T. Then, S_T is the ultimate number of susceptibles escaping the disease, and $Z_T = n + m - S_T$ (the final size) is the total number of infected cases, including the m initial ones. The statistics S_T is of great interest in theory and practice, and it has received by far the most attention in the literature. Moreover, it is generally very difficult to evaluate the epidemic process in transient condition.

To begin with, we will examine SIR models that are built with a Markovian structure (*see* **Markov Chains**). In their majority, the proposed models constitute variants or extensions of two well-known epidemic models, named the Reed–Frost epidemic (*see* **Chain Binomial Model**) and the general epidemic. A Markovian modeling has the advantage to make possible a study of the temporal evolution of the epidemic process. A severe drawback, however, is the associated assumption that the infectious periods are **exponentially distributed**, which is unrealistic for many diseases.

Next, we will turn to SIR models, no longer necessarily Markovian, that precisely allow an arbitrary distribution for the infectious periods. The basic model, named the generalized epidemic, is the direct corresponding extension of the general epidemic. It is a particular case of the so-called collective epidemic in which infectives contact susceptibles by sampling of random size. Studying the temporal behavior of these models is quite complex (or even irrelevant), and the main purpose is to analyze the ultimate epidemic state.

Finally, we will discuss multitype versions of these models that allow us to incorporate heterogeneities in susceptibility, infectivity, and/or mixing behaviors. Such factors play an important role in the mechanism of spread of infection and for the evaluation of control policies (*see* **Epidemic Models, Control**).

The list of references is very partial (by necessity). Additional references can be found in the treatises mentioned above (and in [21] for a review of work prior to 1990).

Markovian Epidemic Models

The Reed-Frost Epidemic

The model assumes that the periods of time between the receipt of infection and the onset of infectiousness (the latent periods) are of fixed length and the subsequent infectious periods are contracted to a single point. Each infective is able to contact any given susceptible with the probability $p = 1 - q$, all these events being independent. A discrete timescale $t = 0, 1, 2, \ldots$ is then used, which corresponds to the successive generations of infections (separated by the latent periods). In other words, if at time t there are $I_t = i$ infectives, any of the $S_t = s$ susceptibles will remain susceptible at $t + 1$ with the probability q^i. Thus, the epidemic process $\{(S_t, I_t), t = 0, 1, \ldots\}$ is a Markov chain and the transition law is of **binomial** form:

$$P(S_{t+1} = s - j, I_{t+1} = j \mid S_t = s, I_t = i) = \binom{s}{j} q^{i(s-j)}(1 - q^i)^j, \quad j = 0, \ldots, s. \quad (1)$$

This chain-binomial mechanism is very convenient for computations with small populations. For

example, with initially two susceptibles and two infectives, four different paths lead to the end of infection: $(2,2) \to (2,0)$ with probability q^4, $(2,2) \to (1,1) \to (1,0)$ with probability $2q^3(1-q^2)$, $(2,2) \to (1,1) \to (0,1) \to (0,0)$ with probability $2q^2(1-q^2)p$, and $(2,2) \to (0,2) \to (0,0)$ with probability $(1-q^2)^2$. In particular, the distribution of S_T is given by $P(S_T = 2) = q^4$, $P(S_T = 1) = 2q^3(1-q^2)$ and the remainder for $P(S_T = 0)$; the law of T also follows.

Enumerating all the transient paths becomes cumbersome with larger populations. The distribution of S_T, however, can be determined recursively. Putting $x_{[k]} = x(x-1)\dots(x-k+1)$ for any naturals x, k, we have the n relations:

$$\mathrm{E}\{S_{T,[k]}q^{kS_T}\} = n_{[k]}q^{k(n+m)}, \quad k = 1, \dots, n. \tag{2}$$

This constitutes a system of n linear equations in the n unknown probabilities $P(S_T = s)$, $s = 1, \dots, n$. It is solved recursively for $k = n, \dots, 1$; then $P(S_T = 0)$ follows [23]. Somewhat surprisingly, the relation (2) can be extended to a variety of SIR models (see below).

The General Epidemic

The model neglects the effects of latency and assumes that the infectious periods are independent and exponentially distributed with parameter μ. When infected, an individual makes contacts with any given susceptible at the time points of a **Poisson process** with rate β, all these events being independent. Thus, the epidemic process $\{(S_t, I_t), t \geq 0\}$ is a Markov process and the infinitesimal transition probabilities are

$$\begin{aligned} &P(S_{t+\mathrm{d}t} = s-1, I_{t+\mathrm{d}t} = i+1 \mid S_t = s, I_t = i) \\ &\qquad = \beta s i \,\mathrm{d}t + o(\mathrm{d}t), \end{aligned} \tag{3}$$

$$\begin{aligned} &P(S_{t+\mathrm{d}t} = s, I_{t+\mathrm{d}t} = i-1 \mid S_t = s, I_t = i) \\ &\qquad = \mu i \,\mathrm{d}t + o(\mathrm{d}t). \end{aligned} \tag{4}$$

The state probabilities $p_{s,i}(t) = P(S_t = s, I_t = i)$ satisfy the forward Kolmogorov differential equations (*see* **Stochastic Processes**):

$$\begin{aligned} \frac{\mathrm{d}p_{s,i}(t)}{\mathrm{d}t} &= \beta(s+1)(i-1)p_{s+1,i-1}(t) \\ &\quad + \mu(i+1)p_{s,i+1}(t) - (\beta s + \mu)i p_{s,i}(t), \end{aligned} \tag{5}$$

for $s = 0, \dots, n$ and $i = 0, \dots, n+m-s$, and with $p_{s,i}(t) = 0$ outside this range; initially, $p_{n,m}(0) = 1$. A Laplace transform solution is given in [19], and a simpler method by recursion is developed in [14, 41]. In [38], the algebraic structure of the solution is exhibited, which allows us to highlight and improve the recursive technique.

For the end of the epidemic, the distribution of S_T is provided by a system of n linear equations similar to (2):

$$\mathrm{E}\{S_{T,[k]}q_k^{S_T}\} = n_{[k]}q_k^{n+m}, \quad k = 1, \dots, n, \tag{6}$$

where $q_k = \mu/(\mu + \beta k)$ (in place of q^k).

Varying Susceptibilities

The hypothesis of a common infection rate for all pairs of susceptible and infective is a simplification. To account for differences between susceptibles, the general epidemic is extended by splitting up the susceptible class into h homogeneous groups, labelled $l = 1, \dots, h$, with initial sizes n_l. The infectives form a single class and act independently as before. Within the susceptible group l, $l = 1, \dots, h$, each susceptible can be contacted by any given infective at the rate β_l; let $\beta^S = (\beta_1, \dots, \beta_1, \dots, \beta_h, \dots, \beta_h)$ be the row vector of the susceptibility rates for the $n = n_1 + \cdots + n_h$ susceptibles.

It seems to be intuitive that more heterogeneous susceptibilities decrease the damage caused to the whole susceptible class. Indeed, this can be established using the concepts of majorization (denoted by $\prec$) between real vectors of n elements with equal sum [29] and of usual stochastic order (denoted by $\leq_{st}$) between random variables [42]. Consider an identical epidemic model but built with another vector β'^S of susceptibility rates; let S'_t be the associated total number of susceptibles at time t. Then, it can be proved [5, 22] that $\beta^S \prec \beta'^S$ (a more diverse vector of susceptibilities) implies $n - S_t \geq_{st} n - S'_t$ (a smaller total infection), for all t and at the end of the epidemic. In particular, the worst situation arises when the susceptibles form a homogeneous group with rate $\overline{\beta}^S = (n_1\beta_1 + \cdots + n_h\beta_h)/n$.

Some Other Epidemics

Various adaptations or generalizations of the previous SIR models have been proposed to account for specificities in the spread of certain infectious diseases. We present two of them in continuous-time.

With *fatal epidemics*, the removal of an infective is inevitably by death. So, at time t, the surviving population being of size $S_t + I_t$, the contact rate per pair of susceptible and infective is no longer constant but equal to $\beta/(S_t + I_t)$. This means that the infection probability (3) is modified as

$$P(S_{t+\mathrm{d}t} = s - 1, I_{t+\mathrm{d}t} = i + 1 \mid S_t = s, I_t = i) = \frac{\beta si}{s + i}\,\mathrm{d}t + o(\mathrm{d}t). \tag{7}$$

Transient and final behaviors of the epidemic are investigated in [9, 37]. In particular, a system of n linear equations still exists for the distribution of S_T:

$$\mathrm{E}\left\{ S_{T,[k]} \prod_{j=1}^{S_T - k} q_{k,j} \right\} = n_{[k]} \prod_{j=1}^{n+m-k} q_{k,j}, \quad k = 1, \ldots, n, \tag{8}$$

where $q_{k,j} = \mu(k + j)/[\mu(k + j) + \beta k]$.

With *carrier epidemics*, infectives are immediately detected and removed, and the disease is propagated by carriers that do not display any symptom. If contacted, a susceptible either becomes a carrier with probability π, or is recognized as an infective, thus removed, with probability $1 - \pi$. Denoting the number of carriers at t by I_t, the infection probability (3) is replaced by

$$P(S_{t+\mathrm{d}t} = s - 1, I_{t+\mathrm{d}t} = i + 1 \mid S_t = s, I_t = i) = \beta\pi si\,\mathrm{d}t + o(\mathrm{d}t), \tag{9}$$

$$P(S_{t+\mathrm{d}t} = s - 1, I_{t+\mathrm{d}t} = i \mid S_t = s, I_t = i) = \beta(1 - \pi)si\,\mathrm{d}t + o(\mathrm{d}t). \tag{10}$$

The model with $\pi = 1$ is equivalent to the general epidemic; $\pi = 0$ is a separate case, simpler because there is no transition from susceptible to carrier. An analysis of the epidemic is carried out in [35, 36]. For the distribution of S_T, the system (6) is changed as:

$$\mathrm{E}\{S_{T,[k]} q_k'^{\,S_T}\} = n_{[k]} q_k'^{\,n} q_k^m, \quad k = 1, \ldots, n. \tag{11}$$

where $q_k = \mu/(\mu + \beta k)$ (as before), and $q_k' = \pi q_k + 1 - \pi$.

Notice that in general, many Markovian epidemics can be viewed as **compartmental models** of *right-shift* type in which the population is subdivided into a finite number of cells (here S, I, R) and transitions are shiftings of one unit from a cell to some other to its right [20, 38].

We also mention that demographic forces can generate recurrent epidemic outbreaks for diseases that confer immunity. A general epidemic model accounting for *demography*, examined in [34], assumes that new susceptibles arrive at a constant rate θn and all individuals die at a rate θ (thus, the population size will fluctuate around n). The study is concerned with the time to extinction as a measure of the persistence of infection; it relies on the concept of quasi-stationary distribution (*see* **Stationarity**).

Collective Epidemic Model

A Common Structure

As shown in [28] and subsequent works, the Markovian approach can be relaxed to some extent when only the final states S_T or Z_T are under investigation. A flexible model in this context is the collective epidemic presented in [25, 36] (its appellation underlines the focus on the final outcome).

The model assumes that the infectives act independently and their infectious periods are independent and identically distributed with an arbitrary distribution. The fates of the susceptibles in front of the risk of infection are similar and interdependent (probabilistically interchangeable). Specifically, each infective fails to contact anyone in any given set of k susceptibles, $k = 1, \ldots, n$, with a probability q_k which is a function of the set size k (and not of the set itself).

These q_k's are the parameters of the model. They can be expressed under the form

$$q_k = \mathrm{E}\left[\binom{n-k}{R} \Big/ \binom{n}{R} \right], \quad k = 1, \ldots, n, \tag{12}$$

for some random variable R valued in $\{0, \ldots, n\}$. An interpretation for (12) is that any infective, j say, contacts susceptibles by drawing a sample of random size R_j without replacement among the n initial susceptibles; all the random variables R_j are independent and distributed as R (see also [30] for this formulation).

A standard special model is the *generalized epidemic*. It assumes, as in the general epidemic, that infectious contacts are ruled by independent Poisson

processes with rate β (i.e. (3) is kept). The novelty is that the infectious periods D_j are independent but with any fixed distribution, that of a random variable D say. Thus, for this model, $q_k = \mathrm{E}[\exp(-\beta k D)]$. In particular, for the general epidemic, D is exponentially distributed with parameter μ, yielding $q_k = \mu/(\mu + \beta k)$ as indicated in (6).

The Reed–Frost epidemic too is a collective model with $q_k = q^k$. This is not true for the fatal epidemic (since the infection rate depends on the surviving population size). The carrier epidemic is an extension of the collective model with two possible types of infection: the carriers, who are removed after a period distributed as D, and the detected infectives, who are directly removed; thus, for the initial carriers, the probabilities of nontransmission are $q_k = \mathrm{E}[\exp(-\beta k D)] = \mu/(\mu + \beta k)$, while for each new infection, the probabilities of nontransmission are $q_k' = \mathrm{E}[\pi \exp(-\beta k D) + 1 - \pi] = \pi q_k + 1 - \pi$.

The Final State

Different representations of this model can be built, which allow the study of its final state S_T. So, let us label the infectives according to their order of removal in the epidemic, and denote by $\hat{S}_j$, $j = 1, 2, \ldots$, the number of susceptibles that escape contact with the first j infectives; put $\hat{S}_0 = n$. It is easily seen that the process $\{\hat{S}_j, j = 0, 1, \ldots\}$ is a Markov chain that has the same final state as the collective epidemic. One can then show that the exact distribution of S_T is provided by the system (6) with q_k defined as above [25, 36].

When considering large populations, however, there is a need for approximation methods. Let $n \to \infty$, and write $R = R_n$ depending on n; for clarity, m is fixed here. Roughly, three different asymptotic behaviors can arise.

(a) A minor infection (S_T is near n). Suppose that $R_n \to R^*$ in distribution with $\mathrm{E}(R^*) \leq 1$. Then, the final size Z_T **convergence in distribution** to Y_∞, where $P(Y_\infty < \infty) = 1$ and Y_∞ is the total progeny in a **branching process** having m ancestors and with all offspring sizes independent and distributed as R^*. The **generating function** of Y_∞ is given by $[\phi(z)]^m$, where $\phi(z)$ satisfies the equation $\phi(z) = f[z\phi(z)]$, $f(z)$ being the generating function of R^*.

(b) A possible major infection (with S_T around a positive fraction of n). Suppose that $R_n \to R^*$ in distribution with $\mathrm{E}(R^*) > 1$. Then, Z_T still converges to Y_∞ but now $P(Y_\infty < \infty) = \rho^m < 1$ where ρ^m is the extinction probability of the branching process (ρ is the unique root in $(0, 1)$ of the equation $\rho = f(\rho)$). With probability $1 - \rho^m$, a true epidemic occurs that infects infinitely many susceptibles, that is, $S_T/n \to \sigma < 1$ in probability (σ is the unique root in $(0, 1)$ of the equation $\sigma = \exp[-\mathrm{E}(R^*)(1 - \sigma)]$); moreover, $\sqrt{n}(S_T - n\sigma)$ has a normal limit distribution with mean 0 and variance $\sigma(1 - \sigma)\{1 + [\mathrm{var}(R^*) - \mathrm{E}(R^*)]\sigma\}/[1 - \mathrm{E}(R^*)\sigma]^2$.

(c) A drastic infection (S_T is bounded). Suppose that $R_n \to \infty$ in probability. Then, convergence in distribution of S_T to a law nondegenerate in 0 can occur under some conditions on the asymptotic behavior of R_n, and the limit distribution is necessarily a **Poisson** law with random mean. It reduces to a Poisson law with fixed mean b if and only if $n[1 - \mathrm{E}(R_n)/n]^n \to b$ and $\mathrm{var}(R_n)/n \to 0$.

The qualitative difference between the behaviors (a) and (b) depicts a threshold phenomenon (*see* **Epidemic Thresholds**) in which the threshold parameter is $\mathrm{E}(R^*)$ and the critical value is equal to 1. The parameter $\mathrm{E}(R^*)$ is named the basic **reproduction number**; it is usually denoted by R_0 and is interpreted as the expected number of infectious contacts which one infective would make in a large completely susceptible population [17]. Considerable work has been devoted to these questions [4, 8, 27, 30, 39, 44]. The behavior (c) is peculiar to highly infectious diseases; it is studied in [6, 24, 26].

As a special case, let us examine the generalized epidemic, where $\beta = \beta_n$ is function of n (D being fixed). Here, R_n in (12) has a binomial law with n trials and random success probability $1 - \exp(-\beta_n D)$. For (a) and (b), a standard situation is when $\beta_n = \beta/n$ (each infective meets, on the average, a limited number of susceptibles); then, R^* has a Poisson law with random mean βD, with $R_0 \equiv \mathrm{E}(R^*) = \beta \mathrm{E}(D)$. For (c), convergence can occur under some conditions on the tail distribution of D and for a sequence β_n that necessarily satisfies $n\{1 - \mathrm{E}[\exp(-\beta_n D)]\} - ln(n/b_n) \to 0$ with $b_n \to b$; then, the limit distribution is either a Poisson law with fixed parameter b or a Poisson law with a random mean based on an asymmetric **Cauchy** stable law.

We point out that the alternative situation where $m_n \to \infty$ as $n \to \infty$ can also lead to different asymptotic regimes. Results are given in [26, 27, 30]; an extensive analysis for the generalized epidemic is carried out in [43].

Varying Infectivities

It is intuitively clear that a lower infectivity power decreases the total damage caused by the epidemic. To make this precise, we use the concept of s-increasing convex order between nonnegative random variables (denoted by $\leq_s$ in the arithmetic case and by $\leq_{s*}$ in the continuous case). When $s = 1$, it corresponds to the usual stochastic order and when $s = 2$, to the classical increasing convex order [25, 42]. Consider a new collective model with parameters q'_k given by (12) with some random variable R' substituted for R; let $S'_{T'}$ be the associated final susceptible size. Then, it can be proved [25] that $n - R \leq_s n - R'$ (a smaller number of contacts per infective) implies $S_T \leq_s S'_{T'}$ (a larger final susceptible state).

For the generalized epidemic, we get that $\exp(-\beta D) \leq_{s*} \exp(-\beta D')$ (a shorter infectious period) yields $S_T \leq_s S'_{T'}$ (a better protection for the susceptibles). This result is of practical interest when the law of D is not known except a few moments. For instance, suppose that $E(D) = d_1$ and $\mathrm{var}(D) = d_2$ are given. One shows that $\exp(-\beta D'') \leq_{2*} \exp(-\beta D) \leq_{3*} \exp(-\beta D')$ where D'' is a random variable degenerate in d_1, while D' is a two-points random variable of values $(d_1^2 + d_2)/d_1$ with probability $d_1^2/(d_1^2 + d_2)$ and 0 otherwise. Thus, bounds for S_T are $S''_{T''} \leq_2 S_T \leq_3 S'_{T'}$. Note that replacing D by its mean d_1 leads to underestimate, in the increasing convex sense, the ultimate number of susceptibles.

Multitype Epidemic Models

Individual Heterogeneities

Variability in individual susceptibilities and/or infectivities is a first kind of potential heterogeneity. This factor is easily incorporated in the previous models. For that, we subdivide the whole population into h homogeneous groups of individuals, labeled $l = 1, \ldots, h$, with initially n_l susceptibles and m_l infectives. Going back to Markovian epidemics, let us consider the *general multitype epidemic*. In group l, each infective is removed at the rate μ_l, and while infected, it contacts any given susceptible within group l' at the rate $\beta_{l,l'}$. In particular, the case called *proportionate mixing* is when $\beta_{l,l'}$ is of product form $\beta_l \gamma_{l'}$. The *collective multitype epidemic* is constructed in a similar way. In group l, each infective fails to transmit infection within any given set of k_1 susceptibles in group $1, \ldots, k_h$ susceptibles in group h, with a probability $q^{(l)}_{k_1,\ldots,k_h}$, where $k_1 = 0, \ldots, n_1, \ldots, k_h = 0, \ldots, n_h$ with $k_1 + \cdots + k_h \geq 1$. In particular, for the *generalized multitype epidemic*, then $q^{(l)}_{k_1,\ldots,k_h} = \mathrm{E}[\exp(-\beta_{l,1}k_1 + \cdots + \beta_{l,h}k_h)D^{(l)}]$ where $D^{(l)}$ is the length of an infectious period in group l.

The study of these multitype models is, roughly, similar to the homogeneous case. Let us concentrate on the ultimate numbers of susceptibles $S_T^{(l)}$, $l = 1, \ldots, h$, that escape the disease in the different groups. For their exact joint distribution, we have the relations:

$$\mathrm{E}\left\{\prod_{l=1}^{h} S^{(l)}_{T,[k_l]}[q^{(l)}_{k_1,\ldots,k_h}]^{S_T^{(l)}}\right\} = \prod_{l=1}^{h} n_{l,[k_l]}[q^{(l)}_{k_1,\ldots,k_h}]^{n_l+m_l}, \tag{13}$$

where $k_1 = 0, \ldots, n_1, \ldots, k_h = 0, \ldots, n_h$ with $k_1 + \cdots + k_h \geq 1$. This is a system of $(n_1 + 1)\ldots(n_h + 1) - 1$ linear equations in the final state probabilities $P[S_T^{(1)} = s_1, \ldots, S_T^{(h)} = s_h]$, for $s_1 = 0, \ldots, n_1, \ldots, s_h = 0, \ldots, n_h$, with $s_1 + \cdots + s_h \geq 1$; $P[S_T^{(1)} = \cdots = S_T^{(h)} = 0]$ follows [36].

Large population limits still hold true. So, putting $n = n_1 + \cdots + n_h$, consider the generalized epidemic where the contact rates are of normalized form $\beta_{l,l'}/n$ and each group size is large with $n_l/n \to \nu_l > 0$; $D^{(l)}$ is fixed, and m_l too say. Then, the final sizes vector $(Z_T^{(1)}, \ldots, Z_T^{(h)})$ converges in distribution to the total progeny vector $(Y_\infty^{(1)}, \ldots, Y_\infty^{(h)})$ in a multitype branching process having $(m_1, \ldots, m_l)$ ancestors, with independent lifetimes distributed as $(D^{(1)}, \ldots, D^{(h)})$ and **matrix** of birth rates $\{\beta_{l,l'}\nu_{l'}\}$, $1 \leq l, l' \leq h$. Thus, there exists a threshold parameter (basic reproduction number) R_0 which is the largest **eigenvalue** of the matrix of mean offspring $\{\mathrm{E}(D^{(l)})\beta_{l,l'}\nu_{l'}\}$, $1 \leq l, l' \leq h$. If $R_0 \leq 1$, the total progeny of the branching is finite with probability one: the epidemic is minor. If $R_0 > 1$, the total progeny can explode with a strictly positive probability; on this part, the epidemic is major and the final sizes vector has asymptotically a **multivariate normal distribution** [7]; see also [40].

Structural Heterogeneities

Nonuniform mixing caused by the social or geographical structure of the population is another kind of

potential heterogeneity. A simple case with two levels of mixing, local and global, is motivated by *epidemics among households* in which the infection power of an infective is much higher within its own household than outside. Extending in this sense the above generalized epidemic, one obtains again a threshold behavior for the asymptotic situation in which the number of households tends to infinity [10]. Such a model is useful especially when evaluating potential strategies for the control of disease transmission [13] (*see* **Epidemic Models, Control**).

In *spatial epidemics*, individuals are located in different sites, and infectives contact others according to a given spatial distribution (*see* **Epidemic Models, Spatial**). Important aspects are the threshold phenomenon and the velocity of the spread of the disease. Results can be obtained for some spatial extensions of the generalized epidemic [15, 33].

CLAUDE LEFÈVRE

Skewness

A statistical distribution which is not symmetric about some point is said to be skew. The extent of skewness may be measured in a variety of ways. For example, the mean, median, and mode generally do not coincide for a skew distribution, and so their relationships may be used to quantify skewness. Two candidates are:

$$\text{skew}_1 = \frac{\text{mean} - \text{mode}}{\text{standard deviation}},$$
$$\text{skew}_2 = \frac{\text{mean} - \text{median}}{\text{standard deviation}}.$$

Both were considered by Pearson [6], who noted the empirical fact that for many distributions, $\text{skew}_1 \approx 3\text{skew}_2$ (Pearson's law of skewness). Pearson gave an explanation in terms of his family of type III distributions (*see* **Gamma Distribution**). The definition skew_1 is unattractive in the case of multimodal distributions, and since the main motivation for skew_2 is via Pearson's law, which also fails in multimodal cases, neither skew_1 nor skew_2 has general application (*see* **Unimodality**).

Today, skewness is usually defined in terms of the third cumulant of a distribution (*see* **Characteristic Function**), rather than through relationships among its mean, median, and mode. Nevertheless, the two approaches are linked; see, for example, Haldane [1] and Hall [2], who provided an explanation for Pearson's law in terms of the third cumulant and the **central limit theorem**.

Given a random variable X with mean $\mu = \text{E}(X)$, let σ^2 denote its variance, let $\mu_3 = \text{E}(X - \mu)^3$ be its third cumulant, and define

$$\beta_1 = \frac{\mu_3^2}{\sigma^6}, \qquad \text{skew}_3 = \sqrt{\beta_1} = \frac{\mu_3}{\sigma_3}.$$

The latter is sometimes referred to simply as "the skewness of the distribution of X". Its multivariate analog, for a d-vector X, is the set of all $\frac{1}{6}d(d^2 + 3d + 2)$ third **moments** of components of $\mathbf{Y} = \Sigma^{-1/2}\mathbf{X}$, where $\mathbf{\Sigma}$ denotes the **covariance matrix** of $\mathbf{X}$. (There are d terms of the form $\text{E}(Y^{(i)^3})$, $d(d-1)$ terms like $\text{E}(Y^{(i)}Y^{(j)^2})$, and $\frac{1}{6}d(d-1)(d-2)$ terms like $\text{E}(Y^{(i)}Y^{(j)}Y^{(k)})$.)

If the distribution of X has been standardized for location and scale (i.e. $\mu = 0$ and $\sigma = 1$), then the first terms in Edgeworth and Gram–Charlier expansions of the distribution or density function of X are proportional to $\sqrt{\beta_1}$; see, for example, [3, pp. 28, 30]. This indicates the central role which $\sqrt{\beta_1}$ plays in determining properties of "regular" distributions, relative to other measures of skewness.

Van Zwet [7] proposed a partial ordering of distributions in terms of skewness, and suggested defining a distribution with distribution function F to be *skewed to the right* if $F^{-1}\{1 - F(x)\}$ is convex in x. Oja [5] noted that some skewness measures (e.g. skew_3) preserve van Zwet's ordering, while others (e.g. skew_1) do not.

Descriptions of skewness in terms of moments are not always well defined. More robust definitions include that attributed to F. Galton, whose statistical work stressed the importance of quartiles (*see* **Quantiles**):

$$\text{skew}_4 = \frac{\text{lower quartile} + \text{upper quartile} - 2 \times \text{median}}{\text{upper quartile} - \text{lower quartile}}.$$

Each of $\text{skew}_1, \ldots, \text{skew}_4$ is estimable, although the difficulty of estimating the mode makes skew_1 unattractive for data analysis. The sample skewness, for data $X_1, \ldots, X_n$, is often defined as

$$\sqrt{b_1} = \frac{n^{-1}\sum_{i=1}^{n}(X_i - \overline{X})^3}{\left\{n^{-1}\sum_{i=1}^{n}(X_i - \overline{X})^2\right\}^{3/2}},$$

and is an estimate of $\sqrt{\beta_1}$. In normal samples, $\sqrt{b_1}$ is approximately normally distributed with zero mean and variance $6/n$. More extensive properties of its moments are addressed in [4, pp. 316–318].

PETER HALL

Slope–Ratio Assay

Slope-ratio bioassays are analytic dilution assays (*see* **Biological Assay, Overview**) that arise mainly from microbiologic applications. The subject is usually an inoculum of specified amount of a bacterial culture. The response is typically either a measure of the bacterial growth during a fixed time interval or the amount of a base (alkali) needed to neutralize the acid that is formed during growth of the bacteria following application of fixed doses (d_i) of test and standard preparations.

The statistical model relating fixed doses of the standard and test preparations to the response leads to straight lines that intersect at zero dose. Generally, the expected response of the standard is assumed to be linear in some known power of dose. The regression line for the standard is then

$$\mathrm{E}[y_\mathrm{S}|d_\mathrm{S}] = \alpha + \beta_\mathrm{S} x,$$

where $x = d_\mathrm{S}^\lambda$ is the dose metameter. In practice, setting the power parameter (λ) equal to one often provides an adequate approximation [2]. The dosage of the test preparation (d_T) that provides an equivalent response to a specified dose of the standard is $d_\mathrm{S} = \rho d_\mathrm{T}$, where ρ designates the relative potency. The regression line for the test preparation is thus

$$\begin{aligned}\mathrm{E}(y_\mathrm{T}|d_\mathrm{T}) &= \mathrm{E}[y_\mathrm{S}|\rho d_\mathrm{T}] = \alpha + \beta_\mathrm{S}(\rho d_\mathrm{T})^\lambda \\ &= \alpha + \beta_\mathrm{S}\rho^\lambda d_\mathrm{T}^\lambda.\end{aligned}$$

When λ equals one and $x = d_\mathrm{T}$, then $\beta_\mathrm{T} = \beta_\mathrm{S}\rho$ (Figure 1).

The fundamental assumption for validity (condition of similarity) in a slope-ratio assay implies that the standard and test preparations intersect at zero dose. Therefore, the relationship can alternatively be expressed as a multiple regression equation, such that

$$\mathrm{E}(y) = \alpha + \beta_\mathrm{S} x_\mathrm{S} + \beta_\mathrm{T} x_\mathrm{T}.$$

The solution for the relative potency is the ratio of the two slopes from the multiple regression:

$$\rho = \left(\frac{\beta_\mathrm{T}}{\beta_\mathrm{S}}\right)^{1/\lambda}.$$

When $\lambda = 1$, the relative potency is

$$\rho = \frac{\beta_\mathrm{T}}{\beta_\mathrm{S}}.$$

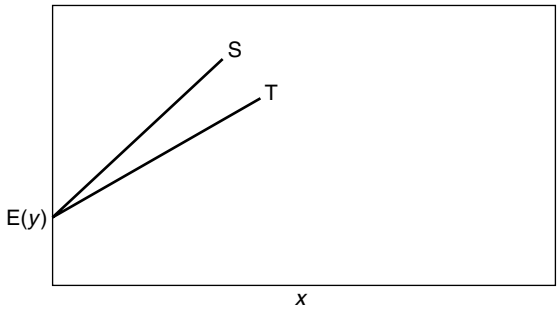

Figure 1 Expected response (E(y)) vs. dose metameter (x) for standard (S) and test (T) preparations in a slope-ratio assay

Relative Potency Estimation and Validity Tests

Estimates of the slopes for the standard and test preparations are readily calculated using conventional **multiple linear regression** techniques. To evaluate fully the model's assumptions, measurements of the response at zero dose (blanks) need to be incorporated in the experiment. For computational purposes, it is convenient to regard the doses as N triplets $\{x_0, x_\mathrm{S}, x_\mathrm{T}\}$ with associated response y, where $N = N_0 + N_\mathrm{S} + N_\mathrm{T}$ (total observations across blanks, standard, and test preparations). Here, dose levels are coded as "0" in the triplet for other than the preparation specified; in other records, (1, 0, 0) corresponds to blanks, $\{0, x_\mathrm{S}, 0\}$ to standard, and $\{0, 0, x_\mathrm{T}\}$ to test doses, respectively. A comprehensive analysis, including estimation of the relative potency, and validity tests entails computation of three regression analyses: (i) estimation of three regression coefficients ($\hat{\beta}_{03}, \hat{\beta}_{\mathrm{S}3}, \hat{\beta}_{\mathrm{T}3}$) simultaneously using all N observations; where $\hat{\beta}_{03}$ estimates the response at zero dose; (ii) estimation of two regression coefficients $\hat{\beta}_{\mathrm{S}2}$ and $\hat{\beta}_{\mathrm{T}2}$, simultaneously for the N observations including the blanks; and (iii) estimation of $\hat{\beta}_{\mathrm{S}1}$ and $\hat{\beta}_{\mathrm{T}1}$ as separate lines based, respectively, on the N_S and N_T observations of the standard and test preparations. Generally, the slopes from (ii) are utilized to estimate relative potency; that is,

$$\hat{\rho} = \frac{\hat{\beta}_\mathrm{T}}{\hat{\beta}_\mathrm{S}} = \frac{\hat{\beta}_{\mathrm{T}2}}{\hat{\beta}_{\mathrm{S}2}},$$

assuming that $\lambda = 1$. However, when validity tests indicate a significant F test for blanks (see below)

in the absence of other forms of invalidity, suggesting curvature at very low doses, it may be advisable to use $\hat{\beta}_{T3}$ and $\hat{\beta}_{S3}$ from (i) as well as their corresponding variance terms for calculating **confidence intervals** (see below).

Before proceeding to calculate the confidence intervals for ρ, verification that there is no serious evidence of invalidity of the assumptions of the design model is important. The general form of the **analysis of variance** formulas needed for slope ratio assay validation is shown in Table 1. Calculated F tests are conventionally compared to tabulated values of the ***F* distribution**, $F_{(df_1,df_2)}$, at a 5% significance level. The specific hypotheses of interest and the corresponding variance ratio statistics are as follows:

1. $H_1 : \alpha = \alpha_S = \alpha_T$; reject if
$$F = \frac{MS_I}{MS_E} > F_{(1,N-K_S-K_T-1)}.$$
Failure to reject indicates that the fundamental assumption of validity (the condition of similarity) is not seriously violated. It is analogous to the test for parallelism in a parallel-line assay.
2. $H_2 : \alpha =$ average response for blanks; reject if
$$F = \frac{MS_B}{MS_E} > F_{(1,N-K_S-K_T-1)}.$$
Rejection of this test suggests the presence of curvature at very low doses.
3. $H_3 : \beta_S = \beta_T = 0$; reject if
$$F = \frac{MS_R}{MS_E} > F_{(2,N-K_S-K_T-1)}.$$
A valid assay will have a highly significant test for regression.
4. H_4 : test of deviation of lines from linearity; reject if
$$F = \frac{MS_{NL}}{MS_E} > F_{(K_S+K_T-4,N-K_S-K_T-1)}.$$
Rejection indicates invalidity of the statistical assumption of linearity. If H_4 is rejected, there is a need to consider alternative approaches.

When no evidence of invalidity is present, confidence intervals for
$$\hat{\rho} = \frac{\hat{\beta}_T}{\hat{\beta}_S}$$
are calculated through direct application of **Fieller's theorem** for a ratio estimator [1]. In the slope-ratio assay, the $(1-\alpha) \times 100\%$ confidence intervals are

$$\hat{\rho}_L, \hat{\rho}_U = \left[\hat{\rho} - \frac{g\nu_{12}}{\nu_{11}} \pm \frac{t\hat{\sigma}}{\hat{\beta}_S}\left\{\nu_{22} - 2\hat{\rho}\nu_{12} + \hat{\rho}^2_{\nu_{22}} - g(\nu_{22} - \nu_{12}/\nu_{11})^{1/2}\right\}\right] \Big/ 1 - g,$$

where

$$g = \frac{t^2\hat{\sigma}^2\nu_{11}}{\hat{\beta}_S^2}, \qquad \hat{\sigma} = (MS_E)^{1/2}$$

and $t_{(1-\alpha/2)}$ is based on $N - K_S - K_T - 1$ df.

The terms ν_{11}, ν_{12}, and ν_{22} are the coefficients in the variance–**covariance matrix** from which the slopes are estimated. In practice, g is often small in slope-ratio assays and thus has little effect on the computations.

For more detailed presentation of the design and analysis of slope-ratio assays, Chapters 7 and 8 in Finney's text [2] and Chapter 3 in Hubert [3] are useful references.

Additional Remarks

The formulas presented above are general in form and do not depend on having a symmetrical, balanced design for the assay or equal spacing between doses. While a symmetric design with equal numbers of subjects at each dose level, including the blanks, is preferable on the basis of efficiency considerations, modern computing tools obviate the need for the simplified formulas that accompany such designs. At least three dose levels of the test and standard preparations and inclusion of blanks are needed to test validity assumptions fully. Such a design would usually be referred to as a $(3K + 1)$ design.

The methodology can easily be extended to accommodate designs in which multiple test preparations are simultaneously compared to the same standard. For designs with more than one test preparation, consideration of optimal allocation among preparations given a total number of subjects is relevant. If N_0 is prespecified, then optimal allocation of the remaining

Nonlinearity	$K_\mathrm{S} + K_\mathrm{T} - 4$	$\mathrm{SS}_\mathrm{NL} = \sum_{\mathrm{S,T}} \left[\sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (y_{pij} - \overline{y}_p)^2 \right] - \sum_{\mathrm{S,T}} \left(\frac{S^2_{x_p y_p}}{S_{x_p x_p}} \right)$	$\mathrm{MS}_\mathrm{NL} = \mathrm{SS}_\mathrm{NL}/(K_\mathrm{S} + K_\mathrm{T} - 4)$	$\mathrm{MS}_\mathrm{NL}/\mathrm{MS}_\mathrm{E}$
Within doses (error)	$N - K_\mathrm{S} - K_\mathrm{T} - 1$	$\mathrm{SS}_\mathrm{E} = \mathrm{SS}_y - \mathrm{SS}_\mathrm{D}$	$\mathrm{MS}_\mathrm{E} = \mathrm{SS}_\mathrm{E}/(N - K_\mathrm{S} - K_\mathrm{T} - 1) = \hat{\sigma}^2$	

Notation (adapted from [2]):

n_{pi} = number observations at dose i of preparation p,
y_{pij} = response of subject j to dose i of preparation p,
x_{pij} = dose metameter for subject j to dose i of preparation p,

where

$i = 1, 2, \ldots, K_p$, $p = 0$ (blanks), S (standard), or T (test)

and

$$K_p = \text{number dose levels of preparation } p,$$

$$N_p = \sum_{i=1}^{K_p} n_{pi}, \qquad N = \sum_{\mathrm{O,S,T}} N_p,$$

$$S_{y_p y_p} = \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (y_{pij} - \overline{y}_p)^2;$$

where

$$\overline{y}_p = \left(\sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} y_{pij} \right) \Big/ N_p,$$

$$S_{x_p x_p} = \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (x_{pij} - \overline{x}_p)^2,$$

where

$$\overline{x}_p = \left(\sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} x_{pij} \right) \Big/ N_p,$$

$$S_{x_p y_p} = \sum_{i=1}^{K_p} \sum_{j=1}^{n_{pi}} (x_{pij} - \overline{x}_p)(y_{pij} - \overline{y}_p).$$

$N_S + N_T$ subjects among r test preparations and the standard would be

$$N_S = r^{1/2} N_T,$$

assuming that the variance of $\hat{\rho}$ is approximately proportional to $1/N_S + 1/N_T$.

Relative potency estimation also assumes both homoscedasticity and normality for the distribution of the random errors in y at each dose level. Whenever sufficient data are available, appropriate tests should be conducted to assess whether these assumptions are violated. As noted in **Biological Assay, Overview** the statistical properties are suspect for the small to moderate sample sizes that characterize most bioassays. Finney [2] demonstrates that the analyses described above may provide very similar estimates of the relative potency and its confidence intervals even when the normality assumption is not fulfilled, but other model assumptions are not seriously violated. The choice of an appropriate response metameter should rely not primarily on the statistical evidence within a single assay, but should reflect information derived from evaluation of validity across a related class of independent assays.

CAROL K. REDMOND

Slutzky–Yule Effect

The practice of smoothing a **time series** by forming a **moving average** of some kind is common, and is, provided there is no seasonality (*see* **Seasonal Time Series**), a very useful tool; if there is (or may be) seasonality, it remains useful, but the span and other details need more careful attention.

It is, however, not without some drawbacks, first discovered, independently, by Slutzky [2] and Yule [3].

As a very simple example, suppose that $\{X_t\}$ is a time series of completely independent observations, with a common distribution, *white noise* (*see* **Noise and White Noise**), and that $\{Y_t\}$ is the result of applying a moving average of order 3,

$$Y_t = \frac{(X_{t-1} + X_t + X_{t+1})}{3}. \tag{1}$$

Then $\{Y_t\}$ consists of correlated observations, even though $\{X_t\}$ was made up of uncorrelated observations: it is easily calculated that the autocorrelation (*see* **Autocorrelation Function**) of $\{Y_t\}$ is 2/3 at lag 1, 1/3 at lag 2, and 0 at greater lags. In other words, the process of averaging, and thereby smoothing, has introduced correlation. (This is not surprising: a series will appear smooth(er) if values nearby in time are close(r) together, which is another way of saying that they are (more) correlated.)

The same is true if $\{X_t\}$ is operated on by *any* linear filter (*see* **ARMA and ARIMA Models**): if

$$Y_t = \sum_{i=-c}^{d} g_i X_{t-i}, \tag{2}$$

say, then again $\{Y_t\}$ consists of correlated observations, even though $\{X_t\}$ was made up of uncorrelated observations.

A different perspective may be had by considering the spectral approach (*see* **Spectral Analysis**). The spectral density of $\{X_t\}$, as white noise, is constant for all frequencies. The spectral density of $\{Y_t\}$ is then given by the product of this constant and the transfer function of the linear filter (*see* **ARMA and ARIMA Models**); unless the filter is the trivial one which corresponds to multiplication by a constant the transfer function will not be constant as a function of frequency, hence neither will the spectral density of $\{Y_t\}$ be, and consequently $\{Y_t\}$ will have nonvanishing autocorrelations. In the special case of the moving average above, the spectral density of $\{Y_t\}$ will be proportional to $(1 + 2\cos\omega)^2$ at circular frequency ω.

In fact this effect can have rather more serious consequences than might appear at first sight. Suppose that the transfer function of the filter takes its maximum (modulus) at a single nonzero frequency ω_0, and suppose the filter is applied several (many) times in succession: the resulting combined filter will strongly emphasize ω_0 relative to the rest – in other words $\{Y_t\}$ will show some approximately periodic behavior; this is the essence of the Sinusoidal Limit Theorem. The above moving average cannot directly produce this effect, but suppose the moving average is used to estimate the trend, which is then subtracted from the original series to produce a "detrended" series for further analysis: the resulting filter is of the form

$$Y_t = \frac{(2X_t - X_{t-1} - X_{t+1})}{3},$$

whose transfer function is proportional to $(1 - \cos\omega)$, with a maximum at $\omega = \pi$, or equivalently at frequency (in the usual sense) 1/2 and period 2.

Thus we can produce some oscillatory behavior in a completely nonperiodic series by operating on it with a linear filter. Slutzky and Yule noted that the analysis of data (or even its collection, if in the collection process we necessarily subject it to a linear filter) can, for this reason, produce periodicities which have no real basis and thus some of those actually observed could be artifacts caused by data processing or collection.

The effect in practice, with filters that are likely to be used, will be less immediately striking – for example, the oscillations will not be regular, either in period or in amplitude – but the overall impression may nevertheless suggest the presence of an oscillatory component in the process, and a statistical analysis is then quite likely to confirm its existence. Kendall & Stuart [1] give some results about, and illustrations of, the average distance apart of peaks and of upcrossings of the axis, showing the effect of applying filters. The oscillations observed in real economic time series, and very likely in those arising in other fields of application, do have an appearance similar to those which can be generated in this way.

The detailed discussion has assumed that $\{X_t\}$ is white noise, but clearly the argument applies for any $\{X_t\}$.

R.M. LOYNES

Small Area Estimation

Federally sponsored sample surveys have been designed to meet the needs of government agencies, legislative bodies, and health professionals for the comprehensive national estimates needed in the formulation and analysis of national policy initiatives directed to social, economic, or health related issues. These national data collection efforts are generally limited, however, in their capacity to produce reliable estimates (*see* **Estimation**) at the subnational or small area level. While **unbiased** direct estimates can often be derived at the **census** region or census division level for most nationally based survey efforts, sample size requirements and budget constraints preclude the capacity for the derivation of state level estimates and for geographic areas at the sub-state level such as counties. In spite of these budgetary constraints, a strong demand persists for accurate and reliable estimates of sociodemographic, economic, and health parameters at the subnational level.

Small area estimation can be defined as the application of model-based or indirect estimators, using data from surveys primarily designed to produce estimates of criterion measures at the national or regional level, to derive comparable estimates at more geographically disaggregated levels such as counties or other small areas. These techniques are typically characterized by prediction models or indirect estimators that make use of available survey data at the national or regional level, data on population characteristics at the state or local level, and available auxiliary (predictor) data at the local level that are related to the criterion measure of interest [21, 22, 26]. A survey design with sufficient sample size in every state or local area for which separate estimates are desired would permit the derivation of unbiased direct estimates of core survey measures with acceptable levels of precision to satisfy underlying analytic objectives. Budget and logistical considerations, however, make sample sizes too small to support estimates of criterion variables at the subnational level in most federally sponsored surveys. This has resulted in the development of indirect small area estimators. Such estimators use auxiliary survey data and population information that characterize the state or small area, together with national survey data, to develop a model-based small area estimate. The level of accuracy and reliability achieved by these small area estimation strategies is completely dependent on the degree to which underlying model assumptions are satisfied. The type of predictor information available, the functional relationship of the predictor information to the specified criterion variables, and the assumptions underlying each prediction model narrow the number of procedures that are appropriate for a particular application.

As a consequence of empirical tests of validity and widespread usage, a set of small area estimation strategies has gained respectability under certain qualifying assumptions. This article provides a review of these alternative small area estimation techniques that have been developed and are currently being implemented. Attention is given to the underlying assumptions and data requirements to operationalize the respective estimation strategies. Furthermore, examples of specific applications of the small area estimation techniques are also provided to illustrate their pervasive utility.

Small Area Estimation Techniques

The NCHS Synthetic Estimator

The NCHS synthetic estimator is an approach formalized by the **National Center for Health Statistics** [20, 21, 26]. The underlying assumption of the model is that within a demographic subgroup, the estimate of the criterion variable for the small area is equivalent to that obtained for the nation or the census region in which the small area is located.

Sociodemographic information such as age, race, ethnicity, sex, and income must be available both for the sample survey and for the small areas. D domains are formed by cross classification of these demographic variables. To estimate the **mean** of the characteristic Y for the small area l, the estimate of $\overline{Y}(d)$ for each of the D domains is calculated from the survey data. The small area estimate, $\overline{Y}_s(l)$, for area l is the sum of the weighted average of $\overline{Y}(d)$ across all domains, where the weight $(P(ld))$ is the proportion of the population of small area l that is in each domain. More specifically,

$$\overline{Y}_s(l) = \sum_{d \in l} P(ld)\overline{Y}(d),$$

where $\overline{Y}_s(l)$ is the NCHS small area estimator of the mean for criterion variable Y in small area l,

$P(ld)$ is the proportion of the lth area's population that belongs to domain d, and $\overline{Y}(d)$ is a national or regional survey estimate of the mean value of the criterion variable Y for domain d.

The Sample Regression Estimator

The sample regression estimator is based on a **regression** model using selected predictor (symptomatic) variables as independent variables and sample data for the variable of interest as the criterion or dependent variable. This approach is generally attributed to Ericksen [8, 9]. Criterion variable data must be available for a sample of n small areas selected from the set of N small areas in the total population. These small areas are referred to as primary sampling units (PSUs) and the n small areas in the sample as sampled PSUs. Estimates of the criterion variable are computed for these sampled PSUs. For most national household surveys, the PSUs are defined as counties or groups of contiguous counties. Predictor information is also needed for the sample PSUs and the nonsampled PSUs for which small area estimates are desired. Using predictor data for these PSUs, a regression model is developed to predict Y_r. More specifically,

$$Y_r = X\beta + \varepsilon,$$

where Y_r is an $n \times 1$ vector of values for the criterion variable in the n sample PSUs, X is an $n \times (p+1)$ matrix containing the set of p symptomatic indicators for the n sampled PSUs and an indicator for an intercept term, β is a $(p+1) \times 1$ vector of regression coefficients, and ε is an $n \times 1$ vector of stochastic errors.

The values of the symptomatic indicators for small areas, defined at the same level of geographic aggregation as the PSUs, are then substituted into the estimated regression model to derive the estimate of the criterion variable for the small areas. Specifically, the sample regression estimator for small area l (e.g. county level) is obtained as

$$Y_r(l) = X(l)\hat{\beta},$$

where $Y_r(l)$ is the sample regression estimator of the mean for the criterion variable in small area l, $X(l)$ is the $(p+1)$ vector of symptomatic information for local area l, and $\hat{\beta}$ is the regression estimate obtained in fitting the model for the data from the sample PSUs.

If the small area of interest is at the state level (S), the sample regression estimator developed at the county level would be applied in the following manner:

$$\overline{Y}(S) = \sum_{l \in S} P(lS) Y_r(l),$$

where $P(lS)$ is the proportion of the population in state S in small area (county) l.

The Base Unit Estimator

For those situations in which the linearity assumption of the sample regression model is suspect, an alternative strategy has been developed, which is referred to as the base unit or **poststratified** estimator [5, 14]. This small area estimation technique divides the small area of interest into constituent geographic sectors or base units, which might be counties, enumeration districts, or other geographic subunits. The small area l for which a criterion variable estimate is to be derived is referred to as the target area and further subdivided into target area base units. Counties would be the base units within target areas such as states. Unlike other methods that use symptomatic information directly for estimation, this procedure uses the symptomatic information to group the base units. G groups are formed using a suitable clustering **algorithm** or by a minimum variance **stratification** method. All target base units belonging to the small area of interest are assigned to one of the G poststrata based upon the symptomatic information. An estimate of the criterion variable for each of the target base units is obtained from the sample base units in the poststratum to which it has been assigned. In essence, each target base unit estimate can be considered as a small area estimate [4, 6].

An estimate of $\overline{Y}(g)$, the mean of the criterion variable of interest, is calculated for each of the G groups or poststrata by taking a weighted average of the estimates of the criterion variable across the sample base units that comprise each group. The mean estimate of the criterion variable for the gth group ($g = 1, 2, \ldots, G$) is given by

$$\overline{Y}(g) = \sum_{i \in g} W(i)\overline{Y}(i),$$

where $W(i)$ estimates the proportion of the total population of sample base units in group g that is represented by base unit i, and $\overline{Y}(i)$ is an estimate

of the criterion variable for the ith sample base unit. The base unit estimate of the criterion variable for each small area l is calculated as

$$\overline{Y}_b(l) = \sum_{g \in l} P(lg)\overline{Y}(g),$$

where $P(lg)$ is the proportion of the population of small area l that is classified in group g.

The base unit estimator bears a striking resemblance to the NCHS synthetic estimator. The primary difference lies in the method of poststrata construction vs. domain formation [24]. The base unit estimator links all individual observations within a sample base unit to a particular group or poststrata, based on symptomatic information for the entire unit.

The Composite Small Area Estimator

The composite small area estimator takes the form of a weighted average of two component small area estimators for small area l,

$$\overline{Y}_c(l) = C(l)\overline{Y}_1(l) + [1 - C(l)]\overline{Y}_2(l),$$

where $C(l)$ is an appropriately chosen weight and $\overline{Y}_1$ and $\overline{Y}_2$ are alternative small area estimators for local area l.

Schaible [25] has demonstrated that, with a judicious selection of composite weights, the composite estimator will have a **mean square error** that is smaller than the mean square error of the individual estimators. When the expected value of $\mathrm{E}[\overline{Y}_1(l) - \overline{Y}(l)][\overline{Y}_2(l) - \overline{Y}(l)]$ is small relative to the mean square error of $\overline{Y}_2(l)$, the weight that will minimize the composite estimator's mean square error can be approximated as

$$\frac{C(l) = 1}{[1 + R(l)]},$$

where

$$\frac{R(l) = \mathrm{MSE}[\overline{Y}_1]}{\mathrm{MSE}[\overline{Y}_2]}.$$

Bayesian Methods Using Hierarchical Models

A **hierarchical model** has also been utilized to model the geographic variation of health care measures expressed in terms of **binary** outcomes. The primary objective of this approach is to account for the **small area variation** that is generally ignored by the other small area estimation strategies [17]. As part of the estimation scheme, available **covariates** at the local level are incorporated in the model specification to improve on the predictive capacity for small areas. In addition, the variable of response due to local effects is explicitly incorporated into the model. Estimates and their accuracy are derived using **Bayesian** predictive **inference** [17].

Using this approach, the small area estimator, $Y_{h,s}$, of a mean for criterion measure of interest at the state level (s) is based on the posterior mean of $Y_{h,s}$,

$$\overline{Y}_{h,s} = \sum_{cbk \in sp} \frac{Y_{cbk}}{N} + \sum_{cb \in sp} (N_{cb} - n_{cb}) \times \frac{\mathrm{E}(p_{cb}|Y_{sp})}{N},$$

where b represents a demographic class; c represents a county in state s; k represents an individual in demographic class b and county c; sp indicates selection in the sample; N_{cb} and n_{cb} are the population and sample sizes in class b of county c; p_{cb} denotes the probability than an individual in demographic class b, county c, has criterion measure outcome of interest (Y has binary measure: $Y = 1$ indicates yes; $Y = 0$ indicates no); and $\mathrm{E}(p_{cb}|Y_{sp})$ represents the posterior mean of p_{cb}, where

$$\ln\left[\frac{p_{cb}}{(1 - p_{cb})}\right] = X_{cb}\beta_c$$

is defined as a **logistic regression** model, so that X_{cb} is a vector of covariates which characterizes the demographic class within county c.

In this setting the logistic parameter is allowed to vary across counties to incorporate local error in the model [17]. Efforts to approximate the mean squared error for this type of small area estimator have been made by Prasad & Rao [23].

Applications of Small Area Estimation Techniques

These small area estimation strategies, and variants of the techniques described, have been applied to a widespread set of social, demographic, economic, and health related criterion variables for which local area estimates are desired. With respect to health

specific applications, the NCHS synthetic estimator has been used to produce state specific estimates of mortality [15], disability [15, 18, 19, 20], utilization of medical services [15], infant and maternal health characteristics [11], and functional dependency [7]. In addition, the base unit method has been used to derive state specific estimates of health insurance coverage [3].

Postcensal estimates of population growth have been derived at the state, county, and local level, using variants of the sample regression small area estimator [8, 16]. In addition, indirect regression type small area estimators have been used to produce state and county level estimates of personal income and annual income by the Bureau of Economic Analysis [1]. A composite type small area estimator has also been used by the Bureau of the Census to produce state estimates of **median** annual income for four-person families [10].

The Bureau of Labor Statistics produces state and local area employment and unemployment estimates under a federal–state cooperative program using indirect regression type estimators [27]. The NCHS synthetic estimator has also been used to produce small area unemployment and housing estimates [12]. In addition, the Department of Agriculture has implemented regression type small area estimators in the derivation of county estimates of crop acreage [2] and has used composite type estimators to derive county estimates of crop production and livestock inventories [13].

STEVEN B. COHEN

Small Area Variation Analysis

This area of investigation in health services research seeks to detect and explain variation in the amount of health care consumed by residents in different "small areas" [7] (*see* **Small Area Estimation**). Areas in which the utilization is higher than average may be investigated further in the interests of lowering the costs of health care by preventing unnecessary services. Areas with particularly low utilization are of interest as places in which access to health care may be inadequate. Ideally, one would study variation about the desirable utilization rate, but the desirable or appropriate rate at which a procedure should be performed is not usually known. Small area variation analysis was pioneered by John Wennberg and Alan Gittelsohn, who showed that the probability of having a tonsillectomy, hysterectomy, or prostatectomy varied substantially among small geographic areas in the northeast United States, while rates for cholecystectomy, appendectomy, and herniorrhaphy showed substantially less variation [9]. Such studies were the impetus for the growth in **outcomes research**, and a variations analysis is one of the first steps recommended in outcomes research.

A small area may be a zip (postal) code area, a county, a state, or at times a country. (Related studies treat all the patients in a hospital or a dental practice as a "small area".) Some small areas are created specifically for variations analysis, e.g. a **hospital market area**.

A variations analysis begins with calculation of a utilization rate, in which the denominator is the number of residents in the small area and the numerator is the number of procedures utilized by the *residents* of the small area, no matter where they actually received the procedure. The data for calculating such rates usually come from hospital billing data, which are available from some Canadian provinces and, in the US, from some states and also from the Health Care Financing Agency for patients enrolled in Medicare. The rates are usually standardized by age and sex, often using the method of indirect **standardization** because the number of procedures in some strata may be very small.

Statistical analysis of area variations is often informal, consisting of graphs of the admission rates by area, and descriptive statistics. Descriptive statistics usually include the extremal coefficient (maximum rate divided by minimum rate), and the weighted or unweighted *coefficient of variation* (*see* **Standard Deviation**). These statistics are unsatisfying unless the numbers of procedures per area are very large, because they do not distinguish variation among the areas from variation within the area. The systematic component of variation (SCV) [6] does make this distinction, under the assumption that no individual has more than one procedure. The square root of the SCV is an estimate of the coefficient of variation under this assumption. The variance among areas can be calculated from a mixed model **analysis of variance**. An estimate of the coefficient of variation based on a **moment** estimate of the **variance** among areas is the coefficient of variation from analysis of variance (CVA) [4]. Of all the simple statistics, only the CVA incorporates a **confidence interval** and a significance test (*see* **Hypothesis Testing**).

Simulation work has shown that the most popular descriptive statistics are sensitive to such factors as the **prevalence** of the procedure under study, the number of small areas being considered, the likelihood of multiple admissions per person, and the population sizes and relative population sizes of the small areas [2]. The unweighted coefficient of variation and the extremal quotient are also less likely than other statistics to demonstrate true variation when it occurs [3].

"Variation" is not well defined, and graphs of admission rates for small areas do not always agree with the usual descriptive statistics, because the usual statistics adjust the variance among areas by the prevalence, permitting a highly prevalent procedure to have more variation than a low prevalence procedure. The rationale for this has never been formally justified. The CVA has been shown to be the best of the usual descriptive statistics that adjust for prevalence, in that it is relatively uncorrelated with the prevalence of the procedure under study [4].

Multivariable statistical methods have been used to estimate or display the area variation, and importantly to allow the incorporation of **covariates**. One method models the number of admissions per area as following a **Poisson distribution** with extra-Poisson variation (*see* **Overdispersion**) [10]. The Poisson assumption effectively assumes that there are no multiple admissions [10]. If there are multiple admissions per person, the extra-Poisson variability can be due

to that fact, as well as to true variation among the small areas. Formal **hierarchical modeling** permits assessment of trends at the person level as well as at the area level [5, 8].

Investigators often wish to answer whether there is "too much" variation, since this could signal a diagnosis, procedure, hospital, or small area that merits further study. If there are not multiple admissions per person, one can test whether the observed variation is significantly different from zero, using a simple **chi-square test**. Although the **alternative hypothesis** is unlikely to be true, some very small data sets will not pass this test. A second approach is to compare the variation for (say) the diagnosis of interest to the variation of another "standard" diagnosis. Hernia surgery has been suggested as a standard surgical diagnosis because it usually shows low variation. Confidence intervals for the CVA can be used in this way, and there is an associated F-test (*see* ***F*** **Distributions**) for the SCV statistic [4, 6]. Similarly, one can compare the variation in one geographic region to the variation in another for the same diagnosis.

Once the existence of variation has been established, it is common to test each area for significant differences from the standard (usually the average rate), with the **outlier** areas subjected to further study and perhaps intervention. A chi-square test is usually employed, without accounting either for the possibility of multiple admissions per person [1] or for **multiple comparisons**. Such adjustments should probably be made, however, in situations where conservative results are important, such as finding differences in mortality rates among hospitals. Attempts to explain why rates are too high or too low often fail to find any inappropriate utilization of services, and often find that variation in coding practices is responsible for the observed discrepancies.

Other statistical issues arise when investigators wish to perform variations analyses in very small areas, in which a substantial number of areas will have zero events. Investigators often combine several years of data in order to increase the number of events, but this could cause other problems in that the probability of multiple admissions will increase. Expanding the procedure or diagnosis of interest to include additional events may cloud the interpretation of the findings. Hierarchical modeling is another approach for handling very small numbers.

PAULA DIEHR

Smith, Cedric Austen Bardell

Born: February 5, 1917, in Leicester, UK.
Died: January 16, 2002, in London, UK.

Cedric Smith, Weldon Professor of Biometry at the Galton Laboratory, University College London, from 1964 to 1982, was a leading exponent of biostatistical human genetics in the United Kingdom. His genetic work centered on the detection and measurement of human linkage, and he was influential in the growing use of Bayesian methods. As Edwards [1] noted, he was "the principal link between the modern development and the 1930 pioneers F. Bernstein, L. **Hogben**, L.S. Penrose, Julia Bell, R.A. **Fisher** and J.B.S. Haldane", but his major work was done before the computer-based revolution.

Smith was born on February 5, 1917 in Leicester, and after his schooling there and subsequently in London, he went in 1935 to Trinity College, Cambridge. Here, he obtained first-class honors in Part II of the Mathematical Tripos and a distinction in Part III. He started graduate studies in statistics in 1938 and obtained a doctorate in 1942. Undergraduates of this period will remember a fascinating talk by Smith on recurrent functions, entitled "On growing fish from seed" (these being invented names for specific functions), as an early example of his quirky humor and curious ingenuity. He was a member of the Society of Friends and worked during the war as a hospital porter.

In 1946, he joined the Galton Laboratory at University College London. He remained there throughout his career and became Weldon Professor of Biometry in 1964. J.B.S. Haldane was a strong influence and encouraged Smith to work on problems in the testing and estimation of **linkage** in human genetics. Smith was attracted to the use of the **likelihood** function to provide a test of the **null hypothesis** and as a basis for the estimation of the recombination fraction. In 1953, he applied the word "lods" (log **odds**) used earlier by G.A. **Barnard**. In 1955, N.E. Morton used lods in applying Wald's **sequential** probability ratio test to the testing for linkage, but Smith disliked this approach, having moved firmly toward the **Bayesian** position. His Bayesianism, though, was not entirely orthodox. For instance, he investigated the possibility of using ranges of approximation to prior probabilities, related to the range of betting odds that the subject would accept. In 1957, in joint work, he introduced counting methods for estimation of **gene frequencies** and **segregation ratios**, which were early examples of the **EM algorithm** for **maximum likelihood** estimation.

In 1954, Smith published *Biomathematics*, nominally the third edition of a book by W.M. Feldman first published in 1923, but essentially a new and highly original work. This was followed in 1966 and 1969 by a fourth edition in two volumes. As Edwards [1] remarks, "its charming idiosyncrasies endeared it to its admirers but rather distracted the orthodox student."

Smith was an active member of the **Royal Statistical Society**, particularly in the Research Section and on the Editorial Board of the **Journal**, *Series B*; of the British Region of the **International Biometric Society**, serving as President from 1971 to 1972; and of the Genetical Society. He was a notable coeditor of the *Annals of Human Genetics*, frequently contributing personally to the flow of important statistical papers published in that journal.

PETER ARMITAGE

Smoking and Health

Tobacco was introduced to Spain and England in the sixteenth century by explorers returning from the New World. In England an import duty of 2 pence a pound was imposed in 1590. Tobacco attained rapid popularity and was even praised as a prophylactic against many ills. Nonetheless, from early times it was condemned as a "noxious vice", foul smelling, loathsome custom, and harmful to the brain and lungs.

In 1900 an increase in cancer of the lung was noted by vital statisticians but definite trends in mortality and disease incidence really only became apparent after 1930. Two studies in Germany [24, 32] were particularly notable. Müller [24] documented the rise in the proportion of cases of lung cancer at postmortem from 0.2% to 1% over the period 1918 to 1937 in his institute in Cologne. He associated this with the 82% increase in tobacco consumption in Germany over this period, and contrasted this to a fall in alcohol and coffee consumption. He emphasized that over the years the preparation of cigarettes had changed–over time more and more of the coarse materials (e.g. stems) from tobacco leaves were incorporated in the final product. The relation between experimental production of cancer in animals by tobacco tar was described. Müller then went on to describe a clinical investigation in which he questioned the surviving relatives of 96 patients who had died from lung cancer. Only 3% of these patients had not smoked, while 75% were classified as heavy smokers. He compared this with a group of healthy men of the same ages and stated that 16% of these were nonsmokers and 36% heavy smokers. The latter group were estimated to smoke 1259 g tobacco per day, while the cancer of the lung group smoked 2900 g tobacco per day. He investigated the patients' exposure to other carcinogenic agents, and found that 17 had worked in industries where they were exposed to possible risk, e.g. painters, printers, and lead workers. He also investigated their experience of other respiratory illnesses, particularly influenza, but found no records of such illness in about half the cases. He concluded that tobacco consumption was the major cause of lung cancer.

Schairer & Schöniger [32], referring to Müller's study, went further, since similar increases in postmortems from lung cancer had been shown in their institute in Jena. They posted questionnaires on smoking habits, including quantity, illnesses, and occupational exposure to polluted air, to the relatives of 195 cases of cancer of the lung who had died between 1930 and 1941. They posted similar questionnaires to the relatives of individuals who had died of stomach, colon, esophagus, and tongue cancer as controls. Completed questionnaires were returned by 50–60% of those posted. In addition they mailed 700 similar questionnaires to living male residents of Jena aged 53–54 years (the average age of death of the cancer of the lung patients). Of these 39% were satisfactorily completed. Of the cancer of the lung cases, 3% were nonsmokers and 52% were heavy smokers. Amongst the other groups between 11% and 16% were nonsmokers and 21%–38% heavy smokers. They were unable to find any association of cancer of the lung with air pollution or previous respiratory illnesses. They concluded that one of the causes of the rise in lung cancer deaths was due to heavy smoking, but that this could not be the only cause.

Case–Control Studies

Following these early clinicopathologic investigations, a series of more carefully controlled studies were designed and undertaken independently by Wynder & Graham [40], Levin et al. [21], and Doll & **Bradford Hill** [6], and published almost simultaneously. They all commented on the increase in mortality of cancer of the lung. Doll & Hill discussed possible reasons for this increase, in particular general atmospheric pollution, e.g. from industry, coal fires and traffic, and from smoking tobacco. They concluded that, in view of the studies described above, the most likely association was with tobacco.

The British studies were promoted by the **Medical Research Council**, which also initiated the studies by Lawther [19] on bronchitis and air pollution. All three of these studies followed a similar pattern. Patients diagnosed as having cancer of the lung and admitted to hospital were notified to the investigators and interviewed. In all studies a group of **controls** from either the same or similar hospitals was also interviewed (*see* **Case–Control Study, Hospital-based**).

The study by Doll & Hill [6] has been considered as the model of a **case–control study**, and so will be described in some detail. Twenty London hospitals notified all patients admitted to them with carcinoma

of the lung, stomach, colon, or rectum. "On receipt of the notification a research almoner (medical social worker) visited the hospital to interview the patient using a set questionnary". In addition the almoners were required to make similar inquiries of a group of "noncancer control" patients of the same sex, within the same 5-year age group, and at the same hospital at or about the same time.

The interviewers had not been told of the hypothesis that was being tested; thus, apart from questions on smoking habits there were others on, for example, place of residence, exposure to war gases, occupational hazards, etc. Obviously the interviewers could not be blinded by the illnesses of the patients they were interviewing (*see* **Blinding or Masking**). However, a number of the patients thought to have carcinoma at the time of the interview were subsequently found not to have the condition. The smoking habits of the patients incorrectly considered to have lung cancer were "sharply distinguished from the habits of those patients who did in fact have carcinoma of the lung", but did not differ from those of the other patients interviewed. Thus the authors concluded that the results could not be attributed to the results of **interviewer bias**.

All these case–control studies showed that patients with cancer of the lung were more likely to be smokers than those with other cancers or noncancer patients, and that those who smoked, smoked more cigarettes. None of the other possible suspected agents, e.g. air pollution, area of residence, or exposure to war gases, showed such a clear differentiation between the cases and controls. Doll & Hill, in particular, looked at other possible sources of **bias**, e.g. selection of the patients and controls, and were unable to find any particular bias in their groups (*see* **Bias, Overview**; **Bias in Case–Control Studies**; **Bias in Observational Studies**).

All three groups of authors concluded that the smoking of cigarettes was associated with cancer of the lung. Levin went so far as to state "the data suggest, although do not establish, a causal relation between cigarette and pipe smoking and cancer of the lung and lip respectively". When these results were reported to the main board of the Imperial Tobacco Company, according to a participant, the chairman was so appalled by the findings that he turned to his board and said "surely these results cannot be correct since we produce a clean, hygienic product"!

Prospective Surveys

The results of these **retrospective studies** were confirmed by a series of prospective studies (*see* **Cohort Study**). In these the smoking habits of a defined group were first ascertained and then the **causes of death** during several years' observations recorded. Different populations and strategies were used in these investigations. Doll & Hill [7, 8] sent a simple questionnaire to doctors on the medical register. They were notified of all deaths in the 34 000 who provided usable replies by the Registrar General. The group was enrolled in October 1951, aged 35 years or more. This group has been followed since that time. Hammond & Horn [12] enrolled a large number of American Cancer Society Volunteers, each of whom was asked to have a questionnaire on smoking completed by 10 white men aged 50–69 years. These were followed for 44 months only. **Dorn** [9] questioned 248 000 men who had served in the armed forces between 1917 and 1940 and who held US Government Life Insurance polices. Dunn et al. [10] questioned 67 000 men aged 35–64 years in nine occupations in California who were suspected of being subject to a higher than usual occupational risk of lung cancer, and followed them for about 48 months. Best et al. [4] questioned 78 000 Canadian veterans and their dependents (pensioners) aged 35 or more years, and followed them for 72 months.

All these studies showed a consistent gradient in the total mortality ratio (after adjusting for age) (*see* **Standardization Methods**) from nonsmoker to heavy smokers, ranging from 1.06 to 1.55 for those smoking less than 10 cigarettes per day, to 1.85 to 2.5 for those smoking 40 or more cigarettes per day. For lung cancer the ratios for these amounts varied from 4.4 to 8.4, and 15.1 to 43.7.

The investigators looked at causes of death other than cancer of the lung, and consistently demonstrated an association with smoking for bronchitis and emphysema, cancer of the larynx, cancer of the oral cavity, cancer of the esophagus, stomach and duodenal ulcers, other circulatory diseases, and coronary artery disease.

Other aspects of smoking, such as pipes, cigars, inhalation and stopping smoking, were investigated. The studies all showed that the **risks** of developing cancer of the lung were much less for "pure" cigar and pipe smokers, and the risks of lung cancer

diminished with the length of time since the individual had stopped smoking.

The subjects in these studies were selected by the answering of a questionnaire, which might have introduced bias by the inclusion of more or fewer smokers who are in ill-health at the beginning of the study. However, in all studies it was shown that the association between deaths from lung cancer and smoking was more evident in the later than the earlier part of the observation period, the reverse of what would have been expected if there had been **selection bias**. A further source of bias might have been the accuracy of diagnosis, for example, if smokers were likely to be "overdiagnosed" as having cancer of the lung. But all studies showed an excess of total mortality associated with smoking, hence if cancer of the lung had been overdiagnosed, other causes would have been "underdiagnosed" (*see* **Bias in Cohort Studies**).

These retrospective and prospective studies of smoking and cancer of the lung were the seminal works which laid the benchmark for good case–control and prospective studies. The use of defined, comparable groups of cases and controls, clearly defined questions, blinding of interviewers, and demonstrating that patients originally included as "cases", but not confirmed, resembled controls are a model of a good study. The prospective investigations which showed the need for very large defined groups, adequate follow-up, and consistent diagnostic criteria have illustrated how the imaginative use of certain groups, for example, doctors, veterans, and voluntary organizations, makes such large studies feasible both financially and operationally.

Policy Toward Smoking

As a result of these studies a variety of bodies were set up between 7 and 14 years after the initial studies to examine the evidence of the relationship between smoking cigarettes and cancer of the lung, e.g. Medical Research Council [22], Ministry of Health [23], National Cancer Institute of Canada [27], and Netherlands Ministry of Social Affairs and Public Health [28]. All agreed that the relationship was established. However, the most thorough reviews of the evidence were those of the Royal College of Physicians, London [31], in 1962, and of the US Surgeon-General in 1964 [33].

The former considered a number of possible explanations of the association of cancer of the lung and smoking:

1. Years before cancer of the lung becomes manifest some early process produces the desire to smoke. This was considered improbable.
2. Smoking may not cause cancer but only determine the site at which it appears. This is disproved as other forms of cancer are not less common among smokers than nonsmokers.
3. The rising death rate from lung cancer was a consequence of the falling death rate from tuberculosis. There was no evidence for this, and the gender effects were not consistent.
4. Some factors might be independently associated with both lung cancer and smoking (*see* **Confounding**). This hypothesis was contradicted by studies, for example, in Seventh Day Adventists (all nonsmokers), when the only cases of lung cancer were in converts who were ex-smokers.
5. **Berkson** [2, 3] suggested that nonsmokers are a highly selected group who are "biologically self-protective", and endowed with "robustness in meeting mortal stress from disease generally" while Eysenck [11] stressed the "accelerated rate of living" of cigarette smokers as a possible explanation of their higher death rates. This hypothesis fails to account for the disproportionate increase in death rates among smokers from lung cancer as compared with other causes. Berkson's objections were refuted by the finding that the 1952 London smog episode increased the death rate for a number of causes, in particular bronchitis and coronary heart disease, but no one doubted its importance as a cause of mortality.
6. Since heavy smoking is associated with heavy drinking the latter was incriminated – but all studies showed that the effect of smoking was independent of alcohol consumption.
7. The possibility that motor vehicle exhausts might be an important cause of the rise in deaths of lung cancer was dismissed because road haulage workers and those living near roads did not show an excess risk independent of smoking.
8. The role of general air pollution was more complex, but since the relation of smoking and lung cancer could be shown in both urban and rural

areas this was considered of lesser importance that the smoking of cigarettes. The differences between mortality of rural and urban dwellers were explained, in part, by the duration of smoking.

The Surgeon-General's Committee judged the causal significance of the association on a number of criteria which had to include:

1. Consistency of the association
2. Strength of the association
3. Specificity of the association
4. Temporal relationships of the association
5. Coherence of the association.

Hill [14] expanded these criteria to:

1. Strength of the association
2. Consistency
3. Specificity
4. Relationship in time
5. Biological gradient
6. Biological plausibility
7. Coherence
8. Experiment
9. Reasoning by analogy (*see* **Hill's Criteria for Causality**).

This account does not deal with all the other evidence, pathological, biochemical, physiological, etc. considered by the Surgeon-General's and RCP Committees. Both concluded that cigarette smoking was causally related to lung cancer (*see* **Causation**), and that cigarette smoking far outweighs all other factors.

As a result of these reports, and others, governments and most members of the public began to take the problem of smoking more seriously. Tobacco companies reduced the amount of tobacco in cigarettes (from 1 g per cigarette to 0.75 g per cigarette) and introduced filters in most brands. They also became involved in a search for what they hoped would prove to be less harmful products.

Less Harmful Cigarettes

The government in the UK reacted to these initiatives by setting up an Independent Scientific Committee under the chairmanship of Lord Hunter [16] in 1973. The failure of these efforts is chronicled in Holland & Wood [15] and Waller & Froggatt [37]. A very large randomized controlled trial (*see* **Clinical Trials, Overview**) was mounted by Withey et al. [38, 39] in 1985 to determine the efficacy of reducing the tar and nicotine levels in cigarettes. They found that lowering the tar intake did not lead to any improvement in respiratory health, and there was some evidence that smokers of the low-tar cigarettes compensated in the way they smoked these cigarettes in order to absorb more tar and nicotine. In the US a workshop held at the World Conference on Smoking and Health [26] had recommended a number of measures, such as labeling of cigarettes as being harmful, addition of filters, and redesigning the cigarette to reduce inhalation. The main recommendations, however, were to reduce the tar and nicotine content of cigarettes in the hope that this would reduce harmful effects. The trial by Withey et al.demonstrated that this strategy was unlikely to be effective – and thus that only stopping smoking is likely to lead to any reduction of risk.

Prevention

In view of the failure to reduce the harm from cigarettes we are left with the options of stopping people from smoking, or better still stopping them from taking it up.

The attempt to stop people from smoking through providing an alternative source of nicotine, such as nicotine-containing skin patches or nicotine chewing gum, medicalizes the problem of tobacco addiction. It does lead to some benefit and governments and others have supported such efforts. Other approaches, for example the use of counseling, have had some success – but none is effective in more than a small proportion of individuals [17, 30].

Discouraging children from taking up smoking is perhaps even more important. But this must involve parents and teachers as well as others such as the children's peers. Several studies endeavored to determine the major factors that lead children to take up smoking. One of the largest of these studies by Swan et al. [25, 34] followed about 6000 children from entry to secondary school at age 11 to young adulthood, age 21, in Derbyshire from 1972 to 1983. The results showed that 30% of smoking was attributable to peer pressure and to exposure to parental smoking at 11–12 years of age. More than 70% of children will try smoking before age 16 irrespective of their attitudes and circumstances, but

only about 3.5% try for the first time after this age. There was a maximum incidence of regular smoking of about 20% per annum as children moved into the third year of secondary school, and their smoking behavior changed after they become dismissive of the health hazards. Thus to prevent regular smoking in adults one needs to create programs before age 11 which demonstrate and maintain awareness of the health hazards. This implies changes to the way education is organized.

Passive Smoking or Environmental Tobacco Smoke

That cigarette smoking contaminates the atmosphere and that people exposed to others smoking may experience nose and eye irritation, cough, and headache has always been recognized. But there was little evidence of any objective harm to health until two papers appeared in March and November 1974 in the *Lancet*. Harlap & Davies [13] showed in a study of over 10 000 infants studied prospectively that the infants of mothers who smoked had significantly more admissions to hospital for bronchitis and pneumonia, especially in the winter, and more injuries. This was dose-related and independent of birthweight, social class or birth order. Colley et al. [5, 20] confirmed the greater incidence of bronchitis and pneumonia in children aged less than 1 year, and also demonstrated that it was related to the amount of exposure to smoking by the parents of the baby. These effects were independent of sex, parental symptoms and disease, and number of siblings. Many studies have since been published of the effects of passive smoking on health. The most recent authoritative reviews in the UK [18] and US [35] have confirmed that environmental tobacco smoke increases the risk of chronic respiratory disease in adults by about 25%, the risk of respiratory illness in children by 50%–100%, and of lung cancer by about 24% (95% **confidence interval**: 11% to 38%). It may also increase the risk of ischemic heart disease, and exposure in pregnancy may lower **birthweight**.

Conditions Associated with Smoking

Apart from cancer of the lung, a number of other conditions are also related to smoking. It has been estimated that about 3 million people die each year from smoking-related diseases in developed countries [36]. The number dying in the whole world is of course, much greater, and will rise considerably [29]. Other cancers which have been considered as satisfying the Surgeon-General's and Hill's criteria are upper respiratory, bladder, pancreas, esophagus, stomach, kidney, and leukemia. Respiratory heart disease, chronic obstructive lung disease, stroke, pneumonia, aortic aneurysm, ischemic heart disease, peripheral vascular disease, cataracts, hip fracture, and periodontal disease also satisfy these criteria. In pregnancy, smoking increases the risk of limb reduction defects, spontaneous abortion, ectopic pregnancy, and low birthweight [36]. Some suggestions have been made that smoking protects from the occurrence of uterine fibroids, endometriosis, hypertensive disorders, vomiting in pregnancy, ulcerative colitis, and Parkinson's disease [1].

Current Concerns

The importance of smoking as a health hazard has now gained universal acceptance amongst the health professions and most governments. It has become far less acceptable in society now than it was 20 years ago. The suppression of smoking on transport, in offices, and in restaurants has had a profound influence in some countries. However, there have been counter-pressures. Although some governments appreciate the effect of a ban on cigarette advertising, or other governmental measures, there has been a consistent lack of willingness to suppress the promotion of this health hazard by most Western governments. Some even continue to subsidize the growth of tobacco. The problem of smoking in developing countries, in spite of valiant efforts by the **World Health Organization** (WHO) are even greater. Here smoking is still considered a status symbol and tobacco companies intent on preserving their market export to these countries cigarettes with much higher tar and nicotine levels than permitted in Western countries in order to foster habituation.

Concluding Comments

The epidemiologic investigation of smoking has been responsible for the development of case–control and prospective methods of investigation and for the formulation of acceptable criteria for assessing

cause–effect relationships. The studies over the past 50 years have provided superb examples of how to perform descriptive and experimental epidemiologic studies. The problem has also illuminated the relations between epidemiology, medical statistics, and health policy, and has led to the development of appropriate preventive strategies.

Although the proportion of individuals who smoke in the UK and US is now less than half of what it was in the 1950s, smoking is still the most important health hazard in these countries. More worrying is the changes in those who smoke. Whereas up to about 20 years ago the great majority of smokers were men, now more and more women have adopted this habit. In the early years of this century smoking was practiced by upper social class groups; now it is most common in the poor and deprived, who are least able to afford it. A further major concern is the targeting of developing countries in tobacco promotion, whose populations are only too ready to mimic the more developed countries.

Smoothing Hazard Rates

Introduction

In the analysis of lifetime data or time-to-event data, a primary interest is to assess the risk of an individual at certain times (or ages) (*see* **Survival Analysis, Overview**). Let T denote a lifetime variable with distribution function $F(t) = \Pr(T \leq t)$ and probability density function $f(t) = \mathrm{d}F(t)/\mathrm{d}t$. The risk of an individual at age t can be measured by the so-called **"hazard rate"** or "hazard function", which is defined as:

$$\lambda(t) = \frac{f(t)}{1 - F(t)}, \quad \text{for } F(t) < 1. \tag{1}$$

That is, $\lambda(t)\,\mathrm{d}t$ represents the instantaneous chance that an individual will die in the interval $(t, t + \mathrm{d}t)$ given that this individual is alive at age t. The hazard rate provides the trajectory of risk and is widely used also in other fields. Engineers refer to it as "failure rate function" and demographers refer to it as "force of mortality function". The term "lifetime" simply denotes the time until the occurrence of an event of interest.

While parametric models provide convenient ways to analyze lifetime data, the necessary model assumptions, when violated, can lead to erroneous analyses and thus need to be checked carefully (*see* **Parametric Models in Survival Analysis**). We give a brief survey on hazard rate estimation in this article. No shape restriction on the hazard rate is assumed except for smoothness. Such a model-free approach is data driven and can be used for parametric model checking. The nonparametric approach of hazard rate estimation typically involves the smoothing of an initial hazard estimate. The brief survey of various smoothing hazard rate estimators provided here covers grouped lifetime data on the one hand and continuously observed lifetime data on the other.

For grouped data, the observations occur in the form of scatter plots (t_i, q_i), where q_i is an initial hazard estimate at the midpoint t_i of the ith time interval. Smoothing for such data corresponds to a scatter-plot smoothing or **nonparametric regression** step. As for continuously observed data, hazard rate estimation resembles **density estimation** (smoothing the increments of a cumulative function estimate). Almost any density estimation method can be adapted for hazard rate smoothing. The simplest such method is the kernel method, which should however be employed with care in the boundary region. More details are given later in the section "More on Kernel Hazard Estimators for Continuously Observed Data".

Smoothing Hazard Rates for Grouped Data: Nonparametric Graduation of Lifetables

The earliest nonparametric hazard rate estimate was the **life table** estimate based on grouped lifetimes (*see* **Grouped Survival Times**), which has been known for centuries. Assume for simplicity that lifetimes are grouped into intervals of unit length with midpoints $t_1, \ldots, t_p$. Let n_i denote the number of individuals alive (or at risk) at the beginning of interval i, and d_i denote the number of observed deaths during this interval. An ad hoc estimate of the hazard rate for the ith interval is the so called death rate, $q_i = d_i/n_i$ (for intervals of length Δ the death rate is replaced by $d_i/(\Delta n_i)$). A plot of the raw death rates at various times t_i typically yields a curve that is ragged, indicating high variability; see Figure 1 for an example concerning the death rates of 1000 female Mediterranean fruit flies. Dead flies were counted daily, and q_i is the death rate at day i.

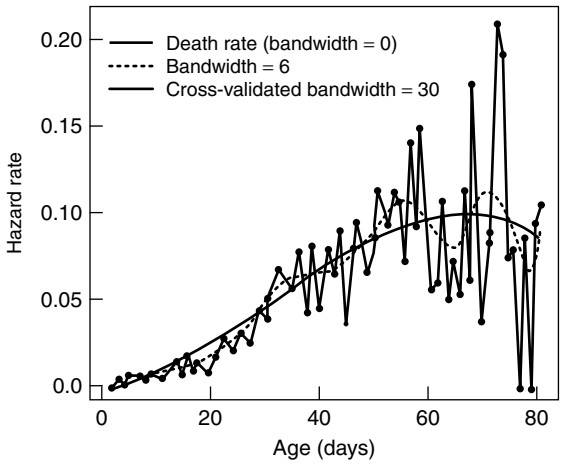

Figure 1 Three hazard rate estimates for the survival of 1000 female Mediterranean fruit flies. (a) death rates (thin line) (b) smoothed hazard rate with fixed bandwidth $b = 6$ (solid line) (c) smoothed hazard rate with least-squares cross-validated bandwidth choice $b = 30$ (bold line)

Since the actual hazard rate λ is typically assumed to be a smooth function, smoothing the death rates provides an aesthetically improved estimate (see Figure 1 for two versions of smoothed death rates). A smoothing procedure, when applied properly, also improves the statistical performance of the resulting hazard rate estimator.

For example, the smoothed death rates typically have a faster convergence rate than the unsmoothed death rates. The smoothing of death rates was pioneered by actuaries who referred to these smoothing methods as "linear graduation" or "nonparametric graduation", in contrast to "analytic graduation" based on parametric models (*see* **Actuarial Methods**). The term "linear" refers to the fact that these nonparametric graduation methods yield hazard estimates of the form

$$\hat{\lambda}(t) = \sum_{i=1}^{p} c_i(t) q_i, \text{ where}$$

$$\sum_{i=1}^{p} c_i(t) = 1, \text{ at each time } t. \qquad (2)$$

That is, the resulting hazard estimate at age t is a weighted average of the death rates with weights $c_i(t)$ specified by the method of graduation and adjusted locally at each age t.

The graduation (or smoothing) process typically reduces the variance of the resulting hazard estimates at the expense of introducing biases. The graduated or smoothed hazard estimate converges to the true hazard rate at a slower rate than the $\sqrt{n}$ rate, which holds for a parametric (or analytic) graduated hazard estimate.
