Event-related Potential

Event-related potentials (ERPs) are brain electrical potentials used to study sensory and cognitive processing [8]. In a typical ERP experiment, a sensory stimulus is presented to a human subject or experimental animal, and the brain electrical activity following the stimulus is recorded by electrodes on the scalp or implanted in the skull or brain. Commonly used stimuli include tones presented to one or both ears, and symbols presented to a specified part of the visual field. ERPs allow millisecond time resolution of brain electrical activity, so they can be used to study the fast time course of sensory and cognitive processing. Brain imaging techniques, such as functional magnetic resonance imaging (fMRI), yield much better spatial resolution, but they have poor time resolution measured in seconds or minutes.

Vaughan [9] proposed the term "event-related potential" to include potentials related to either cognitive or sensory events. The more specific term "evoked potential" refers to responses directly related to sensory processing of stimuli. Data containing both evoked potentials and cognitive ERPs are shown in Figure 1. These data were collected in an auditory oddball experimental design. In this design, the subject is presented with a series of stimuli, each of which is one of two different tones. The two tones are presented in a random sequence, but one tone ("standard") occurs with probability 0.8, while the other ("rare target") occurs with probability 0.2. The subject is instructed to count the number of occurrences of the rare target tone. The recorded **time series** show a large negative trough near 100 milliseconds ("N100"), which occurs equally in response to either the standard or the rare target tone. In contrast, the positive wave occurring approximately 300 milliseconds after the stimulus ("P300") has a larger amplitude in response to the rare target tone, which is more salient to the subject's task. Based on results such as these, investigators have concluded that the N100 is an evoked potential reflecting sensory processing of the stimulus, while the P300 is an ERP related to cognitive processing.

The characteristic peaks and troughs that appear in plots such as Figure 1 are called "components". Many components occurring within the first 100 milliseconds after the stimulus can be attributed to activity in localized anatomic structures along known sensory pathways [2]. Later components appear to arise from more dispersed cortical sources [2].

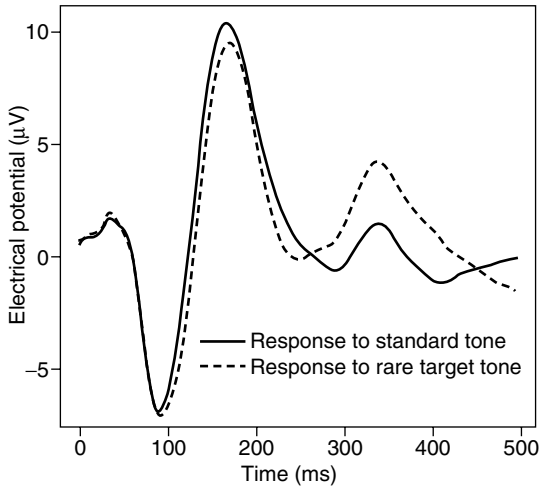

Figure 1 Human auditory event-related potentials. The response is plotted against time from stimulus presentation. Each time series is the average of ERPs acquired from 10 subjects, each of which is the average of responses to many stimulus presentations. The peak between 300 ms and 400 ms has much greater amplitude in response to the target stimulus, which indicates that it is related to cognitive processing. The large trough near 100 ms is an evoked potential reflecting sensory processing

Statistical analysis of ERPs is challenging, since typical ERP data sets consist of a large number of time series, which vary among individuals, recording channels, and **explanatory variables** such as stimulus type, drug condition, and disease state. Investigators commonly wish to decompose these many time series into meaningful component waveforms, estimate the effect of the explanatory variables on the amplitude and latency (time since stimulus presentation) of each component, and estimate the locations of the brain sources of the components.

The simplest and most commonly used method for analyzing ERP data is to measure the amplitudes and latencies of various peaks and troughs in the recorded time series, and then apply **analysis of variance** and other traditional statistical methods to these derived measures. This approach is not always satisfactory, since two or more brain processes may be simultaneously active, resulting in superposition of components

in the recorded time series. Furthermore, identification of relevant peaks can be highly subjective when noisy recordings are analyzed, and analysis of peaks does not provide estimates of the component waveforms themselves.

Donchin [3] proposed analyzing ERPs using **principal component analysis** (PCA) by treating each time point as a separate "variable" and each time series from a particular individual, combination of explanatory variables, and recording channel as a multivariate "observation". Investigators typically apply **varimax rotation**, interpret the **factor loadings** (rotated eigenvectors) as ERP components, and use analysis of variance to test for effects of explanatory variables on the **factor scores**. Several authors have criticized this use of PCA. The factor scores are necessarily uncorrelated, which can lead to misleading inference, and the choice of rotation sometimes seems arbitrary.

Implicit in the use of PCA is a bilinear statistical model in which the expected responses are represented by unknown linear combinations of unknown component time series. Möcks [4] noted that while bilinear models are not identifiable due to rotation, multilinear models are identifiable up to scaling, and he proposed multilinear models for ERPs.

Brillinger [1] and several other statisticians have suggested analyzing ERPs by modeling the Fourier coefficients of the data. This approach is particularly useful when the explanatory variables are assumed to change the amplitude and latency of some underlying common response, as in the following time-domain model:

$$Y_{jt} = \beta_j \gamma(t + \tau_j) + \varepsilon_{jt},$$
$$j = 1, \ldots, m; \quad t = 1, \ldots, n, \qquad (1)$$

where Y_{jt} is the recorded potential at time t under the jth combination of explanatory variables, β_j is the amplitude, τ_j is the latency, and $\gamma(t)$ is an underlying mean function, with appropriate constraints to make the model identifiable. The noise vector $(\varepsilon_{j1}, \ldots, \varepsilon_{jn})$ is assumed to be generated by a stationary, mixing random process. This simple model assumes a single component and applies to data from a single recording channel and a single subject, but more general frequency domain models have been proposed.

Applying the discrete Fourier transform to (1) yields an approximate frequency domain model in which the latency effects τ_j appear as phase shifts. When n is large, the errors in the frequency domain model are approximately independent and normally distributed with variances proportional to the **spectral** power of the noise process. This representation leads to inference based on an approximate **multivariate normal** likelihood.

The frequency domain model can be generalized to more than one ERP component (assuming that constraints are introduced to ensure identifiability), but it will be less useful when each component is localized in time, since such components will not be parsimoniously represented by their Fourier coefficients. If the Fourier transform is replaced by the wavelet transform (or one of the many related transforms), then localization in both time and frequency is achieved, but some of the advantages of the frequency domain approach are lost.

Estimation of the location of the brain sources of ERPs is of great scientific interest, but poses a variety of difficult problems in biophysical modeling. A statistical approach was proposed by Raz et al. [7], who used a relatively simple biophysical model of the head as part of a frequency domain method for source localization.

When a time series of brain electrical potentials is acquired following an experimentally controlled stimulus, the response to the stimulus is small and is usually obscured by unrelated brain activity. Investigators almost always average the responses to many stimulus presentations ("single trials") to enhance the signal-to-noise ratio and obtain an estimate of the ERPs, which are the brain potentials that are time-locked to the stimulus. The average recorded potential, however, may be a poor estimator of the expected brain response ("signal") if the brain responds differently to different stimulus presentations; that is, if the signal is heterogeneous. Several statisticians have considered the problem of estimating heterogeneous signals and testing the null hypothesis of signal homogeneity [5, 6].

ERP data continue to present challenges for statisticians. Open problems include: constructing statistical models that realistically account for the variability among subjects, recording channels, levels of explanatory variables, and single trials; further advancing a statistical perspective on the difficult problem of source localization; and developing statistical methods for relating ERPs to brain images.

Evidence-based Medicine

Evidence-based medicine has been defined by its proponents as the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients [10] (*see* **Decision Analysis in Diagnosis and Treatment Choice**). In this definition, the practice of evidence-based medicine means integrating individual clinical expertise with a critical appraisal of the best available external clinical evidence from systematic research. By individual clinical expertise is meant the proficiency and judgment that individual clinicians acquire through clinical experience and clinical practice. Increased expertise is reflected in many ways, but especially in more effective and efficient diagnosis and in the more thoughtful identification and compassionate use of individual patients' predicaments, rights, and preferences in making clinical decisions about their care. By best available external clinical evidence is meant clinically relevant research, often from the basic sciences of medicine, but especially from patient-centered clinical research into the accuracy and precision of **diagnostic tests** (including the clinical examination), the power of **prognostic factors**, and the efficacy and safety of therapeutic, rehabilitative, and preventive regimens [4].

The practice of evidence-based medicine is a process of lifelong, self-directed learning in which caring for one's own patients creates the need for clinically important information about diagnosis, prognosis, therapy, and other clinical and health care issues, and in which its practitioners:

1. Convert these information needs into answerable questions.
2. Track down, with maximum efficiency, the best evidence with which to answer them (and making increasing use of secondary sources of the best evidence). Examples of such secondary sources are the Cochrane Library and journals of critically appraised clinical articles such as *ACP Journal Club* and *Evidence-Based Medicine*.
3. Critically appraise that evidence for its validity (closeness to the truth) and usefulness (clinical applicability).
4. Integrate the appraisal with clinical expertise and apply the results in clinical practice.
5. Evaluate one's own performance.

Evidence-based medicine is one of several disciplines that has evolved from **clinical epidemiology** and critical appraisal. Parallel developments, still with the individual patient as the focus of attention, are occurring in other clinical disciplines (evidence-based surgery, evidence-based nursing, evidence-based dentistry, etc.). Other evidence-based disciplines consider the community as the focus of attention rather than the individual patient (evidence-based public health), or add an explicit economic element and seek to purchase or provide that mix of health care that will maximize some group or public benefit (evidence-based purchasing).

Recent audits in the front lines of clinical care have documented that some inpatient clinical teams in general medicine [3], psychiatry [5], and surgery (P. McCulloch, personal communication) have provided evidence-based care to the vast majority of their patients. Such studies show that busy clinicians who devote their scarce reading time to selective, efficient, patient-driven searching, appraisal, and incorporation of the best available evidence can practice evidence-based medicine.

Common misconceptions about evidence-based medicine include the concern that it might degenerate into "cookbook" medicine. However, because it requires a bottom-up approach that integrates the best external evidence with individual clinical expertise and patient choice, it cannot result in slavish, cookbook approaches to individual patient care. External clinical evidence can inform, but can never replace, individual clinical expertise, and it is this expertise that decides whether the external evidence applies to the individual patient at all and, if so, how it should be integrated into a clinical decision. Similarly, any external guideline must be integrated with individual clinical expertise in deciding whether and how it matches the patient's clinical state, predicament, and preferences, and thus whether it should be applied. Clinicians who fear top-down cookbooks will find the advocates of evidence-based medicine joining them at the barricades.

Others fear that evidence-based medicine will be hijacked by purchasers and managers to cut the costs of health care. This would not only be a misuse of evidence-based medicine but suggests a fundamental misunderstanding of its financial consequences. Doctors practicing evidence-based medicine will identify and apply the most efficacious interventions to maximize the quality and quantity of life for individual

patients; this may raise rather than lower the cost of their care.

Finally, in terms of study designs, evidence-based medicine is not restricted to randomized trials (*see* **Clinical Trials, Overview**) and **meta-analyses**. It involves tracking down the best external evidence with which to answer our clinical questions. To find out about the accuracy of a diagnostic test (*see* **Diagnostic Test Accuracy**), its practitioners seek **likelihood ratios, sensitivities**, and **specificities** derived from proper **cross-sectional studies** of patients clinically suspected of harboring the relevant disorder, not a randomized trial. For a question about prognosis, they search for multivariate prediction rules (*see* **Multivariate Multiple Regression**) generated from proper follow-up studies (*see* **Cohort Study**) of patients assembled at a uniform, early point in the clinical course of their disease; sometimes the evidence will come from the basic sciences such as genetics or immunology. It is when asking questions about therapy that the practitioners of evidence-based medicine avoid the nonexperimental approaches (*see* **Observational Study**), since these routinely lead to **false positive** conclusions about efficacy. Because the randomized trial, and especially the systematic review of several randomized trials [2], is so much more likely to inform clinicians and so much less likely to mislead them, it has become the **gold standard** for judging whether a treatment does more good than harm. Clinically useful measures of the effects of treatment are sought, such as the **number needed to treat** to prevent one additional event (the reciprocal of the absolute risk reduction).

Despite its ancient origins, evidence-based medicine remains a relatively young discipline whose positive impacts [1] are just beginning to be validated, and it will continue to evolve. This evolution will be enhanced as several undergraduate, postgraduate, and continuing medical education programs adopt and adapt it to their students' needs.

For more reading, users can refer to any of the growing number of texts on this subject [6, 8, 9] or examine it on the **Internet** [7].

DAVID L. SACKETT

Exact Inference for Categorical Data

Modern statistical methods rely heavily on **nonparametric** techniques for comparing two or more populations. These techniques generate ***P* values** without making any distributional assumptions about the populations being compared. They rely, however, on asymptotic theory that is valid only if the sample sizes are reasonably large and well balanced across the populations (*see* **Large-sample Theory**). For small, sparse, skewed, or heavily tied data, the asymptotic theory may not be valid; see [5] for some empirical results, and [42] for a more theoretical discussion.

One way to make valid statistical inferences in the presence of small, sparse, or unbalanced data is to compute exact P values and **confidence intervals**, based on the permutational distribution of the test statistic (*see* **Randomization Tests**). This approach was first proposed by R. A. **Fisher** [18] and has been used extensively for the single **2 x 2** contingency table (*see* **Fisher's Exact Test**). Previously, exact tests were rarely attempted for tables of higher dimension than 2×2, primarily because of the formidable computing problems involved in their execution. In recent years, however, the easy availability of immense quantities of computing power combined with many new, fast, and efficient **algorithms** for exact permutational inference have revolutionized our thinking about what is computationally feasible. Problems that would previously have taken several hours or even days to solve now take only a few minutes. Exact **inference** is now a practical proposition and has been incorporated into standard statistical **software** packages.

In the present paper, we present a unified framework for exact inference, anchored in the permutation principle. We demonstrate that, for a very broad class of nonparametric problems, such inference can be accomplished by permuting the entries in a contingency table subject to fixed margins. Exact and **Monte Carlo** algorithms for solving these permutation problems are referenced. We then apply these algorithms to several data sets. Both exact and asymptotic P values are computed for these data so that one may assess the accuracy of the asymptotic methods. Finally, we discuss the availability of software and cite an **internet** resource for performing exact permutational inference.

Exact Permutation Tests for $r \times c$ Contingency Tables

For a broad class of statistical tests, the data can be represented in the form of the $r \times c$ **contingency table** $\boldsymbol{x}$ displayed in Table 1.

The entry in each cell of this $r \times c$ table is the number of subjects falling in the corresponding row and column classifications. The row and column classifications may be based on either **nominal** or *ordered* variables (*see* **Ordered Categorical Data**; **Measurement Scale**). Nominal variables take on values that cannot be positioned in any natural order. An example of a nominal variable is profession – Medicine, Law, Business. In some statistical packages, nominal variables are also referred to as *class* variables, or *unordered* variables. Ordered variables take on values that can be ordered in a natural way. An example of an ordered variable is Drug Dose – Low, Medium, High. Ordered variables may of course assume numerical values as well (for example, the number of cigarettes smoked per day).

The Exact Permutation Distribution of $\boldsymbol{x}$

The exact probability distribution of $\boldsymbol{x}$ depends on the sampling scheme that was used to generate $\boldsymbol{x}$. When both the row and column classifications are categorical, Agresti [1] lists three sampling schemes that could give rise to $\boldsymbol{x}$; full **multinomial** sampling, product multinomial sampling, and **Poisson** sampling. Under all three schemes, the probability distribution of $\boldsymbol{x}$ contains unknown parameters, π_{ij}, relating to the individual cells of the $r \times c$ table (*see* **Loglinear Model**). For instance, for full multinomial sampling, π_{ij} denotes the probability of classification in row

Table 1 Layout for a generic $r \times c$ contingency table

Rows	Col_1	Col_2	...	Col_c	Row_total
Row_1	x_{11}	x_{12}	...	x_{1c}	m_1
Row_2	x_{21}	x_{22}	...	x_{2c}	m_2
⋮	⋮	⋮	...	⋮	⋮
Row_r	x_{r1}	x_{r2}	...	x_{rc}	m_r
Col_tot	n_1	n_2	...	n_c	N

i and column j, whereas for product multinomial sampling π_{ij} denotes the **conditional probability** of falling in column j given that the subject belongs to row i.

Consider the **null hypothesis** of no row by column **interaction**. Since statistical inference is based on the distribution of $\boldsymbol{x}$ under the null hypothesis of no row by column interaction, the number of unknown parameters is reduced (π_{ij} being replaced by $\pi_{i.}\pi_{.j}$ or $\pi_{.j}$ depending on the sampling scheme) but not eliminated. Asymptotic inference relies on estimating these unknown parameters by **maximum likelihood** and related methods. The key to exact permutational inference is getting rid of all **nuisance parameters** from the probability distribution of $\boldsymbol{x}$. This is accomplished by restricting the sample space to the set of all $r \times c$ contingency tables that have the same marginal sums as the observed table $\boldsymbol{x}$. Specifically, define the reference set

$$\Gamma = \left\{ \boldsymbol{y} : \boldsymbol{y} \text{ is } r \times c; \sum_{j=1}^{c} y_{ij} = m_i; \sum_{i=1}^{r} y_{ij} = n_j; \text{ for all } i, j \right\}. \quad (1)$$

Then one can show that, under the null hypothesis of no row by column interaction, the probability of observing $\boldsymbol{x}$ conditional on $\boldsymbol{x} \in \Gamma$ is of the **hypergeometric** form

$$\Pr(\boldsymbol{x} \mid \boldsymbol{x} \in \Gamma) \equiv P(\boldsymbol{x}) = \prod_{i=1}^{r} \prod_{j=1}^{c} \frac{n_j! m_i!}{N! x_{ij}!}. \quad (2)$$

Equation (2), which is free of all unknown parameters, holds for categorical data whether the sampling scheme used to generate $\boldsymbol{x}$ is full multinomial, product multinomial, or Poisson. (See, for example, [2].)

Since (2) contains no unknown parameters, exact inference is possible. The nuisance parameters were, however, eliminated by conditioning on the margins of the observed contingency table. Now some of these margins were not fixed when the data were gathered. Thus, it is reasonable to question the appropriateness of fixing them for purposes of inference. The justification for conditioning at inference time on margins that were not naturally fixed at data sampling time has a long history. R.A. Fisher [18] first proposed this idea for exact inference on a single 2×2 contingency table. At various times since then prominent statisticians have commented on this approach. The principles most cited for conditioning are the **sufficiency** *principle*, the **ancillarity** *principle*, and the **randomization** *principle* (*see* **Conditionality Principle**). An informal intuitive explanation of these three principles is provided below.

Sufficiency Principle. The margins of the contingency table are sufficient statistics for unknown nuisance parameters. Thus, conditioning on them affords a convenient way to eliminate nuisance parameters from the **likelihood** function. For example, if the data are generated by product multinomial sampling, the row margins, m_i, would ordinarily be considered fixed but the column margins, n_j, would be considered random variables. The null hypothesis of interest states that $\pi_{ij} = \pi_{.j}$ for all i. Thus, the probability of $\boldsymbol{x}$ depends on c unknown nuisance parameters, $(\pi_{.1}, \pi_{.2}, \ldots \pi_{.c})$ even under the null hypothesis. By the sufficiency principle, these nuisance parameters are eliminated if we condition on $(n_1, n_2, \ldots n_c)$, their **sufficient statistics**. It follows that by restricting our attention to $r \times c$ tables in Γ, we are implicitly conditioning on $(n_1, n_2, \ldots n_c)$, since the other set of margins, $(m_1, m_2, \ldots m_r)$, are fixed naturally by the sampling scheme. Similar sufficiency arguments can be made for full multinomial and Poisson sampling.

Ancillarity Principle. The principle underlying hypothesis testing is to compare what was actually observed with what could have been observed in hypothetical repetitions of the original experiment, under the null hypothesis. In these hypothetical repetitions, it is a good idea to keep all experimental conditions unrelated to the null hypothesis unchanged as far as possible. The margins of the contingency table are representative of nuisance parameters whose values do not provide any information about the null hypothesis of interest. In this sense, they are ancillary statistics. Fixing them in hypothetical repetitions is the nearest we can get to fixing the values of the nuisance parameters themselves in hypothetical repetitions, since the latter are unknown.

Randomization Principle. The case for conditioning is especially persuasive if the r rows of the contingency tables represent r different treatments,

with m_i subjects being assigned to treatment i by a randomization mechanism. Each subject provides a multinomial response that falls into one of the c columns. Thus, n_j represents the total number of responses of the jth type. Now, under the null hypothesis, the r treatments are equally effective. Therefore, the response that a patient provides is the same, regardless of the treatment to which that patient is randomized. Thus, the value of n_j is predetermined and may be regarded as fixed. The statistical significance of the observed outcome is judged relative to its permutational distribution in hypothetical repetitions of the randomization rule for assigning patients to treatments.

An excellent exposition of the conditional viewpoint is available in [52]. For a theoretical justification of the sufficiency and ancillarity principles, refer to [16, 43]. For a detailed exposition of the randomization principle, highlighting its applicability to a broad range of problems, refer to [17]. Throughout the present paper, we shall adopt the conditional approach. It provides us with a unified way to perform exact inference and thereby compute accurate P values and confidence intervals for $r \times c$ contingency tables (*see* **Stratification**), stratified 2×2 contingency tables, stratified $2 \times c$ contingency tables, and **logistic regression**.

Exact P Values

Having assigned an exact probability $P(\boldsymbol{y})$ to each $\boldsymbol{y} \in \Gamma$, the next step is to order each contingency table in Γ by a test statistic or "discrepancy measure" that quantifies the extent to which that table deviates from the null hypothesis of no row by column interaction. Let us denote the test statistic by a real valued function $D : \Gamma \longrightarrow \mathcal{R}$ mapping $r \times c$ tables from Γ onto the real line $\mathcal{R}$. The functional form of D for some important nonparametric tests is specified in the next section.

The P value is defined as the sum of null probabilities of all the tables in Γ, which are at least as extreme as the observed table, $\boldsymbol{x}$, with respect to D. In particular, if $\boldsymbol{x}$ is the observed $r \times c$ table, the exact P value is

$$p = \sum_{D(\boldsymbol{y}) \geq D(\boldsymbol{x})} P(\boldsymbol{y}) = \Pr\{D(\boldsymbol{y}) \geq D(\boldsymbol{x})\}. \quad (3)$$

Classical nonparametric methods rely on the large-sample distribution of D to estimate p. For $r \times c$ tables with large cell counts and the usual forms for the function D, it is possible to show that D converges in distribution to a **chi-square distribution** with appropriate **degrees of freedom**. Thus, p is usually estimated by $\tilde{p}$, the chi-square tail area to the right of $D(\boldsymbol{x})$. Modern algorithmic techniques have made it possible to compute p directly instead of relying on $\tilde{p}$, its asymptotic approximation. This is achieved by powerful recursive algorithms that are capable of generating the actual permutation distribution of D instead of relying on its asymptotic chi-square approximation. We shall see later that p and $\tilde{p}$ can differ considerably for contingency tables with small cell counts.

The main advantage of using p rather than $\tilde{p}$ is that it is guaranteed to bound the type 1 error rate of the **hypothesis testing** procedure to any desired **level**. Moreover, this guarantee is provided unconditionally even though each P value, p, is calculated conditionally by restricting attention to a specific reference set Γ. To see this, let

$$\mathcal{S}(\Gamma) = \Pr(p \leq \alpha | \Gamma). \quad (4)$$

That is, $\mathcal{S}(\Gamma)$ is the conditional type 1 error rate of a level-α hypothesis testing procedure in which you repeatedly generate $r \times c$ tables from the same reference set, Γ, under the null hypothesis, and reject whenever $p \leq \alpha$. Under the null hypothesis, $\mathcal{S}(\Gamma) \leq \alpha$. Now the unconditional type 1 error rate, where Γ may be different each time you execute the test, is

$$\mathcal{S} = \sum \mathcal{S}(\Gamma) \Pr(\Gamma), \quad (5)$$

the sum being taken over all possible reference sets, Γ. Notice that (5) is a weighted sum of terms of the form $\mathcal{S}(\Gamma)$, where each such term is less than or equal to α, the weights, $\Pr(\Gamma)$, are positive, and they sum to 1. Thus,

$$\mathcal{S} \leq \alpha.$$

That is, the guaranteed protection against the type 1 error of an exact conditional hypothesis test also applies unconditionally. Note, however, that this guarantee does not hold if you use $\tilde{p}$ rather than p in the decision to reject the null hypothesis, since $\Pr(\tilde{p} \leq 0.05 | \Gamma) \leq \alpha$ holds only asymptotically.

Choosing the Test Statistic

As stated previously, the reference set Γ is ordered by the test statistic D. Here, we define D for three

important classes of problems; tests on unordered $r \times c$ contingency tables, tests on singly ordered $r \times c$ contingency tables and tests on doubly ordered $r \times c$ contingency tables.

When both the row and column classifications of the table are nominal the table is said to be unordered and the Fisher, Pearson, and **likelihood ratio test** statistics are the most appropriate. Tests based on these three statistics are known as omnibus tests for they are powerful against any general alternative to the null hypothesis of no row by column interaction (*see* **Chi-square Tests**).

Fisher's exact test orders each table, $\boldsymbol{y} \in \Gamma$, in proportion to its hypergeometric probability, $P(\boldsymbol{y})$, given by (2). Fisher [18] originally proposed this test for the single 2×2 contingency table. The idea was extended to tables of higher dimension by Freeman and Halton [19]. Thus, this test is also referred to as the Freeman–Halton test. Asymptotically, under the null hypothesis of no row by column interaction, $-2 \log \gamma P(\boldsymbol{y})$ has a chi-squared distribution with $(r-1)(c-1)$ degrees of freedom, where γ is a normalizing constant [31].

The Pearson test orders the tables in Γ according to their Pearson chi-squared statistics. Thus, for each $\boldsymbol{y} \in \Gamma$ the test statistic is

$$D(\boldsymbol{y}) = \sum_{i=1}^{r} \sum_{j=1}^{c} \frac{(y_{ij} - m_i n_j / N)^2}{m_i n_j / N}. \qquad (6)$$

Asymptotically, under the null hypothesis of no row by column interaction, the Pearson statistic has a chi-squared distribution with $(r-1)(c-1)$ degrees of freedom.

The Likelihood Ratio test orders the tables in Γ according to the likelihood ratio statistic. Specifically, for each $\boldsymbol{y} \in \Gamma$ the test statistic is

$$D(\boldsymbol{y}) = 2 \sum_{i=1}^{r} \sum_{j=1}^{c} y_{ij} \log \left(\frac{y_{ij}}{m_i n_j / N} \right). \qquad (7)$$

In many textbooks, this statistic is denoted by G^2. Asymptotically, under the null hypothesis of no row by column interaction, $D(\boldsymbol{y})$ has a chi-squared distribution with $(r-1)(c-1)$ degrees of freedom.

When there is a natural ordering of the columns of the $r \times c$ table, but the row classifications are based on nominal categories, appropriate tests are the Kruskal–Wallis test [25] (*see* **Nonparametric Methods**), and its generalization, the one-way **analysis of variance** (ANOVA) test [37]. For example, suppose that the r rows represent r different drug therapies, and the c columns represent c distinct ordered responses (such as, no response, mild response, moderate response, severe response, etc.). One is interested in testing the null hypothesis that the r drugs have the same multinomial response rates. The Kruskal–Wallis and generalized one-way ANOVA tests are more powerful than the Fisher, Pearson, or likelihood Ratio tests for testing this null hypothesis against ordered alternatives which imply that some of these r drugs are more responsive than others. These tests take advantage of the natural ordering of the columns by assigning a rank or column **score** to all the observations in a column. The test statistic is obtained as a quadratic function of an r-dimensional vector whose components are formed by summing the column scores of the observations in each of the r rows and standardizing each sum. For the Kruskal–Wallis test, the observations in a column are assigned their midrank and the special case, $r = 2$, yields the **Wilcoxon–Mann–Whitney** rank-sum test. For the generalized one-way ANOVA test, any monotone scores may be assigned. By suitable choice of these scores, one can construct a large number of tests, including the **normal scores**, exponential scores (*see* **Order Statistics**), and **logrank tests** as special cases. The test statistics for all these tests are given in Chapter 18 of the **StatXact** User Manual [48]. Asymptotically, they are all distributed as chi-square, with $(r-1)$ degrees of freedom under the null hypothesis of no row by column interaction.

When the $r \times c$ contingency table has a natural ordering along both its rows and its columns, the Jonckheere–Terpstra test [24] and the linear-by-linear association test [3] have more power than the Kruskal–Wallis test or the various $(r-1)$ degree of freedom generalized ANOVA tests. For example, suppose the r rows represent r distinct drug therapies at progressively increasing doses and the c columns represent c ordered responses. Now one would be interested in detecting alternatives to the null hypothesis in which drugs administered at larger doses are more responsive than drugs administered at smaller doses. The Jonckheere–Terpstra and linear-by-linear association test statistics cater explicitly to such alternatives for they are better able to pick up departures from the null hypothesis in which the response distribution shifts progressively toward the

right as we move down the rows of the contingency table. The Jonckheere–Terpstra statistic is the normalized sum of $r(r-1)/2$ Wilcoxon rank-sum statistics formed by taking all possible pairs of rows from the r rows of the observed $r \times c$ contingency table and computing a Wilcoxon rank-sum statistic for each resulting $2 \times c$ contingency table. The linear-by-linear association statistic is obtained by standardizing $\sum_{i,j} u_i v_j y_{ij}$, where the u_i's are arbitrary row scores and the v_j's are arbitrary column scores. The row scores often represent progressively increasing doses of a treatment, while the column scores often represent progressively increasing levels of response to treatment. If the u_i's and v_j's represent the original raw data, the linear-by-linear test is a test of significance for Pearson's **correlation** coefficient. However, if the raw data are replaced by Wilcoxon midrank scores, we have a test of **Spearman's rank** correlation coefficient. Refer to Chapter 22 of the StatXact User Manual [48] for the precise functional forms of the Jonckheere–Terpstra and the linear-by-linear test statistics. Under the null hypothesis of no row by column interaction these test statistics are normally distributed. The special case, $r = 2$, yields the family of two-sample linear **rank** tests. For these tests, row scores are irrelevant but a large number of different column scores, covering most of the important nonparametric tests, are listed in Chapters 7, 17 and 18 in the StatXact User Manual [48]; see also **Linear Rank Tests in Survival Analysis**; **Nonparametric Methods**; **Rank Correlation**; **Isotonic Inference**.

Extension to Continuous Data

The methods described above extend naturally to continuous data. In principle, such data can also be represented as contingency tables but the columns of these tables will sum to 1. Thus, these methods provide a unified approach to handling nonparametric data both for the categorical case and the more traditional continuous case. For example, consider the two-sample problem involving continuous data displayed in Table 2. The two groups are "males" and "females". The continuous variable being compared in the two groups is "monthly income".

These data can be represented by the 2×8 contingency table, displayed as Table 3, which may then be permuted in the usual way for exact inference.

The same idea extends to continuous K-sample data with or without stratification, and with or without censoring.

Stratified 2 × 2 Contingency Tables

A very important class of exact nonparametric tests and confidence intervals is defined on data in the form of s 2×2 contingency tables. The ith such table is displayed in Table 4 below.

We may regard the two columns of each table as arising from two independent **binomial distributions**. Specifically, let (x_{i1}, x_{i2}) represent the number of successes in (n_{i1}, n_{i2}) Bernoulli trials, with respective success probabilities (π_{i1}, π_{i2}). The **odds ratio** for the ith table is defined as

$$\Psi_i = \left(\frac{\pi_{i2}}{1-\pi_{i2}}\right) \Big/ \left(\frac{\pi_{i1}}{1-\pi_{i1}}\right). \tag{8}$$

Stratified 2×2 contingency tables arise commonly in prospective studies with binary end points as well as in retrospective **case–control studies**. Thus, although we have specified that the two columns of the 2×2 table represent two independent binomial distributions, this is just a matter of notational convenience. We could equivalently assume that the two rows represent the disease status (present or absent) and the two columns represent the exposure status (not exposed or exposed) in the ith of s matched sets.

Table 2 Two-sample continuous data represented the traditional way

Row_2	x'_{i1}	x'_{i2}	m_{i2}
Col_tot	n_{i1}	n_{i2}	N_i

We shall be interested in deriving an exact test for the null hypothesis that

$$\Psi_1 = \Psi_2 = \cdots = \Psi_s = \Psi. \tag{9}$$

This is known as the homogeneity test. Next, under the assumption of homogeneity, we shall be interested in computing an exact **confidence interval** for the common odds ratio, Ψ, and in testing that it equals 1.

Homogeneity Test

Let $\boldsymbol{x}$ denote the observed collection of s 2×2 contingency tables, where the ith table in this collection is displayed in Table 4, and define

$$t = x_{11} + x_{21} + \cdots + x_{s1}. \tag{10}$$

Let Ω denote a reference set of collections of s 2×2 contingency tables whose margins are fixed at the values that were actually observed:

$$\Omega = \left\{ \boldsymbol{y}\colon \begin{array}{ll} y_{i1} + y_{i2} = m_{i1}; & y'_{i1} + y'_{i2} = m_{i2} \\ y_{i1} + y'_{i1} = n_{i1}; & y_{i2} + y'_{i2} = n_{i2}. \end{array} \right\} \tag{11}$$

Define the more restricted reference set

$$\Omega_t = \{\boldsymbol{y} \in \Omega\colon y_{11} + y_{21} + \cdots + y_{s1} = t\}. \tag{12}$$

Zelen [53] has shown that under the null hypothesis of homogeneity (9)

$$\Pr(\boldsymbol{x}|\boldsymbol{x} \in \Omega_t) = \frac{\prod_{i=1}^{s} \prod_{j=1}^{2} \binom{n_{ij}}{x_{ij}}}{\sum_{\boldsymbol{y} \in \Omega_t} \prod_{i=1}^{s} \prod_{j=1}^{2} \binom{n_{ij}}{y_{ij}}}. \tag{13}$$

An exact test for the homogeneity of odds ratios can thus be constructed by ordering all elements $\boldsymbol{y} \in \Omega_t$ according to the test statistic

$$D(\boldsymbol{y}) = -\log \Pr(\boldsymbol{y}|\boldsymbol{y} \in \Omega_t) \tag{14}$$

and computing the exact P value

$$p = \sum_{D(\boldsymbol{y}) \geq D(\boldsymbol{x})} \Pr(\boldsymbol{y}|\boldsymbol{y} \in \Omega_t). \tag{15}$$

This test is known as Zelen's exact test. A statistic proposed by Breslow and Day [12] is approximately distributed as chi-square with $(s-1)$ degrees of freedom under the null hypothesis (*see* **Breslow–Day Test**).

Common Odds Ratio Inference

Exact inference about Ψ, the common odds ratio, is based on the conditional distribution of

$$T = y_{11} + y_{21} + \cdots + y_{s1} \tag{16}$$

given $\boldsymbol{y} \in \Omega$. It is shown in [32] that

$$\Pr(T = t|\boldsymbol{y} \in \Omega) = \frac{C_t \Psi^t}{\sum_u C_u \Psi^u}, \tag{17}$$

where

$$C_t = \sum_{\boldsymbol{y} \in \Omega_t} \prod_{i=1}^{s} \prod_{j=1}^{2} \binom{n_{ij}}{y_{ij}}, \tag{18}$$

and the denominator of (17) is simply the normalizing constant obtained by summing over all possible values of u in the range $t_{\min} \leq u \leq t_{\max}$.

To test the null hypothesis that $\Psi = 1$ and to compute an exact confidence interval for this common odds ratio, we need the coefficients C_t for all possible values of t. Network algorithms for this and related computations are described in [32]. Once these coefficients have been obtained, the conditional distribution of t for any value of Ψ can be generated by (17) and hypothesis tests and confidence intervals may thereby be obtained as shown in the above references.

Asymptotic inference for Ψ is usually based on the popular **Mantel–Haenszel** [28] method.

Extension to Stratified $2 \times c$ Contingency Tables

In this section, we discuss inference on stratified $2 \times c$ tables, where the ith of s such tables is displayed as Table 5.

This collection of s $2 \times c$ tables, denoted by $\boldsymbol{x}$, can accommodate two situations; two multinomial populations, and c binomial populations. For both cases,

Table 5 Layout for the ith of s $2 \times c$ contingency tables

Rows	Col_1	Col_2	...	Col_c	Row_total
Row_1	x_{i1}	x_{i2}	...	x_{ic}	m_{i1}
Row_2	x'_{i1}	x'_{i2}	...	x'_{ic}	m_{i2}
Col_tot	n_{i1}	n_{i2}	...	n_{ic}	N_i
Col_score	v_{i1}	v_{i2}	...	v_{ic}	

we assume that data are stratified into s independent strata. Inference is conditional on ordering all three-way collections of s $2 \times c$ tables in the conditional reference set

$$\Lambda = \left\{ \mathbf{y}\colon\ y_{ij} + y'_{ij} = n_{ij}, \forall ij; \right.$$
$$\left. \sum_{j=1}^{c} y_{ij} = m_{i1},\ \sum_{j=1}^{c} y'_{ij} = m_{i2}, \forall i \right\} \tag{19}$$

according to some discrepancy measure $D(\mathbf{y})$. We shall be concerned in this section with the special case where the c columns of each $2 \times c$ contingency table have a natural ordering. In this case, an appropriate (unstandardized) discrepancy measure is the linear rank test statistic

$$t(\mathbf{y}) = \sum_{i=1}^{s} \sum_{j=1}^{c} v_{ij} y_{ij} \tag{20}$$

where the v_{ij}'s are arbitrary column scores.

Two Multinomial Populations. The two rows of stratum i represent two independent multinomial populations. Each observation falls into one of c ordinal response categories. Thus, x_{ij} is the number of stratum-i observations, out of a total of m_{i1}, falling into ordered category j for population 1, and x'_{ij} is the number of stratum-i observations out of a total of m_{i2} falling into ordered category j for population 2. The Wilcoxon rank-sum test, the Normal scores test, the Savage test, and the logrank test are examples of tests that are applicable to such data. The v_{ij} scores for these tests are defined in StatXact-3 [48, Chapter 15].

Several Binomial Populations. The c columns of stratum i represent c independent binomial populations with row 1 representing successes and row 2 representing failures. For population j in stratum i, there are x_{ij} successes and x'_{ij} failures in n_{ij} independent Bernoulli trials. The Cochran–Armitage Trend test and the Permutation test with arbitrary scores are applicable to such data, and determine whether the success rates of the c populations are the same, as against the alternative that they follow an increasing or decreasing trend (*see* **Trend Test for Counts and Proportions**). The scores, $v_{i1}, v_{i2}, \ldots v_{ic}$ typically represent doses, or levels of exposure, affecting the success rates of the c binomial populations. Often one uses the equally spaced scores $v_{ij} = j$ for all i.

We shall assume that there exists no three-factor interaction between rows, columns, and strata, although an analogue of Zelen's test does exist for assessing homogeneity in $2 \times c$ tables. This is an extension of the exact test of homogeneity for 2×2 tables that we will discuss further on. Given that there is no three-factor interaction, we are interested in testing the null hypothesis that the row and column classifications in each stratum are independent. This is known as the hypothesis of conditional independence. One can show that, for both the two multinomial and the c binomial settings under the null hypothesis of conditional independence, the probability of observing $\mathbf{y}$ given $\mathbf{y} \in \Lambda$ is

$$\Pr(\mathbf{y}|\mathbf{y} \in \Lambda) = \frac{\prod_{i=1}^{s} \prod_{j=1}^{c} \binom{n_{ij}}{y_{ij}}}{\prod_{i=1}^{s} \binom{N_i}{m_{i1}}}. \tag{21}$$

The exact one-sided P value for testing the null hypothesis of conditional independence is therefore

$$p_1 = \sum_{t(\mathbf{y}) \geq t(\mathbf{x})} \Pr(\mathbf{y}|\mathbf{y} \in \Lambda). \tag{22}$$

The exact two-sided P value is defined by reflecting the observed value of the test statistic an equal distant away from its mean in the opposite tail; see StatXact [48] for details.

Test for Interaction in 2 × c Tables

We wish to test whether the set of odds ratios (1) describing association between a binomial response and exposure, or (2) whether the set of odds ratios describing association between an ordered multinomial response and a dichotomous **covariate**, vary

across strata. This represents a generalization of the Breslow–Day and Zelen tests for homogeneity already described for the stratified 2×2 setting. These tests can be extended naturally regardless of the underlying sampling mechanism. However, as the derivation of these extension to $2 \times c$ tables differs for multinomial versus binomial sampling, we describe the underlying formulation for binomial data. A derivation for multinomial data is given in StatXact [48].

As before, the data are in the form of s $2 \times c$ contingency tables consisting of two rows, c columns, and s strata. Let π_{jk} be the "success" probability associated with population j in stratum k. We begin with a general logistic model for the binomial response probabilities. Specifically, consider the logistic regression model

$$\log\left(\frac{\pi_{jk}}{1-\pi_{jk}}\right) = \alpha_k + (\beta + \lambda_k)w_j. \tag{23}$$

Identifiability of model parameters requires a constraint such as $\sum_{k=1}^{s} \lambda_k = 0$ or $\lambda_1 = 0$. Denote the set of $s(c-1)$ odds ratios that describe associations in the $s \times 2 \times c$ table by

$$\Psi_{jk} = \frac{\pi_{jk}(1-\pi_{1k})}{\pi_{1k}(1-\pi_{jk})}, \tag{24}$$

$k = 1, \ldots, s$ and $j = 2, 3, \ldots, c$. The model yields the odds ratio model

$$\log \Psi_{jk} = (\beta + \lambda_k)w_j, \tag{25}$$

so that the stratum specific sets of $(c-1)$ odds ratios describing association between rows and columns are allowed to vary across strata. Given model (23) and the **identifiability** constraint $\lambda_1 = 0$, the null hypothesis of no interaction across strata is

$$H_0 : \lambda_2 = \cdots = \lambda_s = 0. \tag{26}$$

An asymptotic test can be derived using likelihood-based methods. For binomial data, such a test compares the logistic model (23) that includes the appropriate interaction terms to the logistic model that does not.

Whether the data arise from binomial or multinomial populations, an exact test of interaction is derived by considering a restricted conditional reference set $\Lambda^I = \{\mathbf{y} \in \Lambda : \sum_i \sum_j w_{ij} y_{ij} = t\}$, where Λ is the conditional reference set given in (19), and $t = \sum_i \sum_j w_{ij} x_{ij}$. This additional constraint ensures the elimination under H_0 of all nuisance parameters contained in either the logistic model for stratified binomial populations or the loglinear model for stratified multinomial populations. A probability length test can therefore be carried out by ordering the tables in Λ^I according to their hypergeometric probabilities under the null hypothesis of no interaction. This framework provides a generalization of Zelen's test to stratified $2 \times c$ tables. Further details are given in StatXact [48].

Stratified $2 \times c$ Contingency Tables with Clustered Data

When the data arise from cluster-correlated binomial populations, the dependence among observations within clusters leads to what is known as "extrabinomial variation" or **"overdispersion"** (e.g. see [38], Chapter 6). An investigator must account for this extra variability to obtain an accurate P value. If the researcher naively treats observations within a cluster as independent – for example, by collapsing over the clusters and using the standard trend test already discussed – the most common result is an anticonservative P value, or a P value that is inaccurately smaller due to an artificial inflation of sample size. The question, however, is fundamentally the same as the one addressed in introducing the trend test for several ordered binomial populations described previously: is there an increasing (or decreasing) average success rate for increasing levels of the risk factor under investigation? Many well-known methods may be employed in evaluating this hypothesis for clustered binomial data, including **random-effects** models and **marginal models**. However, these methods are justified by large-sample distributional approximations, and they may fare poorly with samples that are small or sparse.

The formulation is slightly different from that shown in Table 5. In this case, in the ith stratum, there are c_i clusters, with all members of any one cluster exposed to some distinct level of the **risk factor** of interest. The exposure level for the jth cluster in stratum i is quantified by the "score" w_{ij}. The data can hence be represented in stratified form as a collection of s tables, where the ith of these tables is $2 \times c_i$. Note that j is always indexed over $j = 1, \ldots, c_i$, and i is always indexed as $i =$

Table 6 Layout for the ith of s $2 \times c_i$ contingency tables comprised of cluster-correlated binary populations

	Stratum k				
Rows	Col_1	Col_2	...	Col_c_k	Row-total
Row_1	y_{1k}	y_{2k}	...	$y_{c_k k}$	m_k
Row_2	y'_{1k}	y'_{2k}	...	$y'_{c_k k}$	m'_k
Col-total	n_{1k}	n_{2k}	...	$n_{c_k k}$	N_k
Col-score	w_{1k}	w_{2k}	...	$w_{c_k k}$	

$1, \ldots, s$. The ith such table is displayed in Table 6. For unstratified data, $s = 1$.

The tabular representation of stratified *uncorrelated* binomial populations shown in Table 5 has an equal number of populations across strata, where the number of populations is determined by the number of exposure levels. In the case of *correlated* binomial data, however, the number of populations for a given stratum is equal to the number of clusters within that stratum. Hence, the number of populations may differ from stratum to stratum.

In addition, the conditional inference for clustered binomial data varies slightly from that described for uncorrelated data. First, for notational convenience, let

$$u = \sum_{i=1}^{s} \sum_{j=1}^{c_i} y_{ij} y'_{ij}. \tag{27}$$

Analogous to (19), we define the reference set Λ^C as all possible three-way collections of $2 \times c_i$ contingency tables – for $i = 1, \ldots, s$ – whose row and column margins are fixed at the corresponding values of the observed three-way collection of tables, **x**, displayed above, with one additional constraint:

$$\Lambda^C = \left\{ \mathbf{y}\text{: } \mathbf{y} \text{ is } 2 \times c_i \ \forall i;\ y_{ij} + y'_{ij} = n_{ij},\ \forall\ i, j; \right.$$
$$\left. \sum_{i=1}^{c_i} y_{ij} = m_i, \sum_{i=1}^{s} \sum_{j=1}^{c_i} y_{ij} y'_{ij} = u \right\}. \tag{28}$$

The primary difference between the Λ defined in (19) for independent data and Λ^C defined here is the additional constraint that $\sum_{i=1}^{s} \sum_{j=1}^{c_i} y_{ij} y'_{ij} = u$. This conditions out the nuisance overdispersion effect (or the effect due to extra variation) induced by dependence among observations within clusters. Corcoran et al. [14], show that this conditioning leads to a distribution of **Y** that is known, thereby making exact inference possible even where the binomial populations are clustered. Under the null hypothesis of no row and column interaction, the probability of observing any specific $\mathbf{y} \in \Lambda^C$ is

$$\Pr(\mathbf{Y} = \mathbf{y}) = P(\mathbf{y}) = \prod_{i=1}^{s} \frac{m_i! m'_i! \Pi_{j=1}^{c_i} n_{ij}!}{N_i! \Pi_{j=1}^{c_i} y_{ij}! y'_{ij}!}. \tag{29}$$

The linear rank test statistic for clustered binomial data has a form similar to (20):

$$T = \sum_{i=1}^{s} \sum_{j=1}^{c_i} w_{ij} Y_{ij}, \tag{30}$$

where the w_{ij} are chosen to accurately reflect the effect of exposure on the average response probability. As in the uncorrelated case, the observed statistic $t^* = \sum_{i=1}^{s} \sum_{j=1}^{c_i} w_{ij} y_{ij}$ will be used to test the null hypothesis that there is no association between the two rows and c_i columns of each of the s strata. This inference is based on assessing how extreme the observed statistic t^* is relative to other values of t that could have been observed under the null hypothesis of interest. Analogous to the uncorrelated case, in making this assessment, it is convenient to restrict attention to all possible values of $\mathbf{y} \in \Lambda^C$. With the possible values of the test statistic arising from Λ^C ordered, and their exact probabilities determined from (29), the one-sided P value is computed in a manner identical to that shown in (22), and the exact two-sided P value is defined by reflecting the observed value of the test statistic an equal distant away from its mean in the opposite tail; see StatXact [48] for details.

Calculating Exact Power and Sample Size

For unstratified 2×2 and $2 \times c$ contingency tables, we can compute the **power** of the exact test versus a specific **alternative hypothesis**. However, this is a somewhat more computationally challenging problem in comparison to exact conditional inference, as power must be calculated unconditionally.

For example, suppose that an investigator wishes to compare a new drug to a standard therapy, and hence plans an experiment where 50 subjects will be randomized to each of the two treatment groups (*see* **Clinical Trials, Overview**). Note that before the

trial is complete the investigator does not know how many of the 100 subjects will exhibit a response. Once the trial is finished, there are legitimate reasons to condition on the total number of responses (e.g. the ancillarity principle, the sufficiency principle, and the randomization principle) in order to compare the success probabilities of the two regimens. However, when assessing the power of the study *a priori* against a specific alternative, the investigator must consider all 101 possible outcomes: there may be any number of total responses between 0 and 100.

We illustrate first by describing exact unconditional power computations for comparing two binomial proportions, and then for comparing several ordered binomial proportions against an ordered alternative. Such calculations are also available for two ordered multinomial populations, although we do not describe this derivation here (see [23]).

Exact Power when Comparing two Binomial Populations

Consider first the problem of sampling from two independent binomial populations, where π_j is the binomial probability, n_j is the sample size, and x_j is the binomial response of population j, $j = 1, 2$. The observed data may thus be represented as a single 2×2 contingency table, an example of which is shown in Table 4.

We wish to compute the power of tests of the null hypothesis

$$H_0 : \pi_1 = \pi_2 \equiv \pi \tag{31}$$

versus the two-sided alternative hypothesis

$$H_1 : \pi_1 \neq \pi_2 \tag{32}$$

at fixed sample sizes n_1 and n_2.

As discussed previously, the exact probability of $\boldsymbol{x}$ under H_0, conditional on $x_1 + x_2 = m$, is given by

$$\Pr(\boldsymbol{x}|m, H_0) = \frac{\binom{n_1}{x_1}\binom{n_2}{x_2}}{\binom{N}{m}}. \tag{33}$$

Notice that (33) does not depend on the common null response probability π. Thus, this probability need not be specified for purposes of calculating power. The two response probabilities π_1 and π_2 are, however, needed to evaluate the probability of $\boldsymbol{x}$ under H_1.

We will only be concerned here with two-sided tests. To test (31) versus (32), we will consider Fisher's exact test, Pearson's exact test, and the likelihood ratio exact test. For notational convenience, we will denote all three of these statistics by the symbol T.

Our goal is to compute the exact power of two-sided level-α tests based on the statistic T. Recalling that the sample sizes n_1 and n_2 are already fixed, let

$$\Gamma_m = \{\boldsymbol{x} : \; x_1 + x_2 = m\} \tag{34}$$

and define its **critical region**

$$\Gamma_m(t) = \{\boldsymbol{x} \in \Gamma_m : \; T \geq t\}. \tag{35}$$

The exact null distribution of T may then be obtained by evaluating

$$\Pr(T \geq t|m, H_0) = \sum_{\boldsymbol{x} \in \Gamma_m(t)} \left[\frac{\binom{n_1}{x_1}\binom{n_2}{x_2}}{\binom{N}{m}} \right], \tag{36}$$

for each possible value of t.

Let α be the maximum allowable type-1 error and $t_\alpha(m)$ be the smallest possible cut-off such that

$$\Pr(T \geq t_\alpha(m)|m, H_0) \leq \alpha. \tag{37}$$

The *conditional* power is defined as

$$\Pr(T \geq t_\alpha(m)|m, H_1) = \sum_{\boldsymbol{x} \in \Gamma_m(t_\alpha(m))} \times \left[\frac{\prod_{j=1}^{2} \binom{n_j}{x_j} \pi_j^{x_j} (1 - \pi_j)^{n_j - x_j}}{\sum_{\boldsymbol{x} \in \Gamma_m} \prod_{j=1}^{2} \binom{n_j}{x_j} \pi_j^{x_j} (1 - \pi_j)^{n_j - x_j}} \right]. \tag{38}$$

Denote this conditional power by $\beta(m)$. Finally, the *unconditional* power is defined as

$$\beta = \sum_{m=0}^{N} \beta(m) P(m) \tag{39}$$

where

$$P(m) = \Pr(x_1 + x_2 = m|H_1), \tag{40}$$

a convolution of two binomials under H_1. It is relatively straightforward to compute (39) as only 2×2 tables are involved.

Example Suppose $n_1 = n_2 = 5$. The exact distribution of Pearson's statistic, conditional on $x_1 + x_2 = 5$, is given in Table 7 under both the null hypothesis ($\pi_1 = \pi_2 \equiv \pi$), and under the alternative hypothesis ($\pi_1 = 0.2, \pi_2 = 0.8$). Note that the null distribution does not depend on the common value of π, which need not be specified.

From these distributions, it is clear that $t_{0.05}(5) = 10$ so that $\beta(5) = 0.336$. That is, the exact conditional power of Pearson's test conducted at the 5% significance level, given $m = 5$, is 34%. Unconditional power is a weighted sum of conditional powers, one for each value of m, as computed by (39). Table 8 displays each possible value of m, its weight, and the corresponding conditional power. Values of m whose contributions to total power are less than 0.00001 have been ignored in this table as they will not affect the first three decimal digits of the answer.

The exact unconditional power is thus

$$\beta = \sum_{m=0}^{9} \beta(m) P(m) = 0.376 \tag{41}$$

Table 7 Exact conditional distributions under null and alternative hypotheses for comparing two independent binomial populations

t	$\Pr(T \geq t \mid 5, H_0)$	$\Pr(T \geq t \mid 5, H_1)$

10	0.181	0.001

This idea has been extended to power and sample size computations for two ordered multinomial populations by Hilton and Mehta [23], and to several ordered binomial populations by Mehta et al. [35]. Corcoran [15] extend this latter work to compare the exact operating characteristics of the exact trend test versus the asymptotic trend test (*see* **Trend Test for Counts and Proportions**). Further details can be found in StatXact [48].

Unconditional Exact Inference for 2 × 2 Tables

To this point, we have based our inference on conditioning to eliminate nuisance parameters under the null hypothesis. It is possible also, though computationally much more challenging, to eliminate nuisance parameters unconditionally. Because of the relatively greater computational complexity required for unconditional exact inference, such tools are not yet widely available aside from those used to analyze 2×2 tables. We describe one such method here.

We are interested in comparing two population proportions. The starting point is the 2×2 contingency table, $\boldsymbol{x}$, displayed as Table 4 with $s = 1$. As we consider only a single stratum, for convenience, we will drop the subscript i. Without loss of generality, suppose that the row variable specifies the "outcome" of interest, so that we may consider the column totals n_1 and n_2 fixed by design. Then x_1 and x_2 are realizations, respectively, of Binomial(n_1, π_1) and Binomial(n_2, π_2) random variables, where π_1 and π_2 individually represent the outcome probabilities for each population. We wish to test

$$H_0: \pi_1 = \pi_2 = \pi, \tag{42}$$

against two-sided alternatives of the form

$$H_2: \pi_1 \neq \pi_2. \tag{43}$$

Recall that this table was created by taking n_j independent Bernoulli samples from population j, and observing x_j successes, $j = 1, 2$. The unconditional probability of observing $\boldsymbol{x}$ under H_0 is $f_0(\boldsymbol{x})$, specified by (17) with $\Psi = 1$. In order to compute an exact P value, we need to specify a reference set of 2×2 contingency tables and sum the probabilities of tables that are at least as extreme as $\boldsymbol{x}$ in it. For conditional inference, we used the reference set Ω in which both the row and column sums of the 2×2

tables were fixed at their observed values. Unconditional inference uses a larger reference set of 2×2 contingency tables in which only the column sums, or the binomial sample sizes, are fixed. The row sums are treated as random variables. Denote this reference set by

$$\Omega^* = \{\boldsymbol{y}\colon y_j + y_j = n_j,\ j = 1, 2\}, \qquad (44)$$

and order each table $\boldsymbol{y} \in \Omega^*$ according to the test statistic

$$D(\boldsymbol{y}) = \frac{\hat{\pi}_2 - \hat{\pi}_1}{\sqrt{\left(\frac{y_1 + y_2}{N}\right)\left(\frac{y_1 + y_2}{N}\right)\left(\frac{1}{n_1} + \frac{1}{n_2}\right)}}, \qquad (45)$$

where $\hat{\pi}_j = y_j/n_j$, $j = 1, 2$. If $y_1 = y_2 = 0$, or $y_1 = y_2 = 0$, set $D(\boldsymbol{y}) = 0$. The denominator of (45) is the **standard error** of the observed difference of binomial proportions under the null hypothesis. Therefore, the statistic $D(\boldsymbol{y})$ has a mean of 0 and variance of one under H_0. A large positive value for the observed statistic $D(\boldsymbol{x})$ furnishes evidence against H_1, while a large negative value furnishes evidence against H_1'.

The exact P value is the sum of probabilities of all tables $\boldsymbol{y} \in \Omega^*$ that are more extreme than the observed table $\boldsymbol{x}$ with respect to the test statistic (45). The trouble is that each such extreme table has a probability $f_0(\boldsymbol{y})$, which, by (17), depends on the unknown nuisance parameter, π. In our previous discussion of conditional inference, we were able to eliminate the nuisance parameter by conditioning on its sufficient statistic, m_1. But we can no longer do so because we have specified Ω^* rather than Ω to be the reference set. For exact unconditional inference, we utilize a different argument to eliminate π. We consider all possible values of π in its range and select that value, which produces the largest P value. This produces a conservative answer so that no matter what the true value of π might be, the type-1 error of the test cannot exceed its nominal significance level.

The main advantage of using Ω^* is that it is larger than Ω. Consequently, the distribution of any test statistic usually has more support points if it is defined on Ω^* rather than on Ω. This reduces conservatism, since it is possible to construct exact hypothesis tests whose true significance levels come closer to their nominal significance levels under Ω^* than they do under Ω. The main disadvantage is that the nuisance parameter, π, can only be eliminated by considering all possibilities in its range and catering to the worst case. This increases the conservatism of the hypothesis test. There is thus a trade-off between the advantage gained by enriching the reference set and the disadvantage of catering to the worst case for the nuisance parameter. For a single 2×2 contingency table, Mehta and Hilton (1993) [29] have shown that, on balance, the gain in power from using Ω^* outweighs the loss in power because of catering to the worst case. They go on to show, however, that this advantage quickly evaporates as the dimensions of the table increase from 2×2 to 2×3.

We compute the P value in two stages. At the first stage, we express the P value as a function of π. Then, at the second stage, we obtain the supremum of this function over all values of $\pi \in (0, 1)$. We use this supremum as the P value. Since the P value based on the actual value of π can never exceed the supremum over all possible values of π, this procedure guarantees that the type-1 error will always be preserved. In effect, we compute a conservative P value that will preserve the desired type-1 error rate no matter what the true value of π might be, since it is designed to cater for the worst case.

This test is known as Barnard's test, named after George Barnard who first proposed it as an alternative to Fisher's exact test amidst some controversy. (See [7, 8, 9, 10, 52] for interesting philosophical discussions and references). Its critical values for exact testing of H_0 have been tabulated by Suissa and Shuster (1985) [50]. A proposed restriction by Berger and Boos [11] adds stability and reduces the conservatism of the procedure.

Computational Issues

Computing quantities such as (3) is nontrivial. When analyzing an $r \times c$ table, for instance, the size of the reference set grows exponentially so that explicit enumeration of all the tables in Γ soon becomes computationally infeasible. For example, the reference set of all 5×6 tables with row sums of (7, 7, 12, 4, 4) and column sums of (4, 5, 6, 5, 7, 7) contains 1.6 billion tables. Yet, the tables in this reference set are all rather sparse and unlikely to yield accurate P values based on large-sample theory. Network algorithms have been developed by Mehta, Patel, and

coworkers, [30–32, 34, 36] to enumerate the tables in Γ implicitly. In these algorithms, the reference set is represented by a network of nodes and arcs. A sequence of connected arcs from the starting to the terminal node constitutes a path through the network. Each such path represents one and only one table in Γ. The length of a path equals the value of the test statistic for the table to which that path corresponds. The probability of the path equals the probability of the corresponding table. Thus, the problem of computing an exact P value is equivalent to the problem of identifying paths whose lengths equal or exceed a specified value, and summing the probabilities of all these paths. This can be accomplished by well-known **operations research** techniques such as backward induction and forward probing through the network. These methods are very efficient and make it feasible to compute exact P values.

Alternate approaches are provided by Pagano and Halvorsen [39], Pagano and Tritchler [40], Streitberg and Rohmel [49], Baglivo, Olivier and Pagano [6], Vollset, Hirji, and Elashoff [51], and Cheung and Klotz [13]. Sometimes a data set is too large even for implicit enumeration, yet it is sufficiently sparse that the asymptotic results are suspect. For such situations, a Monte Carlo estimate and associated 99% confidence interval for the exact P value may be obtained. In the Monte Carlo method, tables are sampled from Γ in proportion to their hypergeometric probabilities (2), and a count is kept of all the sampled tables that are more extreme than the observed table. For details, refer to [4, 33, 41] and [45].

Analysis of Data Sets

In this section, we will illustrate the techniques developed in the previous sections with some data analyses. Each example will highlight the different conclusions one might draw if an asymptotic analysis were performed instead of an exact analysis. A large number of additional examples are available at the Cytel web site `http://www.cytel.com`. All results were obtained by the StatXact-3 software package [48].

An Unordered Contingency Table

Data were obtained on the location of oral lesions, in house to house surveys in three geographic regions of rural India, by Gupta, Mehta, and Pindborg [22]. Consider a hypothetical subset of these data displayed by Table 9 as a 9×3 contingency table in which the counts are the number of patients with oral lesions per site and geographic region.

The question of interest is whether the distribution of the site of the oral lesion is significantly different in the three geographic regions. The row and column classifications for this 9×3 table are clearly unordered, making it an appropriate data set for either the Fisher, Pearson, or likelihood ratio tests. The exact and asymptotic P values are displayed in Table 10. There are striking differences between the two methods. The exact analysis suggests that the row and column classifications are dependent, but the asymptotic analysis fails to show this.

A Singly Ordered Contingency Table

The tumor regression rates of five chemotherapy regimens, Cytoxan (CTX) alone, Cyclohexylchloroethyl nitrosourea (CCNU) alone, Methotrexate (MTX) alone, CTX + MTX, and CTX + CCNU + MTX were compared in a small clinical trial. Tumor regression was measured on a three-point scale: no response, partial response, or complete response. The results are tabulated in Table 11.

Table 9 Oral lesions data

Site of Lesion	Kerala	Gujarat	Andhra
Labial mucosa	0	1	0
Buccal mucosa	8	1	8
Commissure	0	1	0
Gingiva	0	1	0
Hard palate	0	1	0
Soft palate	0	1	0
Tongue	0	1	0
Floor of mouth	1	0	1
Alveolar ridge	1	0	1

Table 10 Exact and asymptotic P values for oral lesions data

	Three tests of independence		
Type of inference	Pearson	Fisher	Likelihood ratio
Value of $D(\boldsymbol{x})$	22.1	19.72	23.3
Asymptotic P value	0.1400	0.2331	0.1060
Exact P value	0.0269	0.0101	0.0356

Table 11 Chemotherapy pilot study data

Chemo	No resp.	Partial resp.	Complete resp.
CTX	2	0	0
CCNU	1	1	0
MTX	3	0	0
CTX + CCNU	2	2	0
CTX + CCNU + MTX	1	1	4

Small pilot studies like this one are frequently conducted as a preliminary to planning a large-scale randomized clinical trial. For such data, the Kruskal–Wallis test may be used to determine whether or not the five drug regimens are significantly different with respect to their tumor regression rates. The observed value of the Kruskal–Wallis statistic for this table is 8.682. Referring this value to a chi-square distribution with four degrees of freedom yields an asymptotic P value of 0.0695, which is not significant at the 0.05 level. However, on the basis of the permutation distribution of the Kruskal–Wallis statistic, the exact P value is 0.039, which is statistically significant.

Analysis of Stratified 2 × 2 Contingency Tables

Testing the Homogeneity of Odds Ratios. The binary response data tabulated in Table 12 compare a new drug with a control drug at 22 hospital sites.

The data can be thought of as twenty-two 2×2 contingency tables, one for each site. If you examine the 2×2 tables carefully, you notice that site 15 appears to be different from the others. Whereas all the other sites have a low response rate for both the new drug and the control drug, the response rate of the control drug is 79% at site 15. The Homogeneity test can tell you whether the observed difference at site 15 is a real difference or whether it is just a chance fluctuation due to a small sample. Because of the sparseness in the data, the asymptotic (Breslow–Day) statistic might not yield an accurate P value. The exact (Zelen) test is preferred. The exact P value is 0.0135. Thus, we reject the null hypothesis that there is a common odds ratio across the 22 sites. The data strongly suggest that the odds ratio at site 15 is different from the other odds ratios. The asymptotic (Breslow–Day) P value is much larger (0.0785) and is only marginally significant.

Table 12 Site by treatment interaction data

Test site	New drug		Control drug		Test site	New drug		Control drug	
	Resp	No	Resp	No		Resp	No	Resp	No
1	0	15	0	15	12	0	12	1	11
2	0	39	6	32	13	0	24	5	19
3	1	20	3	18	14	2	10	2	11
4	1	14	2	15	15	0	14	11	3
5	1	20	2	19	16	0	53	4	48
6	0	12	2	10	17	0	20	0	20
7	3	49	10	42	18	0	21	0	21
8	0	19	2	17	19	1	50	1	48
9	1	14	0	15	20	0	13	1	13
10	2	26	2	27	21	0	13	1	13
11	0	19	2	18	22	0	21	0	21

Estimating the Common Odds Ratio

The court case of Hogan versus Pierce [20] involved the minority hiring data displayed in Table 13.

The most notable feature of these data is that at each hiring opportunity not a single black was hired, whereas small numbers of whites were hired. This makes it impossible to use the usual large-sample maximum likelihood or Mantel–Haenszel [28] methods for estimating the odds of being hired for whites relative to blacks. These methods simply fail to converge. Only the exact method provides a valid answer and it shows that the odds of being hired for a white relative to a black are no lower than 2.3 to 1, with 95% confidence.

Table 13 Minority hiring data

Date of hire	Whites		Blacks	
	Hired	Not	Hired	Not
7/74	4	16	0	7
8/74	4	13	0	7
9/74	2	13	0	8
4/75	1	17	0	8
5/75	1	17	0	8
10/75	1	29	0	10
11/75	2	29	0	10
2/76	1	30	0	10
3/76	1	30	0	10
11/77	1	33	0	13

Test of Trend in Stratified 2 × c Contingency Tables

The data for this example were provided by the US Food and Drug Administration (FDA). Animals were treated with four dose levels of a carcinogen and then observed (at necropsy) for the presence or absence of a tumor type. The data were stratified by survival time (in weeks) into the four time-intervals 0 to 50, 51 to 80, 81 to 104, and terminal sacrifice. Since there were no tumors found in the first time-interval, this stratum may be excluded from data entry. The data for the remaining three strata are displayed in Table 14.

We use the stratified Cochran–Armitage trend test (Breslow and Day [12], p. 148) to determine if there is a **dose-response** relationship between the level of carcinogen and the presence of tumors. The test statistic is defined by (20), where v_{ij} is the dose-level of carcinogen and y_{ij} is the number of animals with tumors, at the jth dose level in the ith stratum. The results are tabulated in Table 15.

Table 14 FDA Animal toxicology data

Stratum 1: 51–80 weeks of survival					
	Dose of carcinogen				
Disease status	None	1 unit	5 units	50 units	Total
Tumor present	0	0	0	1	1
Tumor absent	7	10	6	8	31
Stratum 2: 81–104 weeks of survival					
	Dose of carcinogen				
Disease status	None	1 unit	5 units	50 units	Total
Tumor present	0	1	0	1	2
Tumor absent	11	9	13	14	47
Stratum 3: Sacrificed at end of 104 weeks					
	Dose of carcinogen				
Disease status	None	1 unit	5 units	50 units	Total
Tumor present	1	1	1	2	5
Tumor absent	29	26	28	20	103

Table 15 One and two-sided P values for FDA data

P values	One-sided	Two-sided	Double one-sided
Exact	0.0651	0.0769	0.1302
Asymptotic	0.0410	0.0820	0.0820

There are large differences between the exact and asymptotic one-sided P values, and they lead to different conclusions about the significance of the dose-response relationship. They also show that the usual practice of doubling the one-sided P value is unnecessarily conservative with asymmetric distributions. But the most interesting finding of all is that the distribution of the linear rank statistic (20) has multiple towers. A normal approximation would be seriously misleading. This is shown in Figure 1.

Software and Related Resources for Exact Inference

We have presented the essential idea behind exact permutational inference, described one numerical algorithm, referenced others, and shown through several examples that exact inference is a valuable supplement to corresponding asymptotic methods.

Software support for these methods is available in many standard packages including StatXact [48], LogXact [26], SPSS Exact Tests [47], and SAS Version 9 [44]. A brief description of the StatXact and LogXact software packages is given elsewhere (*see* **StatXact**).

Some of the newer textbooks on nonparametric methods, for example, [1, 17, 21, 27, 46] devote considerable space to exact and Monte Carlo methods of inference for **categorical data**. A useful survey paper, in which a unified treatment of exact inference for categorical data is presented through the **loglinear model**, was recently published by Agresti

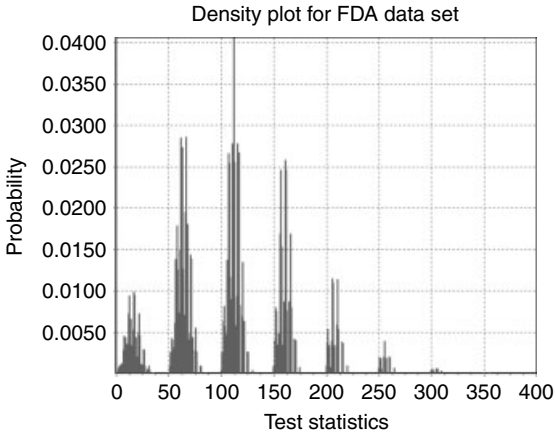

Figure 1 Distribution of trend test statistic for FDA data

[2]. A complete collection of references to statistical methodology, numerical algorithms, commercial software, shareware, and textbooks on exact permutational inference can be obtained by visiting the ExactStats worldwide web site on the Internet. The address is `http://jiscmail.ac.uk/lists/exact-stats.html`.

Excess Mortality

In the modeling of mortality in clinical or epidemiologic studies, it is sometimes relevant to use the mortality of the general population as a reference for comparisons. Rather than establishing a reference sample of the general population from which the study sample is drawn, one usually relies on published life tables and includes the population mortality rate as a known function in the model for the survival times in the study group. Two classes of hazard rate models have been studied in some detail: *multiplicative hazard rate* models, in which the mortality of the study group is described by multiplying the reference rate by some parameter, *the relative mortality*, which may further depend on specific risk factors or follow-up time; and **additive hazard rate** *models*, in which the reference rate is modified by adding a parameter, *the excess mortality*, which again may depend on specific risk factors or follow-up time. Multiplicative models are related to calculation of *standardized mortality ratios* (SMR), a technique that has been employed by epidemiologists for many years (*see* **Standardization Methods**). However, additive models may be viewed as the theoretical basis for calculation of *relative survival* and the *corrected survival curve*.

In a simple additive hazard rate model, the mortality rate $\lambda_i(t)$ of an individual $i, i = 1, \ldots, n$, in the sample satisfies

$$\lambda_i(t) = \mu_i(t) + \gamma(t),$$

where $\mu_i(t)$ is the *known* population rate at time t for an individual of the same sex and born in the same year as individual i. The excess mortality $\gamma(t)$ is assumed common for all individuals in the sample. The integrated excess mortality is defined as

$$\Gamma(t) = \int_0^t \gamma(u)\,\mathrm{d}u.$$

Unlike the multiplicative model, which is mainly a descriptive means for relating the observed mortality in a sample to population mortality rates, the additive model may be given an interpretation in a **competing risk** framework when the excess mortality rate is positive. If the sample consists of individuals suffering from a given disease, one may consider using the population mortality rate for all other causes of deaths as the known rate $\mu_i(t)$ and the excess rate $\gamma(t)$ will then represent mortality due to the disease. In this situation, the model may therefore permit estimation of *cause-specific mortality* without relying on information about cause of death.

For a sample of individuals $i = 1, \ldots, n$, let x_i denote the time of entry and $X_i \geq x_t$ the survival time (in which case $D_i = 1$) or **censoring** time (in which case $D_i = 0$). In a clinical setting the time t would usually be time since treatment and x_i is typically zero, but the model could also be used with age as the underlying time scale and then left truncation, i.e. $x_i > 0$, will often be present. Define $N(t)$ to be the observed number of deaths in $[0, t]$ and let $Y(t)$ denote the number at risk at time t:

$$Y(t) = \sum_{i=1}^{n} Y_i(t) = \sum_{i=1}^{n} I(x_i < t \leq X_i).$$

Following Andersen & Væth [2], the integrated excess mortality may be estimated by

$$\hat{\Gamma}(t) = \sum_{X_i \leq t} \frac{D_i}{Y(X_i)} - \int_0^t \mu^*(u)\,\mathrm{d}u.$$

The first term is the ordinary **Nelson–Aalen** estimate, and the second term is the integral of the average population mortality rate, $\mu^*(u)$, defined for each u as the average of the population mortality rates corresponding to the individuals at risk at time u

$$\mu^*(u) = \frac{1}{Y(u)} \sum_{i=1}^{n} \mu_i(u) Y_t(u).$$

The variance of $\hat{\Gamma}(t)$ can be estimated by

$$\sum_{X_i \leq t} \frac{D_i}{[Y(X_i)]^2}$$

An estimate of the excess mortality rate $\gamma(t)$ can be obtained by kernel smoothing techniques (see, for example, Andersen et al. [3, Section IV.4.2]) (*see* **Smoothing Hazard Rates**). The survival function

$$S^*(t) = \exp\left(-\int_0^t \mu^*(u)\,\mathrm{d}u\right)$$

derived from the hazard rate $\mu^*(t)$ may be viewed as a continuous time generalization of the so-called Ederer Method II for calculation of the *expected survival curve*, which, unlike Ederer Method I, adjusts for deaths and censoring during follow-up (see [6]

or [10]). Furthermore, an estimate of the "survival" function

$$\exp\left(-\int_0^t \gamma(u)\,\mathrm{d}u\right)$$

for the excess mortality is obtained as the *relative* survival function $\hat{S}(t)/S^*(t)$.

A *parametric* version of the simple additive hazard rate model above has been studied by Buckley [4], who considered **maximum likelihood** estimation in a model *with piecewise constant excess mortality rate*. An iterative procedure is required to solve the likelihood equations, but simple, explicit moment estimates are also available (*see* **Method of Moments**). For the special case with a constant excess mortality rate γ for all $t \in [0, \tau]$, $\tau < \infty$ denoting an upper limit for the observed survival times, one may show [2, 4] that the maximum likelihood estimate is the solution to

$$\sum_{i=1}^{n} \frac{D_i}{\hat{\gamma} + \mu_i(X_i)} = T(\tau),$$

where

$$T(\tau) = \int_0^\tau Y(u)\,\mathrm{d}u = \sum_{i=1}^{n}(X_i - x_i)$$

is the total number of *person–years at risk* during follow-up (i.e. the **total time on test**). The moment estimate is simply

$$\tilde{\gamma} = \frac{N(\tau) - \mathrm{E}(\tau)}{T(\tau)},$$

where

$$\mathrm{E}(\tau) = \sum_{i=1}^{n} \int_0^\tau \mu_i(u) Y_i(u)\,\mathrm{d}u$$

may be interpreted as the expected number of deaths during follow-up, and the moment estimate is therefore the excess number of deaths divided by the total time at risk. The variance of the estimate $\tilde{\gamma}$ can be estimated by

$$\frac{N(\tau)}{[T(\tau)]^2}.$$

Within the framework of parametric models, standard large-sample methods provide **goodness of fit** tests for the constant excess mortality model relative to a piecewise constant excess mortality. Alternatively, generalized *total time on test procedures* are available for assessing the goodness of fit of a constant excess mortality rate (see [2] and [3, Section VI.3.2–3]).

Both parametric and nonparametric regression models generalizing the simple, additive excess mortality model have been developed. The parametric models for the excess mortality rate include, among others, **loglinear regression** models studied by Pocock et al. [8] and Hakulinen & Tenkanen [7], and a linear regression model considered by Campbell [5]. A semiparametric **proportional hazards** regression model for the excess rate has been proposed and studied by Sasieni [9], and Zahl [11] has introduced a linear nonparametric regression model for the excess rate, generalizing Aalen's linear hazard regression model [1].

MICHAEL VÆTH

Excess Relative Risk

Relative risks are commonly used to describe the relationship between the **risks** or rates in different populations. For populations with risks R_0 and R_1, the relative risk is $RR = R_1/R_0$. In many situations, it is useful to describe R_1 as $R_0 + E$, where E is the excess risk. In this case we have $RR = (R_0 + E)/R_0 = 1 + ERR$, where *ERR* represents the excess relative risk. The most commonly used approach to modeling relative risks involves **loglinear models** of the form $RR = e^{\beta z}$. But it is often useful, especially in **dose–response** analyses, to model the *ERR* directly.

When exposures vary over a broad range, simple *ERR* models (e.g. linear in dose) can provide a clearer, and in many cases better, description of the exposure effect on the risk than loglinear risk models. Ratios of *ERR*s are more appropriate than ratios of *RR*s as a summary of the impact of exposure. **Effect modification** and analyses of the joint effects of multiple exposures (*see* **Synergy of Exposure Effects**) are often expressed more naturally in terms of effects on the *ERR* rather than as **interactions** in **multiplicative** relative risk models. For additional details about specific *ERR* models and issues related to the use of these models (*see* **Parametric Models in Survival Analysis**; **Poisson Regression in Epidemiology**).

DALE L. PRESTON

Excess Risk

The excess risk or rate in a population is the difference between the **risk** (rate) R_1 for a population exposed to some risk factor (e.g. radiation or smoking) and the risk R_0 in an otherwise identical population without the exposure. In simple terms the excess risk E is defined as $E = R_1 - R_0$. The excess risk is closely related to the **attributable risk** $AR = E/R_1$ and the **excess relative risk** $ERR = E/R_0$.

Since excess risk models involve the sum of background and excess risks, they are intrinsically additive, and it is common, though potentially confusing, to refer to them as **additive models**. The development of adequate excess risk models generally requires that the risk be modeled as a sum of nonlinear functions describing the background and excess risks. Models for both the background and excess risks often involve multiplicative functions of risk-modifying factors. In contrast to **relative risk models**, for which it is possible to use **semiparametric Cox regression models**, fitting excess risk models generally requires explicit parametric modeling of R_0 or specification of R_0 with external rates.

It is both feasible and useful, however, to model background rates directly for problems involving either excess or relative risk by using modern statistical methods, such as **Poisson regression**. (*See* **Parametric Models in Survival Analysis** for additional information on the modeling of excess risks.)

Relative risk models have come to dominate discussion of risk in epidemiologic studies. However, description in terms of excess risks and rates is important for: understanding the impact of an exposure on risk in a population; developing exposure standards to limit risks to the general public or to special groups; and developing and assessing mechanistic models of the effect of exposure on risk.

Historically, attention has focused on the comparison of simple (usually time-constant) excess and relative risk models [3]. However, when one makes use of more general classes of excess and relative risk models, it is best to view these models as complementary, rather than competing, descriptions of risk.

Excess risk and attributable risk can also be estimated from **population-based case–control studies** [1, 2].

Exchangeability

In probability theory, the **random variables** $Y_1, \ldots, Y_N$ are said to be *exchangeable* (or *permutable* or *symmetric*) if their joint distribution $F(y_1, \ldots, y_N)$ is symmetric; that is, if F is invariant under permutation of its arguments, so that

$$F(z_1, \ldots, z_N) = F(y_1, \ldots, y_N)$$

whenever $z_1, \ldots, z_N$ is a permutation of $y_1, \ldots, y_N$. There is a related epidemiologic usage which is described in the article on **confounding**. In many ways, sequences of exchangeable random variables play a role in subjective **Bayesian** theory analogous to that played by independent identically distributed (iid) sequences in classical frequentist theory. In particular, the assumption that a sequence of random variables is exchangeable allows the development of inductive statistical procedures for inference from observed to unobserved members of the sequence [1–3, 5, 6, 9].

Exchangeable random variables are identically distributed, and iid variables are exchangeable. Now suppose that $Y_1, \ldots, Y_N$ are iid given an unknown parameter θ that indexes their joint distribution (*see* **Identifiability**). Such variables will not be unconditionally independent when θ is a random variable, but will be exchangeable. Consider, for example, the case in which $Y_1, \ldots, Y_N$ have a joint density. The unconditional density of $Y_1, \ldots, Y_N$ will be

$$\begin{aligned} f(y_1, \ldots, y_N) &= \int_\theta f(y_1, \ldots, y_N|\theta)\ \mathrm{d}F(\theta) \\ &= \int \prod_i f(y_i|\theta)\ \mathrm{d}F(\theta). \end{aligned}$$

Exchangeability of $Y_1, \ldots, Y_N$ follows from the identity of the marginal densities in the product. However, given that these densities depend on θ, the integral and product cannot be interchanged, so that $f(y_1, \ldots, y_N) \neq \prod_i f(y_i)$. We thus have that a mixture of iid sequences is an exchangeable sequence, but not iid except in trivial cases.

One consequence of this result is that the usual procedures for generating a sequence $Y_1, \ldots, Y_N$ of iid random variables for inference on an unknown parameter (such as Bernoulli trials of **binary data** with unknown success probability) generate only an exchangeable sequence when the parameter is generated randomly and the sequence is considered unconditionally. From a Bayesian perspective, this means that, when your uncertainty about the parameter is integrated with your uncertainty about the realizations of $Y_1, \ldots, Y_N$, the latter are (for you) exchangeable but dependent. This subjective dependence is immediately clear if you consider (say) tossing a coin $N = 99$ times, with Y_i the indicator of heads on toss i. Starting from a **uniform prior** for the chance of heads, you should have $\Pr(Y_{99} = 1) = 1/2$ before seeing any toss, but

$$\Pr\left(Y_{99} = 1 \left| \sum_{i=1}^{98} Y_i = 98 \right.\right) = 0.99$$

after seeing the first 98 tosses come up heads [8].

A generalization important for statistical modeling is *partial* or *conditional* exchangeability [2, 3]. For example, suppose that the sequence $Y_1, \ldots, Y_N$ is partitioned into disjoint subsequences. Then the sequence is said to be partially exchangeable given the partition if each subsequence can be permuted without changing the joint distribution. If the Y_i represent survival times within a cohort of male stroke patients, then a judgment of unconditional exchangeability of the Y_i would be unreasonable if the patient ages were known, because age is a known predictor of survival time. Nonetheless, one might regard the survival times as partially exchangeable, given age, if no further prognostically relevant partitioning was possible based on the available data.

While exchangeability is weaker than iid, de Finetti [[3], Chapter 11] proved that finite subsequences of an infinite exchangeable sequence of Bernoulli (binary) variates must have representations as mixtures of iid Bernoulli sequences – a partial converse of the fact that any mixture of iid sequences is an exchangeable sequence. More precisely, suppose that $Y_1, Y_2, \ldots$ is an infinite sequence of exchangeable Bernoulli variates (that is, every finite subsequence of the sequence is exchangeable), and that θ is the limit of $(Y_1 + \cdots + Y_n)/n$ as n goes to infinity. De Finetti showed that there exists a distribution function $P(\theta)$ for θ such that, for all n,

$$\begin{aligned} \Pr(Y_1 = y_1, \ldots, Y_n = y_n) &\equiv \Pr(y_1, \ldots, y_n) \\ &= \int_0^1 \theta^s (1-\theta)^{n-s}\ \mathrm{d}P(\theta), \end{aligned} \tag{1}$$

where $s = y_1 + \cdots + y_n$. Many Bayesian statisticians find this theorem helpful, because it partially specifies the form of the predictive probability $\Pr(y_1, \ldots, y_n)$ when $Y_1, \ldots, Y_n$ can be considered a subsequence of an infinite exchangeable sequence.

In the representation shown in (1), $P(\theta)$ is recognizable as the *prior distribution* for θ, a distribution that may be developed from what is known about θ before the Y_i are observed. As noted in [7], however, the strength of the theorem's conclusion is easy to overstate: it does *not* imply that all binary data must be analyzed using the representation shown in (1); it merely says that if you judge $Y_1, Y_2, \ldots$ to be an exchangeable sequence, then there is a $P(\theta)$ that allows you to use (1) to specify $\Pr(y_1, \ldots, y_n)$.

Finite versions of the theorem [4] show that, if $Y_1, \ldots, Y_n$ is the start of an exchangeable Bernoulli sequence $Y_1, \ldots, Y_N$ and n/N is small enough, then $\Pr(y_1, \ldots, y_n)$ may be approximately expressed as in (1), with the approximation improving as n/N approaches zero. There are further generalizations to exchangeable sequences of **polytomous** variates, as well as exchangeable sequences of continuous variates [4]. The latter generalization requires a prior distribution on the space of continuous distributions, however, which can be much harder to specify than a prior for a vector of **multinomial** parameters, and which may lead to intractable computational problems [5].

Exclusion Mapping

Exclusion mapping is the identification of the location of a disease **gene** by excluding other possible genomic regions; it relies on the fact that informative meioses can provide evidence for or against linkage (*see* **Linkage Analysis, Model-based**; **Linkage Analysis, Model-free**). If a disease locus exists, then it must be somewhere in the genome. Therefore, if the disease locus is not linked to any of the regions that have already been considered, then it must be present elsewhere in the genome. By using the existing linkage information to define regions of exclusion, efforts can be focused on the remaining regions of the genome that are more likely to contain the gene. Of course, the strength of the evidence for or against linkage in a particular region must be taken into account, since a locus may be present in a region even if it is not detected (e.g. if the sample size is too small). Therefore, in order to create an exclusion map, one must define a measure of the strength of the evidence for or against linkage and a criterion that represents at most a small **likelihood** that the gene is contained in the region. This is done using the lod score.

Consider first the case in which there is a single family or a collection of families but no locus heterogeneity (i.e. a single disease locus predisposes to the disease). All informative meioses provide evidence for or against linkage to a particular location. The *absence* of recombination between a **marker** and the phenotype provides evidence *for* linkage to a particular region, while the *presence* of recombination consistent with a rate expected by chance (1/2 of meioses) provides evidence *against* linkage in that region. The lod score provides us with a yardstick to measure the strength of the evidence for or against linkage in the region. In the context of testing a single marker, the classic limit for exclusion is a lod score of -2 [9], which represents a $100:1$ **likelihood ratio** against linkage in the region. This criterion is quite stringent, and generally results in a small region of exclusion around a marker locus. Larger regions of the genome can be excluded by testing multiple markers that are located close together. In this case, a lod score of -2 is still considered sufficient evidence against linkage, despite the fact that multiple tests are performed.

In the presence of locus heterogeneity (*see* **Genetic Heterogeneity**) and more than one sampled family, exclusion mapping results are more difficult to interpret. The study sample may include some families that are linked to the region and some families that are not linked to the region. The lod score will reflect the proportion of linked families. Therefore, even if we find strong evidence against linkage in a region, a small proportion of the families may be, in fact, linked to the region. Since this is the case for **complex diseases**, evidence for linkage to a region is often more convincing than evidence against linkage to a region, and exclusion mapping is not helpful. Methods that allow for locus heterogeneity within the study sample, such as estimating the proportion of linked families in addition to the recombination fraction [10], may provide a way to use exclusion mapping when locus heterogeneity is present.

Programs that provide a visual representation of the excluded and nonexcluded regions include: Exclude [3], Lodview [5], and Mapmaker/Sibs [7]. In the Exclude program, the probability of containing the gene is computed for each chromosomal region. An equal prior probability of containing the gene for each chromosomal region is assumed. The posterior probability computed by this program incorporates the fact that if a gene is excluded from one region, then the probability must increase in the remaining regions. The Lodview program produces a graphical view to observe regions with a lod score less than -2 from data generated by programs such as Linkage [8]. The method implemented in Mapmaker/Sibs identifies regions of exclusion depending on particular model parameters such as λ_s, the locus-specific sibling recurrence **risk ratio**. Regions are excluded for a gene that confers susceptibility with λ_s greater than some pre-specified value. However, it may be difficult for a user to identify which regions have been excluded for the phenotype of interest because of the difficulty in accurately estimating λ_s [4].

Genes for several diseases have been mapped using exclusion mapping, including Marfan syndrome and Rett syndrome. Marfan syndrome is a connective tissue disorder that is inherited in an autosomal dominant fashion (*see* **Segregation Analysis, Classical**). Blanton et al. [2] produced an exclusion map for Marfan syndrome based on linkage data for 75 marker loci from nine contributing laboratories. Eleven **candidate** regions were suggested

from this analysis, including chromosome 15. Kainulainen et al. [6] found significant evidence for linkage (lod score = 3.92) to a region on chromosome 15 using eight Finnish families with Marfan syndrome, which was later found to include the fibrillin gene. Rett syndrome is a progressive neurodevelopmental disorder that causes mental retardation. Because this disorder is found almost exclusively in females, it was suggested that Rett syndrome is caused by an **X-linked** dominant mutation that is lethal for hemizygous males. Rett syndrome families were used to exclude regions of the X chromosome and to map the locus to the Xq28 region. Amir et al. [1] identified mutations in the MECP2 gene in this region, and found this gene to be responsible for causing Rett syndrome.

KATRINA A.B. GODDARD

Expectation

The *expectation* or *expected value* of a random variable Y, denoted $\mathrm{E}(Y)$, is its **mean**. When Y has density or probability mass function $f(y)$, $\mathrm{E}(Y) = \int f(y)\,\mathrm{d}y$ or $\sum yf(y)$, respectively. A rigorous treatment [1, 2] first defines $\mathrm{E}(Y)$ for simple **random variables** (discrete random variables taking only finitely many values), then extends the definition to arbitrary nonnegative random variables, and then to arbitrary random variables. For a simple random variable Y taking values $y_1, \ldots, y_k$ with respective probabilities $p_1, \ldots, p_k$, $\mathrm{E}(Y)$ is defined as $\sum_{i=1}^{k} y_i p_i$. Any nonnegative random variable Y may be written as a limit $\lim_{n\to\infty} Y_n$ of increasing simple random variables Y_n; $\mathrm{E}(Y)$ is defined as $\lim_{n\to\infty} \mathrm{E}(Y_n)$. Any random variable Y may be written as $Y_+ - Y_-$, where $Y_+ = YI(Y \geq 0)$ and $Y_- = -YI(Y < 0)$ are nonnegative; $\mathrm{E}(Y)$ is defined by $\mathrm{E}(Y_+) - \mathrm{E}(Y_-)$ provided at least one of these is finite. If exactly one is finite, the expectation is $+\infty$ or $-\infty$ depending on whether the infinite term is $\mathrm{E}(Y_+)$ or $\mathrm{E}(Y_-)$. If neither is finite, the expectation does not exist. For example, the mean does not exist for the **Cauchy** density $f(y) = \{\pi(1 + y^2)\}^{-1}$, $-\infty < y < \infty$.

The term "expectation" is a misnomer; a Bernoulli random variable (*see* **Binary Data**) Y with parameter 3/4 has expectation 3/4, though $Y = 3/4$ would be most unexpected since $Y = 0$ or 1. Still, $\mathrm{E}(Y)$ provides the best prediction of Y in that it minimizes the **mean squared error** $\mathrm{E}\{(Y - a)^2\}$ over all constants a, assuming $\mathrm{E}(Y^2) < \infty$. It is a measure of the center of a distribution. Because $(Y - a)^2$ is very sensitive to extreme Y values, $\mathrm{E}(Y)$ is pulled toward them for **skewed** distributions. For such distributions, the **median** is a better measure of central tendency than $\mathrm{E}(Y)$; it minimizes $\mathrm{E}(|Y - a|)$ over a, and $|Y - a|$ is less sensitive to extremes than is $(Y - a)^2$.

The expectation of a random variable Y may also be thought of as its long-run average, assuming $\mathrm{E}(|Y|) < \infty$. If one continually and independently repeats the experiment that generated Y, the average value $\overline{Y} = (1/n)\sum_{i=1}^{n} Y_i$ will be very close to $\mathrm{E}(Y)$ by the strong **law of large numbers**.

Useful Properties of Expectation

E1. If $\mathrm{E}(|Y|) < \infty$, then $|\mathrm{E}(Y)| \leq \mathrm{E}(|Y|)$.

E2. $\mathrm{E}(aX + bY) = a\mathrm{E}(X) + b\mathrm{E}(Y)$ for real numbers a and b, provided the right side is not of the form $+\infty - \infty$ or $-\infty + \infty$.

E3. Jensen's inequality: If $\psi(y)$ is convex and $\mathrm{E}(Y)$ and $\mathrm{E}\{\psi(Y)\}$ are both finite, then $\mathrm{E}\{\psi(Y)\} \geq \psi\{\mathrm{E}(Y)\}$.

E4. Monotone convergence theorem: If $Y_n \uparrow Y$ and $\mathrm{E}(Y_n) > -\infty$ for some n, then $\mathrm{E}(Y_n) \uparrow \mathrm{E}(Y)$.

E5. Dominated convergence theorem: If $Y_n \to Y$ in probability and $|Y_n| \leq Z, \mathrm{E}(Z) < \infty$, then $\mathrm{E}(Y_n) \to \mathrm{E}(Y)$ (*see* **Convergence in Distribution and in Probability**).

E6. If $Y_1, Y_2, \ldots$ are nonnegative or $\sum_{i=1}^{\infty} \mathrm{E}(|Y_i|) < \infty$, then $\mathrm{E}\left(\sum_{i=1}^{\infty} Y_i\right) = \sum_{i=1}^{\infty} \mathrm{E}(Y_i)$.

E7. If Y is nonnegative, then $\mathrm{E}(Y) = \int_0^{\infty} P(Y > y)\,\mathrm{d}y$, whether finite or not.

E8. If $\mathrm{E}(Y^2) < \infty$, then $a = \mathrm{E}(Y)$ minimizes $\mathrm{E}(Y - a)^2$ over all $a \in \Re$.

Expectation can also be taken conditioned on events, random variables, or arbitrary sigma fields (*see* **Conditional Probability**). Assume that $\mathrm{E}(|Y|) < \infty$. If A is an event of nonzero probability, the *conditional expectation of Y given A*, denoted $\mathrm{E}(Y|A)$, is defined as $\mathrm{E}\{YI(A)\}/P(A)$, where $I(A)$ is the indicator of event A. For example, let (X, Y) have joint probability mass function $f(x, y)$, and let $A = \{X = x\}$. Then $\mathrm{E}\{YI(X = x)\} = \sum_y yf(x, y)$ and

$$\psi(x) = \mathrm{E}(Y|X = x) = \sum_y \frac{yf(x, y)}{g(x)}, \qquad (1)$$

where $g(x)$ is the **marginal probability** mass function of X. In other words, we can take the expectation of Y with respect to the conditional probability mass function $h(y|x) = f(x, y)/g(x)$. Similarly, if (X, Y) has a density $f(x, y)$, we could, by analogy, integrate over the conditional density $h(y|x) = f(x, y)/g(x)$:

$$\psi(x) = \mathrm{E}(Y|X = x) = \int \frac{yf(x, y)\,\mathrm{d}y}{g(x)} \qquad (2)$$

when $g(x) \neq 0$. But what if (X, Y) does not have a density or probability mass function? We need a more general definition of conditional expectation given a random variable. Consider the discrete setting and replace x with X in $\psi(x) : \psi(X) = \sum_y yf(X, y)/g(X)$. For any Borel set B of x points

with nonzero probability,

$$\begin{aligned}\mathrm{E}\{\psi(X)I(X \in B)\} &= \sum_{x\in B}\sum_{y}\left\{\frac{yf(x,y)}{g(x)}\right\}g(x)\\ &= \sum_{y}\sum_{x\in B} yf(x,y)\\ &= \mathrm{E}\{YI(X \in B)\}. \qquad (3)\end{aligned}$$

In other words, $\psi(X)$ has the same average value as Y over any X set of nonzero probability. The same thing happens in the continuous situation with sums replaced by integrals. Note that $\mathrm{E}\{\psi(X)I(X \in B)\} = \mathrm{E}\{YI(X \in B)\}$ also holds when $P(X \in B) = 0$ because both sides are 0. This is the generalization we are looking for. For any random vector $\underline{X} = (X_1, \ldots, X_n)$, *the conditional expectation of* Y *given* $\underline{X}$, *denoted* $\mathrm{E}(Y|\underline{X})$, is any (Borel) function $\psi(\underline{X})$ such that

$$\mathrm{E}\{\psi(\underline{X})I(\underline{X} \in B)\} = \mathrm{E}\{YI(\underline{X} \in B)\} \qquad (4)$$

for all n-dimensional Borel sets B.

Strictly speaking, we call $\psi(\underline{X})$ a version of $\mathrm{E}(Y|\underline{X})$ because more than one function satisfies (4). For example, if Y has a density, then $Z_1 = Y$ is a version of $\mathrm{E}(Y|Y)$, but so is $Z_2 = YI(Y \neq 0) + 10I(Y = 0)$. Though Z_1 and Z_2 are not identical, $P(Z_1 \neq Z_2) = P(Y = 0) = 0$. It is clear that by replacing 10 with any other number we can create infinitely many versions. That two versions Z_1 and Z_2 of $\mathrm{E}(Y|\underline{X})$ differ only on a set of probability, 0 is not unique to this example. It always holds.

When (X, Y) has a probability mass function or density $f(x, y)$, one version of $\mathrm{E}(Y|X)$ is (1) or (2). Indeed, we have already seen that (1) implies (4). Sometimes $\mathrm{E}(Y|X)$ is clear without resorting to conditional densities. For example, suppose we draw a **random sample** $X_1, \ldots, X_n$ from a population with expectation μ, and select one of $\{X_1, \ldots, X_n\}$ at random. The randomly selected value, Y, has the same unconditional distribution as an X_i. But conditioned on $X_1, \ldots, X_n$, $Y = X_i$ with probability $1/n$, $i = 1, \ldots n$. Thus, the conditional expectation of Y given $X_1, \ldots, X_n$ is $\sum_{i=1}^{n} X_i(1/n) = \overline{X}$.

Here is an example showing why $\mathrm{E}(Y|X = x)$ should not be thought of as conditioning on the event $A = \{X = x\}$ when A has probability 0. Suppose we want to compare the difference in sample proportions, $\hat{p}_1 - \hat{p}_0$, to the **relative risk**, $\hat{p}_1/\hat{p}_0$ from two independent random samples. Of specific interest is how likely various values of the difference in sample proportions are given the relative risk. Because $\hat{p}_0$ and $\hat{p}_1$ behave asymptotically like independent normal random variables (X, Y) with respective means p_0 and p_1 and respective variances $p_0(1 - p_0)/n$ and $p_1(1 - p_1)/n$, the **delta method** implies that the asymptotic joint distribution of $(\hat{p}_1 - \hat{p}_0, \hat{p}_1/\hat{p}_0)$ is that of $(Y - X, Y/X)$. It seems, therefore, that the conditional distribution of $(\hat{p}_1 - \hat{p}_0|\hat{p}_1/\hat{p}_0)$ must be that of $(Y - X|Y/X)$. To avoid resorting to the use of transformations and Jacobians, write the event $\hat{p}_1/\hat{p}_0 = \lambda$ as $\hat{p}_1 - \lambda\hat{p}_0 = 0$. It is tempting to say that the conditional distribution of $(Y - X|Y/X = \lambda)$ must be that of $(Y - X|Y - \lambda X = 0)$. The latter distribution is easy to compute: $(Y - X, Y - \lambda X)$ is **bivariate normal**, so the conditional distribution of $(Y - X|Y - \lambda X = 0)$ is univariate normal.

A surprising mistake in the above argument is concluding that because the events $\{Y/X = \lambda\}$ and $\{Y - \lambda X = 0\}$ are the same (barring $X = 0$), the conditional distribution of $(Y - X|Y/X = \lambda)$ is that of $(Y - X|Y - \lambda X = 0)$. In fact, Proschan and Presnell [5] show using Jacobians that the former conditional distribution is not normal. This example shows the danger of viewing conditional expectations given a random variable as conditional expectations given an event of probability 0. Incidentally, another flaw in the above argument is the assumption that because the asymptotic joint distribution of $(\hat{p}_1 - \hat{p}_0, \hat{p}_1/\hat{p}_0)$ is that of $(Y - X, Y/X)$, the conditional distribution of $(\hat{p}_1 - \hat{p}_0|\hat{p}_1/\hat{p}_0)$ must be that of $(Y - X|Y/X)$. In general, convergence of (U_n, V_n) to (U, V) in distribution does not imply convergence of the distribution of $(V_n|U_n)$ to that of $(V|U)$ (the converse is also not true; weak convergence of marginal and conditional distributions does not necessarily imply weak convergence of joint distributions; see [7]). Other interesting anomalies in conditional expectation are given in [4–6].

Conditional expectation may be viewed geometrically as a projection [3], Chapter 8. Equation (4) says that $\mathrm{E}\{(Y - Z)I(\underline{X} \in B)\} = 0$ for every n-dimensional Borel set B, where $Z = \mathrm{E}(Y|\underline{X})$. It follows that for any simple random variable W that is a function of $\underline{X}$, $\mathrm{E}\{(Y - Z)W\} = 0$. Because simple random variables are the building blocks used to generate any random variable, it can be shown that $\mathrm{E}\{(Y - Z)W\} = 0$ for any W that is a function of $\underline{X}$ such that $\mathrm{E}\{(Y - Z)W\}$ exists and is finite. To ensure $\mathrm{E}\{|(Y - Z)W|\} < \infty$, assume $\mathrm{E}(Y^2) < \infty$

and consider those W that are Borel functions of $\underline{X}$ with finite variance, $L_2(\underline{X}) = \{W : W = f(\underline{X}),$ f[is a Borel function, $\mathrm{E}(W^2) < \infty\}$. Then $\mathrm{E}\{(Y - Z)W\} = 0$ for all $W \in L_2(\underline{X})$.

When $\mathrm{E}(UV) = 0$ for random variables U and V, we can think of U and V as being **orthogonal** and write $U \perp V$. The analogy with n-dimensional vectors $\underline{u}$ and $\underline{v}$ is that $\underline{u}$ and $\underline{v}$ are orthogonal $\Leftrightarrow \sum u_i v_i = 0 \Leftrightarrow \mathrm{E}(UV) = 0$, where (U, V) is a random draw from a population with values $\{(u_1, v_1), \ldots, (u_n, v_n)\}$. The condition $\mathrm{E}\{(Y - Z)W\} = 0$ means that $Y - Z \perp W$. Picture the random variable Y as a vector in the plane. The set $L_2(\underline{X})$ is a linear subspace, which we can picture as a line. Then $Z = \mathrm{E}(Y|\underline{X})$ is the projection of Y onto $L_2(\underline{X})$ (Figure 1). This geometric perspective makes clear certain properties of conditional expectation. For example, if $L_2(\underline{X}_1) \subseteq L_2(\underline{X}_2)$, then $\mathrm{E}\{\mathrm{E}(Y|\underline{X}_2)|\underline{X}_1\} = \mathrm{E}(Y|\underline{X}_1)$ with probability 1. To see this, let $W \in L_2(\underline{X}_1)$ and set $Z_1 = \mathrm{E}(Y|\underline{X}_1)$ and $Z_2 = \mathrm{E}(Y|\underline{X}_2)$. Then $\mathrm{E}\{(Z_2 - Z_1)W\} = \mathrm{E}[\{-(Y - Z_2) + Y - Z_1\}W] = 0$ because $Y - Z_2 \perp L_2(\underline{X}_2) \supseteq L_2(\underline{X}_1)$ and $Y - Z_1 \perp L_2(\underline{X}_1)$. Because $\mathrm{E}\{(Z_2 - Z_1)W\} = 0$ for every $W \in L_2(\underline{X}_1)$, Z_1 is a version of $\mathrm{E}(Z_2|Z_1)$. Though this geometric argument implicitly assumes $\mathrm{E}(Y^2) < \infty$, the result holds whenever $\mathrm{E}(|Y|) < \infty$.

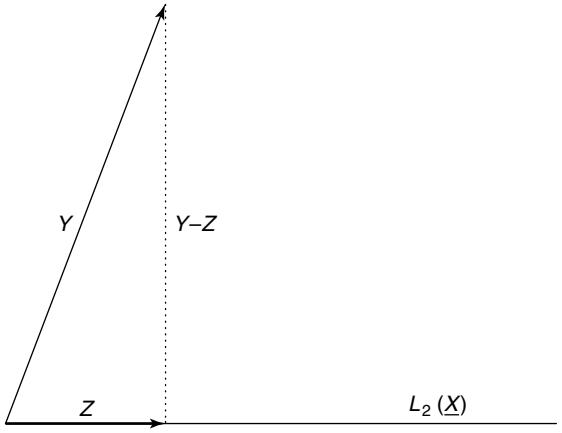

Figure 1 Conditional expectation as a projection. Think of the random variable Y as a two-dimensional vector, and the set $L_2(\underline{X}) = \{W : W = f(\underline{X}) : \mathrm{E}(W^2) < \infty\}$ of potential predictors of Y based on covariates $\underline{X}$ as vectors on a line. Then $Z = E(Y|X)$ is the projection of Y onto $L_2(\underline{X})$. That is, $Y - Z \perp W$ for every $W \in L_2(\underline{X})$

The geometric perspective is useful for understanding another interesting fact about conditional expectation. We have noted that when $\mathrm{E}(|Y|) < \infty$ and in the absence of any other information, $\mathrm{E}(Y)$ is the **prediction** of Y that minimizes the mean squared error $\mathrm{E}\{(Y - a)^2\}$ over all a. But now suppose one is allowed to predict Y after observing random variables $X_1, \ldots, X_n$. Among all predictors $W = f(X_1, \ldots, X_n)$ with finite variance, $Z = \mathrm{E}(Y|X_1, \ldots, X_n)$ minimizes the mean squared error $\mathrm{E}\{(Y - W)^2\}$. This is readily apparent from Figure 1 and the fact that $\mathrm{E}\{(Y - W)\}^2$ is the L_2 distance between Y and W. More formally, $\mathrm{E}\{(Y - W)^2\} = \mathrm{E}\{(Y - Z + Z - W)^2\}$. The cross product term $2\mathrm{E}\{(Y - Z)(Z - W)\}$ is 0 because $Y - Z \perp L_2(\underline{X})$ and $Z - W \in L_2(\underline{X})$, so $\mathrm{E}\{(Y - W)^2\} = \mathrm{E}\{(Y - Z)^2\} + \mathrm{E}\{(Z - W)^2\} \geq \mathrm{E}\{(Y - Z)^2\}$.

The definition of conditional expectation can be generalized. Notice that condition (4) involves X only through the collection of sets $\{\underline{X} \in B, B$ Borel$\}$ it generates, known as the sigma field generated by $\underline{X}$ and denoted $\sigma(X)$. For example, suppose X is the indicator that a patient has a history of hypertension, and Y is his systolic blood pressure on a given day. Further, suppose that $\mathrm{E}(Y|X = 0) = 120$ and $\mathrm{E}(Y|X = 1) = 150$. Even though $\mathrm{E}(Y|X = 0) \neq \mathrm{E}(Y|1 - X = 0)$ and $\mathrm{E}(Y|X = 1) \neq \mathrm{E}(Y|1 - X = 1)$, the random variables $\mathrm{E}(Y|X)$ and $\mathrm{E}(Y|1 - X)$ are the same, namely, 120 on the set where $X = 0$ and 150 on the set where $X = 1$. Similarly, $\mathrm{E}(Y|\underline{X}) = \mathrm{E}\{Y|t(\underline{X})\}$ for any invertible transformation $t(\underline{X})$. Because $\mathrm{E}(Y|X)$ depends only on the sigma field $\Im = \sigma(X)$, some authors prefer the notation $E(Y|\Im)$. It is helpful to think in terms of sigma fields rather than random vectors. Sigma field $\Im_2$ contains more information than sigma field $\Im_1$ if $\Im_1 \subseteq \Im_2$. For example, $\Im_1 = \sigma(|X|) \subseteq \sigma(X) = \Im_2$. Knowing which events in $\Im_2$ occurred tells us which events in $\Im_1$ occurred, but not vice-versa. Similarly, $\Im_1 = \sigma(X_1) \subseteq \sigma(X_1, X_2) = \Im_2$. Conditional expectation can be defined for arbitrary sigma fields (not just those generated by a random vector); $\mathrm{E}(Y|\Im)$ is any $\Im$-measurable random variable Z (meaning that $\{\omega : Z(\omega) \in B\} \in \Im$ for every Borel set B) such that $\mathrm{E}\{ZI(A)\} = \mathrm{E}\{YI(A)\}$ for all $A \in \Im$. Define $L_2(\Im)$ as the collection of $\Im$-measurable random variables W with $\mathrm{E}(W^2) < \infty$. The above results can be generalized as follows.

Useful Properties of Conditional Expectation

C1–C7: same as E1–E7 with expectation replaced by conditional expectation and the phrase "with probability 1" added.

C8. Among all functions $W \in L_2(\Im)$, $Z = \mathrm{E}\{Y|\Im\}$ minimizes the conditional and unconditional mean squared errors: $\mathrm{E}\{(Y-W)^2|\Im\}$ and $\mathrm{E}\{(Y-W)^2\}$, assuming $\mathrm{E}(Y^2) < \infty$.

C9. If W is $\Im$-measurable and $\mathrm{E}(|W|) < \infty$, $\mathrm{E}(|Y|) < \infty$, then $\mathrm{E}(WY|\Im) = W\mathrm{E}(Y|\Im)$ with probability 1.

C10. If $\mathrm{E}(|Y|) < \infty$ and $\Im_1 \subseteq \Im_2$, $\mathrm{E}\{\mathrm{E}(Y|\Im_2)|\Im_1\} = \mathrm{E}(Y|\Im_1)$ with probability 1.

C11. If $\mathrm{E}(|Y|) < \infty$, $\mathrm{E}\{\mathrm{E}(Y|\Im)\} = \mathrm{E}(Y)$.

MICHAEL A. PROSCHAN

Expected Number of Deaths

Several procedures are available if the mortality in a study group is to be compared with the mortality of the general population from which the sample is drawn. In a clinical setting calculation of an *expected survival curve* is often performed, and in epidemiologic studies of geographic or occupational variations of mortality the observed number of deaths is usually compared with *the expected number of deaths* based on published mortality rates for the general population. Calculation of expected number of deaths is an integral part of the **standardization** of vital rates, which is one of the oldest statistical techniques; see Keiding [10] for a review of early applications of the method. Standardization of rates is closely related to **multiplicative** *hazard rate models* and the use of *relative mortality* to describe deviations from the expected mortality (see, for example, Breslow [5], Breslow & Day [6] or Hoem [9]).

Two methods have been developed for the calculation of expected number of deaths. The classical approach, *the person-years method*, is derived as a sum of products of age- and sex-specific rates and the corresponding time at risk, whereas *the prospective method* involves calculation of a sum of conditional survival probabilities. For a further description the following setup is introduced.

Consider a sample of n independent individuals. Individual i is followed from time u_i to time t_i if death does not occur prior to t_i. Let T_i denote the time of death and define $X_i = \min(t_i, T_i)$. The mortality rate at time t, assuming that the individual is subject to the same risks as a person from the external reference population having the same demographic description, is denoted $\lambda_i(t)$. The corresponding survival function is denoted $S_i(t)$. The reference population is usually taken to be the general population, and the mortality rate and the survival function may be determined from published data taking into account the sex, date of birth, and age at entry of the person.

Set D_i to 1 if death occurs during follow-up and to 0 otherwise, i.e. $D_i = I(u_i < T_i \leq t_i)$. The observed number of deaths is then $D = \sum D_i$. Introduce

$$A_i = \int_{u_i}^{X_i} \lambda_i(s)\, \mathrm{d}s,$$

and let $A = \sum A_i$ denote the *total exposure to death*. The probability of dying during follow-up is obtained as

$$p_i = \frac{S_i(u_i) - S(t_i)}{S_i(u_i)}.$$

It is easily seen that $\mathrm{E}(D_i | T_i > u_i) = p_i$. Moreover, one may show (see, for example Breslow [4] or Berry [2]) that also $\mathrm{E}(A_i | T_i > u_i) = p_i$.

These results suggest two different ways of calculating the expected number of deaths, $\mathrm{E}(D)$, on the assumptions that mortality in the study group is identical to that of the reference population.

The prospective method [8, 11] utilizes the relationship $\mathrm{E}(D) = \sum p_i$ directly; the expected number of deaths is simply obtained as $\sum p_i$. Note, however, that the potential follow-up time, t_i, must be known for *all* individuals in order to compute the expected number of deaths by this method. Such knowledge is not available for many **censoring** schemes, and this requirement therefore severely limits the applicability of the prospective method.

Deviations from the expected number of deaths may be assessed by computing

$$X^2_{\mathrm{P}} = \frac{\left(D - \sum p_i\right)^2}{V},$$

where $V = \sum \mathrm{var}(D_i) = \sum p_i(1 - p_i)$. The distribution of the test statistic is approximately a **chi-square distribution** on one **degree of freedom**.

The **person-years** method (see, for example, Case & Lea [7] or Berry [2]) relies on the relationship $\mathrm{E}(A) = \sum p_i$, which shows that A is an unbiased estimate of the expected number of deaths on the hypothesis that the mortality in the study group is identical to that of the reference population. The total exposure to death, A, is therefore used as *an estimate* of the expected number of deaths. Usually the distinction between "total exposure to death" and "expected number of deaths" is not done and the random variable A simply denotes the expected number of deaths. Note, however, that for extended follow-up of old individuals the contribution A_i to the total exposure to death may exceed 1. Consequently, one may encounter situations where the expected number of deaths is larger than the number of individuals in the sample (see Smith [12] for one such example) suggesting that this terminology is misleading.

Note, moreover, that A is not an unbiased estimate of the expected number of deaths if the mortality in the sample differs from that of the reference population. The size of the bias has been studied by Keiding & Væth [11] within the framework of the multiplicative hazard rate model.

With this method the hypothesis of no difference between observed and expected number of deaths may be tested by computing

$$X^2_{\mathrm{PY}} = \frac{(D-A)^2}{A}.$$

On the null hypothesis the distribution of the test statistic is approximately a χ^2 distribution on one degree of freedom. Calculations of **asymptotic relative efficiency** by Anderson & Anderson [1] indicate that the person-years method is more efficient than the prospective method for **proportional hazards** alternatives and that the efficiency gain increases as the proportion of individuals dying during follow-up goes up.

The person-year method is easily adapted to studies of cause-specific mortality (*see* **Competing Risks**). The total mortality rate in the reference population is simply replaced by the relevant cause-specific mortality rate and deaths from other causes are treated as censoring. This solution is not applicable for the prospective method as it would require knowledge of when an individual who dies of the cause in question would have died from one of the other causes. One may instead extend the above model by introducing cause-specific mortality probabilities for each individual taking all causes of mortality into account. Interpretation of deviations from the expected number of deaths is, however, complicated by the fact that excess death for one cause will necessarily imply a deficit for some of the other causes [12].

In application of the person-years method one usually assumes that the mortality rate $\lambda_i(t)$ is constant in one-year (or five-year) intervals, and the contribution A_i is then the sum of products of the age-specific rates and the time spent in the corresponding age category during follow-up. Interchanging the order of summation one obtains the standard formula for the expected number of deaths, $A = \sum \lambda_{\mathrm{as}} Y_{\mathrm{as}}$, where λ_{as} is the sex- and age-specific mortality rate of the reference population and Y_{as} is the total person-years at risk in the corresponding sex and age category. From this formulation it is seen that D/A is the *standardized mortality ratio* (see, for example, Breslow and Day [6, Chapter 2]), which is used extensively in the analysis of epidemiologic data on occupational hazards for comparing mortality in a study population with mortality in a standard population (*see* **Standardization Methods**).

The classical approach of indirect standardization and calculation of a standardized mortality ratio (SMR) follows from a simple, multiplicative model relating the mortality rate $\lambda_i(t)$ of an individual in the study population to the known mortality rate $\lambda_i^*(t)$ for the reference population

$$\lambda_i = \theta \lambda_i^*(t).$$

For this model one may show [3] that the standardized mortality ratio, D/A, is the **maximum likelihood** estimate of the relative mortality θ and that the test statistic, X^2_{PY}, given above is a score test (*see* **Likelihood**) for testing the hypothesis $\theta = 1$. The simple, multiplicative model has been developed further to deal with regression problems using **proportional hazards** regression models of the form

$$\lambda_i(t; \mathbf{z}_i) = \exp(\beta' \mathbf{z}_i)\lambda_i^*(t),$$

where $\mathbf{z}_i$ is a vector of independent variables and β the corresponding vector of regression parameters. With grouped data such models are often referred to as **Poisson regression** models (see, for example, Berry [2] or Breslow & Day [6, Chapter 4]).

MICHAEL VÆTH

Expected Survival Curve

Expected survival curves aim at calculating how an actual group of patients would have survived under "standard" or "historical" conditions, (cf. the general discussion in **Bias from Historical Controls**).

The standard or historical conditions are available as a survival curve $S_i(t)$ for each patient i individually, perhaps based on estimates in a regression model for **survival** data. The *direct adjusted survival curve* or *corrected group prognostic curve* $\overline{S}(t)$ was discussed by Makuch [14], Chang et al. [3], Gail and Byar [5], Markus et al. [15] and Thomsen et al. [18] as

$$\overline{S}(t) = \frac{1}{n}\sum S_i(t). \tag{1}$$

An important objection to the use of the direct adjusted survival function is that is does not take the realized **censoring pattern** into account – on the contrary, it depends strongly on an assumption of independent censoring and involves an averaging operation across the censoring pattern. Invoking each patient's *potential follow-up time* Bonsel et al. [2] proposed what in continuous time would amount to the following estimator. Let $0 < f_1 < \cdots < f_n$ be the potential follow-up times for the n patients, and define iteratively, for $f_j < t \le f_{j+1}$, *Bonsel's estimator*

$$S_B(t) = S_B(f_j)\frac{\sum_{j+1}^{n} S_i(t)}{\sum_{j+1}^{n} S_i(f_j)}. \tag{2}$$

A slightly different definition was proposed by Væth [20], (cf. [9, 12, 19)].

If the historical mortality is given as a **Cox regression model** so that patient i has **hazard** $\lambda_i(t) = \lambda_0(t)e^{\beta' z_i}$, it has been fairly common to calculate the average **covariate** $\overline{z} = \sum z_i/n$ and use $S(t, \overline{z})$ as expected survival curve. This *average-covariate approach* is clearly suboptimal, as explained in [3, 6, 17, 18].

As discussed in the article **expected number of deaths**, it is often unrealistic to assume the potential follow-up times known (possible occurrence of ordinary loss to follow-up gives unknown potential follow-up times), and it may be preferable to base the calculation of the *expected survival curve*, S^*, on exposing each study individual to his/her standard mortality rate over the actually experienced period at risk. One such proposal [18] generalized the classical calculation of expected number of deaths as follows. Assume that the historical mortality is given as a Cox regression model so that patient i has hazard $\lambda_i(t) = \lambda_0(t)e^{\beta' z_i}$. Let $Y_i(t) = I\{\text{patient } i \text{ still at risk at time } t\}$, $Y(t) = \sum Y_i(t)$. Then under the historical hypothesis on the mortality, the average hazard of the patients still under observation at time t would be

$$\lambda^*(t) = \frac{\sum Y_i(t)\lambda_0(t)\exp(\beta' z_i)}{Y(t)}. \tag{3}$$

Defining the cumulative hazard as $\Lambda^*(t) = \int_{u=0}^{t} \lambda^*(u)\,du$, the survival function $S^*(t) = \exp\{-\Lambda^*(t)\}$ is a continuous-time version of the "expected survival rate" [4] or "expected survival curve" [8]. Andersen and Væth [1] pointed out that it has the following desirable property: let the standard **Nelson–Aalen estimator** of $\Lambda(t)$ be defined by

$$\hat{\Lambda}(t) = \sum_{T_j \le t} \frac{1}{Y(T_j)}, \tag{4}$$

where $T_1 < T_2 < \cdots$ are the times of (observed) deaths. Then $\Lambda^*(t) - \hat{\Lambda}(t)$ has expectation zero, under the **null hypothesis** that patient i has hazard $\lambda_i(t)$. Therefore, $S^*(t)$ represents, under the null hypothesis, an *expected survival curve*. Outside of the null hypothesis, it is not so easy to interpret $S^*(t)$, containing as it does information on study group mortality, through $Y_i(t)$, as well as standard mortality, through $\lambda_i(t)$. $S^*(t)$ therefore cannot be recommended as an expected survival function, despite its wide use for this purpose.

$S^*(t)$ is, however, useful for inference on **excess mortality**, as follows. In the particular case where the study group has an *additive* excess mortality $\alpha(t)$ over the standard, that is, patient i has hazard $\alpha(t) + \lambda_i(t)$, one may obtain an estimate of the corresponding "survival" function

$$\exp\left[-\int_0^t \alpha(u)\,du\right] \tag{5}$$

as the so-called *relative* survival function $\hat{S}(t)/S^*(t)$. Andersen and Væth [1] showed that results on **unbiasedness**, **consistency**, and asymptotic **normality** are available. Thomsen et al. [18, 19]

compared this "expected survival curve" to the previously discussed estimators.

These matters were discussed earlier by Hakulinen [7] who considered three estimators of "the expected survival rate". He divided the study population into homogeneous subgroups and considered a weighted average of the group-specific survival functions (his formula (2.2)) and the survival functions corresponding the two different weighted averages of the standard mortality rates (his formulas (2.3) and (2.4)). When each subgroup consists of a single patient, his formula (2.2) equals the direct adjusted survival curve and his formula (2.3) equals S^*. Finally, the mortality rate in his formula (2.4) equals the mortality rate corresponding to Bonsel's estimator; see [17] for a related idea.

Nielsen's Asymptotic Results

Nielsen [16] considered the observed survival curve, $\hat{S}$, estimated by the **Kaplan–Meier** method, and estimated survival curves based on the Cox regression model. He showed the following asymptotic results under the null hypothesis of standard mortality, where $\| \cdot \|$ is $\sup_{\tau \leq t} | \cdot |$,

1. Under standard boundedness regularity conditions, and assuming conditional independence between survival time and censoring time given covariates, $\| S^* - \hat{S} \| \xrightarrow{P} 0$ and $\| S_B - \hat{S} \| \xrightarrow{P} 0$.
2. Assume, in addition that the censoring times are identically distributed and marginally independent of covariates (and hence survival times), then $\| \overline{S} - \hat{S} \| \xrightarrow{P} 0$.

Nielsen also proved asymptotic normality and gave martingale-based test statistics for the historical hypothesis (*see* **Counting Process Methods in Survival Analysis**).

Thus, the use of the direct adjusted survival curve requires marginally independent censoring, but no information about actual survival or potential follow-up is needed. In addition, it has the simple interpretation as the expected survival curve of the study population under standard mortality in the absence of censoring. The use of Bonsel's method requires conditional independence and information on all potential follow-up times. S^* requires neither restrictive assumptions on the censoring pattern nor any knowledge of the potential follow-up times, only information about the actual time at risk is needed. However, the latter depends on both the actual survival of the study group and the standard mortality rates and, therefore, has no interpretation outside the null hypothesis.

Individual Comparison of Prognosis for New versus Old Treatment

Keiding et al. [10] extended the above framework, to also include a fitted regression model for the study patients. Under the Cox model for the historical hypothesis, the survival probability of patient i would be (in obvious notation)

$$S_H^i(t) = \exp\left[-\Lambda_H(t)\exp(\beta_H' z_i)\right], \qquad (6)$$

while under the Cox model for current treatment, the survival probability would be

$$S_T^i(t) = \exp\left[-\Lambda_T(t)\exp(\beta_T' z_i)\right]. \qquad (7)$$

Since the prognostic indices $\beta_H' z_i$ and $\beta_T' z_i$ as well as the underlying intensities $\Lambda_H(t)$ and $\Lambda_T(t)$ will usually be rather different, the relative survival at time t

$$\gamma_i(t) = \frac{S_H^i(t)}{S_C^i(t)} \qquad (8)$$

will usually depend strongly on patient i and time t. Keiding et al. [10], Fig. 5) proposed using $\gamma_i(t)$ as one aid in deciding on the best treatment for each individual patient and developed a diagram to illustrate the rather dramatic variation of $\hat{\gamma}_i(t)$ when comparing **transplantation** to conservative treatment in a set of Nordic primary biliary cirrhosis patients; (*see* **Prognostic Factors for Survival**).

Difficulties in Applying Non- or Semiparametric Models for the Historical Controls

Two largely unnoticed difficulties in applying the Cox regression model and similar non- or **semiparametric** models as historical controls concern the *interpretation of the time variable* in the underlying intensity and the use of **time-dependent covariates**.

The first point is most easily explained through specific reference to the transplantation example hinted at above. The model based on the historical

data specifies that the death intensity at duration t after entrance into the clinical trials is $\lambda_0(t)\exp(\beta' z)$. This is to be compared with survival *since transplantation* for the study patients. Patients would usually be assumed to be at a more advanced stage of disease at transplantation than at entry into a trial, so that the conventional choice of $t = 0$ at transplantation (that is, underlying intensity $\lambda_0(t)$ at time t since transplantation) is ill motivated. Only if $\lambda_0(t)$ is constant over t does the conventional application seem justified, and one ought indeed to always postulate this and (if possible) refit this parametric model to the historical data before the comparison; see [13] for a general discussion of comparing survival after transplantation with conservative treatment.

The other difficulty is related to the use of time-dependent covariates, in particular, when a natural time origin is available prior to the entry on study of the study patients. **Delayed entry** (**left truncation**) methods are then appropriate, but as pointed out by Keiding and Knuiman [11], it is then usually impossible to incorporate time-dependent covariates into the Cox regression model.

NIELS KEIDING

Experimental Design

R.A. Fisher's 1935 text, *The Design of Experiments* [4], unified applied statistics and still shapes the subject today. Fisher had to define and defend his notion of a scientific experiment, of statistical **inference**, and of probability, and then lay out a set of practical procedures for the novice. In the Preface to his text, he proclaims:

> A clear grasp of simple and standardized statistical procedures will ... go far to elucidate the principle of experimentation; but these procedures are themselves only the means to a more important end. Their part is to satisfy the requirements of sound and intelligible experimental design, and to supply the machinery for unambiguous interpretation.

Fisher used the word "experiment" with special force. The investigator was obliged to plan and to control the experiment, leaving only one aspect to chance, the random assignment of the treatments to the study subjects or objects (*see* **Randomized Treatment Assignment**). **Randomization** legitimized the statistical inference by mechanically imposing a probability distribution on the set of potential observations. Using a prespecified type I error, one tested the **null hypothesis** with a set of reproducible arithmetic procedures (*see* **Hypothesis Testing**).

When **William Cochran** and **Gertrude Cox** wrote their 1950 text, *Experimental Designs* [2], nearly all statisticians followed these protocols and most preferred to analyze laboratory-like experiments, such as the first real-data example in the Cochran & Cox text, "to measure the effectiveness of 4 soil fumigants in keeping down the number of eelworms in the soil". Typical experimental units were "a plot of land, a patient in a hospital, or a lump of dough, or it may be a group of pigs in a pen, or a batch of seed" (*see* **Unit of Analysis**).

The term *treatments* has a positive connotation. Treatments cure patients, increase crop yield, and improve the quality of industrial products. Other terms are deliberately bland, such as "blocks, plots, classes, units, and replicates". The experimental layout resembles a rectangle of land, partitioned into blocks or plots that contain units. A typical design allocates treatments in either a regular or a random manner to units within plots or within blocks. Units receiving the same treatment are "replicates".

In Fisher's time "design" connoted choice. One reviewed various shapes and sizes for blocks and plots and ways of making regular or random assignments of units. Then one chose a design to maximize the chance of detecting at a prespecified type I error level a factor producing a pattern of wide dispersion among a set of mean treatment effects. As the novelty of choice has worn off, "design" has come to mean a precise description of the statistical model. Searle et al. [6] have provided a brief, readable, and insightful history that covers this subject in the context of **variance components**.

Today, investigators often conduct experiments in which they cannot entirely control the experimental conditions. Accordingly, the theory and methods have extended to deal with these irregular conditions.

This article gives a narrow overview of the basic theory and methods of classical design of experiments and then briefly discusses some of the major recent extensions. After introducing some terminology, this article addresses: (i) the mathematical core of the subject, the decomposition of the sum of squared deviations, and the associated computational worktable; (ii) the link between the **analysis of variance** (ANOVA) and **linear regression**; (iii) the design of medical experiments; (iv) **fixed** and **random effects**; and (v) balance, **missing data** and **robustness**.

Some Terminology for the Design of Experiments

Fisher had provided a unified theory, a choice of many designs, and a worktable (the ANOVA table) that allowed a novice to carry out tests of significance. He moved study design beyond the adequacy of sample size (statistical **power**). Designs could include several interacting factors such as the factor "fertilizers" with four levels (F, G, H, K) and the factor "fumigants" with two levels (a, b) (*see* **Factorial Experiments**). The investigator could choose to have all possible combinations (Fa, Fb, Ga, Gb, Ha, Hb, Ka, Kb) or a balanced subset such as (Fa, Gb, Ha, Kb) (*see* **Fractional Factorial Designs**). Combinations introduced **"interactions"** between a type of fertilizer and a type of fumigant.

A **balanced incomplete blocks (bib) design** is suited to small block sizes, n units per block, and many treatments, $I > n$; more treatments than one could fit into a block. A typical bib design places n of

the I distinct treatments in each block and has overall balance among treatments. For example, with each column representing a block of size 4, and cyclically listing the seven treatments (ABCDEFG), a layout of a 7-block design is:

A	E	B	F	C	G	D
B	F	C	G	D	A	E
C	G	D	A	E	B	F
D	A	E	B	F	C	G

Crossed and nested designs represent extremes in balanced designs that have two (or more) distinct treatment factors. For example, let factor 1 with levels (ABCD) be completely crossed with factor 2 with levels (efgh). That is, each unit has a pair of treatments, one from factor 1 and one from factor 2. A layout for this crossed design is:

A		B		C		D	
e	f	e	f	e	f	e	f
g	h	g	h	g	h	g	h

A layout for a completely nested design is:

A		B		C		D	
e	e	f	f	g	g	h	h
e	e	f	f	g	g	h	h

A more precise notation such as "Ae Af Ag Ah" lists the explicit pairs with the uppercase treatment level first and the lowercase treatment level second, whereas the notation above shows how the second pair-member in the crossed design varies more than in a nested design.

When the number of levels of factor 1 (blocks) equals the number of levels of factor 2 (treatments ABC) and columns and rows are physically present, as in an agricultural field, then one can simultaneously balance treatments within both columns and within rows by means of a **Latin square design**. For $n = 3$, with columns representing blocks, the layout of a Latin square design is

A	B	C
B	C	A
C	A	B

Lattice designs have a block size n and a treatment factor with $I = n^2$ levels. A lattice design assigns a subset of distinct treatments to each block and each pair of levels appears equally often within the blocks. For example, with 12 blocks, block size = 3, and $I = 9$ treatments (abcdefghi), a layout for a lattice design with columns denoting blocks is:

a	d	g	a	b	c	a	b	c	a	b	c
b	e	h	d	e	f	e	f	d	f	d	e
c	f	i	g	h	i	i	g	h	h	i	g

"Classical" design of experiments contains many other topics (*see* **Magic Square Designs**; **Orthogonal Designs**; **Partially Balanced Incomplete Block Design**; **Youden Squares and Row–Column Designs**).

The Decomposition of the Sum of Squared Deviations

Squared Deviations

Under the **null hypothesis**, all the levels or categories of treatment have the same effect on a continuous outcome, Y. The vague **alternative hypothesis** merely posits that treatment effects differ. The method of analysis, the analysis of variance (ANOVA), does not reveal which treatment appears to work best. For ANOVA, one computes the grand mean of Y and the set of treatment means. If the values in this set substantially deviate from the grand mean, then the factor "treatments" is significant. The individual treatments become anonymous when their deviations from the grand mean enter into a single summary statistic, the sum of squared deviations from the grand mean.

The ANOVA table is a worktable for computing the test of a null hypothesis. The user provides "sums of squares" based on a "decomposition" of the total sum of squared deviations.

As an example, the $N = 8$ observations, Y_{ij}, shown in Table 1, displayed in two rows with $J = 4$ per row, have a grand mean of $\overline{Y}_{..} = Y_{..}/N = 32/8 = 4$. Table 1 also displays the deviations from the mean, $Y_{ij} - \overline{Y}_{..}$. The small sample size that makes it easy

Table 1 Notation for one-way ANOVA with observed data, Y_{ij}

Row	Y_{ij}				Total	Mean	$Y_{ij} - \overline{Y}_{..}$			
1	2	4	4	2	$Y_{1.} = 12$	$\overline{Y}_{1.} = 3$	−2	0	0	−2
2	7	4	6	3	$Y_{2.} = 20$	$\overline{Y}_{2.} = 5$	3	0	2	−1
					$\overline{Y_{..} = 32}$	$\overline{\overline{Y}_{..} = 4}$				

to verify the calculations would, in practice, call for a cautious interpretation of results.

The *total sum of squared deviations*, the *total sum of squares*, or *total deviations* is

$$\sum_{ij}(Y_{ij} - \overline{Y}_{..})^2 = 4 + 0 + 0 + 4 + 9 + 0 + 4 + 1 = 22.$$

The *within sum of squared deviations*, the *within sum of squares*, or *within deviations*, is

$$\sum_{ij}(Y_{ij} - \overline{Y}_{i.})^2 = 1 + 1 + 1 + 1 + 4 + 1 + 1 + 4 = 14.$$

The Decomposition of the Total Sum of Squared Deviations

For the one-way ANOVA model, the decomposition formula is

$$\sum_{ij}(Y_{ij} - \overline{Y}_{..})^2 = \sum_{ij}(Y_{ij} - \overline{Y}_{i.})^2 + \sum_{ij}(\overline{Y}_{i.} - \overline{Y}_{..})^2,$$

$$\text{total deviations} = \text{within deviations} + \text{between deviations}.$$

With J observations per row, the between deviations or the sum of squared deviations between the row mean and the grand mean is

$$\sum_{ij}(\overline{Y}_{i.} - \overline{Y}_{..})^2 = J\sum_{i}(\overline{Y}_{i.} - \overline{Y}_{..})^2,$$

which in Table 1 is $4[(3-4)^2 + (5-4)^2] = 8$.

The general formula allows row i to have n_i columns. When all $n_i = J$, the ANOVA design has "balanced" replications; otherwise replications are "unbalanced".

To prove the decomposition formula, one shows that a cross-term equals zero, thereby linking the formula to the geometry of **least squares**. Specifically, rewrite the deviation $Y_{ij} - \overline{Y}_{...}$ as

$$(Y_{ij} - \overline{Y}_{i.}) + (\overline{Y}_{i.} - \overline{Y}_{..}).$$

Now, the squared deviation has two squared terms and a cross-term. Summing over all i and j yields the decomposition formula when the cross-term drops out; that is,

$$\sum_{ij}(Y_{ij} - \overline{Y}_{i.})(\overline{Y}_{i.} - \overline{Y}_{..}) = \sum_{i}(\overline{Y}_{i.} - \overline{Y}_{..})\sum_{j}(Y_{ij} - \overline{Y}_{i.}),$$

$$= \sum_{i}(\overline{Y}_{i.} - \overline{Y}_{..})0 = 0.$$

The vector of within deviations is **orthogonal** to the vector of between deviations because their inner product is zero. Hence, the decomposition formula illustrates the Theorem of Pythagoras by forming a right-angled triangle from the three vectors of deviations with the vector of total deviations as the hypotenuse.

Other terms are used in place of "between" and "within". If the model for a one-way ANOVA holds, then the data in each row cluster about the row mean. Such a model "explains" between deviations, while within deviations remain as unexplained errors. Hence, instead of the terms "between" and "within", some authors use "model" and "error" or "explained" and "unexplained".

The ANOVA Table

The null hypothesis that the row means are equal is tested by comparing the between-mean square to the within-mean square. A balanced one-way ANOVA (I rows and J columns with $N = IJ$ observations) has the ANOVA table shown in Table 2.

Within a row of the ANOVA table, the mean square equals the sum of squares divided by the **degrees of freedom**. For the data from Table 1, the ANOVA table values are shown in Table 3.

The sum of squares column contains the values for the terms in the decomposition. The degrees of freedom column entries total $N - 1$, one less than the sample size.

Table 2 Balanced one-way ANOVA

Source	Sum of squares	df	Mean square	F-ratio
Between (model)	Between deviations	$I - 1$	Between-mean square	$\frac{\text{Between-mean square}}{\text{Within-mean square}}$
Within (error)	Within deviations	$I(J-1)$	Within-mean square	
Total	Total deviations	$N - 1$		

Table 3 ANOVA table values from data in Table 1

Source	Sum of squares	df	Mean square	F-ratio
Between	8	1	$8/1 = 8.0$	$8.0/2.3 = 3.4$
Within	14	6	$14/6 = 2.3$	
Total	22	7		

The underlying normality assumptions (*see* **Normal Distribution**) imply that the between deviations and the within deviations have independent **chi-squared distributions** with the respective degrees of freedom given in the ANOVA table. The observed F ratio follows an ***F* distribution**.

For Table 1 the row means would differ significantly if the observed F ratio of 3.4 exceeded v, the value of the F distribution with one and six degrees of freedom for which $\Pr(F \geq v) = 5\%$. But the F ratio of 3.4 is less than $v = 5.99$ and the null hypothesis cannot be rejected.

The phrase "degrees of freedom" has a useful interpretation. Typically it arises when discussing the sample **variance**,

$$s^2 = \frac{\sum (x_i - \overline{x})^2}{(n-1)}.$$

The sum has n terms, yet is divided by $n - 1$. This suggests that a degree of freedom is lost because the parameter, the population mean, μ, is estimated by the sample mean, $\overline{x}$. The first column of the ANOVA table identifies a source or a factor associated with each row. The number of degrees of freedom is roughly the number of terms in the sum of squares minus the number of parameters associated with the row source.

The Link Between the Analysis of Variance and Linear Regression

The framework of linear regression helps to specify the model and the null hypothesis (or hypotheses). But the ANOVA model has many simple representations as a regression model. For example, let each row in Table 1 represent a treatment applied to four subjects. The one-way ANOVA model corresponds to a linear regression model with intercept α, namely

$$y = \alpha + \beta t_1 + \text{error},$$

where the zero–one variable $t_1 = 1$ for treatment 1 and $t_1 = 0$ for treatment 2. One might choose this model if treatment 1 were the experimental treatment and if treatment 2 were the control group.

The one-way ANOVA model also corresponds to a no-intercept model

$$y = \beta_1 t_1 + \beta_2 t_2 + \text{error},$$

where t_1 and t_2 are the respective zero–one variables for treatments 1 and 2. Note that in this model if $t_1 = 0$ then $t_2 = 1$ and vice versa. One might choose this model if both treatments were active treatments. One can show that $\alpha = \beta_1 + \beta_2$ and that $\beta = \beta_1$, indicating the sense in which the models are equivalent. The test that the row effects are equal in the ANOVA model, the test that $\beta = 0$ in the intercept model, and the test that $\beta_1 = \beta_2$ in the no-intercept model are all the same test. In each of these three tests under the given constraint the null hypothesis expected value of y does not vary with treatment.

In fact, the ANOVA model is equivalent to an infinite class of equivalent regression models, a source of confusion until one decides to choose one convenient model and ignore all the others.

When adopting the intercept model, one treatment category is viewed as "baseline" or "control" while all other categories of treatment are viewed as "active" compared with the common baseline treatment. A one-way ANOVA model with three treatments, t_1, t_2, and t_3, has the corresponding no-intercept regression model

$$y = \beta_1 t_1 + \beta_2 t_2 + \beta_3 t_3 + \text{error},$$

and lumps all treatments under one global null hypothesis that $\beta_1 = \beta_2 = \beta_3$. In this model if $t_1 = 0$ then $t_2 = t_3 = 0$; if $t_2 = 0$ then $t_1 = t_3 = 0$, and if $t_3 = 0$ then $t_1 = t_2 = 0$. The regression model permits one to break up the global ANOVA test into separate tests for each β coefficient.

ANOVA Equations

ANOVA models simultaneously test all levels of a factor within a row of the ANOVA table. The general procedure for testing each of several factors is as follows: decompose the total deviations into one line of (between) deviations for each factor followed by a final line of within deviations. For each factor, the F ratio is the mean square for a factor (factor deviations/factor degrees of freedom) divided by the within-mean square.

Regression equations list all parameters, while ANOVA equations list only the factors. For example, for the one-way model with I levels of treatment and J replications per treatment, one form of the ANOVA model equation is

$$Y_{ij} = \mu_i + \varepsilon_{ij},$$

where Y_{ij} is replication j of treatment i, μ_i is the mean for treatment i, and ε_{ij} are mutually independent normally distributed random errors each with mean zero and variance σ^2. Another form is

$$Y_{ij} = \mu + \alpha_i + \varepsilon_{ij},$$

where α_i is the difference between the mean for treatment i and the grand mean μ. Note that μ is not the intercept. The ANOVA table yields only tests of the factors. Thus, a variety of post hoc tests, known as "**multiple comparison** tests", typically compare the many pairs of mean values after carrying out the ANOVA F tests. These *post hoc* tests more closely resemble the many tests in a regression model, one for each β coefficient.

The General Linear Model

The mathematical theory behind the design of experiments provides precision and places ANOVA within the general theory of linear regression, "the **general linear model**". Few statisticians can resist this efficient but abstract view of the design of experiments. Hence, most modern texts and articles use the formalisms and notation of the general linear model. It succinctly expresses the decomposition formula and relates it to the geometry of least squares. The vector of estimates of the regression β coefficients are obtained by applying a "projection" matrix that maps from the vector space of observations (total deviations) into the subspace of the model (between deviations). The orthogonal complement to the model subspace is the error subspace (within deviations), thereby completing the right-angled triangle. The notation streamlines the expression of the null hypotheses and the development of the distribution of test statistics associated with these hypotheses. Under normality assumptions, summary statistics based on orthogonal vectors are statistically independent.

The design matrix, $\mathbf{X}$, appears in the regression model equation

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \text{error},$$

where the observation vector $\mathbf{Y}$ is an $N \times 1$ vector, $\mathbf{X}$ is an $N \times k$ matrix, and the vector of regression parameters $\boldsymbol{\beta}$ is a $k \times 1$ vector. The design is specified by the design matrix $\mathbf{X}$ and by the joint distribution of the error terms. The investigator then gathers the data, $\mathbf{Y}$, estimates the unknown vector of parameters, $\boldsymbol{\beta}$, and tests the null hypothesis under the specified distribution.

For the one-way ANOVA model with $I = 2$ rows and $J = 4$ columns as in Table 1, one can write the transpose of the vector $\mathbf{Y}$ as

$$\mathbf{Y}^T = (Y_{11}, Y_{12}, Y_{13}, Y_{14}, Y_{21}, Y_{22}, Y_{23}, Y_{24}).$$

Now, consider again the intercept and no-intercept regression models discussed at the beginning of this section, associating the subscript "1" with "intercept" and "0" with "no-intercept". Then for the intercept-regression model with $\boldsymbol{\beta}^T = (\alpha, \beta)$, and for the no-intercept regression model with $\boldsymbol{\beta}^T = (\beta_1, \beta_2)$ the respective design matrices, $\mathbf{X}_1$ and $\mathbf{X}_0$, are

$$\mathbf{X}_1 = \begin{bmatrix} 1 & 1 \\ 1 & 1 \\ 1 & 1 \\ 1 & 1 \\ 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 0 \end{bmatrix} \quad \text{and} \quad \mathbf{X}_0 = \begin{bmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \end{bmatrix}.$$

Note that the second column of $\mathbf{X}_1$ is the same as the first column of $\mathbf{X}_0$, whence $\beta = \beta_1$. If one adds the first column of $\mathbf{X}_0$ to the second column of $\mathbf{X}_0$, one obtains a column of 1s which is the same as the first column of $\mathbf{X}_1$, whence $\alpha = \beta_1 + \beta_2$. Then $\mathbf{X}_1$ and the transformed $\mathbf{X}_0$ have the same pair of column vectors, but in reverse order. It follows that the columns of each matrix span the same two-dimensional space.

In general, given a regression model of the form, $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \text{error}$, with an $N \times k$ design matrix $\mathbf{X}$ of rank $k \leq N$, let the columns of $\mathbf{X}$ form a basis for k-dimensional subspace E_k of the N-dimensional vector space E. Then the set of all possible design matrices for the ANOVA model corresponding to $\mathbf{X}$ is the set of all possible bases for E_k. This characterizes all regression models that yield the same ANOVA model.

In practice, one specifies a convenient basis for E_k; that is, $\mathbf{X}$ is fixed by choosing a convenient form of the regression model such as the model with an

intercept and a baseline category for each categorical variable.

The Design of Medical Experiments

Currently ANOVA is applied to many contexts that little resemble a laboratory setting. For example, to compare medical treatments one might enroll patients within several hospitals. Ideally, to achieve the same level of control as in an agricultural study, all patients might be brought to a large rectangular room with rows and columns of beds organized in blocks or plots. Setting aside one block of beds for each hospital, treatment might be allocated in regular patterns within each block (*see* **Blocking**).

Obviously, few medical studies can arrange for such convenient designs, but balance and varying adjacent treatments remain important methods of controlling error. For example, one does not want to give treatment A to the first 20 patients that enroll in a study and treatment B to the next 20 patients that enroll. This borrows from agricultural designs; if the left end of a field is the more fertile, then

A B A B A B
B A B A B A

is preferable to

A A A B B B
A A A B B B

Superimposing a structural factor, such as the 2×2 blocks in the first pattern, controls error. Thus, the design for a study that enrolls 40 patients might divide the sequence into 10 blocks of size 4 and within each block randomly assign two patients to treatment A and two patients to treatment B. Unlike the regular pattern in the agricultural design, the medical study randomly assigns treatments within blocks to prevent an investigator from anticipating what treatment the next patient might receive.

Factorial Designs

Factorial designs have one or more factors. For example, patients with systemic lupus erythematosus (SLE) at four hospitals received either at-home counselling or in-hospital counselling. They were stratified by the severity of disease; those without and with system damage (usually cardiac or kidney failure). The factors are treatments, hospitals, and severity of disease. A chronic disease, SLE "flares" take the form of fatigue, rash, and other such symptoms. Experts believe that deteriorating patients have more flares. Counselling promotes taking medications regularly and thereby reduces the number of flares.

Factors often divide into treatment factors that have scientific import and structural factors, like blocks, that pattern the allocation of treatments. The factor, "hospitals", may be structural, may have scientific import (if testing the hypothesis that teaching hospitals do no better treating SLE than other hospitals), or fall into the gray area between "treatment" and "structure", into a third category, "adjustment factors", that include "**confounders**", "**nuisance parameters**", and the type of factor that converts an ANOVA into an **analysis of covariance (ANCOVA)**. The underlying linear regression model absorbs adjustment factors in two ways, as extra terms each with a β coefficient or as a set of **interaction** terms that replace a single term as in the extension form an ANOVA to an ANCOVA model.

The lack of control over hospital protocols, physician practices, counselling practices, patient behavior, and the accuracy of medical charts, combined with uncertainty about how the disease progresses, raise many design issues. Factorial designs capture some of these extra sources of variation by introducing interaction terms. The ANOVA model can include two-way interactions (hospitals and treatments, treatments and disease severity, and hospitals and disease severity) and possibly three-way interactions.

This approach may "overfit" the model. A few ANOVA factors may add so many insignificant factors and interactions that the error (within deviations) shrinks, the F ratios inflate, and null hypotheses are falsely rejected (type I error). Suppose the study includes four hospitals, three levels of severity of disease, and two treatments. Then, while the ANOVA equation has seven terms (three main factors, three two-way and one three-way interaction), the corresponding regression equation has 24 β coefficients including one intercept, six main effect, 11 two-way effect, and six three-way effect parameters.

This calculation also gives the formula for the degrees of freedom in the corresponding ANOVA table. A one-factor design with R rows has R parameters; either a grand mean and $R-1$ of the rows of the factor as in the intercept regression model, or R rows as in the no-intercept model. A two-factor

model with R rows and C columns has RC interaction terms. The mean of column 1 is the grand mean of the R interaction terms with column 1. Thus, after fixing all the row and column means, there remain $(R-1)(C-1)$ two-way interaction terms to determine. Note that $(R-1)(C-1)+(R-1)+(C-1)+1=RC$. Analogously, a three-factor model with R rows, C columns, and S slices partitions the RCS parameters into $(R-1)(C-1)(S-1)$ three-way interactions, $(R-1)(C-1)+(R-1)(S-1)+(C-1)(S-1)$ two-way interactions, $R-1+C-1+S-1$ main effect parameters, and one grand mean.

One must decide which interactions to include, how to model the adjustment factors, in what order to test the hypotheses, and whether to simplify the model after failing to reject a null hypothesis. For instance, should the model drop a "useless" factor? If such a factor and all its interactions are insignificant, should one pool its associated sums of squares with the error sum of squares in subsequent hypothesis tests?

Classical design of experiments [2] contains testing protocols that control for type I error and that specify how to update the model after an insignificant test result. But precisely when to apply such protocols depends on the underlying biology. The biological model dictates which factors belong in the model.

Medical studies often uncover new factors. In the SLE example, the frequency of flares may depend on physicians' practice styles, a factor not considered so far in the model. Previous data or expert opinion may support inclusion of the factor "physicians" in the SLE ANOVA model. One or two physicians may stand out as specialists. Should the model identify them as separate factors, or merely include them, anonymously, among all the physicians?

Cochran & Cox [2] addressed the same issue by extending the eelworm-data model to account for other soil factors. In Chapter 3 of their text, they use the analysis of covariance to add to the ANOVA model an extra **covariate**; namely, the level of eelworm infestation before the experiment began. Taking samples before fumigants were applied determined the initial level of infestation. Without such data the analyst would have had to assume equal initial levels of infestation.

Who recognized the need to gather such data? R.A. Fisher had designed the eelworm experiment conducted in 1935 by the Rothamsted Experimental Station. A major figure in genetics, Fisher knew the pertinent biology and agronomy.

Fixed and Random Effects

Random Effects

The agronomist of Fisher's era fixed the levels of fertilizer and then controlled the allocation of these treatments. The term "**fixed effects**" refers to fixing the levels of a factor. Strictly speaking, "**random effects**" ought to imply making a random selection of levels from an extensive list or "population" of possible levels. Why would anyone make such an odd selection? Typically, in **randomized complete blocks designs**, one randomly assigns treatments to blocks of subjects (the levels of a structural factor) because one has no other choice. For example, in the SLE example, only one form of counselling treatment might be feasible at each hospital because patients counselled at home would "contaminate" the treatments by speaking with those given in-hospital counselling. Many surveys save money by using **cluster sampling**, and hence introduce random effects into the analysis. An interviewer goes to a home and interviews all three adults in this household, rather than traveling to three separate homes and interviewing only one adult in each home, thereby introducing the random factor "household". Individuals who are interviewed several times (e.g. repeated measures) or the aliquots of an individual laboratory specimen introduce the random factor "individual".

In the SLE example, the randomized block design assigns the same treatment to the entire block of patients at each hospital. In contrast, a "completely randomized design" would randomize each subject separately. From what population are the blocks randomly selected? Were the hospitals drawn from a long list of all US hospitals, or from a "convenient" shortlist of hospitals inclined to participate?

Many convenience samples of blocks are treated as "random effects" because this lack of control more closely resembles "random effects" than "fixed effects" and because the former provides more conservative inference than the latter. For example, some forms of **meta-analysis** [5] based on published articles use a random effects model, without any data on the rest of the population; that is, unpublished articles. However, in the SLE example, if one regards the

factor "hospital" as a fixed effect, then critics might argue that a significant treatment difference would only occur at the study hospitals. Hence, regarding the factor "hospital" as a random effect adds credence to the assertion that treatment effects generalize to other hospitals.

Computation Using the ANOVA Table

The ANOVA table and all the foregoing theory assume fixed effects or fixed factor level models. Fisher also used the ANOVA table as a worktable for the random effects model (all factors random) and the mixed model (some factors fixed and some factors random). But each row in the ANOVA table for a random factor now contributes to the error sum of squares and the F ratio becomes much harder to compute. This means that the one-way fixed effects model has only one source of error (within) deviations, while the one-way random effects model has two sources of error, a source within treatments and a source between treatments. Fisher adopted a reasonable, but imperfect, strategy to separate the model deviations from the error deviations. Today, high-speed computing makes feasible other more rigorous solutions [6]. In the fixed effects model, both the between-mean square and the within-mean square have the same expected value, σ^2, the error variance. In the random effects model, these expected mean squares are expressions linear in σ^2 and in the variance of the randomly selected levels of the between factor, σ_{A}^2. Fisher set these two expressions equal to the observed values in the mean square column of the ANOVA table, solved the two simultaneous equations in two unknowns, σ_{A}^2 and σ^2, and set the F ratio equal to the ratio of these solutions.

For the balanced one-way random effects model with $N = IJ$ observations, J replicates of each level $i = 1, 2, \ldots I$, the expected values of the between-mean square, B, and of the within-mean square W, are, respectively, $J\sigma_{\mathrm{A}}^2 + \sigma^2$ and σ^2. It follows that the estimate of σ_{A}^2 is $(B - W)/J$, a negative quantity whenever B is less than W. A negative value undermines the hypothesis test. Mixed or random models with two or more factors generate sets of three or more simultaneous linear equations with solutions that can be negative and that seldom have simple closed forms.

The Abstract Viewpoint

The one-way random effects model has the ANOVA equation

$$Y_{ij} = m_i + \varepsilon_{ij},$$

where the m_i are mutually independent normally distributed random variables with mean μ and variance σ_{A}^2, the ε_{ij} are mutually independent normally distributed random errors each with mean zero and variance σ^2, and each of the m_i is independent of each and every ε_{ij}. Note that the fixed effects model is an extreme case of the random effects model because m_i is fixed when $\sigma_{\mathrm{A}}^2 = 0$. Also, note that when $j = j'$ the variance, $\mathrm{var}(Y_{ij})$, equals the covariance, $\mathrm{cov}(Y_{ij}, Y_{ij},) = \sigma_{\mathrm{A}}^2 + \sigma^2$, but when $j \neq j'$, $\mathrm{cov}(Y_{ij}, Y_{ij},) = \sigma_{\mathrm{A}}^2$. It follows that, when σ_{A}^2 is positive and when $j \neq j'$, the random variables Y_{ij} and $Y_{ij'}$, are dependent and have a positive **correlation** $\sigma_{\mathrm{A}}^2/(\sigma_{\mathrm{A}}^2 + \sigma^2)$ that Fisher named the "intraclass correlation coefficient". In contrast, in the fixed effects model, all the random variables, Y_{ij}, are independent.

The general linear model transforms the dependent normal random variables, Y_{ij}, into independent normal random variables, Z_{ij}. Then, within the framework of the fixed effects models, one obtains from the Z_{ij}, the sum of squares, degrees of freedom, and distribution theory needed for the Y ANOVA table.

This provides formulas and distributions for the simpler mixed models and a theoretical foothold for justifying approximations when the estimation scheme breaks down (e.g. a negative estimate of a variance). However, the abstract approach merely asserts that a factor is "random" without asking what mechanism has generated the associated normal errors.

Balance, Missing Values, and Robustness

Balance and Missing Values

Having "balance" greatly simplifies the theory, the formulas, and the ANOVA table. Generally, when the number of replicates per treatment level varies (imbalance), the F ratio may no longer follow an F distribution and closed formulas and computation become much more complicated. Hence, having a few missing values from a balanced design often calls for restoring the balance by imputing the missing values.

Having many missing values or major imbalance remains a thorny issue. While imputation may restore balance and vastly simplify theory and computation, the investigator still has to justify the assumptions behind the imputation. However, the credibility of computer-intensive solutions (on the basis of **maximum likelihood** or **Bayesian methods**) often depend on the correctness of the model and of the error distributions [6].

Robustness

Until recent advances removed some barriers, limits on computation allowed only simple patterns of correlation among normally distributed errors, such as equal correlation among all observations in a block of units. The body of theoretical results associated with **generalized estimating equation (GEE)** models [3] and **restricted maximum likelihood (REML)** methods [6] addressed the problem of an excess number of parameters destabilizing the parameter estimates. For example, in a one-way ANOVA design with $N = IJ$ observations, J replications for each of I subjects, the maximum number of $I(I-1)/2$ correlations among the I subjects exceeds N whenever $J < (I-1)/2$. Advances, such as the GEE models, have produced **robust** estimates of treatment effects; robust against a wide variety of possible correlation patterns among the error terms. As embodied in the REML solution, one integrates the full **likelihood** function over the possible correlation patterns to obtain estimates from a **marginal likelihood** function containing only the treatment parameters.

Normality assumptions are another source of concern. While recent advances allow other distributional structures for error, notably the **binomial** and **Poisson** families for discrete data, the **multivariate normal distribution** dovetails with the theory of least squares. **Simulation** methods such as the **bootstrap** and well-chosen approximate **nonparametric methods** offer effective validation of results based on normal assumptions.

Errors in variables refers to errors in the measurement of the values in the design matrix, $\mathbf{X}$, that represents the factor levels, as opposed to the error terms associated with the outcome measure, $\mathbf{Y}$, as in the regression model matrix equation, $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} +$ error. For example, a medical study might require a standard form on each patient at the time of diagnosis, but rely on a medical chart review for patients diagnosed before the study began. The quality of medical chart data varies enormously and is seldom as accurate as a standard form. To distinguish these sources let $\mathbf{X}$ denote the data from the standard form and let $\mathbf{W}$ denote the same "surrogate" data abstracted from medical charts.

Solutions for the **errors in variables** problem [1] call for assumptions about the models relating the random variables $\mathbf{W}$, $\mathbf{X}$, and error distribution. These models extend to include other sets of covariates besides $\mathbf{X}$. Carroll et al. [1] have provided robust solutions by extending their results to **nonlinear regression** models and introducing functional modeling that makes minimal assumptions about the distribution of $\mathbf{X}$.

Previous discussion has touched on the lack of randomness when using convenience samples, as in the SLE example where the study hospitals were those inclined to join and in meta-analyses of published articles. One can emulate a randomized study by the methods of **quasi-experimental design** or, more broadly, the methods of choosing controls for a **case–control study**. All such methods try to balance known measurable confounding factors, or at least produce a conservative **bias** in known but hard-to-measure factors. But only randomization can balance unknown factors.

ROBERT LEW

Experimental Study

An experimental study is a study in which conditions are controlled and manipulated by the experimenter. For example, in a comparative **clinical trial** the method of assigning treatments to subjects is determined by the investigator. Often, **randomized treatment assignment** is employed to assure that the innumerable potential **confounding** factors not controlled by the **experimental design** have similar distributions in the various treatment groups. Special design features are used to improve the efficiency of an experimental study, including **stratification**, **matching**, and **factorial experiments** to study several treatments simultaneously. Experimental studies afford good opportunities to reduce the possibility of confounding, to obtain good measurements on various factors that might influence outcomes (*see* **Covariate**; **Effect Modification**), to avoid **biases** in measuring outcomes, and to limit the obfuscating impact of other controllable factors that influence outcomes.

An experimental study is distinguished from an **observational study** in which the investigator does not control the treatment or exposure assignment, nor many other aspects of the process under study. An observational study is thus more subject to problems of confounding, **measurement error**, and bias than an experimental study, but many of these issues must also be carefully considered and controlled in the design, conduct, and interpretation of experimental studies.

MITCHELL H. GAIL

Experiment-wise Error Rate

Medical experiments are frequently designed to perform **multiple comparisons**. For example, a two-treatment cancer trial can require comparisons on the following outcome variables (called endpoints): survival, quality of life, and reduction in weight. Similarly, three pairwise comparisons are possible on a three-treatment trial. Alternatively, patients can be **stratified** and subgroup analysis performed on each stratum. Also, repeated significance testing is possible at different stages of a lengthy trial. Let us suppose that L comparisons are to be made, resulting in M' incorrect decisions. Then, the experiment-wise error rate is defined as $\Pr(M' \geq 1)$. Usually, only false positives (type I errors) are of interest, resulting in the typical definition of the experiment wise error rate as $\Pr(M \geq 1)$, where $M \leq M'$ is the number of type I errors committed (*see* **Hypothesis Testing**). The experiment-wise error rate is frequently called the *family-wise error rate*, although the term family can be more restrictive than experiment, as an experiment can consist of several families of comparisons. Ignoring such differences, the experiment-wise error rate, $\Pr(M \geq 1)$, is denoted by FWE.

A companion measure is the *per-experiment error rate*, defined as $\mathrm{E}(M)$. Clearly, $\Pr(M \geq 1) \leq \mathrm{E}(M)$. For $L = 1$ and significance level α, $\Pr(M \geq 1) = \Pr(M = 1) = \mathrm{E}(M) = \alpha$. More recently, a less stringent measure of error rate, called the *false discovery rate*, has received attention; see, for example, [1, 2].

Consider L independent comparisons, each at size α. Assume that the **null hypothesis** for each comparison is true. Then $\Pr(M \geq 1) = 1 - (1 - \alpha)^L$. If, for example, $\alpha = 0.05$ and $L = 6$, then $\Pr(M \geq 1) = 0.26$, which is far greater than the nominal $\alpha = 0.05$. Medical researchers frequently ignore this multiplicity effect and base their conclusions on multiple individual unadjusted comparisons resulting in the over-reporting of false positive treatment differences [7]. On the conservative extreme, the **Bonferroni inequality**, which uses α/L for each comparison, protects the FWE in the *strong* sense, but at the cost of considerable loss of **power**. Such protection can frequently be achieved more efficiently, for example, by using Tukey's T procedure for pairwise comparisons in a one-way **analysis of variance** (ANOVA). Protection in the *strong* sense means that $\Pr(M \geq 1) \leq \alpha$, even when some of the individual null hypotheses are not true. Similarly, protection in the *weak* sense guarantees that $\Pr(M \geq 1) \leq \alpha$ when the L individual null hypotheses are true. The difference between these two concepts can be illustrated with one-way ANOVA. For that case, the *least significant difference* (LSD) procedure recommends performing first an overall F test of size α, and then making individual comparisons, again of size α, only when the overall test is significant. Although this procedure protects the FWE weakly, it can result in a large FWE value when, for example, one of the treatments differs from the others. This difference leads to a significant overall finding, resulting in a loss of protection on the individual comparisons.

The approach used to handle errors in a multiple comparison experiment depends on the type of experiment being performed. Protection of the FWE in ANOVA procedures has been carefully studied [4]. Group sequential methods based on alpha-spending functions (*see* **Data and Safety Monitoring**) have been devised for adjusting for multiple looks [5]. The handling of *multiple endpoints* and multiple treatments are less developed areas at this stage. Multiple endpoints can sometimes be combined into a single measure, such as the *Karnofsky* performance score in gastroenterology. Alternatively, some endpoints can be viewed as primary, while others are secondary, with control of the FWE only for the primary endpoints. For a more technical discussion of treating multiple endpoints in an experiment, see [6]. Multiple treatments can be compared using the Bonferroni inequality, although less stringent methods are often possible. As an example, the comparison of two different treatments with a control can be viewed as two separate experiments, each at size α, as this is the way in which they would have been viewed had they been performed by different experimenters. An excellent source for discussion of the FWE and multiple comparisons procedures is [3]. In summary, care needs to be exercised during the planning of an experiment to ensure protection of the experiment-wise error rate.

BORIS IGLEWICZ

Expert Witness, Statistician as

Until fairly recently, the applications of inferential statistics (*see* **Inference**) in legal proceedings have been minor and limited. With the advent of civil rights legislation, however, the courts have embraced statistical inference with enthusiasm. The needs of the courts are not well matched with the usual practice of statistics, and this mismatch has serious adverse consequences for both fields. The various sources of difficulty are outlined, and tentative proposals for their amelioration are put forward.

Although the field of statistics can find its origins in matters pertaining to society and its governance, statistics as a formal discipline has only recently received special recognition in legal proceedings. To be sure, statistics in the sense of numerical summaries are pervasive – in legal settings as in many others. But statistical inference based on probability models is another matter, and in that respect statistics has had only a minor and restricted role in the law.

The Howland will case of 1867 [13], in which Benjamin Peirce undertook a statistical analysis of handwriting, is a case in point. The analysis was ingenious, and might even have been persuasive, but the court in that instance found a technical excuse to put it aside. From time to time, most notably in the Collins case a century later [16], statistical analyses of identification evidence have come before the courts, and generally the courts have rejected them, except in rather special cases of genetic evidence of paternity (*see* **Paternity Testing**) and of fingerprint evidence.

Following the passage of the Civil Rights Act of 1964, however, the courts have looked to statistical analysis to decide on the substantiality of evidence of illegal discrimination, and by now the statistical expert witness is definitely in the big time.

It might be thought that this is cause for celebration within our profession. Inference is our field, of course, and what could be more appropriate than a long overdue recognition by the courts of our special expertise. However, there is room for second thoughts as well, when we pause to consider the consequences for other professions that have come to occupy a similar role. The situation of **psychiatry** (to choose a not-at-all random example) is notorious. In the case of the most recent would-be presidential assassin, John Hinckley, neither the prosecution nor the defense had any difficulty in finding distinguished psychiatrists, academics, and others to testify that Hinckley was or was not legally sane at the time he fired the shots. Indeed, it is not stretching matters to say that the courts and the bar, and even the public at large, have come to hold the profession of psychiatry in considerable contempt – as a clan of hired guns, available for a price to whichever side first knocks on the door. That this perception is not altogether fair is beside the point. The statisticians may have cause for congratulation in this new-found status – they also have cause for worry.

Indeed, psychiatry is not alone in its notoriety. The evident ease with which experts in almost any field can be found to testify in support of either side of a case has led to an aphorism in the law that has a familiar ring to statisticians: there are three kinds of liars – liars, damned liars, and expert witnesses. (The origins of this aphorism are uncertain, but it appears in various forms in legal writing during the past century.) Statistics has had a hard time establishing its credibility as a scientific domain, and the credit that it now has may well be threatened by our new-found prominence.

The views expressed here are idiosyncratic, and the interested reader may wish to consult additional sources dealing with the interaction between statistics and law. In particular, the collections edited by Peterson [17], Monahan & Walker [15], and DeGroot et al. [4] present much relevant material and a number of alternate views.

The remainder of this article is divided into four sections: the first reviews the different domains in which statistical testimony is sought; the next discusses the environment in which such testimony is given and contrasts that environment with the quite different system prevalent in Europe. The manifold corrupting influences that lead to the unsavory reputation of expert witnesses in American courts are then reviewed, and I close with a very modest proposal for reform.

Domains of Application of Statistics in Law

I start by distinguishing particular domains in which statistical expertise is called upon.

Scientific Sampling

The simplest and, in many ways, the most satisfactory application of statistics in legal proceedings, is the use of scientific sampling methods (*see* **Probability Sampling**). In this area, W.E. Deming has been the preeminent pioneer [5], and he has taken the pains to lay out a clear recipe for satisfactory performance. This consists largely of eschewing any responsibility for choice of population to be sampled or for the evaluation of sampled units. His advice, which I believe to be eminently sensible, is that the sampling expert limit himself to testimony about the inference from the sample to the population, when the same evaluation process is used for both. Deming emphasizes that although the sampling expert may have become familiar with the substantive field and may have given good advice about other aspects of the study, his *professional* expertise is limited, and he should testify only within that area.

Following in Deming's footsteps, on a number of occasions I have assisted in the sampling of railroad traffic, in connection with studies of the effects of a merger between two railroads or of the effects on railroad A of the abandonment of certain lines by railroad B. I have presented such work before administrative law judges of the Interstate Commerce Commission and have often been cross examined thereon. However, despite strong controversy and aggressive examination of management personnel, the sampling testimony has generally been accepted with minimum fuss, and the cross examination has ordinarily consisted solely of emphasizing the limits of my responsibility.

Sampling testimony is not always so cut and dried, however. An early case is that of *Sears Roebuck & Co. vs. City of Inglewood* [19], in which the sales to nonresidents had been erroneously subject to tax and Sears was seeking recovery. The expert retained by Sears sampled 33 days from the 826 business days in the period at issue, and all sales slips from each of those 33 days were examined and assessed. The estimated overpayment was $27 000, subject to a **standard error** of $2000. No quarrel with the method of sampling was made, but the judge in the case was uneasy about this unfamiliar technique. He ruled that no recovery could be made for individual sales that had not themselves been individually examined, and Sears had to go back and look at each sales slip. The result is a choice teaching example, of course, because it is one of those exceedingly rare cases in which a well-drawn sample is followed by a complete **census**, illustrating the ultimate validation of the statistician's art. In this case the complete count was surprisingly close to the estimate – a deviation of less than $300.

However, even in the clean world of scientific sampling, a witness may find himself in difficulty. He may be asked to comment on the sample drawn by the opposite party – perhaps by a nonstatistician – and it may turn out to have been a **systematic sample**, without **randomization** of any kind. And here a prudent witness has a problem. The failure to randomize opens the way to possible **biases**, but as all experienced in sampling are aware, for a great many **sampling frames** (i.e. those with very little internal structure) the bias in the estimate and even in the calculated standard error is not likely to be large. Should one testify that the job was not competently done and the results should therefore not be given credence? (Counsel for one's own side would believe such testimony is entirely proper and the least that is owed him.) Or should one testify that, although the sample does not adhere to the canons, it is not likely that the result is for that reason wide of the mark? One will be tempted to add that when incompetence is manifest in the visible part of the operation, it is suspect in that which is less visible, and therefore the result should be received with caution. Should one yield to that particular temptation, however, one is most likely to be cut off by an objection from the opposing attorney, protesting testimony that is "mere speculation". Since the court is only interested in the result of one's judgment about design, one is likely either to overstate the objections to the systematic sample or so understate them as to make one's client wonder why he was put to the trouble of drawing a random sample in his case. (And what should one say when the sample one is called upon to criticize was drawn by Dr Deming or Professor **W.G. Cochran**, who – in the exercise of professional judgment – decided that the fuss required to randomize was not worth the trouble in the case at hand? Indeed, Cochran was fond of telling of the occasion on which he was called on to carry out a sampling study of, I believe, a class of retail stores, and he instructed that the sample consist of every tenth establishment of that type listed in the Yellow Pages. The judge, he said, welcomed his expert testimony as a learning experience and remarked, after Cochran

had been sworn, "I am glad to hear and to learn from Professor Cochran about this scientific sampling business, because I know virtually nothing about it. In fact, about the only thing I *do* know is that you should not just start at the beginning and take every 10th one after that".) I confess that, not being Deming or Cochran, I make it a point when drawing a sample to be sure that the design has as much internal credibility as I can give it, and as little dependence on the quality of my own judgment as I can manage.

Paternity and Fingerprints

In the sampling domain, statistical inference works well because we impose the probability model directly on the situation – through randomization – and our testimony has both the appearance and the substance of relative objectivity. We can feel rather sanguine about our contributions to legal proceedings in this domain.

We have somewhat less security when we turn to certain areas of identification evidence. I refer to blood tests for assessing evidence of paternity and to fingerprint evidence. In the former, at any rate, there is a probability element introduced by Mendelian genetics (*see* **Mendel's Laws**), and the statistical expert may have a real contribution to make. Unfortunately, the ultimate probability calculation depends on population **gene frequencies**; even where these are known for the population at large, it is often some subset of the population that is at issue, for which the frequency is not well established, and the expert finds himself on doubly uncertain ground. There are controversies aplenty in this domain, but this is not where most of the action lies.

Observational Data

The broad, almost limitless, domain in which the courts have come more and more to look to statisticians for guidance is in the analysis of **observational data**.

Consider, for example, the association between cigarette smoking and the subsequent development of lung cancer (*see* **Smoking and Health**). First identified as an incidental and highly uncertain association, the accumulated evidence today appears overwhelming, although there are no clinical experiments to support it and only indirect support from cellular biology. The primary evidence is indeed statistical, and it *is* convincing, but not as a result of conventional significance testing (*see* **Hypothesis Testing**). Rather, it is the robustness of that association over time, place, and population that is convincing. For the most part, probability-based statistical testing is irrelevant to the strength of our conviction.

I do not quite share David Freedman's hardline position against formal statistical inference for observational data. As explained in a superb elementary textbook [9], Freedman regards probability-based testing in a situation without a plausible probability model to be at best irrelevant and more likely misleading. I think, in contrast, that such testing serves a useful purpose as a benchmark. If the observed **association** would not be counted statistically significant had it arisen from a randomized study, it could not be counted as persuasive, when even that foundation was lacking. If the observed association is highly statistically significant, however, the extent of its persuasiveness depends on many uncertain judgments about background factors, and its persuasive value is not at all reflected in the significance level itself.

However, the principles of statistical inference relevant to the courts are not the province of the statistics profession alone.

The Courts, Civil Rights, and Statistics

The Supreme Court has canonized formal statistical inference in a series of decisions, beginning with a jury discrimination case, *Castaneda vs. Partida* [3], decided in March 1977. Having noted that the population of Hidalgo County was 79% Spanish surnamed, but that the jury panels selected in accordance with the prevailing Texas "key man" system averaged only 39% Spanish surnamed (i.e. 339 of 870 jurors), the Supreme Court itself – or more likely one of the Justices' law clerks – calculated the familiar critical ratio (*see* **Normal Scores**) according to the **binomial distribution**; that is, the difference (39% minus 79%, or 40%) divided by the standard error $((pq)^{1/2}/n$, which works out to be 1.5%), obtaining a critical ratio of 29. The Court then commented, "as a general rule for such large samples, if the difference between the expected value and the observed number is greater than 2 or 3 standard deviations, then the hypothesis that the jury drawing was random would be suspect to a social scientist".

Formal significance testing next appears in an employment discrimination case, *Hazelwood School*

District vs. United States [14], decided three months later. In that case, the proportion of qualified teachers in St Louis County (excluding the city of St Louis) who were black was estimated to be 6%, and during the two year period at issue, only 15 of 405, or 4%, were black. The *Hazelwood* court now says, "A precise method of measuring the significance of such statistical disparities was explained in '*Castaneda v. Partida*' ...", and the opinion goes on to paraphrase the earlier two or three standard deviation rule, but with a slight shift; that is, "... if the difference exceeds 2 or 3 standard deviations, then the hypothesis that teachers were hired *without regard to race* would be suspect" (emphasis added). The reference to randomness is now absent, as is the social scientist. Since it is self-evident that the process of selection is not – nor is it desirable that it be – random, it is far from clear why either the social scientist or the Supreme Court should look upon a standard based on randomness as appropriate to assess the likelihood of purposeful discrimination. To be sure, there was much other evidence in the case, showing explicit discrimination at earlier dates, but the preceding quotation is the only place in the opinion where the relevance of the statistical significance test is in any way explained. Nonetheless, in *Hazelwood* the court went further, in an obscure remark that pointed clearly to the preeminence of statistics. It said, "Where gross statistical disparities can be shown, they alone may in a proper case constitute prima facie proof of a pattern or practice of discrimination". Thus, in the space of a less than half a year, the Supreme Court had moved from the traditional legal disdain for statistical proof to a strong endorsement of it as being capable, on its own, of establishing a prima facie case against a defendant. (It is sometimes argued that the use of doubtful evidence to support a prima facie – that is, preliminary – finding is a matter of small legal consequence. Such a finding merely shifts the burden of proof from the plaintiff to the defendant. In fact, however, there is nothing at all "mere" about this shifting of the burden, since the difficulty of proving oneself innocent of discrimination turns out to be great indeed.)

The accelerating role of statisticians in employment discrimination cases arises from a combination of the statistical significance testing endorsed in *Hazelwood* with an earlier decision, *Griggs vs. Duke Power Company* [11], in 1971. In *Griggs*, it was found that the requirements of a high school diploma and a certain score on a standardized IQ test for employment in such jobs as maintenance and laboratory work operated to exclude black applicants far more frequently than they did to exclude white applicants. The court concluded that, in the absence of direct evidence that these criteria related to improved performance on the job, the "adverse impact" of those requirements constituted a violation of Title VII, even though there may have been no intent to discriminate on the grounds of race. (To be sure, there was plenty of evidence of intent to discriminate in the *Griggs* case, most especially in the facts that the power company had explicitly excluded blacks prior to passage of the Civil Rights Act, and that it had put in the new requirements at the same time that the jobs were first made available to blacks. The principle established in *Griggs* clearly put the issue of intent aside, however, and the doctrine has been widely applied by lower courts in cases in which there was little or no evidence of invidious intent. Once again, proof of "job relatedness" or, as the Supreme Court says, "business necessity", has proved generally elusive, and a great many employment standards and admissions tests have been found to be in violation of the law for lack of such proof.)

The criterion seems reasonable enough until we are faced, as was the Supreme Court, with a case such as *Washington vs. Davis* [20]. In this case, Walter Washington, mayor of Washington, D.C., and his police chief had set about to recruit blacks into the D.C. police force, with an aggressive campaign to encourage black applications. The campaign was successful and many blacks were recruited, but among the newly encouraged applicants the written test "operated", in the language of the *Griggs* decision, "to disqualify Negroes at a substantially higher rate than White applicants". Thus, affirmative action, clearly intended to recruit blacks, fell foul of the adverse impact principle developed in *Griggs*. The trial court dismissed the charge, but the appeals court reversed, citing *Griggs*. The Supreme Court sidestepped the issue. It supported the district program, but it did so on a technicality that did not require it to comment on the general validity of the *Griggs* principle. In subsequent cases, the *Griggs* principle has continued to guide the lower courts.

It must be acknowledged that there has been some slackening of the tide in Title VII enforcement in the last two or three years, especially with regard

to race and sex discrimination. Under the Reagan administration there was more emphasis on freeing business from government interference and less on righting the wrongs of the oppressed. In response, the courts appear to have given somewhat less weight than before to purely statistical evidence.

The Position of the Statistical Expert

The result of the preceding and related decisions has been to place the statistical expert witness in a most unaccustomed and exalted position. Despite the moderate recent decline in enforcement, the role of the statistical expert remains critical in the cases that are brought. Lawyers gaze with awe as he examines the entrails of complex **multiple regression** computer output, and they await breathlessly his conclusion that the coefficient of the variable designating sex is indeed more than twice the standard error. Similar attention attends his calculation of continuity-corrected 2×2 chi-squares to see whether they are larger or smaller than 3.84 (*see* **Chi-square Tests**). Indeed, the case may be won or lost largely on these outcomes.

That this position is a false one, none can doubt. Certainly the statistical experts know it, and most of them say so to some extent – or at least they assert that the meaningfulness of their numerical results depends on a number of assumptions that they are unable to verify. The courts, however, are not engaged in academic exercises and, having urgent need to come to some conclusion, turn to the Supreme Court instead of to the witness's cautional phrases for guidance. Those opinions have, intentionally, a somewhat Delphic quality. They tell us that "gross disparity" in pass rates is evidence of illegal discrimination, and they also tell us that the hypothesis of random selection is made to appear doubtful when a difference is larger than two or three standard errors. They do not quite say that statistical significance at the 5% level constitutes gross disparity, but that is how the lower courts read them. The statistical experts cannot help but find this heady stuff, and we should not be surprised to find ourselves speaking with far more assurance about our conclusions than an objective appraisal of the evidence might warrant.

Thus we are led to the unedifying spectacle of two well-qualified statistical witnesses providing analyses that they interpret oppositely, each supporting the interest of the party who introduces him. Other categories of expert witnesses have been there before us, of course – the psychiatrists, medical internist and surgeons, and structural engineers, among others. The courts have urgent need for the assistance of these experts, but they seem uncommonly ill served by them. The point was made clearly in an editorial in the *British Medical Journal* [2]:

> Medical evidence delivered in our courts of law has of late become a public scandal and a professional dishonour. The Bar delights to sneer at and ridicule it; the judge on the bench solemnly rebukes it; and the public stand by in amazement; and honourably minded members of our profession are ashamed of it.

This was printed more than a century ago, but little has changed in the intervening years. Statisticians have escaped comparable condemnation because we have been, until recently, too unimportant in the courts to be noticed, not because of any higher ethical standard of our profession.

One cannot help speculating on the possibility of improvement. In fact, I believe that some of the difficulty is structural, and that there are ways in which we could function usefully in legal settings without so large a sacrifice of professional integrity. To this end, I now discuss the players in the game and the key influences on them. Among the players or participants in the legal ballet, I distinguish three: (i) the courts themselves, most especially the Supreme Court, who together with the Congress set the rules by which the system operates; (ii) the lawyers – collectively, the Bar – who primarily control the direction of play within those rules: and (iii) the expert witnesses on whose performance the integrity of the enterprise ultimately depends.

The Courts and the Expert

The obvious objective of the courts in respect to expert testimony is to optimize the search for truth. The courts would like to get the most well-qualified expert, keep him in a situation in which he can devote his best efforts to analyzing the evidence, and have him testify in an atmosphere free of coercion or bias. The courts also want to be sure that the expert is adequately examined to test and verify his qualifications, the adequacy of his preparation, and his objectivity.

To this end, the courts in Germany and France arrange matters very differently from the English

and American courts. In cases in which experts are needed, they are in the first instance appointed by and responsible to the court and not to either party: they are first examined by one of the judges and also cross examined by him. Attorneys for the plaintiff and defendant may also cross examine, but the proceedings are not generally adversarial as are our own, and the appearance of neutrality, at least, is the rule. Thus the continental system seeks the best witnesses and seeks to put them in a neutral setting, primarily by putting the major responsibilities in the hands of the judges.

The Anglo-American system, in contrast, is based on the proposition that truth is most likely to emerge through the best efforts of adversaries. No point in favor of the defendant will be overlooked or undervalued, it is thought, if responsibility for bringing it out is assigned to the defendant's advocate.

Nonetheless, whatever the merits of the adversary system may be in general, it is well recognized that it wreaks havoc with expert testimony, and proposals for reform appear regularly. Chief among them is to borrow from the continental system and to have the primary expert witnesses appointed by and responsible to the court. This reform was vigorously advocated by the past century's revered commentator on legal evidence, John Wigmore [21], and model codes have been proposed to this end. Indeed, Rule 706 of the Federal Rules of Evidence provides explicitly for court-appointed experts. Regardless of the merits, in practice this power is used extremely sparingly. (There may be some cases of court-appointed statisticians in Title VII cases, but I have not heard of any.) One can conceive of many reasons for the ineffectiveness of these "reforms", not least the vulnerability to criticism of a judge who appoints an expert later shown to be inadequate, but it is enough for my purposes to observe that such reforms have not taken hold in this country, and that they do not seem likely to become influential in the near future.

The Bar and the Expert

The position of legal counsel, although in principle identical to that of the judge, is in fact quite different. Having committed himself to the adversary system as the best method of reaching a just conclusion, the lawyer for the plaintiff now accepts his position in the system, that of advocate, and leaves to the court the responsibility for discerning the path of justice. To him, the expert is simply one of the elements that he must fit into place to make the most effective case. To be sure, any lawyer of competence recognizes that it is usually favorable to his case for the witness to appear to be dispassionate and objective. The best lawyers recognize that a witness will make the best appearance of objectivity if he feels that he is indeed free to go where his research and reflection lead him. This is not to say that these excellent advocates are really in the market for unbiased witnesses who may testify to their side's disadvantage.

John C. Shepherd of St Louis, a distinguished trial lawyer who was president of the American Bar Association in 1984–1985, spoke to a conference for lawyers on relations with the expert witness, and this [18, pp. 21–22] is what he said:

> Many people are convinced that the expert who really persuades a jury is the independent, objective, nonarticulate type ... I disagree. I would go into a lawsuit with an objective, uncommitted, independent expert about as willingly as I would occupy a foxhole with a couple of non-combatant soldiers.
>
> If you find the expert you choose is independent and not firmly committed to your theory of the case, be cautious about putting him on the stand. You cannot be sure of his answers on cross-examination. When I put an expert on the stand, he is going to know which side we are on.
>
> The trial lawyer must make of the expert a convincing, persuasive witness. The lawyer deals in words, and he knows how to put the package together to impress the jury favorably. It is his job to instruct the expert, an exercise requiring great tact and firm conviction.

Keep in mind that the lawyer does not need to make bricks without straw. It is perfectly proper for him to consult a great many potential witnesses but to bring to court only that one whose honest convictions fit well with the lawyer's needs. The phenomenon of "shopping for witnesses" is well recognized by the courts, and it contributes to the wary attitude that they have about experts in general. The shopping is done by the lawyers, however, and is thus not subject to exposure in the actual testimony.

Corrupting Influences

As we have just seen, the professional integrity of the expert witness and, through him, of the profession that he represents, is not well protected by the courts

and hardly at all by counsel. But before we assume too readily that simple morality and personal ethics will be an adequate substitute, we should reflect for a bit on what I call, for lack of a more delicate phrase, *corrupting influences*. Some are inherent in the nature of the situation, and others are special to the adversary situation.

First, there is the fact that the expert witness is playing someone else's game and, inevitably, has to accept the rules as he finds them. His instructor in these matters is, of course, his client's counsel, and the witness is ill-equipped to resist the role of adversary when his lawyer thrusts it upon him. But even supposing that the lawyer is less demanding than Shepherd, the expert is beset with temptations.

General. Among the most difficult of the corrupting influences to deal with is what I call *aggrandizement*. In Title VII cases (i.e. those dealing with employment discrimination), the Supreme Court has placed the statistician in the key role. Long ignored and treated with contempt in literature and in the courts, the statistician has been elevated to Olympian levels. Thus the *Hazelwood* court, quoting its remark in an earlier case, commented [12]:

> We also noted that statistics can be an important source of proof in employment discrimination cases, since, "absent explanation, it is ordinarily to be expected that nondiscriminating hiring practices will in time result in the work force more or less representative of the racial and ethnic composition of the population in the community from which employees are hired." Evidence of long lasting and gross disparity between the composition of the work force and that of the general population that may be significant even though paragraph 703 (j) makes clear that a work force need not mirror the general population.

Taken together with the court's embrace of statistical significance testing, the statistician is here given a virtual license for intellectual robbery. Indeed, not only the court but a large contingent of fellow academics (economists numerous among them) give strong endorsement to the particularly magical properties of multiple regression analysis. (Two articles in the *Columbia Law Review* – Fisher [8] and Finkelstein [7] – are noteworthy in this regard.) All in all, the statistician is strongly tempted to give the definitive rather than a qualified answer to the key questions. He will be tempted to ignore or to minimize those qualifications that he might emphasize in a more academic setting, he may fail to emphasize the existence of schools of thought other than his own, and he may lay claim to overly broad scope for the inferences he draws.

Adversarial. The adversary system adds a host of additional influences, some quite direct, but others indirect:

1. *Bribery*. The witness is paid by his client and, as often noted, he who pays the piper feels a right to call the tune. To be sure, all the client is entitled to is an honest report of the expert's best effort, but an expert who habitually finds evidence against his client will not be much sought after.
2. *Flattery*. Some, of course, are not bought by money or the prospect of future money: either they already have enough of it or they are sufficiently on guard against that particular type of seduction. Other corruptions await them.
   I well recall an occasion on which I was asked to consult in a case at a time that was not especially convenient. I explained that I really could not participate on this occasion. The lawyer, with whom I had worked before and for whom I had a great deal of respect, pled the sorry state of statistical testimony in the courts in general, and in the instant case in particular. He read from the transcript some particularly egregious quotes from the statistical expert for the other side, and he urged the importance for the future of statistics in the domain of public affairs of having corrective testimony. That being a viewpoint I could only share, and tacitly mindful of our shared opinion that I was the ideal candidate to champion the honor of the profession, I reluctantly agreed to testify. Imagine my chagrin when, at a later date, I read some other remarks of the trial lawyer, John Shepherd, whom I quoted earlier. He advises on "Approaching the Expert" as follows [18, p. 19]:

   > Almost every one who considers the subject of experts in court will start with the same thought: The first thing you need to get along with your expert witness is money. But the hiring and successful use of an expert may not be that easy – a lot of good experts are rich. Although you will eventually be talking about money with your expert, it is wiser to begin on another tack. Tell your expert how justice will be served if he will testify on your

> side of the case. Remind him that the unfortunate situation in our courts today can be improved if we have people of his caliber to help in the administration of justice. That ploy will impress even the rich expert.

3. *Co-option*. To be sure, effective as this ploy may be, it does not in itself lead the expert away from his duty. It establishes an aura of objectivity and mutual respect, however, which may make the expert especially vulnerable to another inevitably corrupting aspect of the adversary system: that is, the simple fact that the expert's introduction to the case comes from the client's counsel and will inevitably tend to appear in the light most favorable to the client. He will be introduced to the principals – perhaps a plaintiff, movingly indignant about years of abuse and low pay, perhaps a defendant who truly believes that his cause is just and is worried sick about the distraction of his institutional resources from their proper role into the defense against a baseless charge. This goes along with co-option into advocacy arising when one is asked to review the other side's testimony, point out flaws therein, and assist in the development of effective cross examination.
   F. Downton of the University of Birmingham has written cogently about this latter difficulty, in a symposium on statistics and the law [6]. Downton had been consulting with the police on games of chance, because the law prescribed strict rules for games that, if violated, would allow the police to close the clubs. Since the clubs were widely regarded as dens of iniquity, this was clearly a public service. Downton wrote [6, p. 171]:

   > As in any other consulting situation, a certain amount of identification with the aims of the client is inevitable; it is fortunate that probability and statistics are basically mathematical in content, since the constraints of mathematics act as a brake on overenthusiasm. It cannot, however, be denied that a conscious change of attitude was needed to effect the change-over from helpful consultant to objective expert witness. . .. This ambiguity of roles did create a conflict, which presumably can only be resolved by individual witnesses in their own way.

4. *Gladiatorial Role*. The adversarial environment works against objectivity in yet other ways. The object of cross examination is not only to expose weaknesses in the expert's analysis but, if possible, to discredit the witness and the weight that should be given to his testimony generally. Thus the cross examiner may, by adroit framing of questions, force the witness into complex explanations and apparent contradictions. Feeling his credibility slipping away, such a witness may be less likely to give a full and frank answer to a later question that might fairly expose a fact or conclusion operating in favor of the other side. The expert no longer views his interrogator as a fellow searcher for truth, but as an adversary against whom he must defend.
5. *Personal Views*. My final source of corruption is perhaps the most difficult to deal with, and that is the problem of strongly held personal views. Surely there are many cases in which the expert is a priori indifferent between the claims of the contestants, but in other areas, particularly in the great domain opened up by Title VII, there are few of us without strong opinions. In the matter of a contest between a chemical waste disposal company and the residents of a new Love Canal, for example, I would be reluctant to testify on behalf of the company. It might well be, for example, that the evidence of adverse health effects caused by carelessly buried wastes is really nonexistent. Feeling as strongly as I do, however, that such careless behavior is reprehensible and deserving of punishment, I should not like to assist the company's case. I have no problem reconciling my preferences and my professional responsibilities in this case. I am, and should be, free to accept an engagement or not, for whatever personal reason, and reasons of this kind are at least as good as most others.

My problem comes on the other side. Suppose that I should be an expert retained by the residents affected by the dump. I find that, in respect of total mortality, there is no evidence of an effect, but in the matter of childhood leukemias there is an **excess mortality** amounting to 1.8 standard errors greater than the rate in some **control** group. If I ignore the fact that I am reporting on leukemia because it is the disease category showing the largest difference, and if I adopt the conventional 5% significance level as a standard, and if I urge the relevance

here of a one-sided significance test (*see* **Alternative Hypothesis**), I may be able to strike a blow for truth and justice, and it would no doubt be tempting to do so. But to paraphrase a major figure in the Watergate investigation, "I could do that, but it would be wrong". I really do not think one-sided 5% level deviations provide convincing evidence one way or the other, and – whatever one's views on that – I expect that most statisticians would agree with me that it is misleading to the point of dishonesty to quote an unadjusted significance level (*see* **Level of a Test**) when I have chosen to present the most extreme of a number of alternative measures.

Perhaps the point can be brought home most forcefully by addressing an even touchier example. There are many of us who view the legacy of slavery as our most appalling and pressing social problem, and the effort to explain the low status of the oppressed on the grounds of inherent inferiority as an intolerable offense. Indeed, although the possibility of *some* average difference in intellectual capacity among different groups can never be ruled out, the evidence appears clear that whatever differences there might be in *average* innate ability, they are quite small compared with the variation between individuals. The effects ascribed to race in **regression** analyses of school child performance, after adjustment for age, years of schooling, mother's socioeconomic status, and the like, are readily explainable as attenuation and other distracting effects that afflict regression analyses generally, and they need not be interpreted as reflecting a real difference due to race.

At the same time, we observe the past and present systematic discrimination against blacks in many areas of employment. Such discrimination has many forms, but its pervasiveness, except where sharply controlled by law, is hardly in doubt. Being confident, then, that a charge of race discrimination likely corresponds to the existence of actual discrimination, what are we to say about a multiple regression in which a salary difference unfavorable to blacks emerges as significant even after adjustment for age, years of schooling, mother's socioeconomic status, and the like? The problems of attenuation apply with equal force, but we may now be reluctant to dismiss the evidence of bias in pay. This time we may believe that there really is discrimination in the system, but it is by no means clear why we should, as statisticians, take different positions in the two situations.

Ways to Defend the Integrity of Statistical Testimony

With the variety of assaults on the credibility of expert statistical testimony, I turn again to the question of what possible defensive measures could be implemented. A change to the apparently more neutral continental system is the one answer that has come from the courts, but there seems little likelihood of its adoption. There have been proposals that experts who testify falsely should be punished for perjury, as is an ordinary witness who testifies falsely about an event. This, too, seems far-fetched, since the essential nature of expert testimony is that it is largely a matter of informed opinion.

Professional Codes

There seems to be only one other direction in which to turn, and I have only slender hopes for it. Seeing that neither the bench nor the bar will help us, the only alternative is to help ourselves; that is, to develop limited codes of ethical behavior in the context of legal proceedings that may help to ameliorate the worst excesses.

I come to this conclusion reluctantly, because I have little taste for collective moral instruction and little confidence in its efficacy in general. And yet one cannot deny that codes of ethics for judges, while they do not eliminate venality, are good to have. Violation of these rules can and does lead to discipline, on occasion, as in the case of a distinguished Supreme Court Justice a few years ago, and reminders such as that help to keep others on the right path. Similarly, codes of medical ethics dealing with the proper relationship between physician and patient serve a useful purpose.

A quarter of a century ago, Gibbons [10] reviewed our society's efforts in the direction of developing such codes, and she clearly laid out some of the problems that such codes might help to solve. Evidently, there was some movement in that direction in the early 1950s, but momentum was lost, and nothing came of it. The issue of ethical codes continues to elicit debate, a recent instance being the report of the Ad Hoc Committee on Professional Ethics [1]. I see no sign, however, that this or any other code is likely to be adopted as a guide by any of our major professional organizations. Indeed, although discussion of codes of ethics for statisticians continues, I know of

only one instance in which such a discussion has had any noticeable practical effect.

The exception is an interesting one, and it may be instructive. As I mentioned earlier, in the context of sample survey design and analysis, W. Edwards Deming established a code that he provided to clients, explaining the reach and the limitation of his methods. The code is notable for its careful restriction of the role of the statistician. In effect, Deming acknowledges that the statistical consultant may come to have a good deal of knowledge about the subject matter under study, and that this knowledge may help him to design an effective sample. He makes clear, however, that responsibility for the choice of population to be sampled (*see* **Target Population**), and for the processing of each sampled unit, belongs to the client and not to the sampling consultant. The consultant undertakes to say only that, had the entire population been processed in the same way that the sampled elements were processed, the sample estimate for the population would be found to be close to the population value, subject to error limits that can be given in the usual probability sense. It might seem that the scope of the sampling expert's testimony is so narrow according to this code that his contribution will have little weight in the proceedings. In fact, of course, the contrary is true. By not reaching beyond well-stated boundaries, the testimony of sampling experts has achieved an enviable level of credibility.

Deming's code, effective as it is in a specific context, gives only a little guidance for the expert testifying in a Title VII case. I submit that a proper code for the latter expert should copy Deming by being specific to the situation and rather restrictive as to the scope of the testimony. I do not think it will pay to start with an ethical code trying to embrace all statistical activities. Let me try to clarify my proposal by being specific. (Here I borrow from Deming where I can.)

I suggest that a statistician asked to testify in court should require that he be given access to all data thought by the client to be relevant, and to all previous analyses of that data, and he should demand a commitment on the part of the client to a "good faith" effort to supply whatever other data the statistician may judge relevant.

He should advise the client that in his professional role he will remain neutral between the parties (and he should pray for strength when he does this, for he will need it). He undertakes to provide his best effort to analyze the data in ways that seem to him pertinent, and he undertakes further to provide a written report. His report, if it is to be used, must be taken in its entirety.

When testifying, the expert will explain the limitations of his techniques, as seen by a professional statistician, regardless of any statistical principles anointed by the Supreme Court. He will explain the variety of schools of thought within the profession and his place among them.

Doubtless there are a number of other principles to be enunciated, but this is not the time or place for full details. Some will think that the principles given are simple and obvious, but they can be assured that they are not obvious to most lawyers. Many lawyers, for example, think it proper to select for attention the principles laid down by the high court as a basis for expert testimony. (I cannot help but wonder if, should a court declare that $\pi = 3$, these lawyers would insist that we accept that too.) Gratuitous testimony about limitations will be especially unwelcome (and, in my opinion, especially necessary). The point is that the expert should be much more his own man and much less the puppet of his client's counsel than is typically the case today.

Consequences

The consequences of such a code, should we adopt and use it, are substantial and not entirely welcome. I do not believe it would help us much in protecting against the influence of our own strongly held social views or against the biases that arise because we are oriented and informed by just one of the adversaries. Nor would it keep us from reflexive defensiveness under hostile cross examination.

Adherence to such a code is likely to result in a reduction of the pivotal role that statistical analysis has come to play in discrimination law, and we may see the resulting gap filled, by others whose competence and good will we question even more than our own. It is conceivable that a more modest posture might lead the courts to seek greater clarity by adopting the reforms, if such they be, of the continental system with court-appointed experts. It is certain, I think, that adherence to such a code would improve the credibility of statistical witnesses.

PAUL MEIER

Explained Variation Measures in Survival Analysis

When fitting a **regression** model to survival data, one is frequently faced with a situation in which accurate **predictions** for individual survival cannot be derived from the model even though the regression coefficients are highly significant and the model fits the data well. For example, consider a population where the five-year survival rate drops from 60 to 30% depending on whether a certain **risk factor** is present or absent (*see* **Prognostic Factors for Survival**). Suppose that the risk factor is present in 50% of the population, so that, overall, 45% will survive beyond year five. Although the risk factor has an important impact on survival, it is hard to use it for predictions of whether an individual will be alive after five years. In particular, knowledge of the risk factor does not gain much precision for predictions compared to predictions based on the overall rate of survival. Thus, the predictive power of the risk factor is low. Still, in a sample of sufficient size, a model that accounts adequately for the risk factor will fit the data well and yield a significant regression coefficient. Measures for the proportion of explained variation similar to the *coefficient of determination* used in **multiple linear regression**, R^2, can be helpful in order to quantify predictive power and to separate it conceptually from statistical significance and **goodness of fit** [5].

The first measures of explained variation suitable for survival data appeared around the beginning of the 1990s, and there is as yet no commonly agreed choice [10]. Two proposals are described here in some detail, with more references toward the end of the article.

Korn and Simon [4] took an approach based on **loss functions** to measure the explained variation. Let T be a survival time distributed according to a *survival curve* $S(t) = P(T > t)$ (*see* **Survival Distributions and Their Characteristics**), and let $L(t, p)$ be the loss incurred when survival time p is predicted for an individual with actual outcome t. An optimal predictor $\tilde{p}$ for T is one that minimizes the expected loss $\int_0^\infty L(t, p)\, \mathrm{d}[1 - S(t)]$ over p (*see* **Decision Theory**). Let $R(S)$ be the expected loss (or risk) associated with $\tilde{p}$. Then, on the basis of a sample of size n in which x_i is a **covariate** for individual i and $\hat{S}(.|x_i)$ is an estimate of the survival curve for individual i, the variation explained by the model $\hat{S}(.|x_i), i = 1, \ldots, n$, may be defined as

$$\text{explained variation} = 1 - \frac{\frac{1}{n}\sum R(\hat{S}(.|x_i))}{R(\overline{S})}, \qquad (1)$$

where $\overline{S} = \frac{1}{n}\sum \hat{S}(.|x_i)$ estimates the marginal distribution of survival based on the mean of the estimated conditional survival curves given the covariate. With squared error loss, $(t - p)^2$, the optimal predictor $\tilde{p}$ is the mean, and (1) is a model-based estimator of the proportional reduction of variance achieved when the marginal variance of the survival outcome is compared to the mean conditional variance, given the covariate. Other loss functions [4] include absolute error, $|t - p|$, squared and absolute error loss on log scale, $(\log t - \log p)^2$ and $|\log t - \log p|$, and squared error loss censored at some specified time t_0: This means that a prediction $p = t_0$ is considered successful even if the actual survival t is greater than t_0, and incurs no loss. Thus, compared with simple squared error loss, $\mathrm{var}(\tilde{T})$ is used in place of $\mathrm{var}(T)$, where $\tilde{T} = \min(T, t_0)$. Finally, if all that matters is prediction of whether an individual will have died by time t_0, binary squared prediction error loss, $[I(T > t_0) - p]^2$, with I the indicator function, may be considered. The resulting risk is the **binomial** variance of the survival status at t_0, $S(t_0)[1 - S(t_0)]$. In the introductory example, this gives an explained variation of $1 - \left\{\frac{1}{2}(0.6 \times 0.4 + 0.3 \times 0.7)\right\}/(0.45 \times 0.55) = 0.09$ at $t_0 = 5$ years.

Note that, in this proposal, **censoring** is adequately dealt with in two ways. The choice of a censored version of the loss function allows one to view (1) as an estimator of a population parameter where the range of data to be collected in a sample can be accounted for. For example, in a study that is planned to be analyzed at a median follow-up time of five years, squared error loss censored at year five may be an appropriate choice. On the other hand, if some individuals are censored prior to year five because of limited follow-up, the estimate given in (1) can still be calculated, since estimated survival curves for those individuals will usually be available beyond the time of censoring. If censoring is dealt with adequately in the estimation of survival curves in the sense that it introduces no bias, then so it is in the estimation of explained variation. However, a drawback of the measure is that when misspecified models

are used to estimate survival curves, the explained variation shown in (1) may be misleading: It incorporates no comparison of observed versus predicted survival and thus measures only the variation that the model itself appears to explain.

Graf et al. [2] proposed a measure of explained variation, where observed and predicted values of the survival status are contrasted explicitly. It is based on binary squared prediction error loss. For a sample of size n, let t_i denote the time individual i was under observation, and let the censoring indicator δ_i equal 1 if individual i was observed to fail at t_i, 0 if it was censored at t_i. Then let

$$\text{explained variation} = 1 - \frac{\sum_{i=1}^{n} w_i [I(t_i > t_0) - \hat{S}(t_0|x_i)]^2}{\sum_{i=1}^{n} w_i [I(t_i > t_0) - \hat{S}(t_0)]^2}, \qquad (2)$$

where the weights

$$w_i = \begin{cases} \dfrac{\delta_i}{n\hat{G}(t_i)} & \text{if } t_i \le t_0 \\ \dfrac{1}{n\hat{G}(t_0)} & \text{if } t_i > t_0 \end{cases}$$

incorporate the **Kaplan–Meier** estimator $\hat{G}$ of the censoring or potential follow-up distribution [9] calculated by exchanging the role of censored and uncensored observations, that is, with censoring indicator $1 - \delta_i$. $\hat{S}$ denotes the usual Kaplan–Meier estimator of the entire sample, which is used to estimate the marginal failure time distribution $S(.)$. Under suitable regularity conditions, this measure produces a consistent estimator of the population explained variation

$$1 - \frac{\mathrm{E}_X\{\int_0^\infty [I(t > t_0) - \hat{S}(t_0|X)]^2 \, \mathrm{d}[1 - S(t|X)]\}}{\int_0^\infty [I(t > t_0) - S(t_0)]^2 \, \mathrm{d}[1 - S(t)]}, \qquad (3)$$

in which the sample means given in (1) and (2) are replaced by the expected risks of the covariate-based model and the marginal distribution of failure time. This will hold even if censoring is present and if a misspecified model $\hat{S}(.|X)$ is used instead of the optimal predictor. The measure can be adapted for other loss functions.

Two other explained variation measures were proposed specifically for the context of **proportional hazards** models (*see* **Cox Regression Model**), and censoring is adequately dealt with in both. Schemper and Henderson [8] constructed a measure in which the model-based and marginal variance of the binary survival status $I(T > t)$ at time t is averaged across a time-interval $[0, t_0]$, weighted by the marginal survival distribution. O'Quigley and Xu [7] suggested a measure that compares mean squared Schoenfeld residuals (*see* **Residuals for Survival Analysis**) under a proportional hazards model to the null model of no covariate effect. Although their measure has a range of desirable properties, it actually measures the predictability of a covariate from a given failure time and thus does not directly aim at quantifying the ability of the model to predict time to failure from a given covariate.

Other proposals to modify R^2 in a way suitable for survival analysis rest upon interpretations of R^2 different from the proportion of explained variation. The relation of R^2 to the **likelihood ratio** for a model with covariate against the null of no covariate effect is explored in [6, 11, 12]. Approaches related to the interpretation of R^2 as (squared) correlation between observed and predicted values are taken in [1, 3, 4].

Explanatory Variables

In many studies, multiple measurements are available for each individual. One variable may be considered to be the response of interest or the outcome (*see* **Response Variable**). A model may be developed to investigate the form of the relationship between the outcome and the remaining variables, this usually being some form of **regression** model. These variables are then often termed the explanatory variables. Thus, explanatory variables are distinguished from the response or outcome. They are denoted as explanatory variables because the model will investigate how they explain the outcome. Other terms used for explanatory variables are independent variables, regressor variables, predictor variables, and, in some situations, **covariates**. The term "explanatory variables" is somewhat more generic than the other alternatives, which may or may not be appropriate in different settings. For example, the use of the term "predictor variable" presumes that **prediction** is the goal of model building, and this may not be applicable. Use of the term "independent variable" is not recommended since the dependence between the response variable and explanatory variables is the goal of modeling and since independence among explanatory variables often cannot be assumed.

Various ways of classifying explanatory variables are described in Cox & Snell [1]. In particular, an explanatory variable can be quantitative or qualitative. If it is quantitative, then the way in which it is included in the model must be investigated. One question to consider is whether the explanatory variables enter the model in an **additive** or **multiplicative** manner. Another question is whether the original explanatory variable or some **transformation** of it should be used. A related question is whether polynomial terms should be considered.

If an explanatory variable is qualitative, then **dummy variables** must be defined to represent the explanatory variable. The choice of dummy variable definitions depends on the study situation. In a regression model, the significance of the relationship between the outcome and the qualitative explanatory variable can then be assessed by testing the hypothesis that all regression coefficients for the dummy variables defined from this explanatory variable are equal to 0.

Explanatory variables can be fixed by the design of the experiment, representing factors such as levels of treatment. Explanatory variables can also simply be measurements for an individual obtained without any experimental control, as is generally the case in observational studies.

Exploratory Data Analysis

Statisticians, as well as others who apply statistical methods to data, have often made preliminary examinations of data in order to explore their behavior. In this sense, exploratory data analysis has long been a part of statistical practice. Since about 1970, "exploratory data analysis" has most often meant the attitude, approach, and techniques developed, primarily by John W. Tukey, for flexible probing of data.

Broad Phases of Data Analysis

One description of the general steps and operations that make up practical data analysis identifies two broad phases: an exploratory phase and a confirmatory phase. Exploratory data analysis is concerned with isolating patterns and features of the data and with revealing these forcefully to the analyst. It often provides the first contact with the data, preceding any firm choice of models for either structural or stochastic components (*see* **Model, Choice of**); but it also serves to uncover unexpected departures from familiar models (*see* **Diagnostics**). An important element of the exploratory approach is flexibility, both in tailoring the analysis to the structure of the data and in responding to patterns that successive steps of analysis uncover.

Confirmatory data analysis concentrates on assessing the reproducibility of the observed patterns or effects. Its role is closer to that of traditional statistical **inference** in providing statements of significance (*see* **Hypothesis Testing**) and **confidence;** but the confirmatory phase also encompasses (among others) the step of incorporating information from an analysis of another, closely related, body of data and the step of validating a result by collecting and analyzing new data.

In brief, exploratory data analysis emphasizes flexible searching for clues and evidence, whereas confirmatory data analysis stresses evaluating the available evidence. The rest of this article describes the basic concepts of exploratory data analysis and illustrates some simple techniques.

Four Themes

Throughout exploratory data analysis, four main themes appear and often combine. These are resistance, residuals, re-expression, and display.

Resistance

Resistance is a matter of insensitivity to misbehavior in data. More formally, an analysis or summary is *resistant* if an arbitrary change in any small part of the data produces only a small change in the analysis or summary. This attention to resistance reflects an understanding that "good" data seldom contain less than about 5% gross errors, and protection against the adverse effects of these should always be available.

It is worthwhile to distinguish between resistance and the related notion of **robustness**. Robustness generally implies insensitivity to departures from assumptions surrounding an underlying probabilistic model. (Some discussions regard resistance as one aspect of "qualitative robustness".)

In summarizing the location of a sample, the **median** is highly resistant. (In terms of **efficiency**, it is not so highly robust because other estimators achieve greater efficiency across a broader range of distributions.) By contrast, the **mean** is highly nonresistant. A number of exploratory techniques for more-structured forms of data provide resistance because they are based on the median.

Residuals

Residuals are what remain of the data after a summary or fitted model has been subtracted out, according to the schematic equation

$$\text{residual} = \text{data} - \text{fit}.$$

For example, if the data are the pairs (x_i, y_i) and the fit is the line $\hat{y}_i = a + bx_i$, then the residuals are $r_i = y_i - \hat{y}_i$.

Exploratory data analysis takes the attitude that an analysis of a set of data is not complete without a careful examination of the residuals. This emphasis builds on the tendency of resistant analyses to provide a clear separation between dominant behavior and unusual behavior in the data (*see* **Outliers**). When the bulk of the data follows a consistent pattern, that pattern determines a resistant fit. The residuals then contain any drastic departures from the pattern, as well as the customary chance fluctuations. Unusual residuals suggest a need to check on the circumstances surrounding those observations. As in more-traditional practice, the residuals can warn of systematic difficulties with the data – curvature, nonadditivity, and nonconstancy of variability (*see* **Scedasticity**).

Re-expression

Re-expression involves the question of what scale would help to simplify the analysis of the data (*see* **Measurement Scale**). Exploratory data analysis emphasizes the benefits of considering, at an early stage, whether the scale in which the data are originally expressed is satisfactory. If not, a re-expression into another scale may help to promote symmetry, constancy of variability, straightness of relationship, or additivity of effect, depending on the structure of the data.

The re-expressions most often used in exploratory data analysis come from the family of functions known as **power transformations**, which take y into y^p (almost always with a simple value of p such as $\frac{1}{2}, -1$, or 2), together with the logarithm (which, for data-analysis purposes, fits into the power family at $p = 0$). For example, one investigation of the relationship between gasoline mileage and the characteristics of automobiles gained substantially from re-expressing mileage in a reciprocal scale and working with gallons per 100 miles instead of miles per gallon.

Such changes of scale are not solely a specialized concern of data analysis; they arise in everyday experience. For example, in the Richter scale for intensity of earthquakes, the pH scale for acidity, and the average speeds in an auto race, the numbers reported have already been re-expressed from the scale in which the basic data were collected. Hoaglin [1] discusses these and other examples.

Displays

Displays meet the analyst's need to see behavior – of data, of fits, of diagnostic measures, and of residuals – and thus to grasp the unexpected features as well as the familiar regularities (*see* **Graphical Displays**).

A major contribution of the developments associated with exploratory data analysis has been the emphasis on visual displays and the variety of new graphical techniques. The example below includes one of these, the *schematic plot* or *boxplot*.

Example

An example illustrates the themes of exploratory data analysis, with particular emphasis on re-expression and display.

Table 1 Concentration of nicotine (nanograms per milliliter) in the urine of a group of nonsmokers exposed to a smoke-filled room (NS1), two groups of nonsmokers with customary exposure to smoke (NS2 and NS3), and a group of smokers (S)

NS1	NS2	NS3	S
13	0.8	0	104
33	0.8	0.2	109
35	1.2	0.2	128
45	3.3	2.0	312
45	3.5	2.2	375
61	6.2	4.2	802
92	6.3	5.2	833
93	8.0	9.0	937
98	8.6	12.0	1006
157	10.3	12.0	1049
208	11.3	19.3	1629
	21.0	23.5	1788
	28.6	26.0	1808
	64.3		1967
			1990
			2073

			2732

Source: Russell & Feyerabend [5].

In research that bears on the effects of passive smoking, Russell & Feyerabend [5] studied the effect on nonsmokers of exposure to tobacco smoke. For four groups of volunteers they measured the concentration of nicotine in each subject's urine during the early afternoon. The first group of nonsmokers (NS1) spent an average of 78 minutes seated among smokers in an unventilated smoke-filled room. The second and third groups of nonsmokers (NS2 and NS3) were not subject to any special conditions and simply received their usual exposure to smoke in the workplace. The fourth group, the smokers (S), was included for comparison. For the four groups Table 1 shows the urine nicotine levels (in nanograms per milliliter).

In this scale the data do not yield an effective display. A straightforward plot that includes the data from all the smokers would show almost no detail in the other three groups. This is one of the difficulties that re-expression aims to remedy. For these data, re-expression in a logarithmic scale leads to a much more effective analysis. The results are easy to interpret, because an additive difference in the log scale corresponds to a ratio in the original scale. For example, for logarithms to base 10, the medians

of NS1 and S are 1.8 and 3.0, respectively. The difference, 1.2, corresponds to a ratio of 16, similar to what one would get by comparing observations near the middle of the two groups.

To facilitate comparisons among the four groups, Figure 1 displays their boxplots. In this graphical summary of the data the box extends from the lower hinge (an approximate quartile; *see* **Quantiles**) to the upper hinge and has a line across it at the median. The dashed lines show the extent of the data, except for observations that are apparent strays (defined according to a rule of thumb based on the hinges). Such strays appear individually – in order to focus attention on them – as the lowest observation in NS3 does in Figure 1. The general intent is to indicate the median, outline the middle half of the data, and show the **range**, with more detail at the ends if needed.

Figure 1 shows that the passive smokers (NS1) have relatively little overlap with the smokers (S) above or with the nonsmokers (NS2 and NS3) below. As mentioned previously, the passive smokers' urine nicotine levels are typically about 1/16 of the smokers'. However, the difference of about 1 on the log scale between NS1 and either NS2 or NS3 means that the passive smoking produced about a tenfold increase in urine nicotine. These differences in level are the main story; and it is easy to focus on them because the variation within the four groups is quite similar, whether measured by the length of the boxes or the extent of the dashed lines. Some members of NS3 apparently were more successful in avoiding exposure to smoke, as indicated by the longer dashed line at the lower end of that boxplot and, especially, by the one stray observation. This subject had no detectable nicotine in her urine. As a mathematical function, the logarithm transforms 0 into $-\infty$, but this result does not affect the median or the lower hinge for the group.

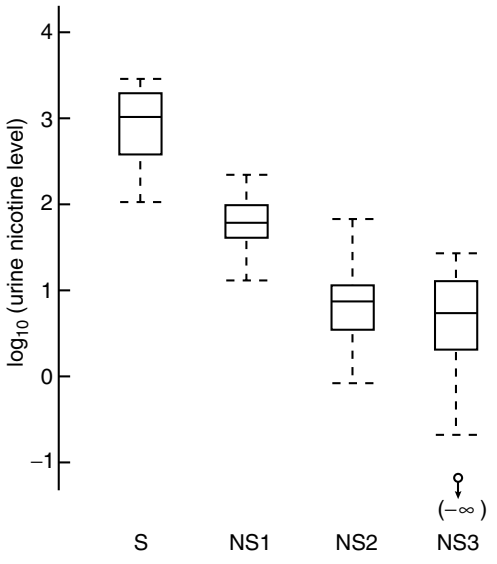

Figure 1 Parallel boxplots for the logarithm (base 10) of nicotine concentration in the urine of the smokers (S) and the three groups of nonsmokers (NS1, NS2, and NS3). The subjects in NS1 were exposed to the smoke-filled room

Literature

The first published presentation of exploratory data analysis was the preliminary edition of the book by John W. Tukey [6]; the 1977 edition [9] represents the definitive account of the subject. A paper by Tukey [8] describes and illustrates a number of the most important displays.

The book by Mosteller & Tukey [4] contains substantial discussions of exploratory attitudes and techniques.

The two volumes edited by Hoaglin et al. [2, 3] provide conceptual, logical, and mathematical support for a number of exploratory techniques. They also explain and illustrate the connections of those techniques to more-conventional techniques and to classical statistical theory.

Broader discussions of the roles of exploratory and confirmatory data analysis in scientific inquiry appear in Tukey [7, 10].

Exponential Distribution

The simplest distribution used to model survival data is the exponential distribution (*see* **Parametric Models in Survival Analysis**). This model has survival function $S(t) = e^{-\lambda t}$ and density function $f(t) = \lambda e^{-\lambda t}$. The exponential distribution is characterized by a constant **hazard** rate, $h(t) = \lambda$. This constant hazard rate implies a lack of aging and leads to several other equivalent characterizations of the exponential distribution.

The first characterization is referred to as the lack of memory property. If T has an exponential distribution, then it follows that

$$\Pr(T \geq t + x | T \geq t) = \Pr(T \geq x).$$

This means that the chance that an individual of age t survives an additional x years is the same as a newborn surviving to age x. Because of this distributional property, it follows that $E(T - t | T \geq t) = E(T) = 1/\lambda$, i.e. the mean residual life is constant. Because the time until the future occurrence of an event does not depend upon past history, this property is called the "no-aging" property or the "old as good as new" property of the exponential.

The second characterization of the exponential distribution is as the distribution of the interarrival times of a **Poisson process**. If $N(t)$ is a Poisson process with intensity rate λ, then the times between successive occurrences of the process are independent exponential random variables with hazard function, λ. Also, the length of the interval from some fixed time to the next occurrence of the Poisson process has an exponential distribution with rate λ.

For an exponential random variable the mean is λ^{-1} and the variance is λ^{-2}, so the coefficient of variation is 1. The median time to the event is $(\log 2)/\lambda$. Based on independent, possibly right-**censored** survival times $X_1, \ldots, X_n$ from the exponential distribution with hazard λ, the **maximum likelihood** estimator for λ is the "occurrence/exposure rate"

$$\hat{\lambda} = \frac{\sum D_i}{\sum X_i},$$

where D_i is an indicator for failure of individual i. For large n, $\hat{\lambda}$ is approximately normally distributed with mean λ and a variance which may be estimated by $\sum D_i / (\sum X_i)^2$.

The exponential model may be checked using the **Nelson–Aalen estimator**, which, under the model, will approximate a straight line with slope λ. Also, **total time on test** (see [1]) techniques are designed especially for testing for exponentiality.

Regression analysis of exponentially distributed survival times was pioneered by Feigl & Zelen [2], who studied uncensored data, and generalized to right-censoring by Zippin & Armitage [3].

A more general form of the exponential distribution is the two-parameter exponential distribution with survival function

$$S(t) = \begin{cases} 1, & \text{if } t < \mu, \\ \exp[-\lambda(t - \mu)], & \text{if } t \geq \mu. \end{cases}$$

Here the parameter μ is a threshold or guarantee parameter. This distribution still has a constant hazard rate and the lack of memory property.

The exponential distribution has found limited use in biomedical applications since its lack of aging property is too restrictive for most problems. It is useful, however, as a special case of both the **Weibull distribution**, the **gamma distribution**, and the distribution with a piecewise constant hazard function (*see* **Grouped Survival Times**). Furthermore, the model is frequently used for **sample size determination** and in **simulation** studies.

Exponential Family

Many of the families of probability distributions arising in biostatistics are of exponential form, e.g. **normal**, **exponential**, **gamma**, **beta, binomial**, **multinomial**, **hypergeometric**, **Poisson**, etc. The class of models is theoretically important because in multiparameter settings exact frequency methods of **inference** exist only for certain exponential family settings and for another general class called transformation models, e.g. **location-scale** models. Much of the underpinnings of general theory of inference arise from consideration of exponential families. Moreover, adequate understanding of some of the most important aspects of biostatistics, e.g. matched case–control studies (*see* **Matching**), requires a grounding in theory of inference for exponential families.

Basic Definitions and Examples

For a collection of data $\mathbf{y}$, an exponential family is a class of distributions with densities (meant to include probability mass functions for discrete data) of the form

$$f(\mathbf{y};\boldsymbol{\theta}) = m(\mathbf{y}) \exp\left[\sum_{j=1}^{k} c_j(\boldsymbol{\theta}) s_j(\mathbf{y}) - d(\boldsymbol{\theta})\right], \quad (1)$$

where $\boldsymbol{\theta} \in \boldsymbol{\Theta}$ is typically a vector parameter. The density is often zero outside some specified set, which must not depend on $\boldsymbol{\theta}$. Very often $\mathbf{y}$ consists of independent *but not identically* distributed observations $y_1, y_2, \ldots, y_n$, which themselves have exponential family distributions of simpler form. The primary aims involve comparison of the distributions of the y_i or studying their relation to **covariates** of interest. Most intermediate-level statistical theory texts focus on the case of identically distributed observations, but this fails to meet practical needs or to raise generally important issues discussed here. The texts by Cox & Hinkley [4], Cox & Snell [6], and Lehmann [12] give treatments closer to the following, with the latter giving mathematical details avoided here. Further mathematical treatment and some interesting general inferential aspects are given in Barndorff–Nielsen [1].

For example, basic modeling concepts of **least squares** regression can be extended to **likelihood** analysis where the component observations y_i have exponential family densities of the form

$$f(y_i;\omega) = a_i(y_i) \exp[\omega y_i - b_i(\omega)] \quad (2)$$

by modeling the parameter for y_i as $\omega_i = \mathbf{x}_i'\boldsymbol{\theta}$, where $\mathbf{x}_i$ is an associated vector of covariables. The joint density can be written in the form of (1), with $c_j(\boldsymbol{\theta}) = \theta_j$, the coordinates of $\boldsymbol{\theta}$, and $s_j(\mathbf{y}) = \sum_i x_{ij} y_i$. An important example is **logistic regression**, where the component observations y_i have **binomial** distributions with probabilities of success π_i which are to be modeled in terms of covariables. The densities can be expressed in the form of (2) as

$$f(y_i;\pi_i) = a_i(y_i) \exp\left\{\log\left[\frac{\pi_i}{(1-\pi_i)}\right] y_i - b_i(\pi_i)\right\},$$

and the logistic model relates the π_i to covariate vectors $\mathbf{x}_i$ in a manner such that $\log[\pi_i/(1-\pi_i)] = \mathbf{x}_i'\boldsymbol{\beta}$, where in more conventional notation we write $\boldsymbol{\beta}$ in place of $\boldsymbol{\theta}$.

Often a single parameter ω is not adequate for modeling the component distributions, and this is generalized to models with a vector parameter $\boldsymbol{\omega}$,

$$f(y_i;\boldsymbol{\omega}) = a_i(y_i) \exp\left[\sum_{j=1}^{l} \omega_j g_j(y_i) - b_i(\boldsymbol{\omega})\right], \quad (3)$$

also leading to the form of (1) for the joint density for some $k \geq l$. An instance of this with $l = 2$ arises in **gamma** regression with scale parameters σ_i and unknown common shape parameter ν, where the densities can be expressed in the form of (3) as

$$f(y_i;\sigma_i,\nu) = a_i(y_i) \exp\left[\left(\frac{-1}{\sigma_i}\right) y_i + \nu \ln(y_i) - b_i(\sigma_i,\nu)\right].$$

A regression model which is theoretically tractable, but not always the most practically useful, takes $1/\sigma_i = \mathbf{x}_i'\boldsymbol{\beta}$. Then, in (1), the $c_j(\boldsymbol{\theta})$ consist of the coordinates of $\boldsymbol{\beta}$ supplemented by ν, and the $s_j(\mathbf{y})$ consist of the quantities $-\sum_i x_{ij} y_i$ supplemented by $\sum_i \ln(y_i)$.

Both of the above examples are **generalized linear models** [10, 14]. Examples not of this form, in

particular where the data **y** do not consist of independent observations, include Gaussian mixed models such as **randomized block designs**, Gaussian **multivariate** and **time series** models, and **multinomial** or **hypergeometric** models.

The likelihood function based on (1) depends on the data only through the collection of statistics $[s_j(\mathbf{y}); j = 1, \ldots, k]$, and thus such a reduction of the data is a **sufficient statistic** – one of the key aspects of exponential families. Ordinarily there are various choices for how (1) is expressed for a given setting, and henceforth we assume that this is in terms of the smallest possible choice of k, which is called the *order* of the family. The collection $[s_j(\mathbf{y}), j = 1, \ldots, k]$ is then minimally sufficient. It is the classical Fisher–Darmois–Koopman–Pitman result that, in general, under regularity conditions, when data **y** consist of n independent observations, a sufficient statistic of fixed dimension k for all n can exist only when the component observations y_i have exponential family distributions as indicated by (3). Even then, when the y_i are not identically distributed, this occurs only under special conditions discussed below. It is assumed that the coordinates of $\boldsymbol{\theta} \in \boldsymbol{\Theta}$ can vary independently of one another, i.e. that the dimension of the space $\boldsymbol{\Theta}$ is really $\dim \boldsymbol{\theta}$. Since the distribution of **y** is determined by $[c_j(\boldsymbol{\theta}), j = 1, \ldots, k]$, unless $k \geq \dim \boldsymbol{\theta}$ the parameter $\boldsymbol{\theta}$ will contain redundancies resulting in lack of identifiability, as in one-way classifications in parameterization $\mu + \tau_j$. We assume here that these redundancies have been eliminated. The present discussion is not mathematically rigorous, but is intended to convey the essential ideas as simply as possible.

Canonical Parameters; Regular and Curved Families

It is useful to consider a reparameterization, taking $[\gamma_j = c_j(\boldsymbol{\theta}); j = 1, \ldots, k]$, and thus to express the model in (1) as

$$f(\mathbf{y}; \boldsymbol{\gamma}) = m(\mathbf{y}) \exp\left[\sum_j \gamma_j s_j(\mathbf{y}) - K(\boldsymbol{\gamma})\right].$$

The γ_j are called the *canonical parameters* of the exponential family, and the statistics $s_j(\mathbf{y})$ the *canonical sufficient statistics*. Note that these are only specified up to linear transformations; any full-rank linear transformation of the collection (γ_j) is another set of canonical parameters, with correspondingly transformed canonical sufficient statistics. The density of **s** takes similar form,

$$f(\mathbf{s}; \boldsymbol{\gamma}) = n(\mathbf{s}) \exp[\boldsymbol{\gamma}'\mathbf{s} - K(\boldsymbol{\gamma})], \tag{4}$$

for a function $n(\mathbf{s})$ which in the discrete case is the sum of $m(\mathbf{y})$ for **y** values mapping into **s**. Another useful parameterization utilized below is in terms of the vector $\boldsymbol{\mu} = \mathrm{E}_\gamma(\mathbf{s})$, which is referred to as the *mean parameter*.

The function $K(\boldsymbol{\gamma})$ is essentially the cumulant generating function (*see* **Characteristic Function**) of the statistic **s**. That is, derivatives of $K(\boldsymbol{\gamma})$ yield moments of **s** in a useful form: $\dot{K}(\boldsymbol{\gamma}) = \mathrm{E}_\gamma(\mathbf{S})$, $\ddot{K}(\boldsymbol{\gamma}) = \mathrm{var}_\gamma(\mathbf{S})$, $\dddot{K} = \mathrm{skew}_\gamma(\mathbf{S})$, and so forth. Here, and in the following, overdots on functions denote derivatives, with respect to parameters if there are additional arguments. As seen above, $\boldsymbol{s}$ is often the sum of independent observations, and in any case normal approximations for its distribution apply as the information in the data becomes large.

Recall that the order of the family is the minimal value of k which can be used in (1) – that is, the minimal dimension of $\boldsymbol{\gamma}$ in the above expressions. There are then two major cases: where $k = \dim \boldsymbol{\theta}$ and where $k > \dim \boldsymbol{\theta}$. If $k = \dim \boldsymbol{\theta}$, as in the two examples above, the family is said to be *regular*, which simplifies inferential issues. In particular, the maximum likelihood estimator of $\boldsymbol{\theta}$ is a one-to-one function of **s**, and hence is a sufficient statistic. In addition, **s** is complete; that is, there is at most one unbiased estimator based on **s** of any given parametric function $\psi(\boldsymbol{\theta})$ [12, Section 4.3]. If $k > \dim \boldsymbol{\theta}$, then the parameters $[\gamma_j(\boldsymbol{\theta}), \boldsymbol{\theta} \in \boldsymbol{\Theta}]$ are functionally related, jointly tracing out a curved space of dimension $\dim \boldsymbol{\theta}$ within k-dimensional Euclidean space $\mathcal{R}^k$, and thus the model is called a *curved* exponential family [7, 8]. The **maximum likelihood** estimator of $\boldsymbol{\theta}$ is then not a sufficient statistic, being of dimension less than that of the minimal sufficient statistic. Ideal inference is severely hampered by the need to utilize the information not contained in the maximum likelihood estimator of $\boldsymbol{\theta}$, and approximate methods, which may be very good, are always employed.

The above examples are readily modified to yield curved exponential families, by modeling quantities other than the canonical parameter as linear in $\boldsymbol{\beta}$. That is, in the binomial example, if $\pi_i = g(\mathbf{x}_i'\boldsymbol{\beta})$

for any function $g(\cdot)$ other than that corresponding to $\log[\pi_i/(1-\pi_i)] = \mathbf{x}_i'\boldsymbol{\beta}$, then the family is curved unless the covariates are very special, i.e. taking on only $\dim \boldsymbol{\beta}$ or fewer values. Without special covariate structure the minimal value of k is the sample size n. In the gamma example, if some function other than $1/\sigma_i$ is modeled as $\mathbf{x}_i'\boldsymbol{\beta}$, then the family is similarly curved. In that setting it is often more natural and practically useful to take $\ln \sigma_i = \mathbf{x}_i'\boldsymbol{\beta}$. Although these are practically important instances, curved exponential families arise in many other ways. An interesting and more tractable example arises in identically distributed negative exponential response times which are **censored** if they exceed a fixed time C. The minimal sufficient statistic is (T, r), where T is the total time on test and r is the number of failures; and the maximum likelihood estimator of the scale parameter is T/r. Another often-considered example arises from identically distributed Gaussian observations with known coefficient of variation.

Basic Issues of Estimation

For inferential purposes it will be best to consider inference about some underlying parameter $\boldsymbol{\theta}$, rather than $\boldsymbol{\gamma}$, with the understanding that in the regular case one may sometimes simply want to consider $\boldsymbol{\theta} = \boldsymbol{\gamma}$. The log likelihood function for $\boldsymbol{\theta}$ in terms of $\mathbf{s}$ is

$$l(\boldsymbol{\theta}; \mathbf{s}) = \boldsymbol{\gamma}(\boldsymbol{\theta})'\mathbf{s} - K[\boldsymbol{\gamma}(\boldsymbol{\theta})]. \tag{5}$$

For regular families where the coordinates of $\boldsymbol{\gamma}$ vary freely, the maximum likelihood equations are $\mathrm{E}_\theta(\mathbf{S}) = \mathbf{s}$; that is, the maximum likelihood estimator of the mean parameter $\boldsymbol{\mu}$ is $\hat{\boldsymbol{\mu}} = \mathbf{s}$. This can be seen by reparameterizing in terms of $\boldsymbol{\gamma}$ and differentiating (5), using the fact that $\dot{K}(\boldsymbol{\gamma}) = \boldsymbol{\mu}$. For curved families $\boldsymbol{\mu}(\boldsymbol{\theta})$ does not vary freely over $\mathcal{R}^k$ and the equations $\hat{\boldsymbol{\mu}} = \mathbf{s}$ generally have no solution. In this case the maximum likelihood estimator $\hat{\boldsymbol{\mu}}$ is a weighted least squares approximate solution to these equations, as described below.

In either case the expected **information** for $\boldsymbol{\theta}$, i.e. $-\mathrm{E}[\ddot{l}(\boldsymbol{\theta}; \mathbf{S})] = \mathrm{var}[\dot{l}(\boldsymbol{\theta}, \mathbf{S})]$, is $i(\boldsymbol{\theta}) = (\partial\boldsymbol{\gamma}/\partial\boldsymbol{\theta})'\ddot{K}(\boldsymbol{\gamma})(\partial\boldsymbol{\gamma}/\partial\boldsymbol{\theta})$, or simply $\ddot{K}(\boldsymbol{\gamma})$ for regular families when $\boldsymbol{\theta} = \boldsymbol{\gamma}$. The observed information given data $\mathbf{s}$ is $j(\hat{\boldsymbol{\theta}}) = -\ddot{l}(\hat{\boldsymbol{\theta}}; \mathbf{s})$, where $\hat{\boldsymbol{\theta}}$ is the maximum likelihood estimator. For regular exponential families, $i(\hat{\boldsymbol{\theta}}) = j(\hat{\boldsymbol{\theta}})$, and for curved exponential families these always differ except for samples with $\mathbf{s} = \hat{\boldsymbol{\mu}}$. In fact, the standard deviation of the ratio $j(\hat{\boldsymbol{\theta}})/i(\hat{\boldsymbol{\theta}})$ of these information measures can provide a useful measure of "how curved" the family is [7, 8]. When the information is substantial the maximum likelihood estimator $\hat{\boldsymbol{\theta}}$ is approximately normally distributed with mean $\boldsymbol{\theta}$ and variance $[i(\boldsymbol{\theta})]^{-1}$. For curved families a dominant part of the information not contained in the maximum likelihood estimator can often be utilized by replacing this by $[j(\hat{\boldsymbol{\theta}})]^{-1}$ [9].

When for regular families the maximum likelihood equations cannot be solved in closed form, or when a least squares solution is called for because the model is curved, numerical methods can often be organized most simply in terms of iterative nonlinear weighted least squares (*see* **Generalized Linear Model**). Often this is for convenience based on a version of (5), where $k = \dim \mathbf{s}$ is not chosen minimally, and in particular may be where $\mathbf{s}$ there is taken as the original data $\mathbf{y}$. Departing momentarily from the assumption that k has necessarily been chosen minimally, the following holds for any choice of $k \geq \dim \boldsymbol{\theta}$, and for either regular or curved models. Let $\mathcal{M}$ represent the space of values of the mean parameter $[\mu(\boldsymbol{\theta}); \boldsymbol{\theta} \in \boldsymbol{\Theta}]$, a space of dimension $p = \dim \boldsymbol{\theta}$ within $\mathcal{R}^k$, which is typically curved even for regular families if k is not minimal. Differentiating (5) and using the relation that $\dot{\boldsymbol{\mu}}(\boldsymbol{\theta}) = \ddot{K}(\boldsymbol{\gamma})\dot{\boldsymbol{\gamma}}(\boldsymbol{\theta})$, it is seen that the vector $(\mathbf{s} - \hat{\boldsymbol{\mu}})$ is orthogonal to $\mathcal{M}$ at the point $\hat{\boldsymbol{\mu}}$ in the sense that

$$(\mathbf{s} - \hat{\boldsymbol{\mu}})'\hat{\boldsymbol{\Sigma}}^{-1}\hat{\mathbf{T}} = \mathbf{0},$$

where $\hat{\boldsymbol{\Sigma}} = \mathrm{var}_{\hat{\theta}}\mathbf{S}$ and the columns of $\hat{\mathbf{T}}$ span the tangent space to $\mathcal{M}$ at $\hat{\boldsymbol{\mu}}$; for example, $\hat{\mathbf{T}} = \partial\boldsymbol{\mu}/\partial\boldsymbol{\theta}$ evaluated at $\hat{\boldsymbol{\theta}}$. This may be solved by iterative nonlinear least squares, with the step from an iterative value $\tilde{\boldsymbol{\mu}}$ given by

$$(\hat{\boldsymbol{\mu}} - \tilde{\boldsymbol{\mu}}) = [\tilde{\mathbf{T}}'\tilde{\boldsymbol{\Sigma}}^{-1}\tilde{\mathbf{T}}]^{-1}\tilde{\mathbf{T}}'\tilde{\boldsymbol{\Sigma}}^{-1}(\mathbf{s} - \tilde{\boldsymbol{\mu}}).$$

This is the Newton–Raphson method if the model is regular, and the Fisher scoring method if the family is curved (*see* **Optimization and Nonlinear Equations**).

Exact Frequency Inference

Exact **inference** for multiparameter exponential families is a fundamental aspect of theory of inference. Consider inference about a scalar-valued

parametric function $\psi = \psi(\boldsymbol{\theta})$ in terms of a significance test of $\psi = \psi_0$ against the alternative $\psi > \psi_0$ (*see* **Hypothesis Testing**). This can then be inverted to yield a lower *confidence limit* given by the smallest ψ-value which would not be rejected at the specified level as a hypothesized value. In our view confidence intervals are best determined by individually determined lower and upper confidence limits. It is useful in theoretical development to consider a reparameterization from $\boldsymbol{\theta}$ to $(\psi, \boldsymbol{\nu})$, where $\boldsymbol{\nu}$ is referred to as a **nuisance parameter**.

The fundamental condition imposed in deriving an inference about ψ is that operating characteristics under the hypothesis of the inferential procedure – that is the size of a test (*see* **Level of a Test**), the ***P* value**, or the coverage probability of a **confidence interval** – should be independent of $\boldsymbol{\nu}$. Exactness is achieved only when the model is regular and ψ is a canonical parameter, i.e. a linear function of any specific choice $\boldsymbol{\gamma}$ of canonical parameters. In this case $\boldsymbol{\nu}$ can be chosen as a complementary set of canonical parameters, and the density of a sufficient statistic can be expressed as

$$f(t, \mathbf{s}; \psi, \boldsymbol{\nu}) = n(t, \mathbf{s}) \exp[\psi t + \boldsymbol{\nu}'\mathbf{s} - K(\psi, \boldsymbol{\nu})]. \tag{6}$$

All inferences which are independent of $\boldsymbol{\nu}$ in the sense indicated above may be based on the conditional distribution of T given $\mathbf{S} = \mathbf{s}$; note that $\mathbf{s}$ is the complete sufficient statistic for $\boldsymbol{\nu}$ in the subfamily, where ψ is fixed at any value [12, Chapter 4; 4, Chapter 5] (*see* **Conditionality Principle**). This conditional distribution depends only on ψ and belongs to a related exponential family of the form

$$f(t|\mathbf{S} = \mathbf{s}; \psi) = n(t, \mathbf{s}) \exp[\psi t - K^*(\psi; \mathbf{s})] \tag{7}$$

for a function $K^*(\psi; \mathbf{s})$, which is, of course, the cumulant generating function of the conditional distribution. The P value for testing $\psi = \psi_0$ against the alternative $\psi > \psi_0$ is $\Pr[T \geq t_{\text{obs}}|\mathbf{S} = \mathbf{s}_{\text{obs}}; \psi_0]$, where $t_{\text{obs}}, \mathbf{s}_{\text{obs}}$ are the observed data.

The conditional distribution involved in this is ordinarily fairly intractable. However, for a variety of settings involving continuous data, in particular Gaussian and gamma models, this P value can be reexpressed in terms of an unconditional probability. The standard t tests for means and regression coefficients for Gaussian data, the standard F *tests* for variances of Gaussian data, and F tests for negative exponential and gamma data can be derived in this manner [12, Chapter 5].

For discrete data this conditional P value can often be computed by enumeration of the sample space for either t or the original data $\mathbf{y}$, within the set where $\mathbf{S} = \mathbf{s}_{\text{obs}}$. Aside from possibly extensive calculations, this is straightforward since the conditional density is simply proportional to $n(t, \mathbf{s}) \exp(\psi_0 t)$, and if necessary the first term can be computed as indicated following (4) by enumerating samples $\mathbf{y}$ mapping into $(t, \mathbf{s})$. In particular, these calculations do not require the function $K^*(\psi; \mathbf{s})$, which may be difficult to calculate. This method leads, for example, to **Fisher's exact test** for comparison of two binomial samples [4, Section 5.2; 6, Section 2.3]. Much of the methodology for matched case–control studies (*see* **Matched Analysis**) is based on this theory. A simple version of this pertains to independent pairs of binomial observations y_{1i}, y_{2i} with probabilities π_{1i}, π_{2i} modeled as $\log[\pi_{1i}/(1 - \pi_{1i})] = \nu_i$ and $\log[\pi_{2i}/(1 - \pi_{2i})] = \nu_i + \psi$. Inference about the common log **odds ratio** ψ is made by conditioning on the sufficient statistics $(y_{\cdot i})$ for the collection of nuisance parameters (ν_i) [6, Section 2.4; 3, Chapter 7].

Sophisticated enumeration **algorithms** have been developed, providing for feasible computation of P values for various settings involving single and multiple **contingency tables**, logistic regression, and related problems (for example, see LogXact [13]; *see* **Exact Inference for Categorical Data**; **StatXact**). However, these methods for discrete data are, in general, an application of theory which applies exactly only for continuous data, and when the discreteness of the distribution of $T|\mathbf{S} = \mathbf{s}$ is substantial the operating characteristics of the procedures are often quite poor. That is, the unconditional size of tests, the unconditional distribution of P values, and even the conditional level of confidence intervals, can be far from the nominal levels (see, for example, [21] and [11]). In our view [16], it is generally best to "smooth the data" by using, without continuity corrections, the best of the asymptotic methods discussed below.

The above theory can also be applied indirectly when $\psi(\boldsymbol{\theta})$ is the ratio of canonical parameters, and this need arises frequently – for example, in testing a Gaussian mean. If $\psi = \gamma_i/\gamma_j$, then testing $\psi = \psi_0$ is equivalent to testing $\gamma_i - \psi_0\gamma_j = 0$, which reduces the problem to a hypothesis for a canonical

parameter. Of course, if ψ is a monotonic function of a canonical parameter, then the theory applies simply by transforming the hypotheses to one involving the canonical parameter. These extensions exhaust the situations where there is even in principle an exact inference for a single parametric function in multiparameter exponential families. Extensions of the exact theory to settings where $\dim \boldsymbol{\psi} > 1$ are rather limited, consisting mainly of the standard F tests for Gaussian regression. There is virtually never an exact inferential method for curved exponential families.

Approximate Methods of Inference

There are several approximate methods of inference, whose definition and most basic properties are not really special to the exponential family setting [4]. However, this setting provides a good opportunity to compare and evaluate them, since they can be referred to exact methods. We continue to write $\psi = \psi(\boldsymbol{\theta})$ as the interest parameter, but for the methods of this section it is not required that this be a canonical parameter. It is assumed in the following that ψ-values of special interest, either maximum likelihood estimators or hypothesized values, are not on the boundary of the parameter space.

The direct use of approximate normality of the maximum likelihood estimator $\hat{\psi}$, often called the Wald method (*see* **Likelihood**), utilizes an approximate standard error computed from $[i(\hat{\boldsymbol{\theta}})]^{-1}$ or $[j(\hat{\boldsymbol{\theta}})]^{-1}$ by using the **delta method** (if necessary). Some caution is required in using this method. If $\rho = g(\psi)$ is a monotonic function of ψ, then ideally most inferences should be essentially independent of the choice of which parameter is used; this is called invariance. For example, a confidence interval for ρ should consist of the mapping of a confidence interval for ψ under the transformation $g(\psi)$. This does not obtain when using the Wald method, and of course the normal approximation will be better for some representations of the parameter than for others. When the information is modest, one should seldom rely on the Wald method without some consideration of choosing a suitable parameterization. The advantage of the method is the simplicity and transparency of reporting a point estimate and its approximate standard error.

The following alternative methods are presented in terms of significance tests for hypothesized values of ψ, which represent a rather incomplete inference without attention to estimation. However, confidence intervals for ψ may serve to rectify this even better than maximum likelihood estimators. These can be obtained from the following approximate methods, in the same manner as indicated above for exact tests, as the set of ψ-values which would not be "rejected" as hypothesized values.

The score test method (*see* **Likelihood**), sometimes called Rao's method, has useful characteristics. Writing (5) in terms of ψ and an arbitrary choice of nuisance parameter $\boldsymbol{\nu}$ as

$$l(\psi, \boldsymbol{\nu}; \mathbf{s}) = \boldsymbol{\gamma}(\psi, \boldsymbol{\nu})'\mathbf{s} - K[\boldsymbol{\gamma}(\psi, \boldsymbol{\nu})], \qquad (8)$$

the score test of $\psi = \psi_0$ is based on the derivative of (8) with respect to ψ, evaluated at ψ_0. Large values of this, in absolute value, indicate evidence against the hypothesis, without the need to compute $\hat{\psi}$ where this derivative is zero. None of the methods in this section depends on the particular choice of $\boldsymbol{\nu}$. In contrast to the Wald method, both the score test and the likelihood ratio method discussed below are invariant under monotonic reparameterizations $\rho = g(\psi)$. For the score test the derivative presented below would then simply be multiplied by the constant $1/\dot{g}(\psi_0)$, which has no effect on the ultimate test.

More precisely, the derivative of (8) is evaluated at ψ_0 and $\hat{\boldsymbol{\nu}}_0$, where the latter is the maximum likelihood estimator of $\boldsymbol{\nu}$ under the hypothesis. When ψ is a canonical parameter this is given by $t - \mathrm{E}_{\psi_0, \hat{\nu}_0}(T)$ in terms of the notation for (6). This special case gives a clear view of the fundamental nature of the score statistic, whose more general form is given by

$$[\partial \boldsymbol{\gamma}(\psi_0, \hat{\boldsymbol{\nu}}_0)/\partial \psi]'[\mathbf{s} - \mathrm{E}_{\psi_0, \hat{\nu}_0}(\mathbf{S})].$$

The expectation of this statistic under the hypothesis is approximately zero, and its approximate variance is the adjusted information for ψ allowing for estimation of $\boldsymbol{\nu}$. This adjusted information is the reciprocal of the $\mathrm{var}(\hat{\psi})$ element in the inverse information matrix $[i(\psi_0, \hat{\boldsymbol{\nu}}_0)]^{-1}$. The score test statistic consists of the log likelihood derivative divided by its asymptotic standard deviation, with the P value for alternatives $\psi > \psi_0$ being the probability that a standard normal variate is as large as the observed value of this statistic. The most important characteristic of the score test is that one needs only to compute the maximum likelihood estimator under the

hypothesis, $\hat{\boldsymbol{\nu}}_0$, rather than the full maximum likelihood estimator $(\hat{\psi}, \hat{\boldsymbol{\nu}})$, which may simplify computations substantially. For example, consider the logistic regression example above when x_i consists of a constant term and a single covariable, and testing whether the regression coefficient of the covariable is zero. Writing m_i for the binomial sample sizes, the numerator of the score test is simply $\sum x_i(y_i - \hat{\pi})$, where $\hat{\pi} = \sum y_i / \sum m_i$; its asymptotic variance is given by $\hat{\pi}(1-\hat{\pi}) \sum m_i (x_i - \overline{x}_w)^2$, where $\overline{x}_w$ is the average of the x_i using weights m_i.

Generally, the most reliable inference is based on the asymptotic distribution of the generalized likelihood ratio (*see* **Likelihood Ratio Tests**), which is sometimes referred to as Wilks' method. Denoting the likelihood function by $L(\boldsymbol{\theta}; \mathbf{y})$, this likelihood ratio is defined as

$$W(\psi_0, \mathbf{y}) = \max_{\boldsymbol{\theta}} L(\boldsymbol{\theta}; \mathbf{y}) / \max_{\boldsymbol{\theta}:\psi(\boldsymbol{\theta})=\psi_0} L(\boldsymbol{\theta}; \mathbf{y}),$$

which will tend to take large values when the data do not support the hypothesis. In terms of a reparameterization to $(\psi, \boldsymbol{\nu})$ as above, computing the constrained maximum of the denominator amounts to fitting the nuisance parameter $\boldsymbol{\nu}$ by maximum likelihood when $\psi = \psi_0$. When the hypothesis is true, the sampling distribution of $2\ln[W(\psi_0; \mathbf{Y})]$ is approximately **chi-square** on 1 **degree of freedom** (df). Moreover, the distribution of

$$z(\psi_0, \mathbf{Y}) = \text{sign}(\hat{\psi} - \psi_0)\{2\ln[W(\psi_0; \mathbf{Y})]\}^{1/2} \quad (9)$$

is approximately **standard normal**, and can be used for directional inference. A P value for alternatives $\psi > \psi_0$ is taken as the chance that a standard normal variate is as large as $z(\psi_0, \mathbf{y}_{\text{obs}})$. This normal approximation is the best of the three discussed in this section, and is ordinarily adequate in practice unless $\dim \boldsymbol{\nu}$ is moderately large in relation to the available information. Improvements for that case are discussed in the following section.

Inversion of tests based on (9) to obtain confidence limits is often best carried out in terms of the **profile likelihood** function

$$L_p(\psi; \mathbf{y}) \propto \max_{\boldsymbol{\theta}:\psi(\boldsymbol{\theta})=\psi} L(\boldsymbol{\theta}; \mathbf{y}).$$

In practice one typically chooses a suitable grid of ψ-values and computes $L_p(\psi; \mathbf{y})$ by numerical methods or otherwise for each value in the grid. A plot of the result is useful, and a confidence interval corresponding to the likelihood ratio test can be taken as those ψ-values for which the ratio of $L_p(\psi; \mathbf{y})$ to its maximum value is at least a threshold value. For a $100\alpha\%$ level confidence interval this threshold value is taken as $\exp(-\frac{1}{2}\chi^2_{1-\alpha})$. Although this may be a computationally intensive method, with modern computing capabilities it is quite feasible once one organizes the calculations, or uses software with such procedures incorporated. It is noteworthy that the information computed from differentiation of the log profile likelihood is the same as the adjusted information for ψ as defined earlier.

All of these approximate methods generalize naturally to the case that $\dim \psi > 1$ in terms of chi-square tests. For tests based directly on the maximum likelihood estimator, and for score tests, a quadratic form is computed using the multivariate statistic and its asymptotic variance matrix. For the likelihood ratio test, the approximate distribution of $2\ln[W(\psi_0; \mathbf{Y})]$ is chi-square on $\dim \psi$ df.

Improved Approximations Based on Higher-Order Asymptotics

For regular families more accurate approximations to the distribution of $\mathbf{s}$ may be obtained from so-called saddlepoint approximations, which might better be referred to as likelihood ratio approximations. These are readily computed from $K(\boldsymbol{\gamma})$ and the maximum likelihood estimator $\hat{\boldsymbol{\gamma}}$ corresponding to the value of $\mathbf{s}$ at which the approximation is desired. In terms of the density of $\mathbf{s}$ this is discussed by Barndorff–Nielsen & Cox [2], and approximations to the distribution function are reviewed by Pierce & Peters [15]. These approximations are both very accurate and theoretically intriguing due to their connections with likelihood ratio concepts. The text by Severini [17] gives a thorough treatment of the following, in the general setting not restricted to exponential families.

Improvements on the above classical approximations, based on these methods, are relatively simple to implement for regular exponential families, and are particularly useful when $\dim \boldsymbol{\nu}$ is moderately large in relation to the information available. The Cox–Reid [5] adjusted profile likelihood function

approximates more closely the conditional likelihood function based on (7), and when ψ and $\boldsymbol{\nu}$ are canonical parameters it takes the form

$$L_{\mathrm{ap}}(\psi;\mathbf{y}) \propto L_{\mathrm{p}}(\psi;\mathbf{y})|\partial^2 K(\psi, \hat{\boldsymbol{\nu}}_\psi)/(\partial \boldsymbol{\nu})^2|^{1/2},$$

where $\hat{\boldsymbol{\nu}}_\psi$ denotes the maximum likelihood estimator when ψ is held fixed (see also Pierce & Peters [15]). This also applies without modification when $\dim \psi > 1$. With some modification it applies to noncanonical parameters and also outside of exponential family settings. The matrix whose determinant is involved is the expected information for $\boldsymbol{\nu}$ when ψ is fixed, and is available when one uses the iterative method indicated above for computing $\hat{\boldsymbol{\nu}}_\psi$. The maximizing value of L_{ap}, and confidence intervals computed from it as indicated above in terms of L_{p}, have reduced bias when $\dim \boldsymbol{\nu}$ is moderately large.

For inference about canonical parameters when $\dim \psi = 1$ it is possible through these approximations to modify the likelihood ratio statistic, (9), to obtain an improved estimate of $\Pr(T \geq t_{\mathrm{obs}}|\mathbf{S} = \mathbf{s}_{\mathrm{obs}}; \psi_0)$. This makes more accurate allowance both for the conditioning which eliminates the nuisance parameter, and for nonnormality of the conditional distribution involved [15]. This modification is simple to compute, and again the quantities required are ordinarily byproducts of the fitting process required for computing (9).

Bayesian Inference

Bayesian inference is also particularly tractable for exponential families. Consider the form (4) of an exponential family, and a family of prior distributions for $\boldsymbol{\gamma}$, with parameters $\boldsymbol{\lambda}$ and κ, of the form

$$\pi(\boldsymbol{\gamma};\boldsymbol{\lambda},\kappa) \propto \exp\{\kappa[\boldsymbol{\gamma}'\boldsymbol{\lambda} - K(\boldsymbol{\gamma})]\}.$$

This is referred to as a *conjugate family* of **prior distributions**, attractive in that the posterior distribution based on data with sufficient statistic $\boldsymbol{s}$ following (4) is

$$\pi(\boldsymbol{\gamma}|\mathbf{s};\boldsymbol{\lambda},\kappa) \propto \exp\left\{(\kappa+1)\left[\boldsymbol{\gamma}'\frac{(\mathbf{s}+\kappa\boldsymbol{\lambda})}{(\kappa+1)} - K(\boldsymbol{\gamma})\right]\right\}$$
$$\propto \pi(\boldsymbol{\gamma};\boldsymbol{\lambda}^*,\kappa^*),$$

which is an updated member of the conjugate family with parameters $\boldsymbol{\lambda}^* = (\mathbf{s}+\kappa\boldsymbol{\lambda})/(\kappa+1)$ and $\kappa^* = \kappa + 1$. Not only is this highly tractable but it provides an interpretation of the prior information specified by $(\boldsymbol{\lambda}, \kappa)$ as equivalent to hypothetical data with sufficient statistic $\boldsymbol{\lambda}$ but having weight κ times that of $\mathbf{s}$, combined with an initially locally uniform prior distribution. Asymptotic methods for Bayesian inference are closely related to those discussed above, both in terms of the classical results and the higher-order asymptotics [18–20].

Exposure Effect

An exposure effect is a quantitative measure of the impact of exposure on an outcome measure. Estimates of exposure effects are derived by contrasting the outcomes in an exposed population with outcomes in an unexposed population or in a population with a different level of exposure. **Relative risk, excess risk**, and **relative odds** are examples of exposure effects used in connection with dichotomous outcomes, whereas **relative hazards** are used to characterize exposure effects when the outcome is time-to-response or the event rate per **person–year** exposure time. **Mean** differences are often used to characterize exposure effects for quantitative outcomes.

When **regression** models are used, exposure effects correspond to model parameters. For example, consider a model with **multiple linear regression** $\beta_0 + \beta_1 E + \beta_2 X$, where E indicates a level of exposure and X some other factors influencing outcome. The exposure effect, β_1, measures the effect on outcome of a unit increase in exposure, with other factors, X, held constant. If E only takes on values 1 for exposed and 0 for unexposed, β_1 is the adjusted mean difference between exposed and unexposed; and if, in addition, the outcome is dichotomous, β_1 is the adjusted risk difference. If the effect of exposure depends on levels of another factor, say X_1, an **interaction** term involving $X_1 E$ is needed in the previous regression. Then no single number characterizes the exposure effect, and **effect modification** is said to occur.

In the theory of **causation**, each individual or study unit is hypothesized to have two responses, the response if exposed and the response if unexposed. Only one such response is observed on each individual, but hypothesized individual-level effects can be defined, such as the difference in responses the individual would have if exposed and if unexposed. In the context of this "counterfactual" theory of causal effects, the exposure effects described in the previous paragraph can be regarded as summary measures of individual-level causal exposure effects.

MITCHELL H. GAIL

Extrapolation, Low Dose

At high doses, most substances are toxic to humans. Thus, it is imperative to establish conditions for the use of toxic substances that are relatively safe. Because of its devastating effects, cancer is a major concern. Considerable research is focused on identifying chemical substances (carcinogens) that cause cancer. Occasionally, it is possible to identify carcinogens in human populations by epidemiologic studies. Since humans are exposed to many substances, generally at unknown dose levels, it is difficult to quantify the risk (probability) of cancer from human studies. Cancer risks are generally estimated from **bioassays** conducted in laboratory animals (*see* **Tumor Incidence Experiments**). Animals are generally exposed at a few dose levels, and unexposed control animals are used, for a lifetime (from weaning up to two years in rodents). Chemicals are administered in the diet, drinking water, subcutaneously, via gavage, or by inhalation. Usually fewer than 100 animals are used per dose level. Thus, high doses must be used to elicit potential cancer effects at incidence rates high enough to be detected and measured in animal bioassays. However, humans are usually exposed to much lower levels of toxic substances. This requires extrapolation (estimation) of cancer incidence (risk) at doses well below the experimental dose range.

The dose of interest is the active dose at the target tissue. Many chemicals are metabolized by the body to an active or inactive state. Physiologically based **pharmacokinetic** studies are often conducted to study the absorption, distribution, and excretion of chemicals in the body. In some cases it is possible to measure the dose of the active chemical at the target tissue site. Generally, this information is not available and it is assumed that the target tissue dose is proportional to the administered dose. The nonlinearity of dose–response curves can be due, in part or wholly, to the pharmacokinetics of a chemical (*see* **Dose–Response Models in Risk Analysis**). In general, it is not known whether a test species is more or less sensitive than humans to a carcinogen. In the absence of such information, the US Environmental Protection Agency [22] proposes equal sensitivity across species when dose is expressed as a ratio of body weight to the 3/4 power. This is nearly equivalent to expressing dose as concentration in the diet or drinking water.

Risk is generally expressed as the probability that an individual will develop cancer by some age, usually lifetime, when exposed to a specified dose of a carcinogen (*see* **Risk Assessment**). For a population of individuals exposed to different doses, the expected number of cancer cases is

$$\text{expected number} = \sum_i N_i \Pr(d_i),$$

where N_i is the number of individuals exposed at dose d_i and $\Pr(d_i)$ is the probability (proportion) developing cancer at that dose. The average risk for the population is

$$\Pr = \frac{\sum_i N_i \Pr(d_i)}{\sum N_i}.$$

If the dose–response is linear, then the population risk is simply the slope (risk per unit dose) times the average dose level in the population.

One of the earliest procedures for low-dose cancer risk estimation was proposed by Mantel & Bryan [19]. They noted for many chemicals that the doses that produced cancer appeared to be **lognormally** distributed. That is, plots of tumor incidence as probits vs. log dose were approximately linear (*see* **Quantal Response Models**). Mantel & Bryan [19] observed that the probits versus log dose slopes were steep and generally much greater than one. They proposed extrapolating from the low end of the observable experimental dose–response to lower doses using a conservative shallow slope of one. Mantel & Bryan [19] postulated that this procedure should overestimate the true cancer incidence at low doses and provide conservative overestimates at doses with low levels of risk.

Theoretically, one molecule of a genotoxic carcinogen can interact with the DNA of a cell and initiate a carcinogenic process. In such cases there is no threshold dose below which cancer does not occur; that is, there is a positive slope as the dose approaches zero. Furthermore, if the chemical under study augments an existing carcinogenic process that is already producing tumors, then no threshold dose for the added chemical exists, as the endogenous dose already exceeds the threshold dose, if one exists. Hence, there is an increase (positive slope) for tumor

incidence at low doses of the administered chemical with additivity to the background carcinogenic process [6, 20].

Since the slope of the log probit procedure of Mantel & Bryan [19] approaches zero at low doses, that procedure is not compatible with the nonthreshold, low-dose positive slope expected for genotoxic chemicals or with additivity to background. For any dose–response that is curving upward in the low-dose region, linear extrapolation to zero excess risk at zero dose from the low end of the dose–response curve provides an overestimate of the risk at low doses. Since the shape of the dose–response curve cannot be determined at low incidence rates with the numbers of animals typically used, Gaylor & Kodell [10] proposed linear extrapolation to zero from an upper **confidence** limit on the estimate of risk at the lowest experimental dose, to provide a conservative procedure for low-dose extrapolation. Since the accuracy of the estimate at the lowest experimental dose could be poor, Farmer et al. [7] modified the procedure to extrapolation from a dose with a minimum excess risk of 1% or the lowest experimental dose, whichever was larger. The choice of the form of the dose–response model generally makes little difference above this point, as long as an adequate fit to the data is obtained.

Where a chemical operates independent of any background carcinogenic process, the total risk can be expressed as

$$\overset{*}{\Pr}(d) = \Pr(0) + [1 - \Pr(0)]\Pr(d),$$

where the excess risk due to the chemical of interest is

$$\Pr(d) = \frac{\Pr^*(d) - \Pr(0)}{1 - \Pr(0)}.$$

This is also known as Abbott's correction (*see* **Quantal Response Models**). In general, the total risk can be expressed as

$$\overset{*}{\Pr}(d) = \Pr(0) + \Pr(d),$$

where the excess risk due to the chemical under study is

$$\Pr(d) = \overset{*}{\Pr}(d) - \Pr(0).$$

The **multistage carcinogenesis model** [2] is used widely to describe cancer risk by a specific age as a function of dose:

$$\overset{*}{\Pr}(d) = 1 - \exp\left[-\prod_{i=0}^{k}(\beta_{0i} + \beta_{1i}d)\right],$$

where $\beta_{0i} > 0$ is the spontaneous rate for the ith stage and $\beta_{1i}d \geq 0$ is the increase in the rate of the ith stage due to dose d. For fitting dose–response data, the model is written in a generalized form [6]:

$$\overset{*}{\Pr}(d) = 1 - \exp\left[-\sum_{i=0}^{k}(\beta_i d^i)\right],$$

where $\beta_i \geq 0$. For small d, the risk is approximately

$$\overset{*}{\Pr}(d) = 1 - \exp[-(\beta_0 + \beta_1 d)],$$

which is approximately linear at low doses:

$$\overset{*}{\Pr}(d) = \beta_0 + \beta_1 d.$$

Since low-dose linearity cannot be excluded, the upper confidence limit for the generalized multistage model becomes linear at low doses. An upper limit of excess risk at low doses is provided by

$$\Pr(d) = q_1^* d,$$

where q_1^* is an upper limit on the estimate of β_1 also referred to as the low-dose slope (risk per unit dose) or carcinogenic potency. The above process has been used widely by US regulatory agencies to provide conservative overestimates of cancer risks at low doses. Conversely, doses can be estimated that correspond to specified levels of allowable risk; for example, risks of less than one in 100 000.

In addition to upper limit estimates of risk, a best (central) estimate can be obtained over the range where the dose–response is linear. **Maximum likelihood** estimates of the linear term in the generalized multistage model are quite unstable with sample sizes commonly used, and a discontinuity occurs where the estimate changes from zero to a positive value. Gaylor et al. [14] provide a stable estimate of the low-dose slope for the linear dose–response region

$$\hat{\Pr}(d) = \hat{\beta}_1 d,$$

where $\hat{\beta}_1 = 0.01/\mathrm{ED}_{01}$ and ED_{01} is the estimate of the dose producing an excess tumor incidence of 1%.

An upper limit can be estimated by

$$\mathrm{UL}(\hat{\beta}_1) = \frac{0.01}{\mathrm{LED}_{01}},$$

where LED_{01} is a lower confidence limit on a dose producing an excess risk of 1%.

Krewski et al. [17] proposed a model-free approach to low-dose extrapolation without making an assumption other than low-dose linearity. For each of the dose groups an upper confidence limit (L_i) on the tumor incidence is calculated. A lower confidence limit (L_0) is calculated for the tumor incidence of the control group. An upper limit for the low-dose slope for the ith dose group is

$$\hat{\beta}_i = \frac{(U_i - L_0)}{d_i},$$

where d_i is the dose level. The minimum of these values is then used for low-dose excess risk of cancer:

$$\hat{\mathrm{Pr}}(d) = (\min \hat{\beta}_i)d.$$

Because the minimum of k slopes is selected, the individual confidence limits must be adjusted so that the overall confidence level is maintained. Using the **Bonferroni inequality**, the individual confidence limits are set at the $\{1 - [0.05/(k+1)]\} \times 100\%$ level to maintain an overall confidence level of 95%. In general, upper limits of estimates of low-dose risk based on this model-free approach and the multistage model are comparable. For convex dose–response curves with low background tumor rates, upper limits of risk estimates based on the model-free procedure are typically twofold or more higher than those based on the multistage model.

One measure of carcinogenic potency is the TD_{50} (the daily dose that causes a tumor in 50% of the exposed animals that otherwise would not develop that type of tumor in a standard lifetime, generally two years for rodents). Variation in the TD_{50} appears to be approximately described by a lognormal distribution. Gaylor et al. [12] show that, for near-replicate bioassays, approximately 95% of the TD_{50}s are within a factor of four of their mean. Among strains within species and among species, approximately 95% of the TD_{50}s are within a factor of their means of 11 and 32, respectively. For a select group of 20 chemicals that have been shown to be carcinogenic in both humans and animals, the overall variability in the TD_{25}s is about a factor of 110 [1]. Based on these 20 chemicals, about 2/3 of the time the potency of human carcinogens is within a factor of ten of the potency in animals at doses high enough to produce a measurable incidence of cancer. This does not include the uncertainty in the shape of the dose–response relationship at lower doses.

The maximum tolerable dose (MTD) is used as the highest dose for chronic bioassays conducted by the US National Toxicology Program. The purpose of using the MTD is to maximize the probability of detecting carcinogenicity. The optimal experimental design for estimating cancer potency depends on the shape of the dose–response relationship. For typical shapes of dose–response curves and the limited number of animals generally used, Portier & Hoel [21] and Gaylor et al. [13] concluded that a good all-purpose design for both testing and estimation is to allocate equal numbers of animals at the MTD, MTD/2 and MTD/4 or MTD, MTD/3 and MTD/9, plus unexposed control animals.

Human exposure to carcinogens often is via exposure to mixtures of carcinogens. At low doses well below saturation of physiologic or metabolic processes, the total risk may be estimated by the sum of the risks of the individual components. In such cases an upper limit of the total risk can be approximated by $U = (\sum U_i^2)^{1/2}$ where U_i is the upper limit for the ith component [8]. For the two-stage clonal expansion model of carcinogenesis (the Moolgavkar–Venson–Knudson model), the age-specific **relative risk** is **multiplicative** for simultaneous exposure to an initiator and a completer or to an initiator and a promoter. At low levels of risk, additive and multiplicative risks of mixtures are nearly identical. Kodell et al. [16] show that simultaneous exposure to two promoters results in supra-multiplicative relative risks.

In most bioassays, animals are exposed to chemicals for a lifetime (generally two years in rodents). Exposures of humans to carcinogens often are intermittent. Based on the multistage model of carcinogenesis, Kodell et al. [15] show that using the average daily lifetime dose to estimate cancer risk is not likely to underestimate the risk by more than a factor of six. Using the **two-mutation carcinogenesis model** (the Moolgavkar–Venson–Knudson model), utilizing the average daily lifetime dose is not likely to underestimate the risk by more than a factor of ten [4].

Several researchers have noted a strong correlation between the MTD and cancer potency. This is due in

part to the limited range of doses used in bioassays and the limited range of tumor incidence observable for animal carcinogens with relatively small numbers of animals per dose group. Gaylor & Gold [9] show that a quick estimate of potential cancer potency can be obtained from a 90-day MTD without conducting a two-year bioassay. Based on a survey of chemicals shown to be carcinogenic by the US National Toxicology Program, the TD_{01} is generally within a factor of ten of the MTD/74.

As discussed earlier, linear extrapolation is used for low-dose risk estimation for genotoxic carcinogens. Also, low-dose linearity is expected when a substance augments a carcinogenic process (additivity to background) that is already producing tumors due to endogenous or other exogenous exposure. For other conditions, it is generally postulated that adverse health effects do not occur at low doses, where the body is capable of excreting or detoxifying small amounts of potentially toxic substances. That is, it is often postulated that there are threshold doses below which no toxicity occurs. However, this becomes a rather tenuous assumption for a heterogeneous population. The recent US Environmental Protection Agency [23] carcinogen risk assessment guidelines propose estimation of the ED_{10} (the dose producing an excess 10% tumor incidence), being a dose that is in or near the experimental dose range and can generally be determined with adequate precision. A lower confidence limit LED_{10} is used to account for experimental variation. The LED_{10} is then used as a point of departure for low-dose extrapolation. Where linearity is expected, low-dose risk estimation is obtained by linear extrapolation to zero. That is, the probability of cancer produced by a dose d is $\Pr(d) = (0.10/\mathrm{LED}_{10})d$, where $(0.10/\mathrm{LED}_{10})$ is the low-dose slope (carcinogenic potency). Where a nonlinear dose–response is expected, biologically based dose–response models may be used to estimate risk or the LED_{10} may be divided by a series of safety (uncertainty) factors to arrive at a dose with an acceptably low level of risk, and perhaps zero risk.

Noncancer Endpoints

For biological endpoints other than cancer, quantitative risk estimation generally is not used. Here it is assumed that excretion and/or detoxification at low doses will eliminate any adverse health effects. That is, it is assumed that there is a threshold dose below which no adverse health effects occur. This may be a tenuous assumption for heterogeneous populations or where a chemical exposure may contribute to an ongoing process that already results in adverse effects in unexposed individuals. In this case, additivity of a dose to an endogenous/exogenous dose that already surpasses a threshold dose will result in increased risk.

The general safety assessment procedure for noncancer endpoints is to divide the no observed adverse effect level (NOAEL) by safety (uncertainty) factors to obtain an acceptable daily intake (ADI) or reference dose (RfD)

$$\mathrm{ADI} = \mathrm{RfD} = \frac{\mathrm{NOAEL}}{(\mathrm{U}_1 * \mathrm{U}_2 * * *)}.$$

A safety (uncertainty) factor of ten is generally used for extrapolation from animals to humans. Another factor of ten is generally used for sensitive individuals in a population. Another factor of up to ten may be used for shortcomings in the available data. If all the doses in a bioassay produce an adverse effect, a NOAEL is not present. In this case, the lowest observed adverse effect level (LOAEL) is used, and an additional factor up to ten is introduced to account for the ratio of the LOAEL to the NOAEL. Barnes & Dourson [3] state that: "RfD (reference dose) is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to a human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime". Biologically based dose–response models have been developed sparingly to estimate risk below the NOAEL or LOAEL.

The process utilizing the NOAEL is limited to the dose levels used in an experiment, and does not make use of the dose–response information. Poorer experiments with higher NOAELs are unjustly rewarded with higher ADIs or RfDs. To overcome these shortcomings, Crump [5] proposed a benchmark dose (BMD) approach. Here the dose–response data are used to estimate a low level of excess risk; for example, 1%–10%. This dose is generally in or near the experimental dose range and is directly estimable without extrapolation. To account for experimental variation, a lower confidence limit on the BMD is used. This rewards better experiments with tighter limits with a higher ADI or RfD. This limit on the BMD can then be used as a substitute for the

NOAEL in calculating an ADI or RfD. This procedure eliminates the use of NOAELs with potentially high levels of risk, perhaps greater than 20%, for quantal data [18].

Often, continuous (nonquantal) data are obtained for noncancer endpoints; for example, clinical chemistry, hematology, and body and organ weights. For such cases, there generally is no sharp demarcation between normal and adverse levels of an effect. Gaylor & Slikker [11] proposed that the distribution of the results in unexposed control animals be used to establish an abnormal range; for example, below the 1st percentile or above the 99th percentile (*see* **Quantiles**). From the distribution of levels in dosed animals – for example, normal or lognormal – it is possible to estimate the proportion in the abnormal range as a function of dose. This procedure can also be used to estimate benchmark doses for low-dose safety assessment.

Extrapolation

As used here, the term, *extrapolation*, refers to a projection made at a point that is beyond the range of the data used to estimate the parameters of the statistical model on which the projection is based. For example, data from a hypothetical **observational study** among persons 20–64 years of age may have been used to derive a **simple linear regression** model that states that the expected maximum heart rate, y, for a person x years of age follows the relationship given by

$$y = 210 - 0.5x.$$

If this model, derived from subjects 20–64 years of age, were applied to teenagers or to very elderly persons, then it may be that the resulting extrapolation does very poorly. While the relationship may be linear within the range of the data used in the estimation of parameters, the same linear model may not fit outside this range.

In spite of the dangers involved in extrapolation, policy decisions on the health risks of certain environmental exposures are sometimes based on evidence found in studies in which the exposures are much higher than those found in even the most highly polluted environments (*see* **Risk Assessment for Environmental Chemicals**). For example, human studies on the existence and strength of the putative relationship between asbestos and lung cancer are invariably based on epidemiological investigations conducted in occupational settings, where the exposure to asbestos among workers (*see* **Occupational Epidemiology**) is orders of magnitude higher than what would be found in the environment. Likewise, in studying the association with cancer of variables such as the intake of micronutrients, food additives, pharmaceutical drugs, etc. evidence is often presented on the findings of relationships in animal experiments (*see* **Tumor Incidence Experiments**). In these experiments, however, it is frequently the case that the animals are tested not only at levels of the particular substance that are much higher than those experienced by humans, but also under conditions that cannot be duplicated in humans. An example of this is the decision made by the Food and Drug Administration in the late 1960s to ban the food additive *cyclomate*, because a Canadian Study conducted at very high levels of cyclomate seemed to indicate an association with bladder cancer.

In **time series** studies, models are constructed showing the relationship of a variable with time and the parameters fit on the basis of available current and past data. The main objective of these studies, however, is to extrapolate from these models into the future.

In conclusion, extrapolation is risky but sometimes necessary, and investigators should be aware that they are extrapolating and should exert extreme caution in the interpretation of their findings.

PAUL S. LEVY

Extreme Values

Extreme-value statistics, or statistics of extremes, is concerned with the occurrence and sizes of rare events, be they larger or smaller than usual. Examples are the ages of the oldest members of a population, highest annual tides [5] or rainfall [7] or wind speeds [8], athletics records [33], and the time to failure of a system with many components. This last example makes a connection with *reliability theory* and **survival analysis**, to which statistics of extremes is connected, though it has a somewhat different emphasis. Primarily under the impetus of problems in environmental science and engineering, statistics of extremes has developed very rapidly in the two decades. Coles [2] gives an excellent introduction to the subject, and the more mathematical book-length treatment [12] is oriented toward applications in finance. A recent overview is provided by the edited volume [14], while [31] and [23] give other accounts.

The discussion below concerns high extremes – maxima – but in applications, minima can be dealt with by reversing the signs of the observations and applying procedures for maxima.

Maxima

The commonest approach to extremes is through sample maxima. A key result in this context is the Extremal Types Theorem [15–17], which addresses the following question: given a sample of independent identically distributed **random variables** $X_1, \ldots, X_k$, what are the possible limiting distributions of $M_k = a_k[\max(X_1, \ldots, X_k) - b_k]$ as $k \to \infty$? The answer the theorem gives is that if a nondegenerate limiting cumulative distribution function (cdf) exists for some sequences of constants a_k and b_k, it must fall into one of the following three classes

$$\begin{aligned}
&\text{I: } F(x) = \exp[-e^{-x}], \quad -\infty < x < \infty,\\
&\text{II: } F(x) = \begin{cases} 0, & x \le 0,\\ \exp(-x^{-\alpha}), & x > 0, \alpha > 0,\end{cases}\\
&\text{III: } F(x) = \begin{cases} \exp[-(-x)^{\alpha}], & x < 0, \alpha > 0,\\ 1, & x \ge 0.\end{cases}
\end{aligned} \tag{1}$$

These distributions are known collectively as the extreme-value distributions, with types I, II, and III known as the Gumbel, Fréchet, and Weibull types (*see* **Parametric Models in Survival Analysis**). The more usual form for the **Weibull distribution** arises as a limit for minima rather than for maxima, and is given by the type III class with x replaced by $-x$. The importance of the Extremal Types Theorem is that it guarantees that if a limit exists for maxima, it must have one of the specified forms. Consequently, much of the older literature [18, 30] on extreme values focuses on fitting these distributions to sample maxima. The modern approach is to combine them into the generalized extreme-value distribution (GEV) with cdf

$$H(y) = \exp\left\{-\left[1 + \xi\left(\frac{y-\eta}{\tau}\right)\right]^{-1/\xi}\right\}, \quad -\infty < \eta, \xi < \infty, \tau > 0, \tag{2}$$

defined for values of y for which $1 + \xi(y - \eta)/\tau > 0$. Apart from a location and scale change parameterized by η and τ, this gives the type II and III classes for $\xi > 0$ and $\xi < 0$, and the type I arises in the limit as $\xi \to 0$. Consequently, the shape parameter ξ plays a key role, with $\xi > 0$ giving distributions with heavy upper tails and $\xi < 0$ giving distributions with a finite upper endpoint, while the Gumbel distribution has cdf

$$H(y) = \exp\left\{-\exp\left[-\left(\frac{y-\eta}{\tau}\right)\right]\right\}, \quad -\infty < y < \infty, \tag{3}$$

and lies between the two.

A typical hydrological application of the GEV is to fit it to a sample of annual maxima of daily river levels and to use the fitted distribution to estimate the $1/p$-year return level, that is, the river level exceeded once on average every $1/p$ years; here $0 < p < 1$. The quantity $1/p$ is known as the return period and is important in engineering design. The usual return level estimate is the $1 - p$ **quantile** of the GEV,

$$y_{1-p} = \eta - \frac{\tau}{\xi}\left\{1 - [-\ln(1-p)]^{-\xi}\right\}, \tag{4}$$

with parameters replaced by estimates. Two concerns in practice are that inference is often required for a return period longer than the amount of data available and that the fitted GEV is very sensitive to the values of the most extreme observations; these difficulties are inherent in the subject.

Many methods [22] have been proposed for fitting extreme-value distributions to an independent identically distributed sample of maxima, $Y_1, \ldots, Y_n$. Most attention has been focused on the Gumbel case, for which a *probability plot* of sample **order statistics** $Y_{(1)} \leq \cdots \leq Y_{(n)}$ is a valuable tool. This plots $Y_{(r)}$ against the quantiles $-\ln\{-\ln[r/(n+1)]\}$, $r = 1, \ldots, n$, and is useful for detecting **outliers** and assessing the fit of the distribution, in addition to providing graphical estimates of η and τ from the intercept and slope of the graph. Other methods of fitting include the use of **moments** (*see* **Method of Moments**) – which can be highly inefficient – and of probability-weighted moments [19], but these approaches are hard to extend to the more complicated models needed when data are **censored**, for example. **Bayesian** modeling is discussed by Coles and Powell [3] and Coles and Tawn [6].

Usually, **maximum likelihood** estimates of the GEV parameters can be obtained numerically and their **standard errors** calculated from the observed **information matrix**, though convergence problems can arise. There are theoretical difficulties when $\xi < -\frac{1}{2}$, in which case the usual properties of maximum likelihood estimates do not apply [34]. **Confidence intervals** for the estimated return level $\hat{y}_{1-p}$ can be obtained from its **profile loglikelihood**, or by applying the **delta method** to get standard errors for $\ln \hat{y}_{1-p}$. Similar techniques can be applied to more complex situations, for example, where η and τ depend on **explanatory variables**.

Point Process Characterization

A serious objection to the approach sketched above is that the use of maxima alone is wasteful of data: most of the information in the sample is ignored. This has led to other approaches, based on the following characterization. Let $X_1, \ldots, X_{nk}$ be a set of nk independent identically distributed random variables, and consider the pattern in the plane with points at (x, y) coordinates $(j/(nk+1), a_k(X_j - b_k))$, $j = 1, \ldots, nk$. Then, provided a_k and b_k are chosen in such a way that a limiting distribution for M_k exists as $k \to \infty$ with n fixed, the pattern of points above a sufficiently large threshold t will converge to a nonhomogeneous **Poisson process** with the properties that: (a) the numbers of points in nonoverlapping regions of the set $(0, 1) \times (t, \infty)$ are independent; and (b) if $u > t$, the probability that there are no points in the rectangular region $(x_1, x_2) \times (u, \infty)$ in the (x, y)-plane can be written as

$$\exp\left[-n(x_2 - x_1)\left(1 + \xi\frac{u-\eta}{\tau}\right)^{-1/\xi}\right]. \quad (5)$$

This characterization can be used to derive a variety of limiting results for maxima. The simplest is given by noting that the rescaled maximum of k observations, M_k, is less than $y > t$ only if there are no points in the set $(0, 1/n) \times (y, \infty)$, in which case (5) immediately gives (2). For a second result, the characterization shows that if N observations, $y_1, \ldots, y_N$, exceed a threshold $u > t$ over a period of n years, their joint probability density function (pdf) is

$$\exp\left[-n\left(1 + \xi\frac{u-\eta}{\tau}\right)^{-1/\xi}\right] \times \prod_{j=1}^{N} \frac{1}{\tau}\left(1 + \xi\frac{y_j - \eta}{\tau}\right)^{-1/\xi-1},$$

which can be used as a **likelihood** for η, τ, and ξ. Maximum likelihood inference can be performed numerically for this point process model and regression models based on it [36].

One practical matter is the choice of level t above which this characterization can be used. Too high a value for t will result in loss of information about the process of extremes, while too low a value will lead to **bias** because the point process model applies only asymptotically for high thresholds and will not fit the data adequately, if t is too low. The value of t is usually chosen empirically, by calculating the quantities of interest for a number of thresholds and choosing the lowest above which the results are relatively stable.

Further uses of this characterization are outlined below.

Resnick [32] discusses related point process representations for extremes.

r-largest Extremes

Clearly, the r largest observations among $X_1, \ldots, X_k$ will contain more information about the extremes than the maximum alone. Let us denote the r

largest observations by $M_k^1 \geq \cdots \geq M_k^r$. Then on setting $u = M_k^r$ in the point process characterization described above, we see that the asymptotic joint pdf of $M_k^1, \ldots, M_k^r$ at $m_k^1, \ldots, m_k^r$ is

$$\exp\left[-\left(1+\xi\frac{m_k^r-\eta}{\tau}\right)^{-1/\xi}\right] \times \prod_{j=1}^{r}\frac{1}{\tau}\left(1+\xi\frac{m_k^j-\eta}{\tau}\right)^{-1/\xi-1},$$

which can be used to form a likelihood for the parameters. In applications, r is chosen in order to trade off the increased precision from large values of r against the bias incurred if r is too large; a typical choice is to take r in the range from 5 to 10 values per year of data. Once again, likelihood inference for more complicated situations can be based on this model; see Smith [35] and Tawn [37].

Threshold Methods

A further approach is based on the idea of modeling exceedances of the data over a high threshold. The characterization sketched above can be used to show that the cdf of the amount by which an observation exceeds a high threshold t, given that it has done so, is

$$\begin{aligned}\text{pr}(X \leq t+y \mid X > t) &= G(y)\\ &= 1-\left(1+\xi\frac{y}{\tau}\right)^{-1/\xi}, \quad y>0; \end{aligned} \tag{6}$$

this is called the generalized **Pareto distribution** (*see* **Parametric Models in Survival Analysis**). As $\xi \to 0$, $G(y)$ becomes the **exponential distribution** with mean τ, which here occupies the same central role as the Gumbel distribution for maxima. Notice that the conditioning in (6) removes dependence on the location parameter η. Equation (6) can be used as the basis for a likelihood for τ and ξ, and its properties also lead to procedures for choosing the threshold t, for example, by taking the lowest threshold above which the *mean residual life plot* of the exceedances is straight (*see* **Life Expectancy**).

Davison and Smith [9] give an extensive discussion of this model.

Dependence

In practice, extreme values generally arise from series of dependent observations, rather than from independent data, and this would seem to limit the usefulness of the results described above. Problems might potentially be raised either by long-range or short-range dependence of the series.

An extensive mathematical theory summarized in Leadbetter et al. [25] and Leadbetter and Rootzén [26] shows that provided there is no long-range dependence between extremes, the same limiting results apply for maxima of dependent series as for independent series. Independence of widely separated extremes seems reasonable in most applications, but they almost always display short-range dependence, in which clusters of extremes occur together.

Suppose that a stationary series $X_1, \ldots, X_k$ with no long-range dependence of extremes has short-range dependence, which leads to extremes occurring in clusters with mean size $1/\theta$, where $0 \leq \theta \leq 1$; θ is called the extremal index of the process. The notion of a cluster here is deliberately vague. Let $X_1^*, \ldots, X_k^*$ be a sequence of independent variables with the same marginal distribution as the X_j. Then a key result [24] is that the rescaled maximum $M_k = a_k[\max(X_1, \ldots, X_k) - b_k]$ has a nondegenerate limiting distribution $H(y)$ if and only if $M_k^* = a_k[\max(X_1^*, \ldots, X_k^*) - b_k]$ has a nondegenerate limiting distribution $H^*(y)$, and $H(y) = [H^*(y)]^\theta$. The importance of this is to show that the type of limit distribution is unaffected by short-term dependence, as although the values of η and τ for $H(y)$ and $[H^*(y)]^\theta$ will differ, they have the same value of ξ. The usual solution to **clustering** therefore is to identify clusters, fit the point process model to their maxima, and then to adjust the estimated values of η and τ to allow for the clustering through an estimated extremal index. Ferro and Segers [13] give a recent discussion of estimation of θ.

Multivariate Extremes

Multivariate extremes arise when there is interest in rare values of two or more different series. Suppose, for example, that there is a series of bivariate observations (X_{1j}, X_{2j}), $j = 1, \ldots, k$, and that interest is focused on the componentwise maxima $M_{1k} = \max(X_{11}, \ldots, X_{1k})$ and $M_{2k} = \max(X_{21}, \ldots, X_{2k})$. The analogue of the Extremal Types Theorem is then

to seek sequences of constants a_{1k}, b_{1k}, a_{2k} and b_{2k} such that

$$\text{pr}\,[a_{1k}(M_{1k} - b_{1k}) \leq x_1, a_{2k}(M_{2k} - b_{2k}) \leq x_2] \quad (7)$$

converges to a nondegenerate limiting distribution. If they exist, the marginal limiting distributions for the rescaled versions of M_{1k} and M_{2k} must be of form (2). The joint distribution can then be of a wide range of possible forms, subject to mild conditions. Suppose that the probability integral transform is used to transform each of the rescaled maxima into a minimum, with a unit exponential distribution. Then the possible joint limiting distributions of maxima correspond to a class of bivariate exponential distributions for minima Z_1 and Z_2, whose joint survivor function $S(z_1, z_2) = \text{pr}(Z_1 > z_1, Z_2 > z_2)$ can be written as

$$S(z_1, z_2) = \exp\left[-(z_1 + z_2)A\left(\frac{z_2}{z_1 + z_2}\right)\right], \quad (8)$$

where the dependence function $A(w)$ is a convex function on $w \in [0, 1]$, with its graph lying entirely in the triangle with vertices $(0, 1)$, $(1, 1)$ and $\left(\frac{1}{2}, \frac{1}{2}\right)$. An example of such a function is $A(w) = [w^{1/\alpha} + (1 - w)^{1/\alpha}]^{\alpha}$, with parameter α such that $0 \leq \alpha \leq 1$ [20], though numerous other functions have been proposed [23, Chapter 3]. The usual approach to estimation of such a model based on a sample of pairs (Y_{1j}, Y_{2j}), $j = 1, \ldots, n$, is to maximize the likelihood for the parameters of the dependence function and both marginal distributions.

Ledford and Tawn [27–29] have investigated the behavior of joint extremes when the underlying variables are close to asymptotic independence.

For problems with several maxima, a somewhat different approach is better [11], though the basic ideas are similar; the extension to extremal processes of maxima [1, 7, 10] is more complicated. There is a related approach based on threshold analyses of the marginal series [4, 21].

F Distributions

This is a statistical distribution with considerable practical importance. Suppose that X_1^2 and X_2^2 have independent **chi-square distributions** with m and n degrees of freedom, respectively. The ratio of these two χ^2 distributed variables, each divided by its degrees of freedom, has an F distribution. The F distribution is sometimes called the variance ratio distribution, or Snedecor's F distribution, and is related to Fisher's z distribution. A formal theorem which defines the F distribution is as follows.

Theorem. Let χ_1^2 have a distribution with m degrees of freedom; and let χ_2^2 have an independent χ^2 distribution with n degrees of freedom. Then the random variable

$$F = \frac{(\chi_1^2/m)}{(\chi_2^2/n)}$$

has an F distribution with m and n degrees of freedom. Such an F distribution is described by the density function

$$f(x) = \frac{m^{m/2}n^{n/2}}{B(m/2, n/2)} \frac{x^{m/2-1}}{(n+mx)^{(m+n)/2}}, \quad x \geq 0.$$

The expression $B(m/2, n/2)$ represents a beta function evaluated at $m/2$ and $n/2$. The density function for a typical F distribution with degrees of freedom $m = 5$ and $n = 40$ is displayed in Figure 1.

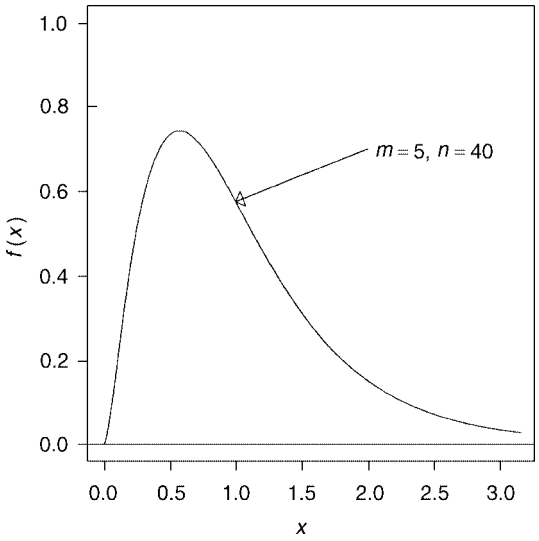

Figure 1 A typical F distribution: degrees of freedom $m = 5$ and $n = 40$

Properties

Like most density functions, the density $f(x)$ defines the **moments** of the F distribution. The expectation is

$$\mathrm{E}(F) = \frac{n}{n-2}, \quad n > 2,$$

with associated variance

$$\mathrm{var}(F) = \frac{2n^2(m+n-2)}{m(n-1)^2(n-4)}, \quad n > 4.$$

For an F distribution with $m = 5$ and $n = 40$ degrees of freedom, the expectation is $\mathrm{E}(F) = 1.053$ with $\mathrm{var}(F) = 0.529$. Values of the parameters m and n define a family of F distributions. Examples are illustrated in Figure 2 ($m = \{3, 5, \text{ and } 10\}$ and $n = 40$) and Figure 3 ($m = 10$ and $n = \{5, 10, \text{ and } 20\}$). The shape of the F distribution is called quasi-symmetric, since

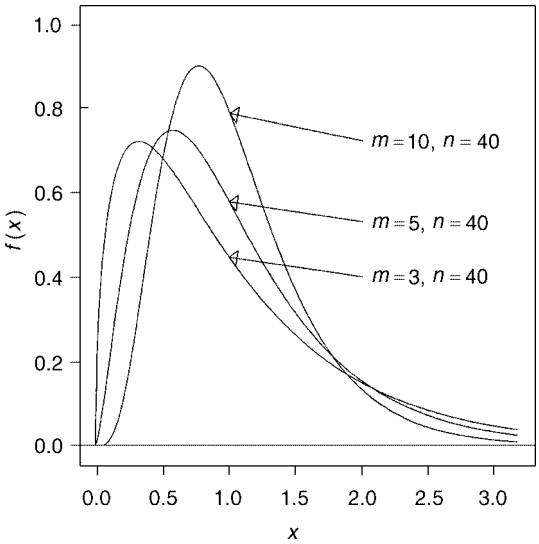

Figure 2 A family of three F distributions where $m = 3, 5$, and 10 for $n = 40$

$$F_\alpha[m, n] = \frac{1}{F_{1-\alpha}[n, m]},$$

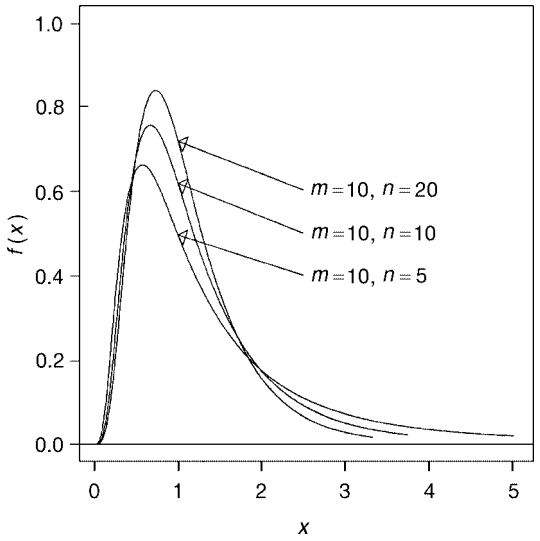

Figure 3 A family of three F distributions for $m = 10$, where $n = 5$, 10, and 20

where $F_\alpha[m, n]$ is the α-level **quantile** of the F distribution (i.e. $\Pr(F \leq F_\alpha[m, n]) = \alpha$). In more concrete terms, $\Pr(F \leq 0.75) = 0.409$ when $m = 5$ and $n = 40$ and $\Pr(F \leq 1/0.75) = \Pr(F \leq 1.333) = 0.591 = 1 - 0.409$ when $m = 40$ and $n = 5$. This quasi-symmetry property is displayed in Figure 4.

The probabilities associated with an F value (a random value with an F distribution) can be found in tables (e.g. [3]) for a variety of degrees of freedom, particularly when the m and n are small. For F values not in tables, a number of approximations exist [1]. A remarkably accurate ($n > 10$ or so) but relatively simple approximation based on the Wilson–Hilferty approximation [2] to the χ^2 distribution produces a value z from the standard normal distribution given by

$$z = \frac{\left[\left(1 - \frac{2}{9n}\right)x^{1/3} - \left(1 - \frac{2}{9m}\right)\right]}{\left(\frac{2}{9n}x^{2/3} + \frac{2}{9m}\right)^{1/2}}$$

where $\Pr(F \leq x) \approx \Pr(Z \leq z)$. For example, $\Pr(F \leq 0.75) \approx \Pr(Z \leq -0.235)$, where $z = -0.235$ is calculated from the Wilson–Hilferty expression when $m = 5$ and $n = 40$. Specifically, $\Pr(Z \leq -0.235) = 0.407$ from a standard normal distribution [3]. The exact value is 0.409, as before.

Relationships to Other Statistical Distributions

Several important statistical distributions are related to the F distribution. The random variable mF has a

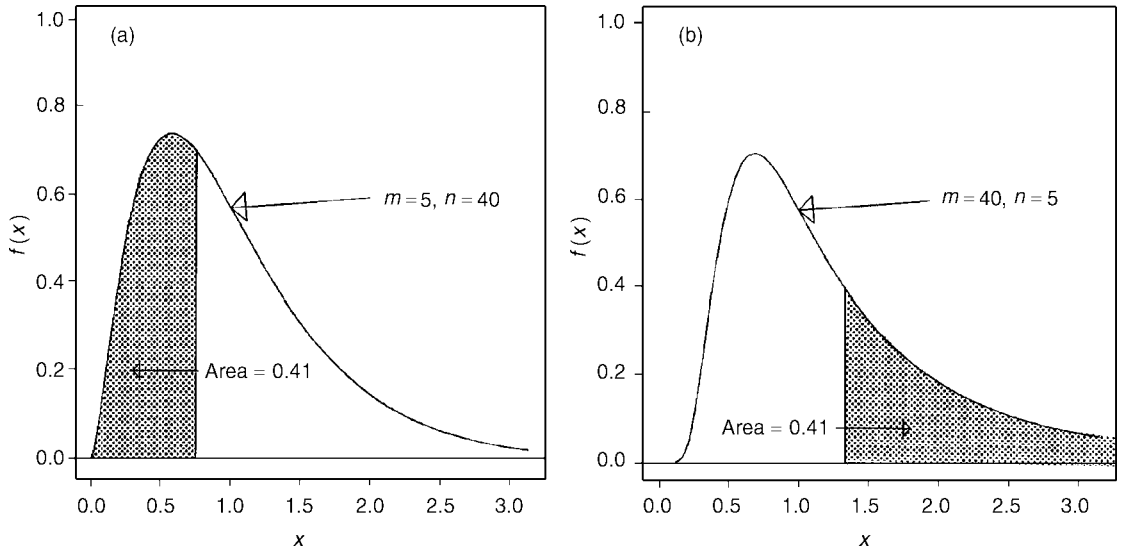

Figure 4 An example of the quasi-symmetry property of the F distribution (degrees of freedom $m = 5$ and $n = 40$). (a) df = 5, 40; (b) df = 40, 5

χ^2 distribution with m degrees of freedom when the variable F has an F distribution with m and infinite (∞) degrees of freedom. Similarly, the random variable $\sqrt{F}$ has a **Student's *t* distribution** with n degrees of freedom when F has an F distribution with 1 and n degrees of freedom. If k is an integer ($0 \leq k \leq N$), then

$$\Pr\left[F \geq \frac{(1-p)n}{pm}\right] = \Pr(B \geq k)$$

and B has a **binomial distribution** with parameters N and p when F has an F distribution with $m = 2(N-k+1)$ and $n = 2k$ degrees of freedom. The F distribution can be viewed as a special case of the β distribution. When the value F has an F distribution with m and n degrees of freedom, then the random variable $Y = mF/(n+mF)$ has a **beta distribution** with shape parameters $m/2$ and $n/2$. Also, Fisher's z distribution is simply another version of the F distribution, where $Z = (1/2)\log(F)$.

Applications of the *F* distribution

The most fundamental application of the F distribution comes from exploring differences between two estimated variances. If observations represented by y_{ij} are sampled independently from two normally distributed populations, the estimated variances are

$$S_1^2 = \frac{\sum_{j=1}^{n_1}(y_{1j}-\overline{y}_1)^2}{n_1-1} \quad \text{and} \quad S_2^2 = \frac{\sum_{j=1}^{n_2}(y_{2j}-\overline{y}_2)^2}{n_2-1},$$

where n_i represents the number of observations sampled from each population ($i = 1, 2$). The ratio $F = S_1^2/S_2^2$ has an F distribution with $n_1 - 1$ and $n_2 - 1$ degrees of freedom when both sampled populations have the same variance. Large or small values of the test statistic F are unlikely when the two population variances are equal. The F distribution, therefore, makes it possible to assign formal significance probabilities to the likelihood associated with differences observed between two estimated variances using an F ratio (*see* **Hypothesis Testing**).

The primary importance of the F distribution derives from its application to a large number of statistical tests involving the comparison of nested analytic models. A general approach to testing hypotheses involves collecting a random sample of n observations (represented by y_i) and contrasting the "fit" of the sampled data to two models developed under differing conditions. The first set of conditions (H_1) is evaluated by

$$SS_1 = \sum_{i=1}^{n}(y_i - [\text{mean estimated under specified conditions}])^2,$$

with associated degrees of freedom df_1. The degrees of freedom equal the number of sampled observations minus the number of independent estimates necessary to establish the components of the analytic model. The quantity SS_1 measures the goodness of fit of the data under the conditions specified by H_1 and is referred to as a residual sum of squares. A more restricted model (nested) is then postulated (H_0, called the null hypothesis) and a second residual sum of squares calculated, where

$$SS_0 = \sum_{i=1}^{n}(y_i - [\text{mean estimated under more restricted conditions}])^2,$$

with associated degrees of freedom df_0. One model is nested within the other when the second model is a special case of the first (*see* **Hierarchical Models**). Frequently, a nested model is created by deleting terms (H_0) from a more extensive model (H_1). The property that H_0 is a restricted case of H_1 guarantees that SS_0 will be equal to or larger than SS_1 and df_0 will be larger that df_1. The difference $SS_0 - SS_1$ reflects the impact of the additional restrictions which created the second model. Furthermore, if the y_i values are sampled from normal distributions with the same variances, then the random variable

$$F = \frac{(SS_0 - SS_1)/(df_0 - df_1)}{SS_1/df_1}$$

has an F distribution with $df_0 - df_1$ and df_1 degrees of freedom when the restrictions have only random effects on the sampled values y_i. Again, this makes it possible to use the F distribution to assign formal probabilities to observed test statistics. The comparison of residual sums of squares produces a systematic approach to statistical testing called the **analysis of variance**.

A test of two simple hypotheses concerning the mean value illustrates the contrasting of two nested models using an F test. The question addressed

is whether the sampled data are consistent with a population mean value of $\mu = 2[H_0]$ or whether there is evidence that the population mean value is not $\mu = 2[H_1]$. A small data set consisting of $n = 20$ observations independently sampled from a normal distribution is

$$y = \{0.4,\ 1.4,\ 2.0,\ 0.4,\ 1.4,\ 0.9,\ 2.5,\ 2.6,\ 0.5,\ 1.6,\ 0.7,\ 1.0,\ 2.4,\ 2.9,\ 2.1,\ 0.9,\ 0.4,\ 1.2,\ 2.7,\ \text{and}\ 2.3\}.$$

The residual sum of squares assessing the conjecture that the population mean is not equal to $2[H_1 : \mu \neq 2]$ is

$$SS_1 = \sum_{i=1}^{20} (y_i - \overline{y})^2 = 14.026,$$

where

$$\overline{y} = \frac{1}{n} \sum_{i=1}^{n} y_i = 1.515.$$

For the more restricted conditions where the population mean is postulated to be $\mu = 2[H_0 : \mu = 2]$, the second residual sum of squares is

$$SS_0 = \sum_{i=1}^{20} (y_i - 2)^2 = 18.730.$$

An F statistic ($df_1 = n - 1 = 19$ and $df_0 = n - 0 = 20$) allows a significance probability to be calculated reflecting on the likelihood that the difference $SS_0 - SS_1 = 4.705$ arose by chance when the mean of the sampled population is in fact $\mu = 2(H_0$ is true). The F statistic is $F = 4.705/0.738 = 6.373$ and the corresponding significance probability is 0.021. Using an F test (analysis of variance) approach, the data indicate that it is not likely that the 20 observations are a random sample from a population with a mean value of $\mu = 2$. This same comparison can be made with Student's t test ($\overline{y} = 1.515$ vs. $\mu = 2$). However, the pattern of comparing nested models with an F ratio is the basis of a large variety of statistical testing procedures.

Factor Analysis, Confirmatory

The purpose of a **factor analysis** is to study the intercorrelations among p observed variables by postulating a set of common **factors**. Ideally, the number of common factors, say m, is less than the number of the observed variables, p. In a common-factor analysis model, each observed variable is written as a weighted sum of m common-factor scores and one unique-factor score. The collection of these equations for all p variables is called a *factor pattern*. It is given as follows:

$$\begin{aligned} X_1 &= a_1 A + b_1 B + \cdots + m_1 M + u_1 U_1, \\ X_2 &= a_2 A + b_2 B + \cdots + m_2 M + u_2 U_2, \\ &\vdots \qquad\qquad \vdots \\ X_p &= a_p A + b_p B + \cdots + m_p M + u_p U_p, \end{aligned}$$

where $X_1, X_2, \ldots, X_p$ represent the standardized measurement of the p observed variables, $A, B, \ldots, M$ represent the standardized scores in the uncorrelated common factors, $a_i, b_i, \ldots, m_i, i = 1, \ldots, p$, are the *common factor loadings*, $U_1, U_2, \ldots, U_p$ represent the standardized scores on the p unique factors, and $u_1, u_2, \ldots, u_p$ are the *unique factor loadings*. In the above model the m latent factors and the p unique factors are uncorrelated.

Through this linear model, we attempt to find a small number of underlying factors, which contain all the essential information about the **correlations** among the observed variables. In general, there are two steps to perform this analysis: (i) initial factoring of the data determining the number of salient factors to be retained (*see* **Battery Reduction**); and (ii) **rotating** the factors to obtain unique and interpretable results. There are various procedures available to carry out each of the three steps. Discussion on those procedures can be found in the articles on **Factor Analysis**, **Principal Components Analysis**, **Rotation of Axes**, and articles on different rotation methods. In the above we use factor analysis to explore the underlying construct of the data and to find and interpret the factors through the estimated factor matrices.

Sometimes, an investigator may have a hypothesized factor pattern or she may have obtained a factor matrix from a previous study which contains

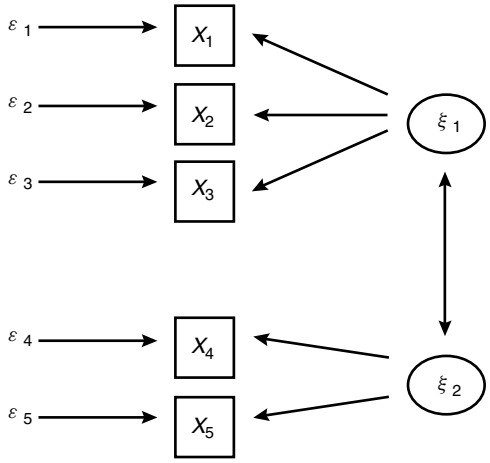

Figure 1 Path diagram for confirmatory factor analysis

the relationships between the variables and the factors. Instead of exploring the underlying construct of new data, the investigator might wish to estimate and test the fit of the data to the hypothesized factor model or to the model obtained from the previous study. In other words, she wants to perform an analysis to find out how the estimated factor matrix from the data matches with the hypothesized factor matrix. We call this analysis a *confirmatory factor analysis*. Figure 1 shows an example of a path diagram for a confirmatory factor analysis. It shows the paths that link the observed variables X_i with the factors ξ_j and the error terms ε_i involved in the system. In the Figure, the observed variables are enclosed in boxes, the factors are enclosed in circles, and ε_i represent the error terms. The single-headed arrow indicates the influence of the factors and error terms on the observed variables. The double-headed arrow indicates that the factors are correlated. The mathematical model for this confirmatory factor analysis is

$$\begin{aligned} X_1 &= a_1 \xi_1 + \varepsilon_1, \\ X_2 &= a_2 \xi_1 + \varepsilon_2, \\ X_3 &= a_3 \xi_1 + \varepsilon_3, \\ X_4 &= b_1 \xi_2 + \varepsilon_4, \\ X_5 &= b_2 \xi_2 + \varepsilon_5. \end{aligned} \tag{1}$$

Krzanowski [3] presented the **Procrustes** analysis, which is appropriate to use in a confirmatory factor analysis. The procedure involves standardization of

matrices in terms of their relative positions, orientations, and scales and also computation of the test statistic based on the standardized matrices. Lawley & Maxwell [4] have outlined some **least squares** methods for rotating to factor structures that come as close as possible to an a priori pattern of ones and zeros. Jöreskog & Sörbom [2] developed the **LISREL** package which consists of computer programs for such confirmatory factor analysis. There is also a computer package in SAS (*see* **Software, Biostatistical**) that can perform a confirmatory analysis [5]. The procedure is known as PROC CALIS. Hatcher [1] presented a detailed step-by-step approach on how to perform the confirmatory factor analysis using PROC CALIS and how to interpret the output obtained from the program.

Factor Analysis, Overview

Suppose that we have measurements on a moderate or large number of variables. The central idea of factor analysis is that a smaller number of unobservable "factors" underlie the measured variables. More specifically, each measured variable can be written as a linear function of the factors, apart from a residual, or specific, factor.

Spearman [19] is generally acknowledged to be the "inventor" of factor analysis. However, as Bartholomew [2] points out, Spearman's original paper has little in common with the later developments which led to factor analysis as it is currently known. Spearman's "two-factor theory" assumed that scores of individuals on a number of tests could be decomposed into a "general" factor, common to all variables, measuring general intelligence, and a "specific" factor which was different for each variable. Bartholomew [2] describes Spearman's contribution more fully.

In current factor analysis terminology, Spearman's theory involves only a single (common) factor, whereas most factor analyses involve multiple factors. A key early reference to the idea of multiple factors is Thurstone [20]. The "factors" which were sought and modeled in much of the development of factor analysis were psychological factors. For example, Yule et al. [22] measured the scores, between 0 and 20, for 150 children aged $4\frac{1}{2}$–6 years, on ten subtests of the Wechsler Pre-School and Primary Scale of Intelligence. Five of the tests were "verbal" tests and five were "performance" tests so the expectation might be that the ten scores could be largely explained by two underlying factors, measuring "verbal" and "performance" abilities, respectively. This is, to some extent, true but as we shall see later when we look in detail at this example, this is not the whole story. Although factor analysis was developed largely as a tool for psychometricians (*see* **Psychometrics, Overview**), it has increasingly found use elsewhere in biostatistics. It has the potential to model and explain successfully a data set whenever the measured (continuous) variables can be linearly related to a smaller number of unobservable factors.

The Factor Model

Suppose that $\mathbf{x}$ is a vector of p variables (measurements, test scores) $x_1, x_2, \ldots, x_p$. The most usual model for factor analysis is, in matrix form,

$$\mathbf{x} = \boldsymbol{\mu} + \boldsymbol{\Lambda}\mathbf{f} + \mathbf{e}, \tag{1}$$

where a typical equation in the system given by (1) is

$$x_i = \mu_i + \lambda_{i1} f_1 + \lambda_{i2} f_2 + \cdots + \lambda_{im} f_m + e_i, \quad i = 1, 2, \ldots, p. \tag{2}$$

In (1), $\boldsymbol{\mu} = \mathrm{E}(\mathbf{x})$; in (2) $f_1, f_2, \ldots, f_m$ are unobservable common factors comprising the vector $\mathbf{f}$, and e_i is a residual or specific factor for variable x_i, $i = 1, 2, \ldots, p$. (1) and (2) imply that the measured variables can be expressed as linear combinations of the common factors, apart from a factor specific to each variable.

Certain assumptions are usually associated with the factor model, namely

$$\mathrm{E}[\mathbf{f}] = \mathrm{E}[\mathbf{e}] = \mathbf{0},$$

$$\mathrm{E}[\mathbf{f}\mathbf{e}'] = \mathbf{0} \text{ (matrix of zeros)},$$

$$\mathrm{E}[\mathbf{e}\mathbf{e}'] = \boldsymbol{\Psi} \text{ (diagonal)},$$

$$\mathrm{E}[\mathbf{f}\mathbf{f}'] = \mathbf{I}_m \text{ (identity matrix)}.$$

The assumptions concerning the expectations of $\mathbf{f}$ and $\mathbf{e}$ are conventional, convenient, and lose no generality. The first two covariance assumptions are simply stating that the elements of $\mathbf{e}$ are specific to each x_i (hence uncorrelated), and that these specific factors are uncorrelated with any common factors. The final assumption is not always made. It states that the common factors are uncorrelated and is a common and convenient assumption. However, some factor analysts argue that in reality common factors are often correlated (oblique) and so relax the assumption. For the moment we impose all the assumptions above. An additional assumption is sometimes made, namely that the x_is are standardized, so $\mathrm{E}[\mathbf{x}\mathbf{x}'] = \mathbf{I}_p$. We shall not use this assumption at present.

The factor model is one type of latent variable model in which a set of measured variables is "explained" by postulating the existence of unobserved "latent" variables. Factor analysis is a simple case in which both the measurements **(x)** and the latent variables **(f)** are continuous and relationships are linear. Bartholomew and Knott [3] describe models in which either $\mathbf{x}$ or $\mathbf{f}$ define categories. Some recently developed techniques such as **structural equations models** [4] and the **neural network** [5] also involve latent variables.

Estimation of the Factor Model

In the factor model there are a number of parameters which need to be estimated. The vector $\boldsymbol{\mu}$ is usually estimated by the vector $\bar{\mathbf{x}}$ of sample means for $x_1, x_2, \ldots, x_p$, but estimation of the elements of the matrices $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$ is more complex. The matrix $\boldsymbol{\Lambda}$ comprises so-called *loadings* (*see* **Factor Loading Matrix**), which describe how the variables are related to the common factors, while $\boldsymbol{\Psi}$ tells us how much of the variation in each x_i cannot be explained by the common factors. To understand some of the subtleties in estimating $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$, we find the **covariance matrix** of each side of (1) which, using our assumptions, gives

$$\boldsymbol{\Sigma} = \boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}, \tag{3}$$

where $\boldsymbol{\Sigma}$ is the covariance matrix of the vector of variables $\mathbf{x}$.

In practice $\boldsymbol{\Sigma}$ is unknown, but a sample covariance matrix, $\mathbf{S}$, is available, and fitting a factor model can be viewed as finding $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$ which satisfy

$$\mathbf{S} = \boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}$$

as closely as possible. If the x_is are standardized, then $\mathbf{S}$ is replaced with the sample correlation matrix $\mathbf{R}$.

There is indeterminacy in finding $\boldsymbol{\Lambda}$, for suppose that $\mathbf{T}$ is an orthogonal matrix and that $\boldsymbol{\Lambda}^* = \boldsymbol{\Lambda}\mathbf{T}$. Then

$$\begin{aligned}\boldsymbol{\Lambda}^*\boldsymbol{\Lambda}^{*'} &= (\boldsymbol{\Lambda}\mathbf{T})(\boldsymbol{\Lambda}\mathbf{T})' = \boldsymbol{\Lambda}(\mathbf{T}\mathbf{T}')\boldsymbol{\Lambda}' \\ &= \boldsymbol{\Lambda}\boldsymbol{\Lambda}',\end{aligned}$$

so $\boldsymbol{\Lambda}^*$ is as acceptable as $\boldsymbol{\Lambda}$ in fitting the model. This multiplication of $\boldsymbol{\Lambda}$ by an orthogonal matrix is known as *rotation* and, having found an initial solution, it is used to "simplify" the elements of $\boldsymbol{\Lambda}^*$ as much as possible. Simplification can be even greater if $\boldsymbol{\Lambda}$ is multiplied by a nonorthogonal matrix, leading to oblique, rather than orthogonal factors. In this article we concentrate on how to find an initial solution. Details of rotation in factor analysis are given elsewhere (*see*, in particular, **Orthogonal Rotation**; **Oblique Rotation**; **Oblimin Rotation**).

We describe three commonly used methods for finding initial estimates. A number of other methods have been proposed over the years, though few are widely used.

Maximum Likelihood Estimation

Maximum likelihood is perhaps the most "respectable" method of **estimation**, statistically speaking, but it makes the strong assumption that $\mathbf{f}$ and $\mathbf{e}$, and hence $\mathbf{x}$, have a **multivariate normal distribution**. We can then write down the **likelihood** function for $\boldsymbol{\Lambda}$, $\boldsymbol{\Psi}$ and $\boldsymbol{\mu}$ as

$$\begin{aligned}L(\boldsymbol{\Lambda}, \boldsymbol{\Psi}, \boldsymbol{\mu}; \mathbf{x}) &= (2\pi)^{-p/2}|\boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}|^{-1/2} \\ &\quad \times \exp\left[-\tfrac{1}{2}(\mathbf{x} - \boldsymbol{\mu})'(\boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi})^{-1}(\mathbf{x} - \boldsymbol{\mu})\right].\end{aligned}$$

Maximizing this with respect to $\boldsymbol{\mu}$, $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$ gives $\hat{\boldsymbol{\mu}} = \bar{\mathbf{x}}$, and the following equations for $\hat{\boldsymbol{\Lambda}}$ and $\hat{\boldsymbol{\Psi}}$ (for details of the derivation, see [3]):

$$\begin{aligned}&\hat{\boldsymbol{\Psi}}^{-1/2}\mathbf{S}\hat{\boldsymbol{\Psi}}^{-1/2}(\hat{\boldsymbol{\Psi}}^{-1/2}\hat{\boldsymbol{\Lambda}}) \\ &\quad = (\hat{\boldsymbol{\Psi}}^{-1/2}\hat{\boldsymbol{\Lambda}})(\mathbf{I} + \hat{\boldsymbol{\Lambda}}'\hat{\boldsymbol{\Psi}}^{-1}\hat{\boldsymbol{\Lambda}}),\end{aligned} \tag{4}$$

$$\hat{\boldsymbol{\Psi}} = \operatorname{diag}(\hat{\boldsymbol{\Lambda}}\hat{\boldsymbol{\Lambda}}' - \mathbf{S}). \tag{5}$$

Eqs. (4) and (5) must be solved iteratively. For fixed $\hat{\boldsymbol{\Lambda}}$ an estimate $\hat{\boldsymbol{\Psi}}$ is found from (5) and substituted into (4). The eigenequation (4) is then solved for $\hat{\boldsymbol{\Psi}}^{-1/2}\hat{\boldsymbol{\Lambda}}$, and hence for $\hat{\boldsymbol{\Lambda}}$. The new estimate $\hat{\boldsymbol{\Lambda}}$ is substituted into (5), and so on until convergence.

Example

Table 1 lists the variables for the example from Yule et al. [22] introduced earlier, together with estimates of the loadings λ_{ij} obtained from maximum likelihood estimation, assuming that the number of common factors, m, is 2. Also given are maximum likelihood estimates of the specific variances, ψ_i, subtracted from 1. ψ_i is the amount of $\operatorname{var}(x_i)$ unaccounted for by the common factors, so $\operatorname{var}(x_i) - \psi_i$, known as the **communality** for variable i, is the variance in variable i explained by the common factors. Recall that often, as in Table 1, factor analysis is done using variables standardized to have variance 1, so that the communality is $1 - \psi_i$. In this case, the covariance matrices $\boldsymbol{\Sigma}$ and $\mathbf{S}$ become correlation matrices.

The results given in Table 1 were produced for the correlation matrix using Minitab, which has a fairly limited range of options for factor analysis (*see* **Software, Biostatistical**). Most standard statistical packages will have some factor analysis procedures, and in some cases an extensive selection of estimation and rotation techniques is available. It can be

Table 1 Maximum likelihood factor analysis for data from [22]: two-factor solution

Block design (x_{10})	0.777	−0.368	0.300	0.805	0.739

seen from Table 1 that the first unrotated factor has nontrivial loadings for all 10 variables, so that it could be interpreted as a general factor, measuring overall ability in the tests. The second unrotated factor contributes mainly to the first, second and fifth variables in a positive sense, and negatively to the eighth and tenth variables.

The communalities show that over 45% of the variability in the first, second, third, fifth, seventh, eighth, and tenth variables is accounted for by the two common factors, but that variables 4, 6, and 9 are rather poorly explained by these two factors.

Also given in Table 1 are the factor loadings after rotation. Different methods of rotation will not be discussed here. (*See* the section on Rotation in **Principal Components Analysis**.) For illustration Table 1 shows the results for the normal **varimax rotation**, which is often the default method in computer software. Different **orthogonal rotation** methods will often give similar results. The effect of rotation is to replace the general factor and the contrast between variables, which we had before rotation, by two factors involving subsets of the variables. The first factor contributes much more strongly to the first five variables than to the last five, reflecting the grouping of the 10 variables into two sets of five, which was noted earlier. The second factor is less clear; it has large loadings for variables 7, 8, and 10 and moderate loadings for variables 3, 6, and 9. The aim of rotation is to simplify the loadings and to produce a **simple structure**. This has been less successful in this example than in many, with substantial contributions from more than one factor to the same variable (x_3). Communalities are unchanged by orthogonal rotation.

The maximum likelihood approach to estimation seems rather restrictive because it assumes that all the variables in the factor model have multivariate normal distributions. In fact, the same solution can be obtained without making this distributional assumption. If the factor model in (1) is valid, together with its usual assumptions concerning means and variances, then the partial correlations between the elements of $\mathbf{x}$, given the values of $\mathbf{f}$, will all be zero. In attempting to fit the model we might therefore try to make all such partial correlations small. We can construct a $p \times p$ matrix of these partial correlations, the determinant of which will be maximized when all off-diagonal elements are zero. If this determinant is expressed in terms of the unknown parameters λ_{ij} and ψ_i, and then maximized, the resulting estimates of λ_{ij} and ψ_i are identical to the maximum likelihood estimates; for more details see [17, Section 8.8]. It can be argued that the use of linear models and correlations goes some way to an implicit assumption of multivariate normality, but the alternative derivation does away with the explicit assumption, and means that the maximum likelihood estimates are relevant in a rather broader range of problems.

Estimation Using Principal Components

This is the most common method of estimating initial factor loadings – it is often the default in computer software. Taking a pragmatic point of view, it is relatively simple to implement and often works well, giving similar results to other estimation techniques. However, its use has been responsible for a great deal of confusion between factor analysis on the one hand and **principal components analysis** on the other [11,

13]. It has led to the common misconception that principal components analysis is simply a special case of factor analysis, whereas they are really quite distinct techniques. We give here a brief introduction to principal components analysis, returning to a more detailed comparison with factor analysis later in the article.

Principal components analysis, like factor analysis, is a dimension-reducing technique, but it does not postulate any underlying unmeasurable factors. It simply finds linear functions of the measured variables $y_1 = \boldsymbol{\alpha}_1'\mathbf{x}$, $y_2 = \boldsymbol{\alpha}_2'\mathbf{x}, \ldots, y_p = \boldsymbol{\alpha}_p'\mathbf{x}$, which successively have maximum variance, subject to each y_i being uncorrelated with earlier y_js. The matrix $\mathbf{A}$, the columns of which are $\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \ldots, \boldsymbol{\alpha}_p$, contains elements which are used to express the derived variables $\mathbf{y}$ in terms of the measured variables $\mathbf{x}$. The properties of principal components analysis mean that $\mathbf{A}$ is orthogonal, and we can also use its elements to express the measured variables $\mathbf{x}$ in terms of the derived variables $\mathbf{y}$. This is beginning to look rather like factor analysis, so the first m columns of $\mathbf{A}$ are often used as an initial estimate of $\boldsymbol{\Lambda}$ in an m-factor model. Table 2 gives the same information as Table 1, except that principal components loadings are presented instead of maximum likelihood loadings. It can be seen that, although there are differences in detail, the general patterns of loadings are very similar in Tables 1 and 2. The communalities are larger in Table 2 than in Table 1 for nine of the 10 variables. This is not unexpected because the definition of principal components analysis implies that it will maximize the sum over the variables of the communalities for any value of m.

After rotation, the general pattern of the loadings in Table 2 is again very similar to that in Table 1. It is quite often the case that the choice of an initial factor solution (and the choice of rotation method, provided we stick to orthogonal rotation) has little effect on the solution. The choice of the number of factors, which is discussed below, is often much more important in determining what the factors "look like".

Principal Factor Solutions (Common Factor Analysis)

Historically, various types of principal factor solution have been widely used; we describe them briefly here. Principal factor solutions recognize that principal components analysis is not really designed to fit the factor model in (1), and attempt to modify it in an *ad hoc*, but appropriate, way. Principal components analysis is based on an eigenanalysis of the covariance matrix $\mathbf{S}$ (*see* **Eigenvalue**; **Eigenvector**), and because principal components maximize variances they concentrate on "fitting" the diagonal elements of $\mathbf{S}$. Factor analysis, on the other hand, is mainly concerned with fitting the off-diagonal elements of $\mathbf{S}$ using common factors. As noted earlier, the variables $\mathbf{x}$ are often standardized, so that $\mathbf{S}$ is a correlation matrix. In this case, common factor analysis concentrates on explaining the correlations between variables using common factors, whilst allowing some of the (unit) variance of each variable to be unique to that variable. What principal factor analysis does is to replace principal components analysis's eigenanalysis of $\mathbf{S}$ by a similar analysis of $\mathbf{S} - \hat{\boldsymbol{\Psi}}$, where $\hat{\boldsymbol{\Psi}}$ is a diagonal matrix containing estimates of ψ_i. The diagonal elements of $\mathbf{S} - \hat{\boldsymbol{\Psi}}$, $s_{ii} - \hat{\psi}_i$, are estimates of the

Table 2 Two-factor solution based on principal components for data from [22]

	Unrotated loadings		Rotated loadings		
Variable	Factor 1	Factor 2	Factor 1	Factor 2	Communality
x_1	0.732	0.413	0.816	0.201	0.706
x_2	0.746	0.393	0.813	0.225	0.711
x_3	0.762	0.109	0.630	0.443	0.593
x_4	0.647	0.253	0.645	0.259	0.483
x_5	0.739	0.343	0.773	0.256	0.663
x_6	0.587	−0.260	0.250	0.591	0.412
x_7	0.706	−0.284	0.320	0.690	0.579
x_8	0.648	−0.539	0.103	0.837	0.711
x_9	0.511	−0.230	0.215	0.518	0.314
x_{10}	0.780	−0.353	0.327	0.791	0.733

communalities in the factor model, and these are the parts of the variances of $\mathbf{x}$ which are explainable by the common factors.

The different varieties of principal factor analysis arise for two reasons. The first is that $\hat{\boldsymbol{\Psi}}$ can be defined in several ways. A popular choice where $\mathbf{S}$ is a correlation matrix is to estimate the communality $(1 - \psi_i)$ by the square of the multiple correlation between x_i and the other $(p - 1)$ x variables. The second reason is that the eigenanalysis may be done just once to get estimates of $\hat{\boldsymbol{\Lambda}}$, given $\hat{\boldsymbol{\Psi}}$, or we can iterate. Iteration involves estimating the communalities by $\sum_{j=1}^{m} \hat{\lambda}_{ij}^2$, and hence ψ_i by $1 - \sum_{j=1}^{m} \hat{\lambda}_{ij}^2$, given some estimate of the λ_{ij}s. An eigenanalysis is then done using the new estimates of ψ_i, leading to new estimates of $\boldsymbol{\Lambda}$, and so on until convergence of $\hat{\boldsymbol{\Lambda}}$ and $\hat{\boldsymbol{\Psi}}$ see [8, Section 5.2] and [9, Section 6.3] for further discussion of communality estimation.

Rotation of Factors

Factor analysis without rotation is not really factor analysis at all. We have seen in the example above that rotation aims to simplify the factor loadings in the sense that each loading should ideally be close to, or far from, zero, so that it is clear whether or not a given factor has an effect on a particular variable. Medium-sized, equivocal, loadings are to be avoided. It was noted above that orthogonal rotation is achieved by postmultiplying the original matrix of loadings $\hat{\boldsymbol{\Lambda}}$ by an orthogonal matrix $\mathbf{T}$, to give $\hat{\boldsymbol{\Lambda}}^* = \hat{\boldsymbol{\Lambda}}\mathbf{T}$, where $\mathbf{T}$ is chosen so that $\hat{\boldsymbol{\Lambda}}^*$ has a **simple structure**. Various criteria exist for achieving this simplification. Usually there are only small differences between results for different forms of orthogonal rotation, but oblique rotation may provide somewhat different, and simpler, structure. Oblique rotation also transforms $\hat{\boldsymbol{\Lambda}}$ to $\hat{\boldsymbol{\Lambda}}^* = \hat{\boldsymbol{\Lambda}}\mathbf{T}$, but here $\mathbf{T}$ is no longer constrained to be orthogonal, and so does not strictly give a "rotation" of rigid axes. If $\boldsymbol{\Phi} = (\mathbf{T}'\mathbf{T})^{-1}$ is the matrix of correlations between factors after rotation, then $\boldsymbol{\Phi}$ is the identity matrix for orthogonal rotation, but is only restricted to have unit elements on the diagonal for oblique rotation, with no restrictions on off-diagonal elements; see [12] for further details.

Estimation of Factor Scores

Factor analysis may stop with the estimation and interpretation of (rotated) factor loadings and communalities. Sometimes, however, it is desirable to "estimate" the values or *scores* of each individual observation on the factors (*see* **Factor Scores**). As an illustration, computing such scores for the 150 children in our example will rank the children with respect to the "ability factors" which the analysis has uncovered. Plotting the scores might reveal groups or clusters of children with similar abilities, or individuals who differ from the bulk of the data set with respect to these factors. Finally, the scores might be used in further analyses, such as **regression** or **linear discriminant analysis**.

In (1) the variables are expressed in terms of the factors, whereas in computing the scores we require the relationship to be in the opposite direction. As Bartholomew [1] has pointed out, "estimation" is really the wrong word here. The factor scores are **random variables**, not unknown parameters, so **prediction** is a better description of what is being attempted.

If we make the normality, and other, assumptions used in deriving maximum likelihood estimates of $\boldsymbol{\Lambda}$ and $\boldsymbol{\Psi}$, the conditional distributional of $\mathbf{f}$, given $\mathbf{x}$, can be found. It is the multivariate normal distribution $\mathrm{N}[\boldsymbol{\Lambda}'\boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu}), (\boldsymbol{\Lambda}'\boldsymbol{\Psi}^{-1}\boldsymbol{\Lambda} + \mathbf{I})^{-1}]$. One plausible way of calculating factor scores is to use a sample version of the mean of this distribution:

$$\hat{\mathbf{f}} = \hat{\boldsymbol{\Lambda}}'\mathbf{S}^{-1}(\mathbf{x} - \overline{\mathbf{x}}). \tag{6}$$

An alternative approach to the prediction of factor scores makes no explicit distributional assumptions, but attempts to find a linear function of $\mathbf{x}$ which minimizes the variance of the prediction error for each factor. This leads to (see [1, Section 3.5])

$$\hat{\mathbf{f}} = (\hat{\boldsymbol{\Lambda}}'\hat{\boldsymbol{\Psi}}^{-1}\hat{\boldsymbol{\Lambda}})^{-1}\hat{\boldsymbol{\Lambda}}'\hat{\boldsymbol{\Psi}}^{-1}(\mathbf{x} - \overline{\mathbf{x}}). \tag{7}$$

Note that (6) can also be written

$$\hat{\mathbf{f}} = [\mathbf{I} + (\hat{\boldsymbol{\Lambda}}'\hat{\boldsymbol{\Psi}}^{-1}\hat{\boldsymbol{\Lambda}})]^{-1}\hat{\boldsymbol{\Lambda}}'\hat{\boldsymbol{\Psi}}^{-1}(\mathbf{x} - \overline{\mathbf{x}}),$$

which is rather similar to (7) in its general form. Other methods are discussed in [3]. At times the factor scores are simplified further to produce a **cluster score**. This involves obtaining groups (or clusters) of variables and generating linear functions for each group (*see* **Cluster Analysis, Variables**; [8, Chapter 14]).

Choice of Number of Factors

The decision on how many factors, m, underlie the data can be a crucial one in the analysis. Consider

Table 3 Three- and four-factor solutions, based on principal components and varimax rotation, for data from [22]

	Three-factor solution			
Variable	Factor 1	Factor 2	Factor 3	Communality
x_1	0.815	0.131	0.182	0.714
x_2	0.805	0.254	0.069	0.717
x_3	0.623	0.335	0.308	0.596
x_4	0.632	0.347	0.001	0.520
x_5	0.775	0.113	0.292	0.698
x_6	0.216	0.818	−0.064	0.720
x_7	0.296	0.714	0.225	0.648
x_8	0.094	0.535	0.672	0.747
x_9	0.231	−0.014	0.847	0.771
x_{10}	0.310	0.646	0.470	0.734

	Four-factor solution				
Variable	Factor 1	Factor 2	Factor 3	Factor 4	Communality
x_1	0.799	0.128	0.202	0.150	0.719
x_2	0.810	0.227	0.211	−0.032	0.753
x_3	0.587	0.330	0.291	0.242	0.596
x_4	0.423	−0.001	0.758	0.223	0.804
x_5	0.819	0.233	0.028	0.166	0.753
x_6	0.076	0.501	0.718	−0.099	0.783
x_7	0.335	0.751	0.213	−0.080	0.728
x_8	0.168	0.803	−0.029	0.352	0.797
x_9	0.174	0.192	0.078	0.911	0.903
x_{10}	0.281	0.682	0.328	0.288	0.734

Table 3, which shows rotated factors for our example, based on a principal component initial solution and varimax rotation, for $m = 3$ and $m = 4$ factors.

As m varies, so does the factor structure. For $m = 2$ (Table 2), the two factors corresponded roughly to the first and last five of the 10 variables. When $m = 3$, the association of the first five variables with a single factor (factor 1) becomes stronger. Factors 2 and 3 are mainly associated with (x_6, x_7, x_{10}) and (x_8, x_9), respectively, although x_8 and x_{10} have nontrivial contributions from both factors 2 and 3.

For $m = 4$, the four factors are associated chiefly with (x_1, x_2, x_5), (x_7, x_8, x_{10}), (x_4, x_6), and (x_9), respectively. The remaining variable, x_3, has nontrivial contributions from all four factors.

The choice of m can be made in a number of ways. One possibility is to examine solutions for several values of m, as we have done, and decide subjectively which gives the most clear-cut structure. With underfactoring (too few factors) the retained factors contain too many high loadings, and are not as "simple" as they might be. Conversely, overfactoring (too many factors) leads to factors which are fragmented and difficult to interpret meaningfully. It is arguable that, on this basis, $m = 3$ is the best choice in our example.

We could also use communalities to decide on m. If prior values are available for communalities, not necessarily the same for all variables, we can choose m to be the minimum number of common factors for which the estimated communalities are no less than the specified values for all variables. In our example, for $m = 2$, communalities for three of the variables are less than 0.5, which is perhaps rather low, although unavoidable when looking for common factors if any of the variables is largely independent of all others. Communalities for two of these three variables are increased substantially if m is increased to 3, and for $m = 4$ only x_3 has a communality less than 0.7.

Another approach to choosing m is to examine the eigenvalues of the correlation matrix $\mathbf{S}$. A well-established, but subjective, way of proceeding is to plot the eigenvalues $l_k, k = 1, 2, \ldots, p$, against

k. Joining these points gives the so-called *scree graph* due to Cattell [6]. On the graph the slope generally becomes less steep as k increases, and we look for an "elbow" where the decrease in slope is substantial. If the elbow occurs at $k = m + 1$, we choose to retain $m = k - 1$ factors. Individual eigenvalues can also be used to choose m. The most common rule (Kaiser's rule [14]) is to keep as many factors as there are eigenvalues greater than 1. The reasoning behind this rule is that individual standardized variables each have variance 1, and for a factor to be worth keeping it must explain more variation than this. The validity of this rule is blurred by the fact that the eigenvalues represent variances of principal components, not factors. Also, after rotation variation becomes more evenly distributed among factors than before rotation. Hence, each of a set of rotated factors may account for more variance than an individual variable even if unrotated factors corresponding to eigenvalues less than 1 have been retained.

In our example two eigenvalues exceed 1, but the third is only just below this threshold. The scree graph is unhelpful – it suggests taking $m = 1$.

A final type of approach to the choice of m is based on **hypothesis testing**. The scree graph is an informal way of looking for eigenvalues which are significantly larger than the remainder, the latter corresponding to "noise" rather than "real factors". More formally, if we make normality assumptions we can construct a **likelihood ratio test** of the null hypothesis that the covariance matrix $\mathbf{\Sigma}$ has the form given in (3) for a specified value of m, against the alternative of an unrestricted $\mathbf{\Sigma}$. The χ^2 approximation associated with this test statistic is often valid even when multivariate normality does not hold [3]. To decide on a suitable value for m we could conduct the test successively for $m = 1, 2, \ldots$ until we first fail to reject the null hypothesis, although the nonindependence of such a sequence of tests makes it difficult to assess the overall significance level of such a procedure. In addition, these procedures are influenced by the total sample size N. There is a tendency for underfactoring to occur for small N, with overfactoring for large N [8, p. 301].

This section is by no means exhaustive – for further discussion and methods, see [3, paragraphs 3.8, 3.13, Chapters 4 and 5], [8, Section 5.5], [9, Chapter 8], [13, Section 6.1] and [14, Section 2.4]. Although [13] is concerned with principal components analysis, many of the techniques described are more relevant to factor analysis.

Comparison with Principal Components Analysis

It was noted above that there is much confusion between principal components analysis and factor analysis. A number of differences between the two techniques have already been mentioned. Here we reiterate these briefly, and discuss some others.

1. Factor analysis postulates a model for the data – principal components analysis does not.
2. Factor analysis concentrates on explaining *covariance or correlation* by means of a few common factors. Principal components analysis is concerned mainly with explaining *variance*.
3. If the number of retained principal components is increased from m to $m + 1$, the first m principal components are unchanged. For rotated factors we have seen in our example that there can be substantial changes in *all* factors if m is changed.
4. Because principal components are defined as linear functions of $\mathbf{x}$, computation of principal component "scores" is unambiguous, unlike factor analysis.
5. Principal components analysis, like factor analysis, can be performed on standardized or on unstandardized variables, corresponding to an eigenanalysis of the correlation or covariance matrix, respectively. For principal components analysis the results of the two analyses are different, and one cannot be derived directly from the other. However, for maximum likelihood factor analysis the results are invariant in the sense that those based on the covariance matrix are equivalent to those derived from the correlation matrix.

Second-order Factor Analysis

When oblique rotation is used in factor analysis, the resulting factors are correlated. The correlation matrix between these (first-order) factors can be used as the input to a factor analysis, in the same manner as the correlation matrix for the original measured variables. This leads to second-order factor analysis (*see* **Factor Analysis, Second-order**).

Confirmatory Factor Analysis

What has been discussed above is exploratory in nature. There is no preconception of what form the factors will take – we let the data tell us this. Although this is what is usually meant by "factor analysis", it may not always be what is required. Sometimes there is some psychological or other theory which leads to a specified factor structure, in the sense that some loadings are known to be zero in this structure. **Confirmatory factor analysis** is concerned with estimating and testing the fit of such models. The technique is a special case of structural equations models, which have a large literature – see, for example, [4].

Further Reading

The multiple-factor approach to psychological data was first described at length in 1947 by Thurstone [21]. A number of substantial texts appeared in the next 40 years; the traditional, psychologist's, approach to the subject is well documented in [7]. Other traditionally based references are [8, 9], and [10]. Lawley & Maxwell [15] gave the first extensive account of the statistical, likelihood-based, approach, and a more recent account is in [3]. Chapter 17 of [11], and Chapter 13 of [15] provide good reviews, together with many references, of various aspects of factor analysis which are noted only briefly in this entry. Lewis-Beck [16] packages together five short monographs on factor analysis and related methods: the first two are readable introductory texts on exploratory factor analysis; the third covers principal components analysis; and the last two discuss confirmatory factor analysis and structural equations models.

Factor Analysis, Second-order

In **factor analysis** we factor a reduced **correlation** matrix $\mathbf{R}^*$ to obtain an initial factor matrix $\mathbf{F}$, which in turn is often *rotated* by means of a transformation matrix $\mathbf{\Lambda}$ to produce a rotated factor matrix $\mathbf{V}$. $\mathbf{R}^*$ is obtained by replacing the estimated **communalities** on the diagonal of the original correlation matrix $\mathbf{R}$. The elements of $\mathbf{F}$ and $\mathbf{V}$ are called loadings (*see* **Factor Loading Matrix**). They are usually correlations of the original variables and the factors. From the high loadings, we interpret the factors of $\mathbf{V}$ in terms of the meanings of the functions measured by the original variables. This analysis is a *first-order factor analysis*. If an **oblique rotation** is used to transform $\mathbf{F}$ to $\mathbf{V}$, the factors of $\mathbf{V}$ are correlated in general. With the correlation of these factors, we may perform a *second-order factor analysis* to push the interpretations a step further.

In second-order factor analysis we first obtain the second-order correlation matrix $\mathbf{R}_s$, which is given by

$$\mathbf{R}_s = \mathbf{T}'\mathbf{T},$$

where $\mathbf{T} = (\mathbf{\Lambda}')^{-1}\mathbf{D}$ is the primary structure transformation matrix. $\mathbf{\Lambda}$ is the matrix that is used to transform the initial factor matrix $\mathbf{F}$ to the first-order factor matrix $\mathbf{V}$. $\mathbf{D}$ is the diagonal matrix that normalizes the columns of $(\mathbf{\Lambda}')^{-1}$. The matrix $\mathbf{R}_s$ contains the correlations among the primary axes of the first-order factor analysis. From $\mathbf{R}_s$, we obtain the reduced second-order correlation matrix $\mathbf{R}_s^*$ (with estimated communalities on the diagonal). We can then factor this $\mathbf{R}_s^*$ to obtain $\mathbf{F}_s$, the second-order initial factor matrix. We can next rotate $\mathbf{F}_s$ to obtain $\mathbf{V}_s$, the second-order rotated factor matrix. Again, the factors of $\mathbf{V}_s$ can be interpreted from the high loadings in terms of the meanings of the functions represented by the first-order factors.

We interpret the first-order factors directly in terms of the original variables. The original variables may have errors of measurement as well as specific factors. These error factors and specific factors lump together in the unique factors and lie outside the first-order common-factor space in which the first-order factors (or factors of $\mathbf{V}$) are defined. Therefore, when we interpret the second-order factors directly in terms of these first-order factors, any error factors existing in this analysis can be due only to imperfect first-order analysis. Usually, the error factors in the second-order analysis are negligible and we can conclude that the second-order unique factors are entirely specific factors which lie outside the second-order common-factor space.

Two First-order Factors

In general, we do not perform a second-order factor analysis when there are only two first-order factors because there is usually very little information this analysis can add to the first-order analysis.

Three First-order Factors

In the case of having three first-order factors, there are three linearly independent correlations in the second-order correlation matrix $\mathbf{R}_s$, namely, r_{12}, r_{13}, and r_{23}. Using the theorems on triads, if these correlations can be accounted for by a factor pattern with one general factor and three unique factors, then all the triads computed from these correlations must be positive or zero and not greater than unity (see [1, Chapter 1, Section 1.5.5] for more related theorems on triads). On the Basis of the theorems, we can perform the second-order analysis by first computing the triads:

$$t_{123} = \frac{r_{12}r_{13}}{r_{23}},$$

$$t_{213} = \frac{r_{12}r_{23}}{r_{13}},$$

$$t_{312} = \frac{r_{13}r_{23}}{r_{12}}.$$

If all the computed triads are at least 0.001 and not greater than 0.999, then these triads correspond to the communalities of the second-order factors. They are usually denoted by h_j^2, where $j = 1, 2, \ldots, m$ and m is the number of the first-order factors. The second-order general-factor loadings, g_j, are the square roots of the communalities, and the specific-factor loadings are $s_j = (1 - h_j^2)^{1/2}$ for $j = 1, 2, 3$. For each factor j, $g_j + s_j = 1$.

To make this second-order analysis possible, we not only need to have all the triads to be within the specified range, we also need to have a very

good first-order analysis with additional refinement of the **simple structure** on the reference vectors (*see* **Primary Factors**). (See [1, Chapter 10] for various refinement transformations.)

Four First-order Factors

In the case of having four first-order factors, there are six second-order correlations, namely r_{12}, r_{13}, r_{14}, r_{23}, r_{24}, and r_{34}. If these correlations can be accounted for by a factor pattern with one general factor and four unique factors, we may proceed to calculate the 12 triads and perform the triad analysis as follows:

$$h_1^2 = \frac{(t_{123} + t_{124} + t_{134})}{3} = \frac{(r_{12}r_{13}/r_{23} + r_{12}r_{14}/r_{24} + r_{13}r_{14}/r_{34})}{3},$$

$$h_2^2 = \frac{(t_{213} + t_{214} + t_{234})}{3} = \frac{(r_{12}r_{23}/r_{13} + r_{12}r_{24}/r_{14} + r_{23}r_{24}/r_{34})}{3},$$

$$h_3^2 = \frac{(t_{312} + t_{314} + t_{324})}{3} = \frac{(r_{13}r_{23}/r_{12} + r_{13}r_{34}/r_{14} + r_{23}r_{34}/r_{24})}{3},$$

$$h_4^2 = \frac{(t_{412} + t_{413} + t_{423})}{3} = \frac{(r_{14}r_{24}/r_{12} + r_{14}r_{34}/r_{13} + r_{24}r_{34}/r_{23})}{3}.$$

Then we can obtain the general factor loadings, $g_j = \sqrt{h_j^2}$, and the specific factor loadings, $s_j = (1 - h_j^2)^{1/2}$ for $j = 1, 2, 3, 4$.

To find out if one general factor is sufficient to account for the second-order correlations, we have to consider the standard errors of the tetrads. The tetrads are computed as:

$$t_{1234} = r_{12}r_{34} - r_{13}r_{24},$$

$$t_{1243} = r_{12}r_{34} - r_{14}r_{23},$$

$$t_{1342} = r_{13}r_{24} - r_{14}r_{23},$$

where $t_{1234} + t_{1342} = t_{1243}$ and a conservative approximation to their standard errors is given by $1/(N-1)^{1/2}$, where N is the total sample size. If the absolute values of all three tetrads are less than $1/(N-1)^{1/2}$, we can tentatively assume that there is only one second-order general factor and proceed to calculate the triads and the factor loadings as described above. If there are any triads that are lower than $-1/(N-1)^{1/2}$ or higher than $1 + 1/(N-1)^{1/2}$ and also if there are any h_j^2 that are less than 0.001 or greater than 0.999, then we have to consider that only one second-order general factor is insufficient.

If one second-order general factor is not sufficient, then we have to use a more complicated procedure to postulate two second-order factors. For postulating one second-order general factor and one second-order group factor, we can use the triads analysis given in [1, Chapter 1, Sections 1.5.10 and 1.6.2–1.6.7]. For postulating two second-order general factors, we can employ the principal-axes method and factor the second-order correlation matrix twice to make the sum of the final communalities close to the sum of the estimated communalities for the second analysis, and then to rotate the second-order factor matrix obliquely.

Five or More First-order Factors

In the case of having five or more first-order factors, we can use principal axes to factor the reduced second-order correlation matrix $\mathbf{R}_s^*$. If there appears to be only one salient second-order factor, we will refactor using the squares of the first-factor loadings from the first factoring as the communality estimates. The first factor of the second factoring is then the second-order general factor, with loadings g_j, $j = 1, 2, \ldots, m$, and m is the number of salient first-order factors. The second-order specific factor loadings are $s_j = (1 - g_j^2)^{1/2}$, and for each factor, $g_j^2 + s_j^2 = 1$. The second-order matrix $\mathbf{G}$ is then formed as

$$\begin{bmatrix} g_1 & h_1^2 & s_1 \\ g_2 & h_2^2 & s_2 \\ \vdots & \vdots & \vdots \\ g_m & h_m^2 & s_m \end{bmatrix}.$$

When there is more than one salient second-order factor, with the number less than half of the first-order factors, we refactor using the row sums of squares of the first $\mathbf{G}$ as the estimated communalities. The resulting second $\mathbf{G}$ may be rotated to obtain a second-order reference-structure $\mathbf{V}$ matrix. Interpretation of

this matrix must be based on quite clear interpretation of the meanings of the first-order factors.

In second-order analysis, one is likely to obtain communality greater than unity. This is called a Heywood case. If this happens, we may try increasing or decreasing the number of second-order factors by one.

Factor Loading Matrix

A factor loading matrix is a matrix of coefficients (or weights) for a set of linear equations relating p observed variables to m factors (or components) (*see* **Factor Analysis, Overview**; **Principal Components Analysis**). Sometimes, it is referred to as a *factor pattern*. The rows of the matrix correspond to the observed variables and the columns correspond to the factors. Consider the hypothetical factor pattern matrix, **F** obtained from a common factor model (see Table 1). The a_i and b_i are the coefficient from the following set of specification equations:

$$X_1 = a_1 A + b_1 B + u_1 U_1,$$
$$X_2 = a_2 A + b_2 B + u_2 U_2,$$
$$X_3 = a_3 A + b_3 B + u_3 U_3,$$
$$X_4 = a_4 A + b_4 B + u_4 U_4,$$
$$X_5 = a_5 A + b_5 B + u_5 U_5,$$

where X_i is the standardized score of the original variable i, a_i and b_i are the coefficients for the common factors A and B of variable i, u_i is the coefficient for the unique factor U_i of variable i. Under this model, we usually call **F** the initial common-factor loadings matrix. Each pair of these loadings (or coefficients) can be expressed as the coordinates of a point in a plane. Figure 1(a) presents a plot of the factor pattern loadings for a variable X with respect to the initial unrotated factor axes a and b. The a coordinate is measured parallel to the axis a from the axis b and the b coordinate is measured parallel to the axis b from the axis a.

The term "factor loading matrix" is also used to refer to the matrix that contains the **correlations** between the variables and the factors. This matrix is then called a *factor structure*. It is obtained by postmultiplying the initial factor matrix, **F**, with a matrix the columns of which represent the coordinates of a set of unit axes. These axes can be a set of primary axes or reference vectors (*see* **Primary Factors**). The row vectors of the resulting factor structure are the correlations between the variables and the factors defined by these axes. In geometrical terms, these structure loadings can be thought of as the projections of the variable point i on the axes that define the factors. They are measured as the distances from

Table 1 Factor pattern matrix, **F**

		Factor	
		a	b
Variable	1	a_1	b_1

	3	a_3	b_3
	4	a_4	b_4
	5	a_5	b_5

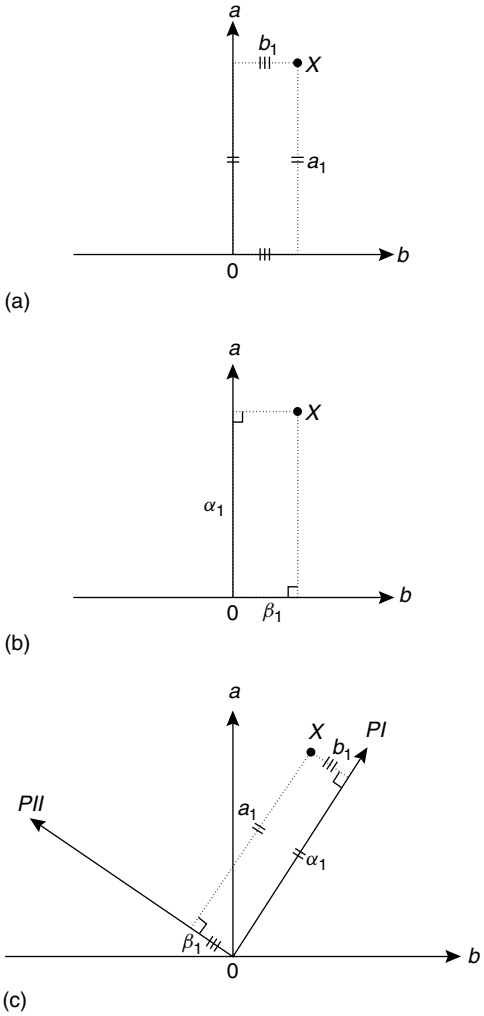

Figure 1 (a) Initial pattern loadings with respect to the initial axes a and b. (b) Initial structure loadings with respect to the initial axes a and b. (c) Orthogonal rotated pattern and structure loadings with respect to the primary axes PI and PII

the origin to the intersection points of the axes and the perpendicular lines dropping from the variable point i. A plot of the structure loadings for a variable X with respect to the initial unrotated axes a and b is presented in Figure 1(b). The pattern and structure loadings are identical in Figures 1(a) and 1(b). In fact, these two types of loadings coincide for any orthogonal rotation of the factor axes. A plot illustrating both the pattern and structure of X with respect to a pair of **orthogonal** primary axes PI and PII is shown in Figure 1(c). As long as we assume that the factors are uncorrelated (orthogonal), there is no confusion in the use of the term "factor loading matrix", because both the pattern and structure matrices provide the same set of loadings.

However, the pattern and structure loadings are not identical after an **oblique rotation**. In this situation, we need to have an explicit designation to indicate if the factor loading matrix is a pattern or a structure. Figure 2 presents plots of the pattern and structure loadings of a variable X with respect to two oblique-rotated primary axes PI and PII. The dotted lines show the projections of the point X on the primary axes.

In Figure 2(a), the vectors $0c$ and $0d$ are the parallel projections on the primary axes PI and PII. They are the **primary factor** pattern loadings, which are the regression coefficients of the variables on the factors. The primary pattern loadings are interpretable as measures of the contribution of each factor to the variances of the variables. The formula to obtain this primary factor pattern matrix $\mathbf{P}$ is given by $\mathbf{P} = \mathbf{F}\mathbf{\Lambda}\mathbf{D}^{-1}$, where $\mathbf{F}$ is the initial factor matrix, $\mathbf{\Lambda}$ is the matrix the column vectors of which represent the coordinates of the reference axis, and $\mathbf{D}$ is the matrix of correlations between the reference vectors and the primary axes. (See Cureton & D'Agostino [1, Chapter 6] for the derivations of each transformation matrix. Also see below for clarification of reference vectors.) This primary factor pattern matrix is useful in the interpretation of the factors because the variables that are highly loaded on one factor usually have low loadings on other factors. We can identify a cluster of similar variables in terms of their coefficients. Unlike correlation coefficients, these coefficients do not lie within ± 1. It is possible for these coefficients to be greater than 1 even when the variables are standardized.

The vectors $0e$ and $0f$ of Figure 2(b) are the perpendicular projections on the primary axes PI and PII. They are the primary structure loadings, which are the correlation coefficients between the variable X and the oblique primary factors if X is a standardized variable. This structure matrix, $\mathbf{S}$, on the primary factors is defined as $\mathbf{S} = \mathbf{FT} = \mathbf{F}(\mathbf{\Lambda}')^{-1}\mathbf{D}$. This matrix need not conform to the **simple structure** principle, so it may not be useful for interpretation. However, it may be used in the determination of **factor scores**.

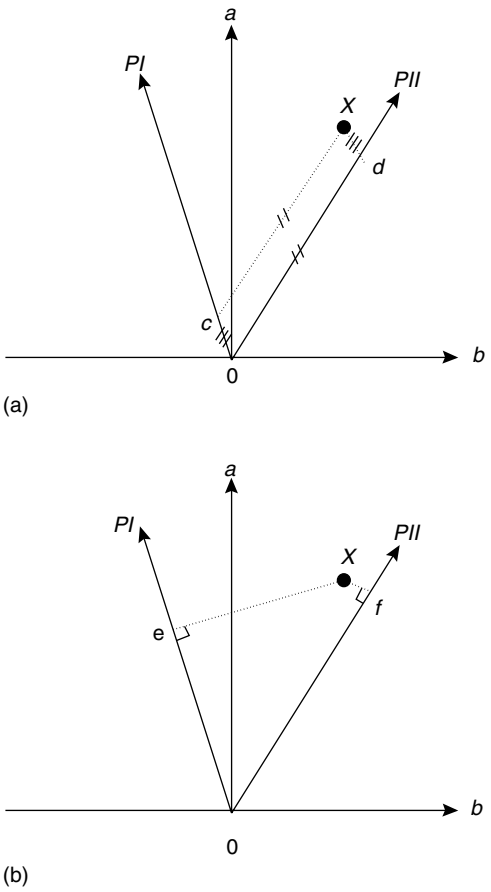

Figure 2 (a) Oblique-rotated pattern loadings with respect to the primary axes PI and PII. (b) Oblique-rotated structure loadings with respect to the primary axes PI and PII

With an oblique rotation, an alternative set of axes may be employed. They are the reference vector axes, which are defined as axes normal to planes or hyperplanes, depending on the number of factors involved, and they usually set a boundary for the primary factor axes unless the angle between the primary factor axes is obtuse (i.e. a rare case). In

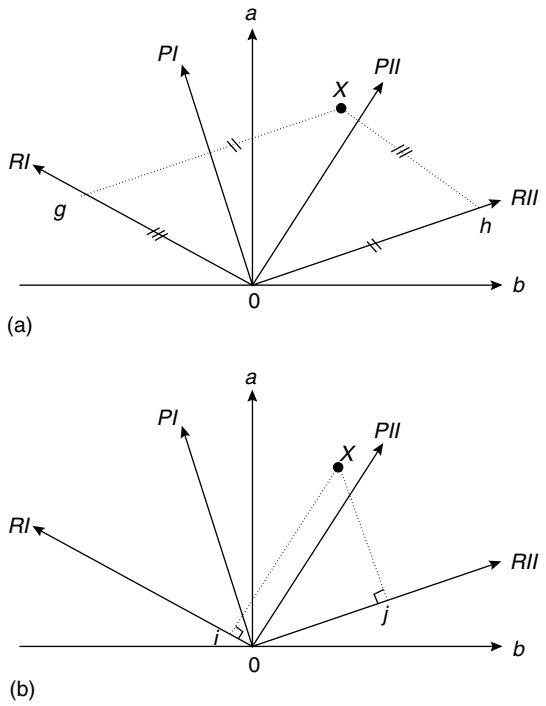

Figure 3 (a) Oblique-rotated pattern loadings with respect to the reference axes RI and RII. (b) Oblique-rotated structure loadings with respect to the reference axes RI and RII

the two-factor case, the reference axes are simply the axes that are orthogonal to the primary factor axes. Plots of the pattern and structure loadings of a variable X with respect to the reference axes RI and RII are shown in Figure 3. The dotted lines show the projections of the point X on the reference axes. Note that since RI is the reference vector for PI, it is correlated with PI and uncorrelated or orthogonal to PII. Similarly, RII is correlated with PII and uncorrelated with PI.

The vectors $0g$ and $0h$ of Figure 3(a) are the parallel projections on the reference vectors RI and RII. They are the reference vector pattern loadings. Figure 3(a) shows that these loadings are in fact proportional to the primary factor structure loadings. The complete pattern matrix on these reference vectors is given by $\mathbf{W} = \mathbf{F}(\mathbf{\Lambda}')^{-1}$. This matrix is seldom used for interpretation.

The vectors $0i$ and $0j$ of Figure 3(b) are the perpendicular projections on the reference vectors RI and RII. They are the reference vector structure loadings. Figure 3(b) shows that these loadings are proportional to the primary factor pattern loadings. These structure loadings usually reflect a simple structure solution to a higher degree than do the loadings on the primary scale [2]. The values of these structure loadings are constrained to lie within ± 1. $\mathbf{V} = \mathbf{F}\mathbf{\Lambda}$ gives the structure matrix on the reference vectors. It is useful for interpretation of factors.

For simplicity and visual convenience, we have focused the discussion of the factor loading matrices in terms of a two-dimensional model throughout this article. The reader should refer to Cureton & D'Agostino [1] for further discussion using models with higher dimension.

Factor Scores

After a set of interpretable **factor loadings** is determined, the next possible step is to compute the factor scores. Exact factor scores can be obtained for a principal components analysis model. These scores are usually referred to as component scores. Methods for computing these component scores are given in **Principal Components Analysis**. In this article we present primarily methods that compute factor scores in the common factor analysis model. Under this model, it is not possible to obtain the exact factor scores because we have more unknowns (m common factors and p unique factors) than the observed variables (of size p). We can only estimate the scores on the m common factors in this case. There are various methods that can be employed to obtain the estimates, but the most common method to estimate the factor scores is least squares regression.

The **linear regression** of any factor score on the p standardized original variables is expressed as follows:

$$\mathbf{Z} = \boldsymbol{\beta}\mathbf{X} + \boldsymbol{\eta}, \tag{1}$$

where $\mathbf{Z}$ is the $m \times N$ matrix of true (unknown) standardized factor scores, $\mathbf{X}$ is the $p \times N$ matrix of standardized original variables, $\boldsymbol{\beta}$ is the $m \times p$ matrix of true regression coefficients, and $\boldsymbol{\eta}$ is the $m \times N$ matrix of residuals. N is the sample size. Each row of $\mathbf{Z}$ of (1) represents one primary factor, and we can solve the scores on each factor separately by minimizing for that row the sum of squares of the residuals. The resulting least squares estimates for the factor scores are given by

$$\hat{\mathbf{Z}} = \boldsymbol{\Delta}\boldsymbol{\Lambda}^{-1}\mathbf{F}'\mathbf{R}^{-1}\mathbf{X}, \tag{2}$$

where $\boldsymbol{\Delta}$ is the $m \times m$ diagonal matrix that normalizes the columns of $(\boldsymbol{\Lambda}^{-1})'$, $\boldsymbol{\Lambda}$ is the $m \times m$ transformation matrix, $\mathbf{F}$ is the $p \times m$ initial factor loading matrix, $\mathbf{R}$ is the $p \times p$ correlation matrix of the original variables, and $\mathbf{X}$ is the matrix of standardized original variables. An alternative formula to (2) is given by

$$\hat{\mathbf{Z}} = \mathbf{R}_s\mathbf{F}'\mathbf{R}^{-1}\mathbf{X}. \tag{3}$$

This formula can be used if $\mathbf{P}$ the primary pattern matrix and $\mathbf{R}_s$ the second-order correlation matrix are available (*see* **Factor Analysis, Second-order**). We can also get the standardized weights for these factor scores from the SAS software package PROC FACTOR [3]. An example of these standardized weights is given in Table 1. These weights are obtained from performing a factor analysis with varimax rotation on the **Framingham** depression data (*see* **Principal Components Analysis** for data description). For a complete discussion on this regression method, readers can refer to [1] for details.

Table 1 Factor scoring coefficients for retained components for Framingham depression data
Rotation method: varimax
Standardized scoring coefficients

	Factor 1	Factor 2	Factor 3
EFFORT	−0.043	0.321	0.034
RESTLESS	−0.006	0.137	0.005

GETGOING	−0.062	0.326	0.050

Even though $\hat{\mathbf{Z}}$ contains good estimates for the true common factor scores, they are still subject to error. A measure of the deviation of the estimates from the true scores is the multiple **correlation** of the estimated factor scores with the p variables of the data. These squared multiple correlations $\mathbf{R}_j^2$, $j = 1, \ldots, m$, can be obtained as the diagonal elements of

$$(\boldsymbol{\Delta}\boldsymbol{\Lambda}^{-1}\mathbf{F}')\mathbf{R}^{-1}(\boldsymbol{\Delta}\boldsymbol{\Lambda}^{-1}\mathbf{F}')'.$$

$\mathbf{R}_j^2$ is shown to be the variance of the estimated factor scores. Since the variance is not equal to unity, these estimates leave parts of the total variance (the total unique variance) unaccounted for. The standard error of estimate for a set of primary factor scores can be computed as

$$\text{se}_j = (1 - \mathbf{R}_j^2)^{1/2}.$$

The higher the $\mathbf{R}_j$, the lower the standard error of estimate. This method maximizes the validity of the factor scores (i.e. it gives the highest $\mathbf{R}_j$).

The drawback of this method is that the regression estimates are not univocal: the correlations of these estimated factor scores are not the same as the correlations between the primary factors. In particular, these scores are correlated even when the primary factors are not. A number of other estimation procedures have been proposed to improve on the criteria of univocality and **orthogonality** of these regression estimates (see [2, Chapter 16]), but none of these methods has the level of validity provided by the regression method.

In general, there is limited value in the use of factor scores, for even though the factors are interpretable, the estimated factor scores are not well determined. Cureton & D'Agostino [1] suggest the use of the **cluster scores** as the more stable score to be used as a summary measure.

Factor

Factor analysis is a set of procedures that use mathematical models to explain the interrelationships of a set of manifest (i.e. observed) variables by a smaller number of underlying *factors* that cannot be observed or measured directly. These underlying factors are sometimes known as the latent variables. In 1927, Spearman [4] developed the common factor analysis model for two factors and Thurstone [5] later extended the model to multiple factors. The Spearman–Thurstone approach expresses a variable as a weighted sum of some unknown *common factors* and a *unique factor*. A *factor pattern* is the set of equations relating the measurements on p variables to the m postulated common factors ($m < p$) and p unique factors. A general factor pattern is given as follows:

$$\begin{aligned} X_1 &= a_1A + b_1B + \cdots + m_1M + u_1U_1, \\ X_2 &= a_2A + b_2B + \cdots + m_2M + u_2U_2, \\ &\vdots \qquad\qquad\qquad \vdots \\ X_p &= a_pA + b_pB + \cdots + m_pM + u_pU_p, \end{aligned} \tag{1}$$

where: $X_1, X_2, \ldots, X_p$ represent measurements (usually the standardized measurements) of the p manifest variables; $A, B, \ldots, M$ represent the standard scores on the m common factors; $a_i, b_i, \ldots, m_i$, $i = 1, \ldots, p$, are the weights or *common* **factor loadings** of the p variables on the m common factors; $U_1, U_2, \ldots, U_p$ represent the standard scores on the p unique factors; and $u_1, u_2, \ldots, u_p$ are the weights or *unique factor loadings* of the p variables on the p unique factors. In many settings the common factor loadings are also the correlations of the manifest variables and the common factors.

The common factors are interpreted with reference to the p manifest variables. The unique factor in each variable is merely whatever part of that variable is uncorrelated with all the other variables, including its error of measurement. The p unique factors are always taken to be uncorrelated with one another and with the common factors. These common factors may or may not be uncorrelated.

The factors or latent variables are not uniquely determined by the intercorrelations among the manifest variables. The factors are only hypothetical constructs that are postulated in order to arrive at an explanation of the intercorrelations of the original set of variables. Once the number of factors m and the final factor pattern model in (1) is determined, the factor complexity is used to interpret the factors. Factor *complexity* refers to the number of manifest variables that have moderate or high factor loadings (or weights) on a factor. What an investigator deems moderate or high depends on the assessment of error in their data, and the overall intercorrelation between the manifest variables and the findings of other similar studies. The various approaches of factor analysis can generate different configurations of factor complexity. So, it is important to decide upon the appropriate procedure for performing the factor analysis. Standard procedures are common factor analysis [2] and maximum likelihood factor analysis [1, 3]. Other procedures are also well developed [1, 3] (also *see* **Factor Analysis, Overview**). Within the concept of factor complexity, different types of factors can be identified. If a common factor has moderate or high loadings on all p manifest variables, it is called a *general factor*. If it has moderate or high loadings on only two or more, but not all, of the variables, then it is called a *group factor*. If a group factor has moderate or high loadings on only two variables, it is termed a *doublet factor*. If the loadings of the group factor are such that there are both high positive and negative loadings, it is called a *bipolar factor*. These different types of factors are illustrated in Table 1.

Table 1

	Factor			
Variable	1	2	3	4
1	+	0	+	0
2	+	+	+	0
3	+	0	0	0
4	+	0	+	0
5	+	+	0	0
6	+	+	0	0
7	+	0	−	0
8	+	0	−	0
9	+	0	0	+
10	+	+	0	+
	general		bipolar	doublet
		group		

Note: + = high or moderate positive loadings.
− = high or moderate negative loadings.
0 = near-zero loadings.

In Table 1, factor 1 is a general factor, while factors 2, 3, and 4 are group factors. Among the three group factors, factor 3 is a bipolar factor and factor 4 is a doublet factor.

One traditional aim in factor analysis is to obtain a **simple structure**, where the m factors are group factors, each highly or moderately correlated to only approximately m manifest variables.

Factorial Designs in Clinical Trials

Factorial experiments test the effect of more than one treatment (factor) using a design that permits an assessment of **interactions** between the treatments. A treatment could be either a single therapy or a combination of interventions. The essential feature of factorial designs is that treatments are varied systematically (i.e. some groups receive more than one treatment), and the experimental groups are arranged in a way that permits testing whether or not the treatments interact with one another.

The technique of varying more than one treatment in a single study has been used widely in agriculture and industry based on work by **Fisher** [10, 11] and **Yates** [33]. Influential discussions of factorial experiments were given by Cox [8] and **Snedecor** & **Cochran** [28]. Factorial designs have been used relatively infrequently in medical trials, except recently in disease prevention studies (*see* **Prevention Trials**). The discussion here will be restricted to randomized factorial **clinical trials**.

Factorial designs offer certain advantages over conventional comparative designs, even those employing more than two treatment groups. The factorial structure permits certain comparisons to be made that cannot be achieved by any other design. In some circumstances, two treatments can be tested in a factorial trial using the same number of subjects ordinarily used to test one treatment. However, the limitations of factorial designs must be understood before deciding whether or not they are appropriate for a particular therapeutic question. Additional discussions of factorial designs in clinical trials can be found in **Byar** & Piantadosi [6] and Byar et al. [7]. For a discussion of such designs related to cardiology trials, particularly in the context of the ISIS-4 trial [17], see Lubsen & Pocock [20]. This article is based on a recent chapter discussing factorial designs in medical studies given by Piantadosi [24].

Basic Features of Factorial Designs

The simplest factorial design has two treatments (A and B) and four treatment groups (Table 1). There might be n patients entered into each of the four treatment groups for a total sample size of $4n$ and a balanced design. One group receives neither A nor B, a second receives both A and B, and the other two groups receive one of A or B. This is called a 2×2 (two by two) factorial design. The design generates enough information to test the effects of A alone, B alone, and A plus B.

The 2×2 design generalizes to higher order factorials. For example, a design studying three treatments, A, B, and C, is the $2 \times 2 \times 2$. Possible treatment groups for this design are shown in Table 2. The total sample size is $8n$ if all treatment groups have n subjects.

These examples highlight some of the prerequisites necessary for, and restrictions on, using a factorial trial.

First, the treatments must be amenable to being administered in combination without changing dosage in the presence of each other. For example, in Table 1, we would not want to reduce the dose of A in the lower right cell where B is present. This requirement implies that the side effects of the treatments cannot be cumulative to the point where the combination is impossible to administer.

Secondly, it must be ethically acceptable to withhold the individual treatments, or administer them at lower doses as the case may be (*see* **Ethics of Randomized Trials**). In some situations, this means

Table 1 Treatment groups and sample sizes in a 2×2 balanced factorial design

	B		
A	No	Yes	Total
No	n	n	$2n$
Yes	n	n	$2n$
Total	$2n$	$2n$	$4n$

Table 2 Treatment groups in a balanced $2 \times 2 \times 2$ factorial design.

	Treatments			Sample
Group	A	B	C	size
1	No	No	No	n
2	Yes	No	No	n
3	No	Yes	No	n
4	No	No	Yes	n
5	Yes	Yes	No	n
6	No	Yes	Yes	n
7	Yes	No	Yes	n
8	Yes	Yes	Yes	n

having a no-treatment or placebo group in the trial. In other cases A and B may be administered in addition to a "standard" so that all groups receive some treatment.

Thirdly, we must be genuinely interested in learning about treatment combinations; otherwise, some of the treatment groups might be unnecessary. Alternately, to use the design to achieve greater efficiency in studying two or more treatments, we must know that some interactions do not exist.

Fourthly, the therapeutic questions must be chosen appropriately. We would not use a factorial design to test treatments that have exactly the same mechanisms of action (e.g. two ACE inhibitors for high blood pressure) because either would answer the question. Treatments acting through different mechanisms would be more appropriate for a factorial design (e.g. radiotherapy and chemotherapy for tumors). In some prevention factorial trials, the treatments tested also target different diseases.

Efficiency

Factorial designs offer certain very important efficiencies or advantages when they are applicable. Consider the 2×2 design and the estimates of treatment effects that would result using an **additive model** for analysis (Table 3). Assume that the responses are group averages of some **normally distributed** response denoted by $\overline{Y}$. The subscripts on $\overline{Y}$ indicate which treatment group it represents. Half the patients receive one of the treatments (this is also true in higher order designs). For a moment, further assume that the effect of A is not influenced by the presence of B.

There are two estimates of the effect of treatment A compared to placebo in the design, $\overline{Y}_A - \overline{Y}_0$ and $Y_{AB} - \overline{Y}_B$. If B does not modify the effect of A, the two estimates can be combined (averaged) to estimate the overall effect of $A(\beta_A)$,

$$\beta_A = \frac{(\overline{Y}_A - \overline{Y}_0) + (\overline{Y}_{AB} - \overline{Y}_B)}{2}. \qquad (1)$$

Table 3 Treatment effects from a 2×2 factorial design

	B	
A	No	Yes
No	$\overline{Y}_0$	$\overline{Y}_B$
Yes	$\overline{Y}_A$	$\overline{Y}_{AB}$

Similarly,

$$\beta_B = \frac{(\overline{Y}_B - \overline{Y}_0) + (\overline{Y}_{AB} - \overline{Y}_A)}{2}. \qquad (2)$$

Thus, in the absence of interactions (i.e. the effect of A is the same with or without B, and vice versa), the design permits the full sample size to be used to estimate two treatment effects.

Now suppose that each patient's response has a **variance** σ^2 that is the same in all treatment groups. We can calculate the variance of β_A to be

$$\text{var}(\beta_A) = \frac{1}{4} \times \frac{4\sigma^2}{n} = \frac{\sigma^2}{n}.$$

This is the same variance that would result if A were tested against placebo in a single two-armed comparative trial with $2n$ patients in each treatment group. Similarly,

$$\text{var}(\beta_B) = \frac{\sigma^2}{n}.$$

However, if we tested A and B in separate trials, we would require $4n$ subjects in each trial or a total of $8n$ patients to have the same precision. Thus, in the absence of interactions, factorial designs estimate main effects efficiently. In fact, tests of both A and B can be conducted in a single factorial trial with the same precision as two single-factor trials using twice the sample size.

Interactions

The effect of A might be influenced by the presence of B (or vice versa). In other words, there might be a *treatment interaction*. Some of the efficiencies just discussed will be lost. However, factorial designs are even more relevant when interactions are possible. Factorial designs are the only type of trial design that permits study of treatment interactions. This is because the design has treatment groups with all possible combinations of treatments, allowing the responses to be compared directly.

Consider again the two estimates of A in the 2×2 design, one in the presence of B and the other in the absence of B. The definition of an interaction is that the effect of A in the absence of B is different from the effect of A in the presence of B. This can be estimated by comparing

$$\beta_{AB} = (\overline{Y}_A - \overline{Y}_0) - (\overline{Y}_{AB} - \overline{Y}_B) \qquad (3)$$

to zero. If β_{AB} is near zero, we would conclude that no interaction is present. It is straightforward to verify that $\beta_{AB} = \beta_{BA}$. When there is an AB interaction present, we must modify our interpretation of the main effects. For example, the estimates of the main effects of A and B [(1) and (2)] assumed no interaction was present. We may choose to think of an overall effect of A, but recognize that the magnitude (and possibly the direction) of the effect depends on B. In the absence of the other treatment, we could estimate the main effects using

$$\beta'_A = (\overline{Y}_A - \overline{Y}_0) \tag{4}$$

and

$$\beta'_B = (\overline{Y}_B - \overline{Y}_0). \tag{5}$$

In the $2 \times 2 \times 2$ design, there are three main effects and four interactions possible, all of which can be tested by the design. Following the notation above, the effects are

$$\beta_A = \tfrac{1}{4}[(\overline{Y}_A - \overline{Y}_0) + (\overline{Y}_{AB} - \overline{Y}_B) + (\overline{Y}_{AC} - \overline{Y}_C) + (\overline{Y}_{ABC} - \overline{Y}_{BC})], \tag{6}$$

for treatment A,

$$\beta_{AB} = \tfrac{1}{2}\{[(\overline{Y}_A - \overline{Y}_0) - (\overline{Y}_{AB} - \overline{Y}_B)] + [(\overline{Y}_{AC} - \overline{Y}_C) - (\overline{Y}_{ABC} - \overline{Y}_{BC})]\}, \tag{7}$$

for the AB interaction, and

$$\beta_{ABC} = [(\overline{Y}_A - \overline{Y}_0) - (\overline{Y}_{AB} - \overline{Y}_B) - (\overline{Y}_{AC} - \overline{Y}_C) - (\overline{Y}_{ABC} - \overline{Y}_{BC})] \tag{8}$$

for the ABC interaction.

When certain interactions are present, we may require an alternative estimator for β_A or β_{BA} (or for other effects). Suppose that there is evidence of an ABC interaction. Then, instead of β_A, one possible estimator of the main effect of A is

$$\beta'_A = \tfrac{1}{2}[(\overline{Y}_A - \overline{Y}_0) + (\overline{Y}_{AB} - \overline{Y}_B)],$$

which does not use β_{ABC}. Other estimators of the main effect of A are possible. Similarly, the AB interaction could be tested by

$$\beta'_{AB} = (\overline{Y}_A - \overline{Y}_0) - (\overline{Y}_{AB} - \overline{Y}_B),$$

for the same reason. Thus, when treatment interactions are present, we must modify our estimates of main effects and lower order interactions, losing some efficiency.

Scale of Measurement

In the examples just given, the treatment effects and interactions have been assumed to exist on an additive scale. This is reflected in the use of sums and differences in the formulas for estimation. Other scales of measurement may be useful. As an example, consider the response data in Table 4, where the effect of Treatment A is to increase the baseline response by 10 units. The same is true of B and there is no interaction between the treatments on this scale because the joint effect of A and B is to increase the response by 20 units.

In contrast, in Table 5 are shown data in which the effects of both treatments are to multiply the baseline response by 3.0. Hence, the combined effect of A and B is a nine fold increase which is greater than the joint treatment effect for the additive case. If the analysis model were **multiplicative**, then Table 4 would show an interaction, whereas if the analysis model were additive, then Table 5 would show an interaction. Thus, to discuss interactions, we must establish the scale of measurement.

Main Effects and Interactions

In the presence of an interaction in the 2×2 design, one cannot speak simply about an overall, or main,

Table 4 Response data from a factorial trial showing no interaction on an additive scale

	B	
A	No	Yes
No	5	15
Yes	15	25

Table 5 Response data from a factorial trial showing no interaction on a multiplicative scale

	B	
A	No	Yes
No	5	15
Yes	15	45

effect of either treatment. This is because the effect of A is different depending on the presence or absence of B. In the presence of a small interaction, where all patients benefit from A regardless of the use of B, we might observe that the magnitude of the "overall" effect of A is of some size and that therapeutic decisions are unaffected by the presence of an interaction. This is called "quantitative" interaction, so-named because it does not affect the direction of the treatment effect. For large quantitative interactions, it may not be sensible to talk about overall effects.

In contrast, if the presence of B reverses the effect of A, then the interaction is "qualitative", and treatment decisions may need to be modified. Here, we cannot talk about an overall effect of A, because it could be positive in the presence of B, negative in the absence of B, and could yield an average effect near zero (*see* **Interaction in Factorial Experiments**; **Treatment-covariate Interaction**).

Analysis

Motivation for the estimators given above can be obtained using **general linear models**. There has been little theoretic work on analyses using other models. One exception is the work by Slud [27] describing approaches to factorial trials with survival outcomes (*see* **Survival Analysis, Overview**). Suppose we have conducted a 2×2 factorial experiment with group sizes given by Table 1. We can estimate the AB interaction effect using the linear model

$$\mathrm{E}\{Y\} = \beta_0 + \beta_A X_A + \beta_B X_B + \beta_{AB} X_A X_B, \quad (9)$$

where the Xs are indicator variables for the treatment groups and β_{AB} is the interaction effect. The design matrix has dimension $4n \times 4$ and is

$$\mathbf{X}' = \begin{bmatrix} 1 & \dots & 1 & \dots & 1 & \dots & 1 & \dots \\ 0 & \dots & 1 & \dots & 0 & \dots & 1 & \dots \\ 0 & \dots & 0 & \dots & 1 & \dots & 1 & \dots \\ 0 & \dots & 0 & \dots & 0 & \dots & 1 & \dots \end{bmatrix},$$

where there are four blocks of n identical rows representing each treatment group and the columns represent effects for the intercept, treatment A, treatment B, and both treatments, respectively. The vector of responses has dimension $4n \times 1$ and is

$$\mathbf{Y}' = \{Y_{01}, \dots, Y_{A1}, \dots, Y_{B1}, \dots, Y_{AB1}, \dots\}.$$

The ordinary least squares solution for the model (9) is

$$\hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}.$$

The **covariance matrix** is $(\mathbf{X}'\mathbf{X})^{-1}\sigma^2$, where the variance of each observation is σ^2.

We have

$$\mathbf{X}'\mathbf{X} = n \times \begin{bmatrix} 4 & 2 & 2 & 1 \\ 2 & 2 & 1 & 1 \\ 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 1 \end{bmatrix},$$

$$(\mathbf{X}'\mathbf{X})^{-1} = \frac{1}{n} \times \begin{bmatrix} 1 & -1 & -1 & 1 \\ -1 & 2 & 1 & -2 \\ -1 & 1 & 2 & -2 \\ 1 & -2 & -2 & 4 \end{bmatrix},$$

and

$$\mathbf{X}'\mathbf{Y} = n \times \begin{bmatrix} \overline{Y}_0 + \overline{Y}_A + \overline{Y}_B + \overline{Y}_{AB} \\ \overline{Y}_A + \overline{Y}_{AB} \\ \overline{Y}_B + \overline{Y}_{AB} \\ \overline{Y}_{AB} \end{bmatrix},$$

where $\overline{Y}_i$ denotes the average response in the ith group. Then,

$$\hat{\boldsymbol{\beta}} = \begin{bmatrix} \overline{Y}_0 \\ -\overline{Y}_0 + \overline{Y}_A \\ -\overline{Y}_0 + \overline{Y}_B \\ \overline{Y}_0 - \overline{Y}_A - \overline{Y}_B + \overline{Y}_{AB} \end{bmatrix}, \quad (10)$$

which corresponds to the estimators given above in (3)–(5). However, if we assume no interaction, then the β_{AB} effect is removed from the model, and we obtain the estimator

$$\hat{\boldsymbol{\beta}}^* = \begin{bmatrix} \frac{3}{4}\overline{Y}_0 + \frac{1}{4}\overline{Y}_A + \frac{1}{4}\overline{Y}_B - \frac{1}{4}\overline{Y}_{AB} \\ -\frac{1}{2}\overline{Y}_0 + \frac{1}{2}\overline{Y}_A - \frac{1}{2}\overline{Y}_B + \frac{1}{2}\overline{Y}_{AB} \\ -\frac{1}{2}\overline{Y}_0 - \frac{1}{2}\overline{Y}_A + \frac{1}{2}\overline{Y}_B + \frac{1}{2}\overline{Y}_{AB} \end{bmatrix}.$$

The main effects for A and B are as given above in (1) and (2).

The covariance matrices for these estimators are

$$\widehat{\mathrm{cov}}\{\hat{\boldsymbol{\beta}}\} = \frac{\sigma^2}{n} \times \begin{bmatrix} 1 & -1 & -1 & 1 \\ -1 & 2 & 1 & -2 \\ -1 & 1 & 2 & -2 \\ 1 & -2 & -2 & 4 \end{bmatrix}$$

and

$$\widehat{\mathrm{cov}}\{\hat{\boldsymbol{\beta}}^*\} = \frac{\sigma^2}{n} \times \begin{bmatrix} \frac{3}{4} & -\frac{1}{2} & -\frac{1}{2} \\ -\frac{1}{2} & 1 & 0 \\ -\frac{1}{2} & 0 & 1 \end{bmatrix}.$$

In the absence of an interaction, the main effects of A and B are estimated independently and with higher precision than when an interaction is present. The interaction effect is relatively imprecisely estimated, indicating that larger sample sizes are required to have a high power to detect such effects.

Examples

Several clinical trials conducted in recent years have used factorial designs. A sample of such studies is shown in Table 6. One important study using a 2×2 factorial design is the Physicians' Health Study [16, 30]. This trial has been conducted, in 22 000 physicians in the US and was designed to test the effects of (i) aspirin on reducing cardiovascular mortality and (ii) β-carotene on reducing cancer incidence. The trial is noteworthy in several ways, including its test of two interventions in unrelated diseases, use of physicians as subjects to report outcomes reliably, relatively low cost, and an all-male (high risk) study population. This last characteristic has led to some unwarranted criticism.

In January 1988 the aspirin component of the Physicians' Health Study was discontinued, because evidence demonstrated convincingly that it was associated with lower rates of myocardial infarction [20]. The question concerning the effect of β-carotene on cancer remains open and will be addressed by continuation of the trial. In the likely absence of an interaction between aspirin and β-carotene, the second major question of the trial will be unaffected by the closure of the aspirin component.

Another noteworthy example of a 2×2 factorial design is the α-tocopherol β-carotene Lung Cancer Prevention Trial conducted in 29 133 male smokers in Finland between 1987 and 1994 [3, 15]. In this study, lung cancer incidence is the sole outcome. It was thought possible that lung cancer incidence could be reduced by either or both interventions. When the intervention was completed in 1994, there were 876 new cases of lung cancer in the study population during the trial. Alpha-tocopherol was not associated with a reduction in the **risk** of cancer. Surprisingly, β-carotene was associated with a statistically significantly *increased* incidence of lung cancer [4]. There was no evidence of a treatment interaction. The unexpected findings of this study have been supported by the recent results of another large trial of carotene and retinol [32].

The Fourth International Study of Infarct Survival (ISIS-4) was a $2 \times 2 \times 2$ factorial trial assessing the efficacy of oral captopril, oral mononitrate, and intravenous magnesium sulfate in 58 050 patients with suspected myocardial infarction [12, 17]. No significant interactions among the treatments were observed and each main effect comparison was based

on approximately 29 000 treated vs. 29 000 control patients. Captopril was associated with a small but statistically significant reduction in five-week mortality. The difference in mortality was 7.19% vs. 7.69% (143 events out of 4319), illustrating the ability of large studies to detect potentially important treatment effects even when they are small in relative magnitude. Mononitrate and magnesium therapy did not significantly reduce five-week mortality.

Similar Designs

Fractional and Partial Factorial Designs

Fractional factorial designs are those which omit certain treatment groups by design. A careful analysis of the objectives of an experiment, its efficiency, and the effects that it can estimate may justify not using some groups. Because many cells contribute to the estimate of any effect, a design may achieve its intended purpose without some of the cells.

In the 2×2 design, all treatment groups must be present to permit estimating the interaction between A and B. However, for higher order designs, if some interactions are thought biologically not to exist, omitting certain treatment combinations from the design will still permit estimates of other effects of interest. For example, in the $2 \times 2 \times 2$ design, if the interaction between A, B, and C is thought not to exist, omitting that treatment cell from the design will still permit estimation of all the main effects. The efficiency will be somewhat reduced, however. Similarly, the two-way interactions can still be estimated without $\overline{Y}_{ABC}$. This can be verified from the formulas above.

More generally, fractional high-order designs will produce a situation termed "aliasing", in which the estimates of certain effects are algebraically identical to completely different effects. If both effects are biologically possible, the design will not be able to reveal which effect is being estimated. Naturally, this is undesirable unless additional information is available to the investigator to indicate that some aliased effects are zero. This can be used to advantage in improving efficiency and one must be careful in deciding which cells to exclude. See Cox [8] or Mason & Gunst [21] for a discussion of this topic.

The Women's Health Initiative clinical trial is a $2 \times 2 \times 2$ partial factorial design studying the effects of hormone replacement, dietary fat reduction, and calcium and vitamin D on coronary disease, breast cancer, and osteoporosis [2]. All eight combinations of treatments are given, but participants may opt to join one, two, or all three of the randomized components. The study is expected to accrue over 64 000 patients and is projected to finish in the year 2007. The dietary component of the study will randomize 48 000 women using a 3:2 allocation ratio in favor of the control arm and nine years of follow-up. Such a large and complex trial presents logistical difficulties, questions about adherence, and sensitivity of the intended power to assumptions that can only roughly be validated.

Incomplete Factorial Designs

When treatment groups are dropped out of factorial designs without yielding a fractional replication, the resulting trials have been termed "incomplete factorial designs" [7]. In incomplete designs, cells are not missing by design intent, but because some treatment combinations may be infeasible. For example, in a 2×2 design, it may not be ethically possible to use a placebo group. In this case, one would not be able to estimate the AB interaction. In other circumstances, unwanted aliasing may occur, or the efficiency of the design to estimate main effects may be greatly reduced. In some cases, estimators of treatment and interaction effects are biased, but there may be reasons to use a design that retains as much of the factorial structure as possible. For example, they may be the only way in which to estimate certain interactions.

STEVEN PIANTADOSI

Factorial Experiments

Experimental designs in which the treatments can be classified by the levels of two or more factors are called factorial experiments. For example, consider a study conducted to compare the effectiveness of four *treatments* in the reduction of blood cholesterol. The treatments were: diet with a palm oil supplement, diet with a rice-bran oil supplement, diet with both the supplements, and diet with neither supplement. The four treatments could be grouped into two *factors*, namely, palm oil (factor A) and rice-bran oil (factor B) each having two *levels*, namely the presence or absence of the respective diet supplement. The various combinations of the factor levels comprise the four treatments.

In the factorial experiment the treatments are randomly assigned to the study subjects (*see* **Randomized Treatment Assignment**) and an *outcome* variable (*see* **Outcome Measures in Clinical Trials**), say the reduction in cholesterol after 8 weeks, is observed. Table 1 presents hypothetical data on the reduction in cholesterol from the experiment. In this example each treatment was *replicated* on two individuals (*experimental units*). The number of replicates on each treatment need not be the same. If the number of replicates is the same for all the treatments, then the experiment is called a *balanced* experiment; if not, then the experiment is called an *unbalanced* experiment.

The design of factorial experiment described here is known as a 2×2 or a 2^2 factorial design. Factorial experiments could have several factors and the number of levels for the factors could vary. For instance, in the cholesterol reduction example, if we include exercise as another factor (factor C) at two levels (whether or not an individual is prescribed an exercises regimen), then the experiment would be 2^3 factorial. That is, it is a factorial experiment with three factors where each factor has two levels. In general, a factorial experiment that has k factors, each having two levels, is called a 2^k factorial design. An example of a more general factorial design would be a $4 \times 5 \times 3$ design that has three factors, where the first factor has four levels, the second has five levels and the third has three levels. The number of experimental units (or *runs*) needed for this design would be $4 \times 5 \times 3 = 60$ per replicate for a balanced design.

Table 1 Hypothetical data from a 2×2 factorial experiment on cholesterol reduction

Factor A: palm oil	Factor B: rice-bran oil	
	Present	Absent
Present	25	11
	20	13
	Mean = 22.5	Mean = 12
Absent	18	−5
	23	4
	Mean = 20.5	Mean = −0.5

Analysis of Factorial Experiments

The purpose of a factorial experiment is to examine whether the factors have significant *effects* on the outcome being measured. In the cholesterol reduction example the purpose would be to test the hypotheses (*see* **Hypothesis Testing**) that: (i) palm oil supplement has an influence on the reduction of cholesterol, and (ii) rice-bran oil supplement has an influence on the reduction of cholesterol. To test these hypotheses, estimates of the effects of each supplement, called the *main* effects, are calculated.

The main effect for palm oil, for example, would be the average of the difference between the two levels of palm oil at each level of the rice-bran oil. That is,

$$\frac{(22.5 - 20.5) + (12.0 - (-0.5))}{2} = 7.25.$$

Similarly, the main effect for the rice-bran oil is

$$\frac{(22.5 - 12) + (20.5 - (-0.5))}{2} = 15.25.$$

These estimates are interpreted as follows: the palm oil supplement, on average, will reduce cholesterol by 7.25 units, while the rice-bran oil will reduce it by 15.25 units. However, notice that the effect of palm oil is much higher $[12 - (-0.5) = 12.5]$ when the rice-bran oil is absent than when it is present (2.0). Viewed in another way, the effect of rice-bran oil is much higher (21.0) when the palm oil is absent than when it is present (10.5). This differential effect could be shown by a plot of the cell means, as shown in Figure 1.

Notice that the line corresponding to the case where the rice-bran oil is present is not parallel

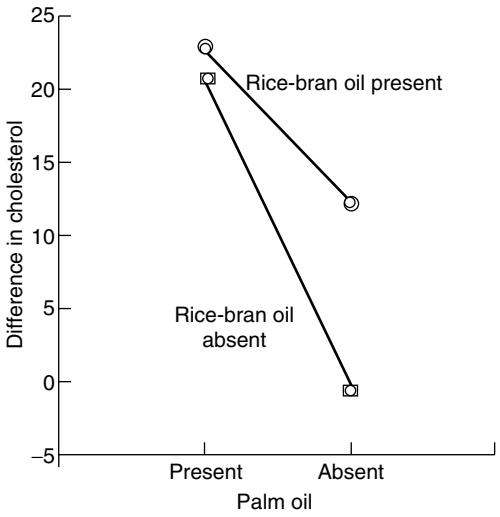

Figure 1 Interaction between the supplements

to the line corresponding to the case where rice-bran oil is absent. This differential effect is called an *interaction* between the factors A and B (*see* **Interaction in Factorial Experiments**). When the interaction effect is statistically significant the main effects are not *additive*, and hence it is not meaningful to interpret them. In that situation the effect of each factor should be interpreted at each level of the other factor. The interaction effect between any two factors is measured by the difference between the average effects of one factor at the two levels of the other factor. For the cholesterol reduction example the interaction effect between palm oil and rice-bran oil is estimated as

$$\frac{(22.5 - 12) - (20.5 - (-0.5))}{2} = 5.25.$$

To test formally whether the effects in a 2^k factorial experiment are statistically significant, an estimate of the **standard deviation** of the effects is needed. Since there are two replicate measurements at each treatment combination, an estimate of the standard deviation could be obtained in this situation. Assuming the **variances** of the four treatments to be equal, an estimate of the variance could be obtained by pooling the variances of each run. Since there are only two replicates in the cholesterol example, the variances for each run could be computed by the square of the difference between the observations divided by 2. Thus the estimate of the pooled standard deviation is

$$s = \left[\frac{(25-20)^2 + (11-13)^2 + (18-23)^2 + (-5-4)^2}{2 \times 4} \right]^{1/2} = 4.12.$$

The **degrees of freedom** for the pooled standard deviation equal the number of runs. Then, assuming the reduction in cholesterol is **normally distributed**, for any given effect, the statistic

$$F = \frac{\text{effect}^2}{s^2/4},$$

which follows an $\boldsymbol{F_{1,4}}$ **distribution** can be used to test the hypothesis that the effect is zero. Thus an **analysis of variance** (ANOVA) table for the example could be constructed (Table 2). The observed F values in the table should be compared with the $F_{1,4}$ distribution to obtain the $\boldsymbol{P}$ **values**.

The **estimation** of the effects in higher-order factorial designs is performed employing similar concepts. Several **algorithms** for facilitating calculations are available (*see* **Yates's Algorithm**). A widely used algorithm that uses **contrasts** is described here. Consider a 2^3 factorial design. Suppose the levels of the factors are denoted by a + (present, high, etc.) or a − (absent, low, etc.) and let y denote the outcome. Then, a table of contrast coefficients is constructed (Table 3).

The first three columns in Table 3 simply represent the treatment combination for the eight runs. For example, if exercise is included as the third factor C in the cholesterol reduction experiment, the combination −,−,− corresponding to the A, B, and C columns, would represent the run in which both palm oil and rice-bran oil supplements were absent in the data and the subject did not exercise. Then the signs in the AB column are obtained by multiplying the A

Table 2 ANOVA for the experiment on cholesterol reduction

Effect	Sum of squares	df	Mean sum of squares	F
Main A	52.56	1	52.56	12.40
Main B	232.56	1	232.56	54.85
Interaction	33.06	1	33.06	7.80
Error	16.97	4	4.24	
Total	45.22	7		

Table 3 Contrast table for calculating effects in a 2^3 factorial design

A	B	C	AB	AC	BC	ABC	Mean	Observation
−	−	−	+	+	+	−	+	y_1
+	−	−	−	−	+	+	+	y_2
−	+	−	−	+	−	+	+	y_3
+	+	−	+	−	−	−	+	y_4
−	−	+	+	−	−	+	+	y_5
+	−	+	−	+	−	−	+	y_6
−	+	+	−	−	+	−	+	y_7
+	+	+	+	+	+	+	+	y_8

column by the B column (and defining $- \times - = +$ and $- \times + = -$) and the AC column is obtained by multiplying the A column by C column, and so on. *The effects are then obtained by summing the observations with the respective signs attached and dividing by 4. (The divisor for the mean column however is 8.)* Thus, for instance the effect for the BC interaction will be estimated by

$$\frac{(y_1 + y_2 - y_3 - y_4 - y_5 - y_6 + y_7 + y_8)}{4}.$$

The same method could be extended to higher-order factorial designs by filling the first k columns by the 2^k treatment combinations and then by multiplying the appropriate columns for interactions. The divisor for each effect in a 2^k factorial design is 2^{k-1}.

Since one of the main advantages of factorial design, especially when there are a large number of factors, is that it is inexpensive, it is primarily employed for conducting pilot studies. Therefore, adequate replicate measurements are seldom available to estimate the **standard error** of the effects with reasonable **power**. Consequently, formal testing of the effects using F tests as described above becomes infeasible without making additional assumptions. For instance, if the higher-order interactions could be assumed to be zero, the corresponding effects could be treated as random variability. Then, using this as an estimate of the variance, formal F tests as above could be obtained. An alternative method for identifying the significant effects is performed using normal probability plots.

Under the assumption that the observations are normally distributed with equal variance, the effects, being linear combinations of the observations, would also be normally distributed with mean zero (under the **null hypotheses**) and equal variance. Therefore, a normal probability plot of the effects should fall on a straight line that has a slope of 1 and passes through the origin. The effects that fall away from this line could then be deemed important.

An example of a normal probability plot for the 15 effects from a 2^4 factorial design is presented in Figure 2. Since in Figure 2 the main effects of A, B, and D, and the interaction between B and D, do fall relatively farther than the other effects from the straight line passing through the origin, they are deemed important.

Fractional Factorial

When the number of factors in a factorial design is large, the number of runs needed may be too large to perform within a reasonable time or with available resources. In such situations a **fractional factorial** design is utilized. In this design, a fraction of the 2^k runs is selected systematically so that all the main effects can be estimated, while compromising some higher-order interactions.

Blocking and Confounding in Factorial Designs

In all factorial experiments, it is desirable to perform the various runs on homogeneous subjects.

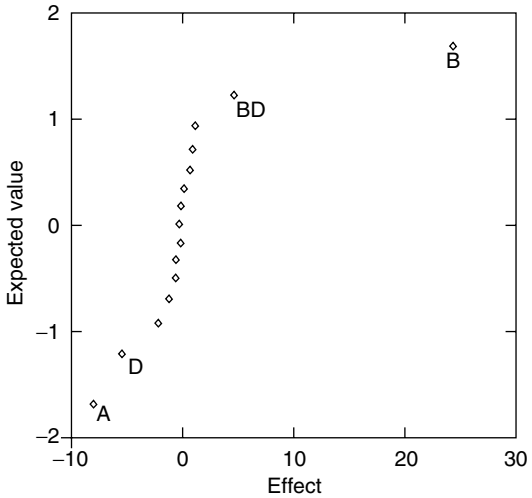

Figure 2 Normal probability plot for a 2^4 factorial experiment. Reproduced from Box et al. [2], Figure 10.9(a), p. 332, by permission of John Wiley & Sons

However, in some experiments the number of homogeneous runs that can be performed together may be restricted. In these circumstances the number of runs is often split into smaller equal-sized homogeneous groups. This procedure is called **blocking**. Suppose in the 2^3 factorial design for the cholesterol reduction experiment (including exercise as factor C) only eight individuals were available, of which four are males and four are females. Considering that the males and females may respond to diet and exercise differently, the eight runs randomly assigned could not be assumed to come from homogeneous individuals. Therefore blocking, in this case by gender, is necessary.

Blocking poses a peculiar problem. How to split the eight runs into four for males and four for females? If four of the runs that include the palm oil supplement are all given to the males and the other four that do not are given to the females, it would be impossible to distinguish the effect of palm oil supplement from the effect of gender. Therefore, the choice of the effects has to be made judiciously. Whichever way the block assignments are made, one of the effects will be indistinguishable from the effect of gender. This phenomenon is called **confounding**. In other words, the block (or gender) effect is confounded with the main effect due to palm oil.

The highest-order interaction is often the choice for confounding where blocks are used. In the cholesterol example the ABC interaction would be the best choice. In other words, assign the runs to the blocks according to the ABC column in Table 3. Therefore, the males will get the first, fourth, sixth, and seventh runs, while the females will get the second, third, fifth, and eighth runs. When more than two blocks are required, more than one effect will be confounded with the block effect. The blocking scheme for these situations is much more complex. The book by Box et al. [2] describes different schemes for constructing the blocks and also provides tables that suggest blocking assignments.

ANOVA for General Factorial Experiments

Typical steps in the analysis of a general factorial (or a multifactor) experiment include: (i) formulating a model; (ii) estimating the effects; (iii) testing the effects; and (iv) model **diagnostics**. For an $a \times b$ two-factor experiment the model could be written

$$\begin{aligned}\text{outcome} = {} & \text{overall average} + \text{effect due to factor A} \\ & + \text{effect due to factor B} \\ & + \text{effect due to AB interaction} \\ & + \text{random error.}\end{aligned}$$

In mathematical notation the model is written

$$Y_{ijk} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + \varepsilon_{ijk},$$

where Y_{ijk} is the observation corresponding to the kth individual receiving the ith level of factor A and the jth level of factor B. The parameter μ corresponds to the overall **mean** and the parameters α_i, β_j, and $(\alpha\beta)_{ij}$ correspond to the main effects of A and B and the interaction effect, respectively. The last term in the model, ε_{ij}, represents the **random error**. The assumptions of the model are that the errors are independent and identically distributed as normal with mean zero and equal variance and the effects summed over the respective levels of each factor add up to zero (*see* **Additive Model**).

The estimates of the parameters are obtained by a **least squares** method that minimizes the sum of the squared errors. This method of estimation requires the equality of the error variance but the normality is not required. However, under normality, the least square estimates coincide with the **maximum likelihood** estimates.

The distribution of the estimates of the various parameters, under the assumption of normality of errors, can be shown to be normal as well and hence, using appropriate quadratic forms, F tests for testing the hypothesis on each effect can be derived. In the case of a balanced design the F tests can be derived as ratios of the respective mean sums of square deviations.

As in all statistical methods, the assumptions of the model must be verified by appropriate diagnostic methods. In the factorial model, the assumptions of normality, equal variance, and independence must be checked. A normal probability plot of the residuals and scatter plots of the residuals vs. specific variables are useful for diagnostics. Books by Cook & Weisberg [3] or Box & Draper [1] are wonderful sources for a more complete understanding of this topic.

Most computer packages carry the procedures that can perform the analyses of factorial experiments.

The SAS package [6] has PROC ANOVA for balanced design and PROC GLM and PROC MIXED for complex factorials that may have unbalanced or missing data. SPSS [7] and MINITAB [5] can also perform these analysis (*see* **Software, Biostatistical**).

An Historical Note on Factorial Experiments

The father of statistics is also the father of the factorial experiment. The term "factorial experiment" itself was coined by **Fisher** [4]. Prior to his introduction of the term these experiments were exclusively known as "complex experiments". **Yates** continued to use the term complex experiments during the earlier years of his work on this topic, but later he also referred to them as factorial experiments. Factorial experiments were primarily used for agricultural experiments. According to Yates [8] the use of factorial experiments (complex experiments) dates back to 1843.

The major extensions and developments of Fisher's presentations of the concepts on factorial experiments were bestowed to the field of statistics by Yates. Other major contributors to the field include **Cochran**, Finney, Kempthorne, Rao, and **Snedecor**.

False Negative Rate

The false negative rate of a **diagnostic** or **screening** test is conventionally taken to be the probability that a true case of disease is given an incorrect, negative result; in other words, the false negative rate is Pr(negative test result | disease). In the table in the article **Sensitivity**, the false negative rate is $c/(a+c)$. The false negative rate is the complement of sensitivity, which is $a/(a+c)$.

As has been pointed out [1, 2], the name implies some ambiguity about the appropriate denominator for the false negative rate. The definition given here uses as denominator the number of true disease cases, $a+c$. Elsewhere, one may encounter this rate based on a denominator $c+d$, i.e. the total number of negative tests.

STEPHEN D. WALTER

False Positive Rate

The false positive rate of a **diagnostic** or **screening** test is conventionally taken to be the probability that a noncase of disease is given an incorrect, positive result, or Pr(positive test result | no disease). In the table in the article on **Sensitivity**, the false positive rate is $b/(b+d)$. Its complement, $d/(b+d)$, is known as the **specificity** of the test.

As with the definition of **false negative rate**, there is some ambiguity about the appropriate denominator. The definition invoked here uses as denominator for the false positive rate the number of true noncases of disease, $b+d$. Elsewhere, one may encounter this rate based on a denominator $a+b$, i.e. the total number of positive tests.

Familial Correlations

In a lecture at the Royal Institution on February 9, 1877, **Francis Galton** [13] described reversion as "the tendency of the ideal mean filial type to depart from the parental type, reverting to what may be roughly and perhaps fairly described as the average ancestral type". Having found it difficult to obtain human data for two generations, Galton reported the analysis of data from carefully selected sweet pea seeds. Galton introduced the first letter of the word "reversion" as a symbol for representing a numerical measure of what he [14] later termed **regression**. Galton had in essence defined the interclass **correlation** coefficient. With the assistance of Hamilton Dickson of Cambridge University, in 1886 Galton [15] reported the discovery of the **bivariate normal distribution** in which the correlation coefficient is expressed as a parameter. In this study of family likeness in stature, he set about the calculation of coefficients of correlation among various pairs of relatives: parent and offspring, brothers, fathers and sons, uncles and nephews, grandparents and grandsons. In considering the correlations among brothers, Galton [15] had in essence defined the intraclass correlation coefficient as the simple correlation over all possible pairs of brothers. The term *co-relation* or *correlation* does not appear until 1889, when Galton [15] defined it in the context of heredity to describe the degree of likeness among family members or so-called *relations*. Galton [16] used the term "partial co-relation" in the path towards the development of the multiple correlation coefficient.

In the process of defining and providing estimates of familial correlations, Galton formulated regression analysis and the **multivariate normal distribution** – two major elements not just of quantitative genetics but also of mathematical statistics.

In 1896, **Karl Pearson** [26] proposed the well-known product-moment estimators of the intraclass and interclass correlation coefficients by replacing the median and probable error (or interquartile range) by the mean and standard deviation, respectively, in Galton's estimators – which incidentally are more robust.

Similarly, Pearson [26] proposed the product-moment estimator of the parent–offspring interclass correlation coefficient as the simple correlation coefficient computed in a sample of k families over all possible pairs of observations in the ith family formed from the parent's value y_i and the offspring's values $(x_{i1}, x_{i2}, \ldots, x_{in_i})$:

$$r_{\mathrm{ms}} = \frac{\sum_{i=1}^{k}(y_i - \overline{y}_n)\sum_{j=1}^{n_i}(x_{ij} - \overline{x}_n)}{\left[\sum_{i=1}^{k} n_i (y_i - \overline{y}_n)^2\right]^{1/2}\left[\sum_{i=1}^{k}\sum_{j=1}^{n_i}(x_{ij} - \overline{x}_n)^2\right]^{1/2}}, \tag{1}$$

where the sample means $\overline{y}_n = (n_1 y_1 + n_2 y_2 + \cdots + n_k y_k)/N$ and $\overline{x}_n = (n_1 \overline{x}_1 + n_2 \overline{x}_2 + \cdots + n_k \overline{x}_k)/N$ for $N = n_1 + n_2 + \cdots + n_k$ and $\overline{x}_i = (x_{i1} + x_{i2} + \cdots + x_{in_i})/n_i$.

Without explicitly stating the formula, Pearson [26] proposed the product-moment estimator of the sibling intraclass correlation coefficient as the simple correlation coefficient computed in a sample of k families over all possible pairs of observations on siblings in each family:

$$r_p = \frac{\sum_{i=1}^{k}\sum_{\substack{j=1 \\ m=1 \\ j\neq m}}^{k}(x_{ij} - \overline{x}_p)(x_{im} - \overline{x}_p)}{\sum_{i=1}^{k}(n_i - 1)\sum_{j=1}^{n_i}(x_{ij} - \overline{x}_p)^2}, \tag{2}$$

where $\overline{x}_{\mathrm{p}} = \sum_{i=1}^{k} n_i (n_i - 1)\,\overline{x}_i / \sum_{i=1}^{k} n_i (n_i - 1)$. Some researchers substitute $\overline{x}_n$ for $\overline{x}_p$ in the above definition for consistency with the previous definition for the pairwise estimator of the interclass correlation – see Konishi [22].

In 1913, Harris [17] simplified the laborious hand calculation of the product-moment estimator r_{p} of the intraclass correlation by considering in the balanced case a decomposition of the pairwise sum of squares which avoids the computation of the cross product in the numerator. This decomposition in the unbalanced case produces

$$r_{\mathrm{p}} = \frac{\sum_{i=1}^{k} n_i (n_i - 1)(\overline{x}_i - \overline{x}_{\mathrm{p}})^2 - \sum_{i=1}^{k}\sum_{j=1}^{n_i}(x_{ij} - \overline{x}_i)^2}{\sum_{i=1}^{k}(n_i - 1)\sum_{j=1}^{n_i}(x_{ij} - \overline{x}_{\mathrm{p}})^2}. \tag{3}$$

In 1915, Fisher [9] derived the **sampling distribution** of the simple (interclass) correlation coefficient and developed the z-transformation as a variance stabilizing **transformation** (*see* **Delta Method**).

In 1918, Fisher [10] studied the impact of dominance, epistasis (*see* **Genotype**), **linkage**, and **assortative mating** on familial correlations under Mendelian inheritance (*see* **Mendel's Laws**) and introduced a new method: the **analysis of variance**. Yet again, a third major element of quantitative genetics and also of mathematical statistics is formulated in the context of familial correlations. Fisher [10] is noted for both laying the foundations of biometrical genetics and reconciling this theory with Mendelian genetics.

In 1921, Fisher [11] derived the exact sampling distribution of the product-moment estimator of the intraclass correlation for the balanced case under normality and developed the z-transformation for this estimator. He also showed that the range of values of the intraclass correlation is given by $[-1/(n-1), 1)$ for families of size n, in contrast to the range of $(-1, 1)$ for the simple correlation coefficient. Fisher [12] later argued that "there is probably nothing in the production of a leaf or a child which necessitates that the number in such a family should be less than any number however great, and in the absence of such a necessary restriction we cannot expect to find negative correlations within such families". This restriction has been accepted by some researchers who have adopted estimators of the intraclass correlation that are truncated at zero. But Fisher [12] also noted in his example of card games that where the number of suits is limited to four, the correlation between the number of cards in different suits in the same hand may have negative values down to $-1/3$, and so some researchers do not use truncated estimators.

In 1925, Fisher [12] proposed an estimator of the intraclass correlation based on a ratio of variance components from the one-way analysis of variance (ANOVA) in the balanced case under the assumption of normality. In so doing, Fisher [12] broadened the scope of application of the intraclass correlation which led to its application in **sensitivity analysis** in the design of experiments, intracluster variation in sample surveys and reliability theory in psychology. From Fisher [12], the statistical model for the jth member (or sibling) of the ith group (or family) is

$$x_{ij} = \mu + a_i + e_{ij},$$

where μ is the mean of the observations in the population, the group effects $\{a_i\}$ are normal and identically distributed with mean 0 and variance σ_a^2, the random errors $\{e_{ij}\}$ are normal and identically distributed with mean 0 and variance σ_e^2, and the $\{a_i\}$ and $\{e_{ij}\}$ are independent. The intraclass correlation coefficient parameter is defined to be $\rho_s = \sigma_a^2/(\sigma_a^2 + \sigma_e^2)$. Furthermore, under Fisher's model [12], it can be shown that $\mathrm{corr}(x_{ij}, x_{ik}) = \rho_s$ for $j \neq k$.

Without explicitly stating the formula, Fisher [12] defined the ANOVA estimator of the intraclass correlation coefficient in the balanced case to be

$$\tilde{\rho}_s = \frac{MSB - MSW}{MSB + (k-1)MSW}, \tag{4}$$

where the mean sum of squares between families is $MSB = \sum_i^k n(\overline{x}_i - \overline{x}_n)^2/(k-1)$ and the mean sum of squares within families is $MSW = \sum_i^k \sum_j^n (x_{ij} - \overline{x}_i)^2/(N-k)$. Note the minimum value that Fisher's ANOVA estimator $\tilde{\rho}_s$ can attain is $-1/(k-1)$, as is the case for Pearson's product-moment estimator r_{p}, which is at odds with the definition of the parameter ρ which takes values on the interval [0, 1). So some researchers use a version of $\tilde{\rho}_s$ truncated at zero.

Fisher [12] commented in comparison that Pearson's product-moment estimator ought to be considered "slightly defective" in that one estimator of a component of variance (*see* **Variance Components**) implicit in the product-moment estimator is biased. The introduction by Fisher [12] of the ANOVA estimator of the intraclass correlation has had the effect of dividing researchers developing and using intraclass correlations into two factions: one faction using estimators based upon the analysis of variance; and the other faction using estimators based upon product moments, that is, those who use the ML method.

Estimation of the Intraclass Correlation Coefficient

Wald [38] and Bhargava [3] independently developed an interval estimator based on a statistic known to follow the ***F* distribution** exactly even in the unbalanced case for **normally distributed** data. By choosing

$$u_i = n_i \frac{1 - \rho_{\mathrm{s}}}{n_i - (n_i - 1)(1 - \rho_{\mathrm{s}})}$$

as a weight associated with the ith family and defining $\overline{x}_u = \sum_i u_i \overline{x}_i / \sum_i u_i$, they showed that the endpoints of a $1-\alpha$ **confidence interval** can be found by solving the nonlinear equation

$$\frac{N-k}{k-1} \frac{\sum_i w_i (\overline{x}_i - \overline{x}_u)^2}{\sum_i \sum_j (x_{ij} - \overline{x}_i)^2} = F_{\gamma,k-1,N-k} \qquad (5)$$

for values of γ equal to $1-\alpha/2$ and $\alpha/2$. By setting $\gamma = 0.5$, a median unbiased estimator of the intraclass correlation can be obtained. The point and interval estimates can be found by iterative algorithms such as the bisection method or the secant method.

Fieller & Smith [8] generalized the ANOVA estimator to the unbalanced case. Smith [30] provided a further generalization of this estimator by allowing arbitrary weights other than the number of offspring when computing the between-family sum of squares. Smith [30] also derived the asymptotic variance of this new generalized weighted ANOVA estimator. Karlin et al. [18] introduced the use of arbitrary weights in a generalization of the product-moment estimator. Eliasziw & Donner [5] provided the asymptotic variance for the generalized weighted product-moment estimator following the method of Smith [30]. These results can be summarized as follows [19]. Associate weights v_i, α_i, and β_i with the ith family. Define $\overline{x}_v = \sum_i v_i x_i / \sum_i v_i$, $SS_i = \sum_j (x_{ij} - \overline{x}_i)^2$, and the following components of variance:

$$SX_v = \sum_i v_i (\overline{x}_i - \overline{x}_v)^2,$$

$$SE_\alpha = \sum \alpha_i SS_i,$$

$$SE_\beta = \sum \beta_i SS_i.$$

Depending on the choice of weights,

$$\tilde{r}_v = \frac{SX_v - SE_\alpha}{SX_v + SE_\beta} \qquad (6)$$

can represent any one of the previously mentioned product-moment or ANOVA point estimators of the intraclass correlation coefficient. Selecting $v_i = n_i(n_i - 1)$ yields the pairwise weights implicitly conceived by Pearson [26]. Selecting $v_i = n_i$ yields the sibship- or group-size weights implicitly conceived by Fisher [11]. Selecting $v_i = 1$ yields the uniform weights explicitly conceived by Smith. Upon selecting v_i, if one sets $\alpha_i = v_i/[n_i(n_i-1)]$ and $\beta_i = v_i/n_i$, the product-moment estimators of Karlin et al. [18] are obtained. Upon selecting v_i, defining $V = \sum_i v_i$, $v_c = \sum_i (v_i - v_i^2/V)/n_i$, and $v_o = (V - \sum_i v_i^2/V)/v_c$, and setting $\alpha_i = v_c/(N-k)$ and $\beta_i = v_c(v_o - 1)/(N-k)$, the ANOVA estimators of Smith [30] are obtained.

Monte Carlo simulations [19, 20] have shown that the efficiency of $\overline{r}_v$ is a function of the parameter value, with some choices of weights being better than others given prior information about the parameter value. The pairwise weights are best for $\rho_s < 0.2$, the uniform weights for $\rho_s > 0.8$, and the group-size weights for the intermediate range. As far as the choice of product moment vs. ANOVA is concerned, the product moment is preferred for pairwise weights and the ANOVA for group-size and uniform weights.

Typically, prior information about the intraclass correlation parameter is unavailable. So following the approach of Srivastava [34] and introducing the weights w_i, κ_i, and λ_i with $W = \sum_i w_i$, $\overline{x}_w = \sum w_i \overline{x}_i / W$, $w_c = \sum_i (w_i - w_i^2/W)/n_i$, and $w_o = (W - \Sigma_i w_i^2/W)/w_c$ for a second estimator

$$\tilde{r}_w = \frac{SX_w - SE_\kappa}{SX_w + SE_\lambda}, \qquad (7)$$

a combination estimator

$$\tilde{\rho}_{vw} = \frac{\tilde{\rho}_v}{1 + \tilde{\rho}_v - \tilde{\rho}_w} \qquad (8)$$

is defined with asymptotic variance given by

$$\begin{aligned} av(\tilde{\rho}_{vw}) = {} & (1 - \tilde{\rho}_{vw})^2 av(\tilde{\rho}_v) \\ & + 2\tilde{\rho}_{vw}(1 - \tilde{\rho}_{vw}) ac(\tilde{\rho}_v, \tilde{\rho}_w) \\ & + \tilde{\rho}_{vw}^2 av(\tilde{\rho}_v). \end{aligned} \qquad (9)$$

The asymptotic variance of either $\tilde{\rho}_v$ or $\tilde{\rho}_w$ and the asymptotic variance of these two estimators can be determined from

$$\begin{aligned} ac(\tilde{r}_v, \tilde{r}_w) = \frac{2(1-\rho)^2}{\psi_v \psi_w} \Bigg\{ & D_{vw} + \sum_i (n_i - 1)\alpha_i \kappa_i \\ & + \sum_i (n_i - 1)[(\alpha_i \lambda_i + \beta_i \kappa_i)\rho + \beta_i \lambda_i \rho^2] \Bigg\}, \end{aligned} \qquad (10)$$

where

$$D_{vw} = \frac{\mathrm{cov}(SX_v, SX_w)}{2\sigma^4} = \sum_{i=1}^{k}\sum_{j=1}^{k} v_i w_j \phi_{vw}^2(i,j),$$

$$\phi_{vw}(i,j) = \delta_{ij}\tau_i - \frac{w_i}{W}\tau_i - \frac{v_j}{V}\tau_j + \sum_l \frac{v_l w_l}{VW}\tau_l,$$

$$\tau_i = \rho + \frac{1-\rho}{n_i},$$

$$\psi_v = v_c + \sum_i (n_i - 1)\beta_i + \left[(v_o - 1)v_c - \sum_i (n_i - 1)\beta_i\right]\rho,$$

$$\psi_w = w_c + \sum_i (n_i - 1)\lambda_i + \left[(w_o - 1)w_c - \sum_i (n_i - 1)\lambda_i\right]\rho$$

with $\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$ if $i \neq j$ by the approach of Smith [30]. A suitable estimator of ρ when estimating the asymptotic variance of either a product-moment or ANOVA estimator is the estimator itself, whereas a suitable estimate of ρ when estimating the asymptotic variance of the combination estimator is the combination estimator.

Choosing the pairwise weights for v_i and uniform weights for w_i in the combination estimator results in a point estimator that is nearly fully efficient, in comparison with the maximum likelihood estimator, for the full range of the intraclass correlation coefficient [20]. An appreciation of this result can be gained from the equation

$$\tilde{\rho}_{vw} = (1 - \tilde{\rho}_{vw})\tilde{\rho}_v + \tilde{\rho}_{vw}\tilde{\rho}_w,$$

which also defines the estimator $\tilde{\rho}_{vw}$. Note that $\tilde{\rho}_{vw}$ shrinks towards $\tilde{\rho}_v$ for small ρ_s and towards $\tilde{\rho}_w$ for large ρ_s. So it is reasonable to expect that $\tilde{\rho}_{vw}$ will perform well for small ρ_s if $\tilde{\rho}_v$ is efficient for small ρ_s – with a similar consideration for large ρ_s if $\tilde{\rho}_w$ is efficient for large ρ_s.

Estimation of the Parent–Offspring Interclass Correlation Coefficient

The parent–offspring interclass estimator assumes only one parent and a variable number of offspring per family.

Karlin et al. [18] developed a generalized weighted version of the pairwise product-moment estimator. Srivastava & Keen [35] developed a generalized weighted version of the ANOVA estimator given by Srivastava [33] based on the uniform weighting scheme. Srivastava & Keen also derived the asymptotic variance of the weighted ANOVA estimator. The asymptotic variance of the product-moment estimator is given by Eliasziw & Donner [5].

Using the notation above for the sibling intraclass correlation and letting y_i denote the parent's value in the ith family, the weighted product moment and a version of the weighted ANOVA estimators of the interclass correlation can be expressed as

$$\tilde{r}_{ms} = \frac{\sum_i v_i (y_i - \overline{y}_v)(\overline{x}_i - \overline{x}_v)}{\left[\sum_i v_i (y_i - \overline{y}_v)^2\right]^{1/2}} \times \frac{1}{\left[\sum_i v_i (\overline{x}_i - \overline{x}_v)^2 + \sum_i \beta_i SS_i\right]^{1/2}}, \quad (11)$$

where $\overline{y}_v = (v_1 y_1 + v_2 y_2 + \cdots + v_k y_k)/V$. Upon selecting v_i, if one sets $\beta_i = v_i/n_i$, then the product-moment estimators are obtained, or if one sets $\beta_i = v_c(v_o - 1)/(N - k)$, then versions of the ANOVA estimators are obtained.

The choices of weights that have been studied in Monte Carlo simulations [5, 35] are the sibship-size weights ($v_i = n_i$) and the uniform weights ($v_i = 1$), with the recommendation of using sibship-size weights when the sibling intraclass correlation $\rho_s < 0.3$ and uniform weights otherwise.

When the sibship-size weights are used, the resulting product-moment and ANOVA parent–offspring interclass correlation estimators have been referred to as pairwise estimators. It must be understood that the pairs are taken with respect to parent and offspring.

A number of other parent–offspring estimators have appeared in the literature. On the basis of Monte

Carlo simulations, Rosner et al. [29] did not recommend the sib-mean and random-sib mean estimators – recommending instead the pairwise and ensemble estimators. (The ensemble estimator is obtained by setting $v_i = 1$ and $\beta_i = (k-1)/(kn_i)$ in the formula for $\tilde{r}_{ms}$.) However, Srivastava & Keen [35] established theoretically, under normality for the uniform ANOVA estimator $\tilde{\rho}_{ms,u}$ and the ensemble estimator $\tilde{\rho}_{ms,e}$, that $av(\tilde{\rho}_{ms,u}) \leq av(\tilde{\rho}_{ms,e})$. In Monte Carlo comparisons of the asymptotic variance formulas for $\tilde{\rho}_{ms,u}$ and $\tilde{\rho}_{ms,e}$, Eliasziw & Donner [5] reached the same conclusion.

The exact sampling distribution of the uniform ANOVA estimator of the interclass correlation is given by Velu & Rao [37].

In parallel with the intraclass correlation, Eliasziw & Donner [6] showed for the interclass correlation that the pairwise product-moment estimator has a smaller asymptotic variance than the pairwise ANOVA estimator.

Maximum Likelihood Estimation of Familial Correlations

Elston [7] derived expressions for the **maximum likelihood** estimators of correlations in nuclear families for the balanced case, together with expressions for the asymptotic variances of these estimators. From this flows the justification of the pairwise estimators of sibling and parent–offspring correlations in the general unbalanced situation, reducing to the maximum likelihood estimators in the balanced case.

In the unbalanced case, closed-form expressions are not available for correlations in nuclear families and it is necessary to resort to iterative numerical algorithms [2, 27, 28, 31, 32, 36, 39] to find these estimates. Nevertheless, closed-form expressions are available for the asymptotic covariances of all parameters (including sibling intraclass correlation) in data consisting of siblings only [4] and for all parameters (including brother intraclass correlation, sister intraclass correlation and brother–sister interclass correlation) in data consisting of brother and sisters only [21]. Of course, the parent–offspring situation can be regarded as a special case of the brother–sister situation.

Estimation of Multivariate Correlations in Extended Families

Suppose that there are q classes of relatives to be considered and a random sample of k independent families is available. Suppose the jth family has n_{ij} observations for the ith class with $k_{ij} > 0$ for at least one class i so the jth family is nonempty. Here the groups may represent a three-generation family or even an extended pedigree structure. Assume the vector of observations for a member of the ith class of relatives has length p_i so the variables measured on members of each class may not be identical either in quality or quantity. Let $\mathbf{x}_{ijs}$ denote the random vector of p_i observations for the sth member in the ith class of relatives in the jth family. The first and second moment structure is defined by

$$\begin{aligned}
\boldsymbol{\mu}_i &= \mathrm{E}(\mathbf{x}_{ijs}),\\
\mathbf{A}_i &= (A_{i\alpha\beta}) = \mathrm{cov}(\mathbf{x}_{ijs}),\\
\mathbf{B}_i &= (B_{i\alpha\beta}) = \mathrm{cov}(\mathbf{x}_{ijs}, \mathbf{x}_{ijt}), \quad s \neq t,\\
\mathbf{C}_{im} &= (C_{im\alpha\beta}) = \mathrm{cov}(\mathbf{x}_{ijs}, \mathbf{x}_{mjt}), \quad i \neq m,
\end{aligned}$$

for $1 \leq i \leq q$ and $1 \leq m \leq q$. The mean vector $\boldsymbol{\mu}_i$ is of length p_i, the $p_i \times p_i$ matrix $\mathbf{A}_i$ is the class covariance matrix of the ith class, the $p_i \times p_i$ matrix $\mathbf{B}_i$ is the intraclass covariance matrix of the ith class, and the $p_i \times p_m$ matrix $\mathbf{C}_{im}$ is the interclass **covariance matrix** between classes. Note that the class and intraclass covariance matrices are symmetric. Although $\mathbf{C}_{im}$ is not symmetric, it is easily verified that $\mathbf{C}_{im} = \mathbf{C}'_{mi}$.

Upon defining the diagonal matrix composed of class variances

$$\mathbf{D}_i = \begin{pmatrix}
A_{i11} & 0 & 0 & \cdots & 0 & \\
0 & A_{i22} & 0 & \cdots & 0 & \\
0 & 0 & A_{i33} & \cdots & 0 & \\
\vdots & \vdots & \vdots & \ddots & \vdots & \\
0 & 0 & 0 & \cdots & & A_{ip_ip_i}
\end{pmatrix},$$

the correlation structure for the model is

$$\begin{aligned}
\boldsymbol{\Lambda}_i &= \mathrm{corr}(\mathbf{x}_{ijs}) = \mathbf{D}_i^{-1/2}\mathbf{A}_i\mathbf{D}_i^{-1/2},\\
\boldsymbol{\Omega}_i &= \mathrm{corr}(\mathbf{x}_{ijs}, \mathbf{x}_{ijt}) = \mathbf{D}_i^{-1/2}\mathbf{B}_i\mathbf{D}_i^{-1/2}, \quad s \neq t,\\
\boldsymbol{\Phi}_{im} &= \mathrm{corr}(\mathbf{x}_{ijs}, \mathbf{x}_{mjt}) = \mathbf{D}_i^{-1/2}\mathbf{C}_{im}\mathbf{D}_m^{-1/2},
\end{aligned}$$

provided $i \neq m$, where $\boldsymbol{\Lambda}_i$ is the class correlation matrix for class i, $\boldsymbol{\Omega}_i$ is the intraclass correlation

matrix for class i, and $\mathbf{\Phi}_{im}$ is the interclass correlation coefficient between classes i and m. The parameters in this model can be estimated in the case of multivariate normality by any number of numerical methods currently available, including the Newton–Raphson method [27, 36]. Standard errors are found by inverting the Hessian matrix (of second derivatives) of the likelihood function evaluated at the maximum likelihood estimates.

Konishi & Khatri [23] have provided generalized noniterative estimators of correlation matrices in the multivariate parent–offspring case based on the product-moment and ANOVA approaches including the uniformly–weighted ANOVA estimators introduced by Srivastava et al. [36].

Konishi et al. [25] discussed the use of **canonical correlations** to find suitable measures for the degree of resemblance between parent and offspring. Konishi & Rao [24] discussed the application of **principal components analysis** for multivariate familial data. Both discussions use the generalized estimators of Konishi & Khatri [23].

Other Estimation Issues

Although the preceding discussion is with respect to continuous random variables, with the exception of the maximum likelihood estimators, the preceding estimators and their standard errors are valid without modification for **binary** random variables and, in the multivariate setting, for combinations of continuous and binary random variables.

With regard to dropping the requirement for the assumption of normality, a discussion of robust M-estimation of the intraclass correlation is given by Bansal & Bhandary [1]. Alternatively, one can return to the early work of Galton, and replace means by **medians** and standard deviation by probable errors (interquartile ranges) in the product-moment estimators.

Family History Validation

A fundamental source of data for any **genetic epidemiologic** study is the family history of the research subject [10, 12, 19, 28]. The essential family history consists of two components: the pedigree structure and the specification of those members of the pedigree who have the trait(s) or disease(s) of investigative interest. Increasingly, the family history also includes information on relatives, such as age of disease onset or diagnosis, or environmental exposures such as tobacco and alcohol use. The family history is obtained by direct interview of or questionnaire administration to an informant, usually the proband or index case (*see* **Ascertainment**). If the proband is deceased, a surrogate or proxy (spouse or other next of kin) is asked to provide the information.

The quality of the family history thus obtained can vary according to the amount of information sought, the way in which the information is collected, and who is providing the information. Depending upon the nature of the study, it also follows that if the family history information sought is detailed or needs to be of high quality, then the process to obtain such data can be time consuming for both the informant and the investigator [17]. A key methodologic issue in this regard is validation of the completeness or accuracy of the information provided by the informant. In turn, what is learned from empirical studies of family history validation can inform the study design and analytic strategies to compensate for missing or inaccurate data.

Validation of Reported Family History

There are two major methods by which a reported family history can be validated:

1. Direct query or health assessment (by interview or questionnaire) of the family members about whom the informant has provided information. A variation of this approach is to interview as many members of the kindred as feasible and compare reported family histories.
2. Obtain documentation of disease in family members by medical records, death certificates, or population-based disease registries.

Table 1 Assessment of agreement of informants' reported family history

	Family member's self-report or medical documentation that family member is:	
Informant reports that family member is:	Affected	Unaffected
Affected	a	b
Unaffected	c	d

When such information has been obtained, family histories are validated by designating as the "gold standard" the self-report given by the relative (Method 1) or the medical documentation (Method 2). The agreement or concordance of the informant's reported family history is then assessed by **sensitivity** $= a/(a+b)$ and/or **specificity** $= d/(c+d)$, according to Table 1.

In general, use of Method 1 can provide fairly complete data to estimate both sensitivity and specificity, and Method 2 yields good data for estimating sensitivity, but less so for specificity – except perhaps when population-based disease registries are employed for validation. The quality of sensitivity and specificity estimates are thus dependent upon the quality and completeness of the "gold standard" data.

Family History Validation Studies

There have been numerous studies that performed validation of reported family histories. The choice of validation method and the accuracy of reported history are often dependent upon the disease under study. Studies of psychiatric disorders [5, 13, 16, 26] and one study of aneurysms [8] validated family history by Method 1, interviewing or directly assessing relatives in the kindreds. These studies found that reported family histories were of variable quality, and that specificity was generally high, but sensitivity was modest.

In contrast, studies of cancer and heart disease have often utilized Method 2, obtaining medical records or pathology reports and death certificates [1–4, 6, 14, 17, 18, 23, 24]. Large-scale, population-based family history validation studies are possible because of the existence of regional or national tumor registries [11]. In general, these studies have found that sensitivity of reporting cancer family history is

high, greater than 70%. As mentioned above, given the type of information used to assess accuracy, specificity often cannot be properly estimated, unless documentation is exhaustive.

An interesting variation on family history validation was conducted by Glanz et al. [7] in which first-degree relatives of patients who were known to have colorectal cancer were asked to complete a family history survey. (The relatives were recruited under the auspices of a different research question.) All respondents were known beforehand to have a relative with colorectal cancer, yet the investigators found that family history of this cancer was underreported by 25.4%.

Factors that Influence Accuracy of Reported Family History

Many of the above studies also investigated the factors that affected the accuracy of family history of disease. It is clear that the type of disease under investigation greatly influences accuracy; how visible the condition is, and the degree of stigma that is associated with the condition (both socially and in the family) have an impact. Personal characteristics of the respondent, including age, gender, affection status, comorbid conditions, education level, and knowledge and concern about the condition can influence accuracy. Finally, degree of relationship between the respondent and the relative being reported on affects accuracy: it has been confirmed in a number of studies that the more distant the relationship, the less accurate the history.

In the context of **case–control studies**, when the validity of reported exposures – such as tobacco or alcohol consumption by family members – has been investigated, the accuracy has been reported to be reasonably high, ranging from 60% to 90% agreement by next of kin or close proxy respondents [9, 15, 20]. However, reports about all relatives across kindreds have not been systematically examined.

Analytic Implications

The results of family history validation studies to date suggest that family histories of some diseases can often be considered reliable, particularly of major cancers or common/familiar conditions among first-degree relatives. However, these studies also suggest that recall **bias** and incomplete data collection can occur, and that the method of querying, demographic and clinical characteristics of the informant, and psychosocial factors may influence the accuracy of the reported history.

The consequence of an inaccurate family history is misclassification or missing data, which can severely influence the results of the analysis [25, 27]. Saito et al. [21, 22] showed the bias that can occur in the estimation of **odds ratios** for family history of stroke and diabetes when the gender and age of the relatives is ignored. Silberberg et al. [24] found that classification of "Don't know" responses by informants with respect to family history of cancer or heart disease about second-degree relatives could result in lower sensitivity. In conclusion, an awareness of these issues should help to guide the design, analysis, and imputation of missing data in studies that use family histories.

GLORIA M. PETERSEN

Family-based Association for Quantitative Traits

Allelic **association** tests have been introduced to analyze the relationship between allelic variability and individual traits (*see* **Gene**). As with ordinary association tests, population **admixture** is a potential source of confounding. Below we describe family-based approaches to adjusting for potential confounding due to population admixture when analyzing a quantitative (continuous) trait. These family-based association tests often aim to extend the transmission/disequilibrium test (TDT) [13, 15] from a dichotomous (affectation status) trait to a quantitative trait (*see* **Family-based Case–Control Studies**).

The approaches can be differentiated by the kind of assumptions they make on the distribution of the quantitative trait (e.g. normal distribution), the ascertainment of the sample (e.g. random sample), and the kind of data that can be evaluated (e.g. only family trios). Most of the approaches test for **linkage** in the presence of association but there also exist tests for association in the presence of linkage.

First we review papers that introduce tests that make assumptions on the distribution of the quantitative trait given the **genotypes**. Later we will turn to nonparametric tests that do not make assumptions on the distribution of the quantitative trait.

Allison [2] developed five test statistics for samples of independent nuclear-family trios. The first test (TDT_{Q1}) is a t-test that assumes random sampling of the family data. The other four tests ($TDT_{Q2}-TDT_{Q5}$) can be used both for random and extreme sampling. Three of the tests (TDT_{Q1}, TDT_{Q3}, TDT_{Q5}) are ordinary least squares approaches, which assume that the residuals are independent and normally distributed; the tests tend to be quite robust to nonnormality because the central limit theorem ensures that the coefficient estimators are asymptotically normally distributed. TDT_{Q5} was found to be more powerful than the other tests under a variety of genetic models. It is an F-test that compares the fit of two regression models. For the three informative mating types (Aa × AA, Aa × Aa or Aa × aa), the first model regresses the offspring phenotype value on the parental mating types. The second model regresses the offspring phenotypes on both the parental mating types and the offspring genotypes.

For data with siblings and no parents, Allison et al. [3] proposed two tests: a mixed effect model and a permutation test, which does not make assumptions on the distribution of the quantitative trait. Simulation studies have shown that the permutation test is more powerful than the mixed effect model test for additive or nearly additive quantitative trait loci.

Xiong et al. [18] developed an approach that is similar to the one by Allison [2]. The test assumes that parental genotype information is available and that the phenotype is normally distributed or that the sample size is large. The test, which allows for more than one child per family, compares the average trait values of offspring inheriting one allele vs. the other from **heterozygous** parents. George et al. [6] proposed a **regression**-based TDT method, which regresses the trait on the parental transmission of a marker allele. Similarly, Zhu & Elston [22] developed a TDT method for quantitative traits by defining a linear transformation to condition out founder information. Both methods allow one to analyze pedigree data since they do not assume independence of observations. Both tests assume normally distributed **residuals** and random sampling. Simulation studies comparing the two regression methods have been described in [21].

Yang et al. [19] defined a different regression-based approach to adjusting for confounding due to population admixture. Their approach involves augmenting linear regression models with additional regressors that are defined through family genotype data. This ensures that the estimates of the regression coefficients that parameterize the influence of allelic variability on the trait are **unbiased**. The basic assumption that underlies the approach is that the offspring genotypes and the residual trait value are independent conditional on the parental genotypes. The validity of the approach has only been derived for settings where individuals are sampled at random. The approach can be extended to general pedigrees and missing parental genotype information.

Clayton & Jones [4] use a **likelihood** framework to derive a quantitative trait TDT-type test for trio families. The authors assume that the quantitative trait for a given individual has a normal distribution conditional on the individual's genotype. Furthermore, they assume that on some arbitrary scale, the genotype effects on the trait mean may be decomposed into sums of **haplotype** effects: if for genotype (i, j) the corresponding mean trait value is denoted $\mu_{(i,j)}$,

then they assume the existence of a function $h(\cdot)$ such that $h[\mu_{(i,j)}] = h(\mu) + \beta_i + \beta_j$. The probability of the offspring genotype data is computed conditional on the parental genotypes (to protect against population stratification effects) and on the offspring trait values (to allow one to use data irrespective of the ascertainment scheme). Finally, the authors derive a score statistic that is similar to the distribution-free test introduced by Rabinowitz [10] (see below).

For normally distributed traits and complete parental genotypes, Van den Oord [16] describes a framework for identifying quantitative trait loci in association studies using structural equation modeling. Fulker et al. [5] introduce a **variance component** model for a combined quantitative trait locus (QTL) linkage and association analysis. The authors simultaneously model the means and covariances of sibling pairs. The linkage test is based on differences in covariances according to the identity-by-descent (ibd) status at the candidate locus. The model for the means is partitioned into between- and within-pairs (i.e. inter- and intra-sibship) components; an association test based on the within-pair component is robust to population stratification. The variance component model is not directly applicable to either samples selected for extreme trait values or nonmoral quantitative phenotypes. Abecasis et al. [1] and Sham et al. [12] extend this variance component approach to nuclear families of any size and to arbitrary sibships, respectively. For randomly ascertained sibships, Sham et al. [12] found that the power of their association test is related to the QTL **heritability** and the square of the **linkage disequilibrium** measure, while the power of the linkage method is related to the square of the QTL heritability.

We now discuss approaches that make fewer or no assumptions on the distribution of the quantitative trait. Rabinowitz [10] introduced an approach that does not make any distributional assumptions on the quantitative trait values. The essence of the approach is to start with a statistic for association between a **marker** and phenotypes and then to use parental information to modify the statistic to avoid the possibility of spurious association induced by population admixture. Because no assumption is made about the distribution of the trait values under this approach, the tests are valid for any type of sampling schemes based on the phenotypes of the individuals. Denote by n the number of families and by n_i the number of offspring in the ith family. Denote the trait value of the jth offspring in the ith family by $Q_{i,j}$. Following the notation outlined in Zhao [20], define the following index function $Y^{\mathrm{m}}_{i,j} = 1/2$ or $(-1/2)$ if the mother in the ith family is heterozygous and transmits the A (or a) allele to the jth offspring, and $Y^{\mathrm{m}}_{i,j} = 0$ if the mother is homozygous; similarly, define $Y^{\mathrm{f}}_{i,j}$ for the father. Under the **null hypothesis** of no linkage between the marker locus and the quantitative trait loci, the trait value and the index functions $Y^{\mathrm{m}}_{i,j}$ and $Y^{\mathrm{f}}_{i,j}$ are conditionally independent given the parental alleles. Thus, for any constant c, conditional on the trait values and the parental genotypes

$$s(c) = \sum_{i=1}^{n} \sum_{j=1}^{n_i} (Q_{i,j} - c)(Y^{\mathrm{f}}_{i,j} + Y^{\mathrm{m}}_{i,j}) \qquad (1)$$

has mean 0. The test statistic proposed by Rabinowitz takes the form $s(c)/\sigma(c)$, where $\sigma(c)$ is an estimate of the conditional variance of $s(c)$. Rabinowitz [10] suggests using the trait average of all the children in all the families to replace c. This approach was generalized by several authors to include families with missing parental information; see Sun et al. [14], Rabinowitz & Laird [11], and Horvath et al. [7].

Waldman et al. [17] propose a **logistic-regression**-based extension of the TDT that also allows one to examine the relation between a marker and one or more continuous or categorical explanatory variables. The method models allelic transmission as the dependent variable and the quantitative and categorical explanatory variables as the independent variables.

Apart from those described in [6, 21] and [22], the tests described thus far test for linkage. However, there are situations when it may be advantageous to test for association in the presence of linkage, e.g. if a chromosomal region is shown to be linked to a trait, association tests may be useful for further localization of a susceptibility locus. For this setting, Monks & Kaplan [9] develop three family-based tests that avoid finding spurious association due to population stratification. The first test (T_{QP}), which adapts the test by Rabinowitz [10] to this new setting, uses genotype information of the parents and all of their children. The second test, T_{QS}, ignores parental information and uses only sibship information. Finally, the third test, T_{QPS}, is a combination of the previous two test types. These tests

make no assumption on the distribution of the quantitative trait and allow one to use information from all available offspring. Lake et al. [8] have generalized the method described in Rabinowitz & Laird [11] to allow tests of association of a quantitative trait in the presence of linkage between the marker and the trait gene, which permits arbitrary family configurations.

Family-based Case–Control Studies

Case–control studies are used often in epidemiologic studies to investigate the **association** between disease and one or more risk factors. With increasing frequency, the set of risk factors being considered includes **genotypes** at one or more susceptibility, candidate, or **marker** loci. The goals of association studies will differ, depending on the state of knowledge about a given disease. For example, once a susceptibility locus has been identified, the goals include estimating the **relative risk** and **penetrance** associated with specific **mutations**, and testing for **interaction** with environmental exposures or other genes [14] (*see* **Disease-marker Association**; **Gene-environment Interaction**). If a candidate locus has been identified on the basis of a biological hypothesis that relates gene function to phenotypic expression, then the primary goal is testing the **null hypothesis** of no association between the locus and disease. Finally, multiple tests of association with finely spaced markers in a chromosomal region that has been previously established to contain loci linked to the disease (*see* **Linkage Analysis, Model-based**) may be used in the hope of detecting **linkage disequilibrium** with a disease locus.

For diseases, **candidate genes** may be part of a larger hypothesized disease pathway that includes other genes and/or environmental exposures. For example, Gilliland et al. [13] have hypothesized that asthma and other respiratory phenotypes are related to air pollution through a pathway of oxidative stress that includes several genetic loci (*see* **Causation**). Even for BRCA1, a major susceptibility locus for breast cancer that substantially increases risk by itself, there is evidence for some effect modification by use of oral contraceptives [56]. It is therefore important in studies of candidate genes to consider not only the main effect of the gene but also its interactive role with other genes and/or environmental factors.

Traditional unmatched or matched case–control studies [1] may not be optimal for the study of genes. A potential problem is that estimates of genetic effect are subject to **confounding** when cases and controls differ in their ethnic backgrounds. This phenomenon, also known as population stratification **bias** [2, 23], can occur when both disease risk and genetic mutation frequencies vary among ethnic groups (*see* **Bias in Case–Control Studies**). If all or part of the disease-risk variation is due to factors other than the candidate gene (e.g. environmental exposures, a second gene), and those other risk factors also vary among ethnic groups, then a spurious association with the candidate gene may occur simply due to the indirect correlation of its distribution with the other risk factor(s). A classic example of such confounding is the reported association between the Gm locus and non insulin-dependent diabetes in American Indians that disappeared when the analysis was restricted to full-heritage Pima–Papago Indians [17]. To avoid the problem of population stratification bias, one can attempt to match cases to controls on ethnic background (*see* **Matched Analysis**; **Matching**). However, determination of ethnicity in a large-scale epidemiologic study is difficult, especially with the great diversity in cultural backgrounds that exists in the urban areas where studies are most likely to be conducted. It should be noted here that the degree to which population stratification can cause spurious findings for a candidate gene is the subject of current debate [57]. There has also been interest in using genetic markers to adjust for population stratification [32, 33, 37].

In this article we review family-based case–control designs that have as one of their primary features freedom from population stratification bias. These include the *case–sibling* and *case–parent* designs. We discuss methods for analyzing these designs that provide parameter estimates and hypothesis tests for genetic main effects and for gene–environment ($G \times E$) or gene–gene ($G \times G$) interactions (*see* **Multilocus (Gene × Gene Interaction)**). We provide comparisons among the case–sib, case–parent, and standard case–control designs of the sample size requirements for testing these hypotheses. Finally, we review alternative study designs that make use of family data.

Case–Sibling Design

In this design, one matches each case to one or more unaffected siblings. For complex diseases with variable age at onset (*see* **Age-of-onset Estimation**), controls should be sampled from the "risk set" consisting of those siblings who were disease-free at the age the case became affected (the *index age*) [12, 61,

65]. A sibling who is disease-free at the index age but is known to later develop the disease should not be eliminated from consideration as a control. In fact, general elimination of such siblings will result in a genetic effect estimate that is biased away from the null [26]. Data on known environmental risk factors *at the index age* should be collected for both cases and controls.

If only recent incident cases are included, then the age-matching requirement restricts control selection to older siblings. This could lead to confounding of the effects of environmental exposures that have secular trends or birth-order effects [12, 61, 65]. For example, older siblings may be less likely in general to take up smoking [47]. While this phenomenon will probably have little effect on an estimate of genetic risk, it should be considered as a potential source of **bias** in estimates of environmental and G × E interaction effects.

Some cases may not have any controls who have attained the index age, effectively excluding them from the analysis. This can be corrected in principle by constructing a **likelihood** involving the probability that younger controls remain disease-free up to the index age. However, inclusion of such controls can still pose problems if time-dependent covariates are involved. The validity of the case–sibling design also depends on the assumption that the ability to recruit cases and controls is not differentially related to their genotype, conditional on parental genotypes [61].

From a practical standpoint, the use of sibling controls may offer several nonstatistical advantages over population controls. The occurrence of disease in the case may make his or her relatives easier to recruit than an unrelated subject from the general population. In addition to reducing cost, this may improve data quality, since family members of controls may be more careful filling out risk-factor questionnaires. Researchers can also cross-validate questionnaire information related to family-specific variables that has been obtained from the case and sibling (*see* **Family History Validation**). The availability of family-based cancer registries can also make finding sibling controls much less expensive than finding controls from the general population. These resources can be used to identify case–sib pairs that are potentially most informative for testing genetic effects; for example, pairs that have a parent affected with the disease of interest [12]. However, care must be taken in using such a restricted sampling design, since bias in parameter estimates can result [16].

Analysis

Standard methods for the analysis of matched case–control data can be applied to the case–sibling design [1]. These include **McNemar's** and Mantel–Haenszel chi-squared tests and the associated estimates of the **odds ratio** [20, 48]. More generally, conditional **logistic regression** can be used to simultaneously model genetic and environmental main effects, as well as G × E interaction. If we let β_g, β_e, and β_{ge} denote parameters for the effect of a gene (G), environmental factor (E), and G × E interaction, respectively, then the conditional likelihood for a sample of N case–sibling sets has the form:

$$L(\beta_g, \beta_e, \beta_{ge}) = \prod_{i=1}^{N} \frac{\exp(\beta_g G_{i1} + \beta_e E_{i1} + \beta_{ge} G_{i1} E_{i1})}{\sum_{j \in M(i)} \exp(\beta_g G_{ij} + \beta_e E_{ij} + \beta_{ge} G_{ij} E_{ij})}. \quad (1)$$

The index 1 refers to the case, and the set $M(i)$ includes the case and all controls from family i. If controls are matched to the case's age and selected according to the principles of risk set sampling as described above, the quantities $R_g = \exp(\beta_g)$, $R_e = \exp(\beta_e)$, and $R_{ge} = \exp(\beta_{ge})$ can be interpreted as the corresponding hazard-rate ratios. If age of onset is not a factor (e.g. the disease is a birth defect), then these quantities represent odds ratios. The genetic **covariate** G is coded according to the assumed susceptibility of each genotype. For example, for a diallelic locus, $G(\mathrm{AA}) = 1$, $G(\mathrm{Aa}) = \delta$, and $G(\mathrm{aa}) = 0$. If the gene is assumed to be dominant, then $\delta = 1$; if recessive, then $\delta = 0$; if log-additive, then $\delta = 0.5$. Alternatively, G could be coded using two dummy variables to allow for separate estimation of the heterozygote (Aa) and homozygote (AA) effects relative to baseline (aa). Any of these coding schemes can be generalized to a locus with more than two alleles [38].

Score, Wald and **likelihood ratio tests** based on (1) can be formed as usual to test hypotheses about main or interactive effects [5]. If there are more than two subjects per family, however, then these

tests will only be valid if outcomes are conditionally independent within families. This will not be the case if the locus under study is simply a marker that is linked to the disease-predisposing locus. A number of different methods have recently been proposed to test for association in the presence of linkage [6, 15, 18, 19, 29, 35, 46].

Case–Parent Design

In this design, no actual controls are selected. Instead, genotypic data are obtained on the parents of the case, and the genotype transmitted to the case is compared with the three genotypes (*pseudo-siblings*) that were not transmitted to the case. For example, if the father's genotype is Aa, the mother's Aa, and the case's AA, then the pseudo-sibling genotypes are Aa (paternal A, maternal a), aA, and aa. The validity of this approach depends on the assumption that parental alleles are transmitted with equal and independent probability in the population. This assumption would fail if, for example, inheriting a certain genotype led to fetal death. Validity also depends on the assumptions that the ability to recruit a case is independent of the genotype given the parental genotypes, and that the genotyped "parents" are in fact the case's biological parents [61].

As with the case–sibling design, parents are more likely to be willing to participate than a population control, and the design will take advantage of information from a family-based registry. The disease status of the parents is not required in this design, nor is any information on their environmental exposures. In practice, the utility of this design is limited to disorders that occur at young enough ages that parents of the cases are likely to be alive.

Analysis

Conditional logistic regression for 1 : 3 matched sets provides a flexible framework for analyzing case–parent data [11, 38–41, 43]. The likelihood including both a genetic main effect and a G × E interaction has the form:

$$L(\beta_g, \beta_{ge}) = \prod_{i=1}^{N} \frac{\exp(\beta_g G_{i1} + \beta_{ge} G_{i1} E_{i1})}{\sum_{G_{ij}|G_{i\mathbf{P}}} \exp(\beta_g G_{ij} + \beta_{ge} G_{ij} E_{i1})}, \quad (2)$$

where again the index 1 refers to the case. The summation in the denominator of (2) is over the four possible genotypes that could be transmitted to an offspring given parental genotypes $G_{i\mathbf{P}}$. As above, the covariate G can be coded to reflect assumptions about the relationship among alleles [38]. The quantities $R_g = \exp(\beta_g)$ and $R_{ge} = \exp(\beta_{ge})$ can be interpreted as relative risks. Estimation of a main environmental effect is not possible since the three pseudo-siblings are perfectly matched to the case except for genotype. Valid estimation of the interaction effect β_{ge} requires that G and E are independently distributed in the population. However, even if independence holds, G×E interactions can be difficult to interpret in this design – absent knowledge of the main effect of exposure [61].

Under a log additive genetic model without G × E interaction, the **maximum likelihood** estimate $\hat{\beta}_g$ and the score test based on (2) are equivalent to the McNemar log odds ratio and chi-square test from the diallelic transmission-disequilibrium test (TDT) [49]. The TDT treats each parent as an independent matched pair of alleles, and compares the alleles transmitted from heterozygous parents of cases to those not transmitted. Schaid & Sommer [42] present the often-confusing history of this statistic and compare it with earlier variants, such as the *haplotype relative risk* [8, 36, 52].

Again, if more than one case per family is included in the analysis, then the usual tests based on (2) will only be valid if outcomes are conditionally independent within families. Multiple cases can be included if the conditioning event in (2) is restricted to genotypes that have the same identity-by-descent status as the cases' observed genotypes [24, 28, 45] or if an empirical estimate of the variance of the score (treating nuclear families as independent) is used [18, 22]. The Pedigree Disequilibrium Test [29, 30] also accommodates multiple-case families.

If genotype information for only one parent is available, then restricting the TDT to parent–child pairs where transmission is unambiguous (e.g. heterozygous parent; homozygous offspring) can induce bias [7]. Several techniques have been introduced in the last few years which remain valid when only one parent is available [34, 51, 54, 59, 63]. Another analysis approach to case–parent data based on Poisson regression instead of (2) can test for **parent-of-origin** effects as well as G × E interaction [55, 60, 62, 64].

Sample Size Considerations

We compare sample size requirements between the case–sibling and case–parent designs, and also compare each of these with the requirements for the standard matched **case–control** design (*see* **Matching**). In the latter design, controls are matched to cases on one or more factors (e.g. ethnicity, age), but are assumed to be genetically unrelated to cases. The conditional likelihood in (1) for the case–sibling design can also be used to estimate hazard-rate ratios or odds ratios for this design. For each design, we compute the minimum number of matched sets required to provide 80% power for testing genetic main effects, G × E interaction, and G × G interaction. Calculations were carried out using the program QUANTO, freely available at `http://hydra.usc.edu/GxE`. Details on the methods used for computing sample size are included in the program documentation, or in Gauderman [11].

In addition to the magnitudes of the relative risks R_g, R_e, and R_{ge}, sample size requirements depend on the prevalence of genetically susceptible individuals in the population [$\Pr(G = 1)$]. We consider four types of genes: rare dominant, common dominant, rare recessive, and common recessive (*see* **Mendel's Laws**; **Segregation Analysis, Classical**). A rare gene is defined as one for which 1% of the population is genetically susceptible, i.e. $\Pr(G = 1) = 0.01$, while for a common gene we assume $\Pr(G = 1) = 0.20$.

Table 1 shows the number of matched sets required to detect a genetic main effect for varying values of the true genetic **relative risk**, $R_g = \exp(\beta_g)$. For rare genes, sample size requirements are prohibitively large for all three designs, unless the genetic relative risk is large. For a more common gene, relative risks in the range of 1.5 to 2.0 can be detected with attainable sample sizes. In all situations, the case–sibling design requires the largest sample size, approximately 1.5 to 2 times greater than the case–control design. This reduced efficiency is due to **overmatching** of cases and their siblings on the genotype of interest [65]. The case–parent design, on the other hand, is nearly equivalent in efficiency to the case–control design for a dominant gene but more efficient for a recessive gene. The reason for the increased efficiency in the recessive situation is based on the fact that here the probability that a parent has the Aa genotype is relatively large. Examination of the likelihood in (2) shows that only parents with the Aa genotype are informative for testing genetic main effects. Thus, for a recessive gene, use of the case–parent design enriches the sample for informative parent-to-case transmissions.

To compare sample sizes needed to detect a G × E interaction, we assume $R_g = R_e = 1$, i.e. that risk is only increased in subjects who are both exposed and genetically susceptible. We also assume that the prevalence of exposure ($E = 1$) is 0.3, and

Table 1 Number (N) of matched sets required for 80% power to detect a genetic main effect with true relative risk R_g

Proportion susceptible [$\Pr(G = 1)$]	Mode of inheritance	R_g	Case–control, N	Case–sibling		Case–parent	
				N	(Ratio)[a]	N	(Ratio)[a]

Assumptions: $R_g = 1$, $R_h = 1$, 0.05 significance level and two-sided alternative hypothesis.

that there is no **correlation** in exposure between siblings. Table 2 shows the required sample size to detect a G × E interaction for varying the magnitude of R_{ge}. Again, for a rare gene and moderate G × E effect, sample sizes are prohibitive. However, the case–sibling and case–parent designs are always more powerful than the case–control design. In this context, siblings' concordance on genotype makes them more informative for testing for G × E interaction (see Table 1 in [12]). However, this increase in efficiency disappears as the at-risk allele becomes more common, or with increasing correlation in exposure between siblings.

The likelihoods in (1) and (2) can be modified to test for the effect of a second measured locus simply by replacing E by a second genetic effect H, which can be coded according to assumptions about inheritance at the second locus. If, for example, both loci are diallelic and recessive, the interaction term G × H will only be 1 if the case is a homozygote carrier at both loci. Table 3 shows the required sample sizes to detect a three-fold gene–gene interaction effect ($R_{gh} = 3$) when H is a common gene and $R_g = R_h = 1$. The case–sibling design is least efficient. The case–parent design, on the other hand, provides large efficiency gains over the case–control design, requiring approximately half the matched sets. Again, this is because the case–parent design enriches the sample for informative parent-to-case transmissions.

Discussion

Family based case–control studies offer an attractive alternative to population-based case–control designs using unrelated controls. Their primary advantage is that they overcome the problem of population stratification that can lead to spurious associations. For the case–sibling design, this protection from bias comes at the price of reduced statistical efficiency for some tests due to overmatching on genotype. For the case–parent design, one can generally expect increased efficiency relative to the case–control design, particularly for tests of gene–gene interaction. One should keep in mind that the case–parent design will probably be more expensive per matched set, as DNA needs to be collected and processed for three subjects rather than for two subjects in the other designs. Finally, family designs offer nonstatistical advantages, such as improved cooperation and reduced cost. These must be weighed against any losses in sample size from cases who do not have a suitable family control and the potential selection bias if such losses are nondifferential (*see* **Bias in Case–Control Studies**; **Validity and Generalizability in Epidemiologic Studies**).

Statistical methodology for the analysis of family-based association studies remains an active area of research. The basic methods described above do not utilize all aspects of family data. For example, if phenotype and genotype information are available on parents *and* siblings of a case, the analytic approaches described above will discard information. Several new approaches make use of cases, parents, and siblings in a unified framework – and have also been extended to utilize data from extended pedigrees [21, 22, 25, 27, 34, 54, 63]. Many of these approaches also allow analysis of a continuous phenotype, in addition to binary and censored-age-of-onset traits. Also proposed are methods that will make use of relatives of cases whose phenotypes are known, but who have not been genotyped. The "**kin–cohort**" and "genotyped proband" designs are examples of these approaches, both of which have been used to estimate age-specific penetrance of BRCA1 and BRCA2 among Ashkenazi Jews [9, 10, 31, 50, 58].

Finally, we mention extensions of family designs that use haplotypes from multiple tightly linked markers instead of analyzing individual loci separately (*see* **Haplotype Analysis**). This approach is becoming possible with the increasing density of available markers, and should improve our ability to localize a disease-causing gene. If the haplotype phase could be unambiguously determined for all subjects, then a set of markers could be analyzed as one highly polymorphic locus. Unfortunately, this phase often cannot be uniquely determined. New methods to handle this situation have been proposed [3, 4, 44, 66], and this will continue to be an active area of future research. Furthermore, the number of possible haplotypes can create **multiple comparisons** problems. Without a plausible biologic model for grouping haplotypes together, one approach to this problem is first to use statistical tools to cluster haplotypes and then estimate relative risk parameters for each cluster [44, 53] (*see* **Cladistic Analysis**). In general, the utility of family-based study designs relative to other alternatives should be re-evaluated in the context of haplotype-oriented studies.

Fan Plot

Introduction

The fan plot is a **graphical** procedure for determining the effect of one or more observations on the **transformation** parameter λ in the Box and Cox family of power transformations of the **response** in **regression**. Such transformations, for example, from $\boldsymbol{y}$ to $\log \boldsymbol{y}$, are often important for ensuring that the assumptions behind **least squares** are satisfied and that therefore, efficient use is made of data (*see* **Power Transformations**). The fan plot is based on a **forward search** through the data to fit subsets of increasing numbers of observations, with any **outliers** being included toward the end of the search. The plot monitors the behavior of the approximate score test for five different transformations and reveals whether the evidence for a transformation depends on a few observations or is, preferably, spread throughout the data.

Interest is in transformation of the response $\boldsymbol{y}$ in the **multiple regression** model

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{1}$$

$\boldsymbol{y}$ is the $n \times 1$ vector of responses, $\boldsymbol{\beta}$ is the $p \times 1$ vector of parameters and it is assumed that the additive errors of observation ε are independently distributed with constant variance σ^2. Also in (1) $\boldsymbol{X}$ is the $n \times p$ **matrix** of carriers, that is, of **explanatory variables** and perhaps functions of them, such as quadratics and interaction terms. To obtain the approximate score test we add a "constructed variable" (*see* **Residuals**) to the regression model and obtain the augmented model

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{w}\gamma + \boldsymbol{\varepsilon}, \tag{2}$$

where $\boldsymbol{w}$ is $n \times 1$ and γ is a scalar parameter. The approximate score test is the **Student *t*-test** t_γ for testing that γ in (2) equals zero. The constructed variable for the transformation is derived in the next section. Testing that $\gamma = 0$ is testing that there is no evidence for any transformation of the response.

A Score Test for Transformations

The analysis of the data on mandible length in the article on **residuals** shows appreciable evidence not only of the normality of the residuals (*see* **Normality, Tests of**, Figure 3) but also of increasing variance with fitted value, Figure 1. Often, normality and constant variance can be achieved by fitting the regression model not to $\boldsymbol{y}$ but to a function of $\boldsymbol{y}$; Figure 1 of the article on **diagnostics** shows the beneficial effect of the transformation to $\log(\boldsymbol{y})$ combined with quadratic regression (*see* **Polynomial Regression**) on the residuals from the mandible length data. The appropriate transformation frequently, but, as will be seen later, not always, also leads to a simple linear model, without quadratic or **interaction** terms.

The logarithmic transformation is one special case of the normalized power transformation [4]

$$z(\lambda) = \begin{cases} \dfrac{\boldsymbol{y}^\lambda - 1}{\lambda \dot{y}^{\lambda-1}} & \lambda \neq 0 \\ \dot{y} \log \boldsymbol{y} & \lambda = 0, \end{cases} \tag{3}$$

where the geometric mean of the observations is written as $\dot{y} = \exp(\Sigma \log y_i / n)$. For inference about the transformation parameter λ, Box and Cox suggest **likelihood ratio tests**. A computationally simpler alternative test is the approximate score statistic (*see* **Likelihood**) derived by Taylor series expansion of (3) as

$$\begin{aligned} z(\lambda) &\doteq z(\lambda_0) + (\lambda - \lambda_0) \left. \frac{\partial z(\lambda)}{\partial \lambda} \right|_{\lambda=\lambda_0} \\ &= z(\lambda_0) + (\lambda - \lambda_0)\boldsymbol{w}(\lambda_0). \end{aligned} \tag{4}$$

In (4), $\boldsymbol{w}(\lambda_0)$ is the "constructed variable" for the transformation and can be treated as is the extra-explanatory variable in (2). To test the transformation $\lambda = \lambda_0$ the response $\boldsymbol{y}$ is transformed to $\boldsymbol{z}(\lambda_0)$ in (3). The approximate score statistic, $T_p(\lambda_0)$, is then the t statistic t_γ for regression of the transformed response on $\boldsymbol{w}(\lambda_0)$ in (2). Details of the constructed variables are in the article on **residuals**.

The Fan Plot

In the **forward search**, the p parameters of the regression model (1) are estimated by least squares applied to a carefully chosen subset of m observations. We start the search with m small, usually p or perhaps $p + 1$, and randomly select 1000 subsamples. The initial subset provides the least median of squares estimator, that is it minimizes the median squared

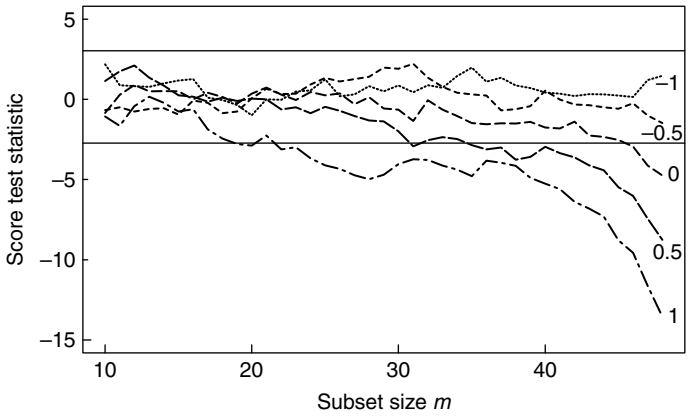

Figure 1 Poisson data: fan plot–forward plot of $T_p(\lambda)$ for five values of λ. The curve for $\lambda = -1$ is uppermost: both $\lambda = -1$ and $\lambda = -0.5$ are acceptable. There is no evidence of any outliers or influential observations

residual [5]. We then order the residuals and augment the subset.

When m observations are used in fitting, the optimum subset yields n residuals $\boldsymbol{e}(m^*)$. We order the squared residuals $\boldsymbol{e}^2(m^*)$ and take the observations corresponding to the $m + 1$ smallest as the new subset. Usually, this process augments the subset by one observation, but sometimes two or more observations enter as one or more leave. Owing to the form of the search, outliers, if any, tend to enter as m approaches n.

We combine calculation of the test statistic $T_p(\lambda_0)$ with the forward search. Since observations that are outlying on one scale may not be outlying for a different transformation, we conduct several searches for different values of λ_0. In most applications, including the examples here, we use five searches for the values $\lambda = -1$, -0.5, 0, 0.5, and 1. If there are outliers for a particular λ, they will enter the search last and influence the value of the test statistic.

As a first example, we use the Poisson Data from Box and Cox [4], partly analyzed in the article on **residuals**. These data are well behaved: there are no outliers or influential observations that cannot be reconciled with the greater part of the data by a suitable transformation. Our fan plot clearly indicates the reciprocal transformation. We then consider a series of modifications of the data in which an increasing number of outliers is introduced. The fan plot reveals the structure in all instances.

The data are the times to death of animals in a 3×4 **factorial experiment** with four observations at each factor combination. All our analyses use an additive model, that is, without interactions, so that $p = 6$, the model used by Box and Cox when finding the reciprocal transformation. The implication is that the model should be additive in death rate, not in time to death.

The fan plot of the values of the approximate score statistic $T_p(\lambda)$ for the five searches as the subset size m increases is given in Figure 1 and shows that the reciprocal transformation is acceptable as is the inverse square root transformation ($\lambda = -0.5$). The horizontal lines are at ± 2.58, corresponding to 1% significance, assuming the statistics have a **standard normal** distribution. The results of Atkinson and Riani [3] show that this is a good working approximation.

Initially, for small subset sizes, there is no evidence against any transformation. During the whole forward search, there is never any evidence against either $\lambda = -1$ or $\lambda = -0.5$ (for all the data $\hat{\lambda} = -0.75$). The log transformation is also acceptable until the last four observations are included by the forward search. These are some of the largest observations, which will be informative about the need to transform. Evidence that some transformation is needed is spread throughout the data, less than half of the observations being sufficient to reject the hypothesis that $\lambda = 1$. There are no jumps in this curve, just an increase in evidence against $\lambda = 1$ as each observation is introduced into the subset. The relative smoothness of the curves reflects the lack of outliers and exceptionally influential cases and

the general shape of the plot justifies the name of "fan plot".

For the introduction of a single outlier into the Poisson data, we follow Andrews [1] and change observation 8, one of the readings for Poison II, group A, from 0.23 to 0.13. This is not one of the larger observations, so the change does not create an outlier in the scale of the original data. The effect on the estimated transformation of all the data is, however, to replace the reciprocal with the logarithmic transformation: $\hat{\lambda} = -0.15$. And, indeed, the fan plot of the score statistics from the forward searches in Figure 2 shows that, at the end of the forward search, the final acceptable value of λ is 0, with -0.5 on the boundary of the acceptance region.

Figure 2 clearly reveals the altered observation and the differing effect it has on the five searches. Initially, the curves are the same as those of Figure 1. But for $\lambda = 1$, there is a jump due to the introduction of the outlier when $m = 41$, which provides evidence for higher values of λ. For other values of λ, the outlier is included further on in the search. When $\lambda = 0.5$, the outlier comes in at $m = 46$, giving a jump to the score statistic in favor of this value of λ. For the other values of λ, the outlier is the last value to be included. Inclusion of the outlier has the largest effect on the inverse transformation. It is clear from the figure how this one observation is causing an appreciable change in the evidence for a transformation.

We now further modify the Poisson data; in addition to the previous modification, we also change observation 38 (Poison I, group D) from 0.71 to 0.14. This creates an example of masking, in which one outlier hides the effect of another, so that neither is evident when using the methods for the deletion of single observations described in the article on **diagnostics**.

The effect of the two outliers is clearly seen in the fan plot, Figure 3. Here, only $\lambda = 0$ is acceptable at the end of the search. The plot also reveals the differing effect the two altered observations have on the five searches. Initially, the curves are again similar to those of the original data shown in Figure 1. The difference is greatest for $\lambda = -1$ where addition of the two outliers at the end of the search causes the statistic to jump from an acceptable 1.08 to 10.11. The effect is similar, although smaller, for $\lambda = -0.5$. It is most interesting, however, for the log transformation. Toward the end of the search this statistic is trending downwards, below the acceptable region. But addition of the last two observations causes a jump in the value of the statistic to a nonsignificant value. The incorrect log transformation is now acceptable.

For these three values of λ, the outliers are the last two observations to be included in the search. They were created by introducing values that are too near zero when compared with the model fitted to the rest of the data. For the log transformation, and more so for the reciprocal, such values become extreme and so have an appreciable effect on the fitted model. For the other two values of λ, the outliers are included earlier in the search. The effect is most clearly seen when $\lambda = 1$; the outliers come in at $m = 40$ and 46, giving upward jumps to the score statistic in favor of

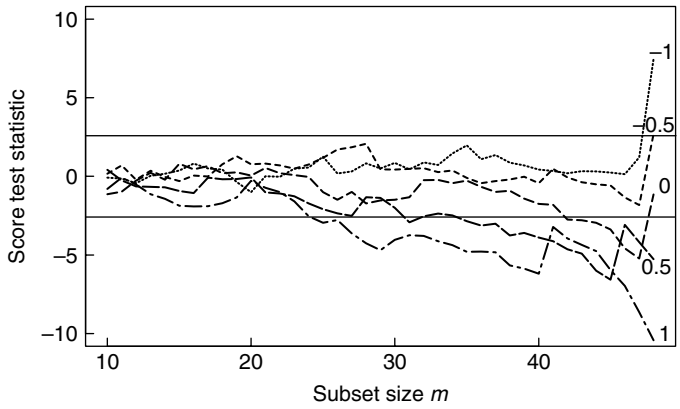

Figure 2 Modified Poisson data: fan plot–forward plot of $T_p(\lambda)$ for five values of λ. The curve for $\lambda = -1$ is uppermost: the effect of the outlier is evident in making $\lambda = 0$ appear acceptable at the end of the search

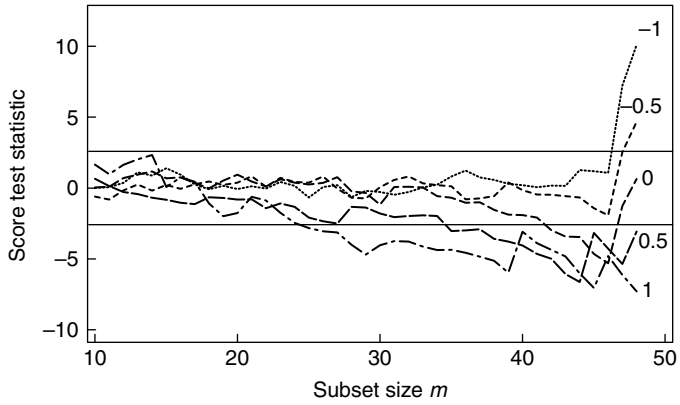

Figure 3 Doubly modified Poisson data: fan plot–forward plot of $T_p(\lambda)$ for five values of λ. The curve for $\lambda = -1$ is uppermost; the effect of the two outliers is clear

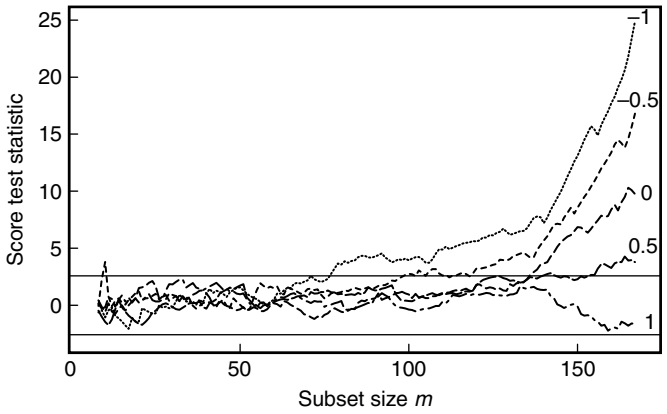

Figure 4 Mandible length data: fan plot–forward plot of $T_p(\lambda)$ for the five transformations of the data when the regression is on age

this value of λ. For the remaining value of 0.5, one of the outliers is the last value to be included.

These three plots exhibit the main features of the fan plot. Further analyses of the examples and comparison with other procedures are in Atkinson and Riani [2, Sections 4.4 and 4.7]. One conclusion is that alternative diagnostic procedures, such as the constructed variable plot in Figure 5 of **residuals**, can fail in the presence of masking and multiple outliers.

Mandible Length Data

The preceding examples calibrate the properties of the fan plot. We now use it to analyze transformations of the mandible length data.

The plot of the residuals of the untransformed data after regression on **gestational age**, for example, Figure 3 of **residuals**, showed three negative outliers as well as many smaller residuals lying outside the simulation envelope. In contrast, the residuals after regression of $\log \boldsymbol{y}$ on a quadratic in age, Figure 1 of **diagnostics**, are much more nearly normal. Is the evidence for this transformation largely dependent on the outlying observations? How is it affected by the linear model?

We start with just simple regression. Figure 4 is a fan plot for the five transformations of the data when the regression is on age. There is no evidence for a transformation – all values except $\lambda = 1$ are rejected by the end of the search. The

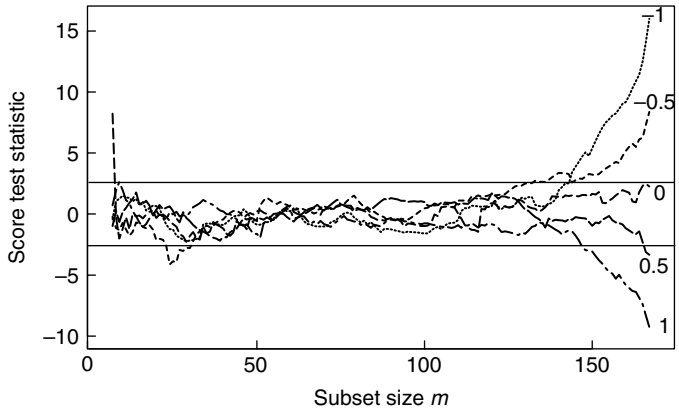

Figure 5 Mandible length data: fan plot–forward plot of $T_p(\lambda)$ for the regression of log $\boldsymbol{y}$ on a quadratic in age

statistic for this value remains within the bounds of ± 2.58 throughout the search. Although the values are toward the lower boundary at the end of the search, there is no obvious evidence of the effect of the three outlying observations, of the kind seen in Figure 3. Such jumps in the curve of the statistic are most in evidence for the reciprocal transformation $\lambda = -1$, where the observations giving negative residuals on the untransformed scale are even more extreme after transformation.

Although there is no evidence for transformation when regression is on age, we know from Table 1 of **diagnostics** that the quadratic term in this regression is significant. The final plot, Figure 5, is therefore the fan plot for the regression of log $\boldsymbol{y}$ on a quadratic in age. It shows that, for this more complicated model with an extra term, the log transformation is the only one that is acceptable. Although the last three observations to enter the search increase the value of the statistic, it does not change dramatically. There are no jumps in the other curves of the kind visible for $\lambda = -1$ in Figure 4.

The general conclusion is that the logarithmic transformation with a quadratic model is to be preferred to simple regression and no transformation. As the forward plots of t statistics for regression coefficients in Figure 4 of the article on the **forward search** show, this conclusion is supported by all the data and is in agreement with the $Q-Q$ plots of residuals mentioned above. An interesting feature of the analysis is that transformation has strengthened the evidence for a more complicated regression model. Often transformations result in a simpler model, but here there is a conflict between the linearity of the plot of $\boldsymbol{y}$ against $\boldsymbol{x}$ and the increasing variance with $\boldsymbol{y}$ evident in Figure 2 of the article on **Goodness of Fit**. This conflict was a reason for the fractional polynomial models used by Royston and Altman [6]. An alternative analysis is to keep the simple linear model, but to transform both sides of the model to obtain errors with constant variance (*see* **Power Transformations**). The forward search for this transformation is illustrated in [2, Section 4.12].

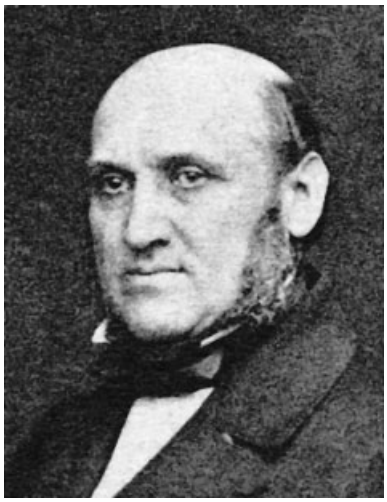
Farr, William

Born: November 30, 1807, in Shropshire, UK.
Died: April 14, 1883, UK.



Reproduced by permission of the Royal Statistical Society

William Farr must be counted as the founder of epidemiology in its modern form [4]. He studied many aspects of the distribution and determinants of health disorders in populations, and the application of the studies to the prevention and control of disease. His publications have been grouped under six headings: population, marriages, births, deaths, **life tables**, and miscellaneous [4]. He developed an interest in accurate mortality statistics by age and sex and changed the British system of death registration into an instrument for measuring the sanitary condition of the country. His studies on mortality differences among different occupations helped in understanding industrial hazards [2].

Farr's work had a great impact and influence on many pioneers in the health field. Among them are Edwin Chadwick and John Simon, who were the driving forces of the new movement for sanitary reform, and the mathematicians **Karl Pearson**, Ronald Ross, and **John Brownlee**, who improved on his method of description. Farr anticipated the germ theory of disease by almost 20 years before John Snow's classic studies of cholera, and he had an extensive and productive relationship with **Florence Nightingale** in her campaign for improving social health and hygiene [1].

Coming from a very poor family, William Farr was apprenticed at age eight to Joseph Pryce of Dorrington, near Shrewsbury, who enabled him to pursue his elementary studies. Farr was a self-taught mathematician and an accomplished linguist who learned Latin, French, Italian, and also studied Hebrew. Recognizing Farr's interest in learning and his insatiable desire for knowledge, Pryce encouraged him to enter a profession. In May 1826 he began his medical education. In November 1828, a legacy of £500, inherited on Pryce's death, made his trip to Paris possible. The Paris school was then the leader in clinical medicine, hygiene, and medical statistics, and there he learned the statistical methods applied by **Pierre C. A. Louis**. In March, 1832, he passed the examination of the Society of Apothecaries – the only examination he ever took [3]. A year later, he married Miss Langford and tried to set up a practice at 8 Grafton Street, Fitzroy Square, London. After the death of his wife, he married Miss Whittall in 1841 and they had eight children, of whom four daughters and one son survived.

In 1830, several of his articles on hygiene and **vital statistics** appeared in the *Lancet*, and in 1835 he served as a medical editor and began to study vital statistics. He also edited his own journal, *British Annals of Medicine, Pharmacy, Vital Statistics, and General Science*, which lasted only from January to August 1837. He wrote six major articles for this journal; four on vital statistics, and two on medical reform. He clearly emphasized that medicine was both a science and a social institution [1]. In his many editorials in the *British Annals of Medicine* he insisted on the restructuring of the medical profession and the potential value of medicine to society, especially in matters of prevention and hygiene.

Farr accounted for the importance of demographic data in determining mortality patterns. He constantly strove to improve the quality and the extent of data collected and devised standard classifications for diseases and for causes of deaths [2]. He examined secular changes in mortality, specific causes of death, deaths by area, season of year, residence, occupation, and by marital status. He observed the association of mortality with the density of the population, including other factors such as water and air pollution. He also made the **census** serve not only as a denominator, but as a vehicle for national surveys of the **prevalence**

of blindness and deafness. He developed descriptive statistics for institutions, thus illuminating the characteristics and the ill-effects of hospitals, workhouses, asylums for the insane, and prisons. Furthermore, Farr envisaged a national system of morbidity statistics that embraced hospitals and other services.

Farr's medical training influenced his statistical career. When he began to consider social problems and public health, his medical perspective remained and tempered both his statistical approach and his ideas of reform. He worked on data analysis, on the procedures of tabulation, comparison, and **inference**. He measured the death-toll by defining standard rates for comparison, invented the standardized mortality rate (*see* **Standardization Methods**), and compared areas and occupations by means of summary statistics unconfounded by demographic differences such as sex and age (*see* **Occupational Mortality**). He used **life tables** to estimate the effects of prevention on the expectation of life. He was the first to describe **epidemic curves** and to use models for **prediction**. He defined the relationship between death, health, and energy of body and mind, between death, birth, and marriage, and he also connected the effect of literacy on the **quality of life**.

In the years 1838–1839, he derived the general "law of epidemics" from the 15-month epidemic of smallpox. In 1839, under the influence of Sir James Clark, he was appointed as the Compiler of Abstracts in the General Register Office, then as superintendent of the Statistical Department. He wrote in his first letter to the Registrar General that "diseases are more easily prevented than cured, and the first step to their prevention is the discovery of their exciting causes" [4]. For the next 40 years, he devoted himself to the task of creating and developing a national system of vital statistics, that was used not only in England but in all the civilized countries. He blamed the appalling number of maternal deaths (*see* **Maternal Mortality**) to the failure of the Royal Colleges to train doctors and midwives in obstetrics. In the cholera epidemic of 1854, he admonished the water companies for supplying water that was dangerously contaminated.

Among the honorary degrees and distinctions that were presented to him are the Honorary M.D. Degrees by the New York University in 1847, and by Trinity College, Dublin, in 1857. Also in 1857, he was elected Honorary Fellow of the Royal Medical and Chirurgical Society. In 1867, he became an Honorary Fellow of King and Queen's College of Physicians, Dublin. In 1868, he became a member of the important Joint Committee on State Medicine of the British Medical Association and the Social Science Association. By 1869, his interest had grown in medical statistics, and social problems – public health in particular – and he was made president of the Section of State Medicine by the British Medical Association. Between 1853 and 1876, he took an active part and interest in the International Statistical Congresses, and between 1876 and 1881 he was a member of the Anthropometric Committee of the British Association [4].

In his later career, Farr was a member of the Scientific Committee appointed by the General Board of Health to investigate the cholera epidemic of 1853–1854. In 1880, William Farr resigned his post at the General Register Office, and retired completely from public life. After Farr's retirement, a resolution was passed by the council of the British Medical Association [3]:

> The Gold Medal of the Association be awarded by the Committee of Council of the British Medical Association to William Farr, M.D., F.R.S., D.C.I., C.B., as an expression of their high appreciation of his long, unwearied, and successful labours in behalf of statistical and sanitary science; as a recognition of the light he has thrown upon many physiological and pathological problems, and on account of the extraordinary services his work has rendered to the advancement of the health of the nation.

William Farr was a man of undoubted genius.

Fast Fourier Transform (FFT)

The discrete Fourier transform (DFT) of the time domain sequence $\boldsymbol{g} = (g_0, \ldots, g_{N-1})^\top$,

$$G_n = \frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} g_t \mathrm{e}^{-i2\pi nt/N}, \tag{1}$$

gives us the discrete-frequency representation of $\boldsymbol{g}$. G_n is often called the "Fourier coefficient" or "Harmonic" associated with frequency $f = n/N$. If t is measured in seconds, then f is in Hertz (or cycles per second). However, there is no reason why t has to be measured in time – it could, for example, be distance. The Fourier transform of the data, whatever the units of measurement, tells us about the periodic structure of the data. Calculation of the DFT is a critical step in many procedures, such as spectral density estimation, which describes how the variance of the process is distributed amongst the frequencies (*see* **Spectral Analysis**). Spectral density estimation finds widespread use across many disciplines including the analysis of electrocardiology (ECG), electroencephalography (EEG) data, and medical **image analysis** (*see* **Clinical Signals**).

The calculation of the N Fourier coefficients can be phrased in terms of **matrix algebra**,

$$\boldsymbol{G} = F_N \boldsymbol{g}, \tag{2}$$

where $\boldsymbol{G}$ and $\boldsymbol{g}$ are $N \times 1$ vectors given by $\boldsymbol{G} = (G_0, \ldots, G_{N-1})^\top$, $\boldsymbol{g} = (g_0, \ldots, g_{N-1})^\top$ and the $N \times N$ matrix F_N is given by,

$$F_N = \begin{bmatrix} 1 & 1 & 1 & \ldots & 1 \\ 1 & w & w^2 & \ldots & w^{N-1} \\ 1 & w^2 & w^4 & \ldots & w^{2(N-1)} \\ \ldots & & & & \ldots \\ 1 & w^{N-1} & w^{2(N-1)} & \ldots & w^{(N-1)^2} \end{bmatrix}, \tag{3}$$

where $w = \mathrm{e}^{-i2\pi/N}$. This matrix is full, in that none of the elements are zero, this implies that direct calculation of the DFT is of order N^2, and as such would quickly become unfeasible for the majority of datasets, particular high-resolution images.

The fast calculation of the DFT is possible via a family of fast Fourier transform (FFT) **algorithms**. While the FFT has been attributed originally to **Gauss** (see [3]), it has been popularized by the Cooley–Tukey [1] algorithm. When N is a power of 2, the matrix can be factorized into the multiplication of three matrices as follows:

$$F_N = \begin{bmatrix} I_{N/2} & D_{N/2} \\ I_{N/2} & -D_{N/2} \end{bmatrix} \begin{bmatrix} F_{N/2} & 0_{N/2} \\ 0_{N/2} & F_{N/2} \end{bmatrix} \Pi_N, \tag{4}$$

where $I_{N/2}$ is the identity matrix, $0_{N/2}$ is a matrix of zeroes, and $D_{N/2}$ is a diagonal matrix with diagonal $(1, w, w^2, \ldots, w^{N/2})$. The second matrix is only half-full compared to F_N, which implies less arithmetic. Π_N is a permutation matrix that converts $(g_0, g_1, \ldots, g_{N-1})^\top$ into $(g_0, g_2, \ldots, g_{N-2}, g_1, g_3, \ldots, g_{N-1})^\top$. The effect of this factorization is to split the data into an *even* and an *odd* vector and calculate the DFT of these half-length vectors, the first matrix then recombines this vector to produce the right answer. This process can be repeated for the matrix containing $F_{N/2}$, until the matrix is reduced to the multiplication of very sparse matrices. The order of arithmetic calculations is required to evaluate the DFT drops from N^2 to $N \log_2 N$; this decrease in computational need becomes more pronounced the larger N becomes. For an excellent tutorial of FFTs, see [2].

The FFT can be used as a vital step in determining underlying periodicities in data. Given data $(X_0, \ldots X_{N-1})^\top$, the simplest spectral density estimator is the periodogram,

$$I(f_j) = \frac{1}{N} \left| \sum_{t=0}^{N-1} X_t \mathrm{e}^{-i2\pi f_j t} \right|^2, \quad f_j = \frac{j}{N}, \quad j = 0, \ldots, \frac{N}{2}. \tag{5}$$

and so utilizes the DFT of the data sequence.

Figure 1 shows some simulated data with an underlying annual and daily periodicity and the associated periodogram. While the annual cycle is evident in the time domain plot, the higher frequency daily periodicity is harder to distinguish. The peaks in the spectrum clearly show both inherent periodicities in the data – namely, at frequencies $1/365$ (annual) and $1/7$ (weekly).

Fiducial Probability

What is fiducial probability? Introduced in a brief article [5] for the Cambridge Philosophical Society on "inverse probability", that is inference from sample to population, **R.A. Fisher** proposed fiducial probability as his alternative to **Bayesian** posterior probability. Consider a continuous univariate distribution parameterized by a parameter θ. Let $F(x, \theta)$ denote the one-parameter cumulative distribution function (cdf) for the **random variable** x, with density $f(x, \theta) = \partial F/\partial x$ (with respect to the Lebesgue measure). With $\text{fid}(\theta|x)$ denoting the fiducial probability density for θ given x, Fisher [5, p. 534] defined it as

$$\text{fid}(\theta|x) \propto -\frac{\partial F}{\partial \theta}. \tag{1}$$

Example 1 [7, p. 346]

Let $x_i \sim \text{N}(\mu, \sigma^2)$, $i = 1, \ldots, n$, be independent, identically distributed (iid) normal variates, where μ and σ^2 are the unknown population parameters. The sample statistics $\overline{x} = (1/n)\sum_{i=1}^{n} x_i$ and $s^2 = \{1/(n-1)\}\sum_{i=1}^{n}(\overline{x} - x_i)^2$ are jointly **sufficient** for the two population parameters. Note that s^2 has a distribution that depends only on σ^2. Specifically, $(n-1)s^2/\sigma^2$ follows the **chi-square distribution** on $n-1$ **degrees of freedom**. Applying (1) to this distribution we obtain a fiducial probability for σ^2 that is inverse-χ^2, based on the sample variance s^2.

Following the 1930 publication, during the remaining 32 years of his life, through two books [[23], Chapter 10; [24], Section III.3] and numerous articles [6–15, 17–22, 25], Fisher steadfastly held to the idea captured in (1). However, his reasoning behind (1) evolved quite noticeably and contributed to the enigmatic quality of fiducial probability. If we distinguish between fiducial probability, (1), and the reasoning leading to it, which we may call "fiducial inverse inference", then there is little wonder that Fisher caused such puzzles with his novel idea.

There were confusions between fiducial inverse inference and, on the one hand, Bayesian posterior probability, such as **H. Jeffreys** advocated [27, 28, Section 7.1] at about the same time. Fisher [6] acknowledged that, at least sometimes, there were straightforward Bayesian models, i.e. "**prior densities**" $p(\theta)$, which resulted in the same inverse probabilities through **Bayes' theorem** [$p(\theta|x) \propto f(x, \theta)p(\theta)$] as his $\text{fid}(\theta|x)$ gave directly. Also, there were confusions between fiducial probability and the rival theory of **confidence intervals**, developed by Neyman [33] only a few years later. (Fisher's contribution to the discussion of Neyman's 1934 paper [33] only added to such confusions.) Here is an elementary case illustrating how all three theories might look alike.

Example 2

Consider x **uniformly distributed** on the interval $[0, \theta]$. That is, let $x \sim \text{U}[0, \theta], \theta > 0$. Thus, $f(x, \theta) = 1/\theta$ for $0 \le x \le \theta$, and $f(x, \theta) = 0$ otherwise, and $F(x, \theta) = x/\theta$ for $0 \le x \le \theta$, $F(x, \theta) = 0$ for $x \le 0$, and $F(x, \theta) = 1$ for $x \ge \theta$. Evidently, $\text{fid}(\theta|x) \propto -\partial F/\partial\theta = 1/\theta^2$ for $x \le \theta$, and $\text{fid}(\theta|x) = 0$ otherwise. [The normalizing constant here equals x, so that $\text{fid}(\theta|x) = x/\theta^2$.] Evidently, this is also a Bayesian posterior density for θ given x, based on the "improper" prior density $p(\theta) = 1/\theta$. This is nothing less than Jeffreys' recommended prior for a scale parameter, which θ is. Also, since the **likelihood** function [$f(x, \theta)$ taken as a function of θ] is monotone decreasing in θ for $x \le \theta$, by a well-known result of Neyman, there is a system of "best" confidence intervals for this problem. These are obtained by inverting on the family of uniformly **most powerful** (UMP) **likelihood ratio tests** for the different possible values of the null hypothesis $\theta = \theta_0$ against the two-sided alternative $\theta \ne \theta_0$. All three approaches produce the same numerical values for interval estimates. For instance, each assigns, respectively, a fiducial or posterior or confidence level of $1 - \alpha$ to the interval $[x \le \theta \le x/\alpha], 0 < \alpha \le 1$, e.g. the level 0.5 is assigned to the interval estimate $x \le \theta \le 2x$.

Fisher generalized his 1930 fiducial reasoning by focusing fiducial inference on pivotal quantities. Let θ be a real-valued parameter, let t be a statistic of the data, and let h be some real-valued function of them both. Call $v = h(\theta, t)$ a *pivotal* quantity if the distribution of v, $F(v)$, does not depend upon the parameter θ. Then pivotal reasoning in support of fiducial probability is just to say that $F(v) = F(v|t)$; that is, the **information** contained in t is irrelevant to v. From Example 1, let $t = (n-1)s^2$ and then $v = t/\sigma^2$ is pivotal, having a χ^2 distribution on

$n - 1$ degrees of freedom. Fiducial probability for the parameter is obtained by inverting on the distribution for the pivotal variable given the data, assuming the data are irrelevant to that pivotal.

When do pivotal variables exist? In the one-dimensional, continuous case they always do, as the cdf $F(x, \theta)$ is itself a pivotal! The cdf, F, is uniformly distributed on the closed unit interval, independent of $\theta : F \sim U[0, 1]$. If we invert on F as a pivotal, the resulting fiducial probability is Fisher's [5] $\text{fid}(\theta|x) \propto -\partial F/\partial\theta$, as given by (1). In Example 2, the pivotal $F = x/\theta$ illustrates this technique. (See Fraser [26] for important extensions of fiducial pivotal reasoning with group structures.)

Fiducial Probability and Confidence Intervals

Evidently, such pivotal reasoning conforms to confidence interval theory. However, not all pivotals support a fiducial probability, as the following illustrates.

Example 2 (Continued)

Suppose, as before, that $x \sim U[0, \theta]$, $\theta > 0$. However, let the parameter space be **truncated** with a known upper bound, $\theta \leq k$. Since the "best" confidence intervals for this problem are based on inverting UMP tests, they do not change with the upper bound, they merely get truncated. That is, the "best" system of confidence intervals for this problem assigns a confidence level of $1 - \alpha$ to the interval $[x \leq \theta \leq \min(x/\alpha, k)]$, $0 < \alpha \leq 1$. However, this system results in interval estimates that, at less than 100% confidence, cover the full parameter space consistent with the data. For example, if $k = 20$ and $\alpha = 0.1$, then this confidence interval system covers all possible parameter values at a 0.90 level whenever $x \geq 2$. Thus, inverting on a pivotal does not always produce a fiducial probability, since it does not always produce a probability, though it supports estimation by confidence intervals.

In the light of the phenomenon just illustrated, to permit the assumption that the data are irrelevant to the distribution of the pivotal, Fisher restricted fiducial reasoning with pivotals to those that have the same range and which are one-to-one for all possible data (and which are based on a sufficient statistic for the parameter of interest; see Tukey [39]). A practical case in point arose with interval estimates for the ratio of two normal means, where the pivotal reasoning supporting confidence intervals is invalid for fiducial probability, since those interval estimates cover the full parameter space at less than 100% confidence: the so-called "Creasy–Fieller" problem (*see* **Fieller's Theorem**). (See Fisher [14].) However, the difference between fiducial probability and confidence interval statements became evident 20 years earlier, in connection with Fisher's treatment of the so-called **"Behrens–Fisher" problem**: inference about the difference in two normal means from independent populations with unknown variance ratios. To appreciate that development, we need to consider more carefully the relationship between fiducial probability and Bayesian posterior probability.

According to Fisher, fiducial probability is special only by its genesis, not by its content. (He says this in numerous places, e.g. [24, p. 59].) That is, whatever we call fiducial probability must satisfy the mathematical calculus of **probability**. The uniqueness of fiducial probability is, supposedly, that it provides statements of inverse probability without admitting into the inference any (unwarranted) "prior" probability for statistical hypotheses, i.e. without relying on Bayes' theorem to derive inverse probability from a likelihood and prior probability. More accurately, fiducial inference attempts to derive inverse probability in the absence of statistically based prior probability. As Fisher expresses it [24, p. 59], a precondition for fiducial inference is that there is insufficient background knowledge to determine an initial (or "prior") value for probability about unknown parameters by direct inference using, say, a hyperpopulation.

Fisher's claim that fiducial probability is probability becomes the basis for its use in Bayes' theorem to solve other forms of statistical inference. In what follows we illustrate three such applications: inverse inference with data of two "kinds", inverse inference involving **nuisance parameters** – multiparameter fiducial inference, and predictive inference.

Data of Two "Kinds"

Suppose datum x admits fiducial inference about parameter θ, but that (independent) datum y (where y's distribution also depends only on θ) does not

allow fiducial inference. For instance, θ may be continuous though y is discrete and there is no acceptable pivotal connecting y and θ. Bayes' theorem yields: $p(\theta|x, y) \propto p(y|\theta)p(\theta|x)$. Fisher relies on fiducial inference to derive the inverse probability term "$p(\theta|x)$" and uses it in Bayes' theorem in this way, as illustrated in the next example.

Example 3 [24, Section 5.6]

Let x be **exponential**, with $F(x, \theta) = 1 - \exp(-x\theta)$ for $0 < \theta$, $0 \leq x$. Let y be a binomial count of a successes and b failures out of n independent trials, each trial with a chance of success $\rho = \exp(-c\theta)$. Then, given x, there is an inverse fiducial density $\text{fid}(\theta|x) = x\exp(-x\theta)d\theta$. Let $\lambda = x/c$. Transformed to express inverse probability for ρ, $\text{fid}(\rho|x) = \lambda\rho^{\lambda-1}\,\text{d}\rho$. But $p(y|\rho) \propto \rho^a(1-\rho)^b$. Hence, with the fiducial probability serving as a "prior" for ρ in Bayes' theorem, $p(\rho|x, y) \propto \rho^{a+\lambda-1}(1-\rho)^b\,\text{d}\rho$.

Fiducial Inference With Nuisance Factors – the "Step-by-step" Argument [24, Section 6.12]

Suppose δ, the parameter of interest, is bound to a nuisance parameter ζ, $p(\text{data}|\delta, \zeta)$ depends on ζ. That is, there is no satisfactory pivotal connecting (a sufficient summary of) the data with δ alone. Instead, let the likelihood factor in two components, for example,

$$p(g, h|\delta, \zeta) = p(g|\delta, \zeta, h)p(h|\zeta),$$

where (g, h) are a jointly sufficient reduction of the data with respect to the two parameters. Suppose the second factor, $p(h|\zeta)$, supports fiducial inference to yield $p(\zeta|g, h) = \text{fid}(\zeta|h)$. This corresponds to the claim that, in the absence of knowledge of δ, h summarizes all the relevant evidence about ζ. (The claim makes sense, I believe, only in connection with the step-by-step method, which affords a Bayesian check for the coherence of the claim. It is used in Example 1, for instance, to say that s^2 contains all the relevant information about σ^2 in the absence of knowledge of μ.) Last, suppose the first factor supports fiducial inference for δ from g, given ζ and h, $\text{fid}(\delta|\zeta, g, h)$. Then these terms may be combined using Bayes' theorem to yield

$$p(\delta|g, h) = \int_\zeta p(\delta|\zeta, g, h)p(\zeta|g, h)\,\text{d}\zeta.$$

This is Fisher's "step-by-step" method for solving the infamous Behrens–Fisher problem.

Example 4: The Behrens–Fisher Problem

Let x_i be iid $\text{N}(\mu_x, \sigma_x^2)$, $i = 1, \ldots, n$. Likewise, let y_i be iid $\text{N}(\mu_y, \sigma_y^2)$, $i = 1, \ldots, n$. All four parameters are unknown, but we are interested in the difference in means: $\delta = \mu_x - \mu_y$. The variances, σ_x^2 and σ_y^2, are nuisance factors. Define $\zeta = (\sigma_x^2/\sigma_y^2)$, the population variance ratio, and let $z = s_x^2/s_y^2$, the sample variance ratio. Last, define the quantity

$$d' = \frac{\overline{x} - \overline{y}}{\left\{\left[s_x^2 + \left(s_y^2\right)\zeta\right]\left[\dfrac{(\zeta+1)}{2\zeta}\right]\right\}^{0.5}}.$$

Then, given ζ, there is a simple fiducial inference from d' to δ, yielding: $p(\delta|d', \zeta)$, as $p(d'|\delta, \zeta)$ is a **Student's *t*** (with $2n - 2$ df), centered on the parameter of interest, δ. Fisher uses a fiducial inference from z to ζ, yielding $p(\zeta|z)$, as $p(z|\zeta)$ has Fisher's ***F* distribution**. (Here is where Fisher assumes z is sufficient for ζ in the absence of knowledge of δ.) Then these fiducial probabilities are combined using Bayes' theorem:

$$p(\delta|\text{data}) = \int_\zeta p(\delta|\,\text{d}', \zeta)p(\zeta|z)\,\text{d}\zeta.$$

It is important to understand that there can be no (exact) confidence intervals or "direct" fiducial argument obtained by inverting on a pivotal, duplicating this inference about δ [32]. That is, to appreciate the Bayesian aspects of the Behrens–Fisher solution, where Bayes' theorem is used to integrate out the nuisance parameter ζ, let us contrast it with the "step-by-step" fiducial method for inference about an unknown normal mean, μ, when σ is a nuisance parameter.

Example 5: Student's t-distribution as a Fiducial Probability

Let x_i be iid $\text{N}(\mu, \sigma^2)$, with both parameters unknown, but with μ, alone, the parameter of interest.

The two sample statistics $\overline{x}$ and s^2, are jointly sufficient for the two parameters. Recall that the likelihood for the data factors:

$$p(\overline{x}, s^2|\mu, \sigma^2) = p(\overline{x}|\mu, \sigma^2)p(s^2|\sigma^2).$$

The second term, $p(s^2|\sigma^2)$, supports fiducial inference about the nuisance factor σ^2, given s^2, as in Example 1. The first term, $p(\overline{x}|\mu, \sigma^2)$, supports fiducial inference about the parameter of interest, μ, given $\overline{x}$ and σ^2. Fiducially, $p(\mu|\overline{x}, \sigma^2)$ is normal $\mathrm{N}(\overline{x}, \sigma^2/n)$. These fiducial probabilities may be used in Bayes' theorem to solve for the marginal, inverse probability for the parameter of interest, just as in the Behrens–Fisher problem:

$$p(\mu|\overline{x}, s^2) = \int_\sigma p(\mu|\overline{x}, \sigma^2)p(\sigma^2|s^2)\ \mathrm{d}\sigma.$$

This yields the familiar Student's t distribution ($n - 1$ df) as a fiducial probability for μ. However, unlike the Behrens–Fisher distribution for δ, the t distribution may also be derived in a one-step, "direct" argument using the pivotal variable: $t = \mathrm{N}^{1/2}(\mu - \overline{x})/s$, which has Student's t distribution (with $n - 1$ df).

Alas, there is no guarantee that such "direct" fiducial reasoning coheres with what the "step-by-step" methods yields. The difficulty is illustrated in the next example.

Example 5 (Continued): The Buehler–Feddersen Problem

Let $n = 2$, so we have two (iid) observations from $\mathrm{N}(\mu, \sigma^2)$. Trivially, there is the direct probability,

$$p(x_{\min} \leq \mu \leq x_{\max}|\mu, \sigma^2) = 0.5, \qquad (2)$$

for each pair (μ, σ^2). Likewise, the fiducial "marginal" t probability (1 df) satisfies,

$$p(x_{\min} \leq \mu \leq x_{\max}|x_1, x_2) = 0.5, \qquad (3)$$

for all samples (x_1, x_2). Define the statistic $u = |x_1 + x_2|/|x_1 - x_2|$. Then, as Buehler & Feddersen [1] proved, within a year of Fisher's death, for each pair (μ, σ^2),

$$p(x_{\min} \leq \mu \leq x_{\max}|\mu, \sigma^2, u \leq 1.5) > 0.518. \qquad (4)$$

If the observed sample satisfies $u \leq 1.5$, then does not the inequality (4) give relevant information that conflicts with the statement (2), thus precluding (3)? Given $u \leq 1.5$, is not the fiducial step invalid for the t pivotal? Is the evidence $u \leq 1.5$ relevant to inference about the pivotal quantity: $p(t) \neq p(t|u \leq 1.5)$? The question remains open. For some recent discussion of this apparent conflict, see Seidenfeld [37, 38] and Zabell [40].

Fiducial Prediction

Prediction of independent observations offers a third variety of fiducial inference using fiducial probabilities in Bayes' theorem. Suppose that the joint likelihood for our data factors: $p(x_1, x_2|\mu) = p(x_1|\mu)p(x_2|\mu)$. Bayes' theorem leads to the result:

$$p(x_2|x_1) \propto \int_\mu p(x_2|\mu)p(\mu|x_1)\ \mathrm{d}\mu.$$

We can use the fiducial probability $\mathrm{fid}(\mu|x_1) = p(\mu|x_1)$ in this simple consequence of Bayes' theorem to derive a fiducial prediction for x_2 given x_1. Fisher [19] gives this analysis for a case of normal prediction when both μ and σ^2 are unknown. That problem involves the joint fiducial posterior for (μ, σ^2) given an observed sample, which then is integrated out to yield the fiducial prediction for a second, independent sample from the same population.

Non-Bayesian Aspects of Fiducial Inference

The fiducial argument displays its non-Bayesian character through reliance on the sample space of possible observations to locate its Bayesian model. That is, the prior in a Bayes' model for fiducial inference may depend upon which component of the likelihood is used to drive the fiducial argument.

Example 6: Inconsistent Fiducial Inferences Using Bayes' Theorem

Let $x \sim \mathrm{N}(\mu, 1)$ and, independently, let $y \sim \mathrm{N}(\nu, 1)$, where $\mu = \nu^3$. Such a variety of data might arise by using different measurement techniques for the same (theoretical) unknown parameter. However, because μ and ν are not linearly related, there is no real-valued sufficient statistic for the pair (x, y) – they

are minimally sufficient by themselves. The joint likelihood factors:

$$p(x, y|\mu) = p(x|\mu)p(y|\mu),$$

so there is the opportunity for using Bayes' theorem with a fiducial probability based on (either) one of these factors:

$$p(\mu|x, y) \propto p(x|\mu)\ \mathrm{fid}(\mu|y)$$

and

$$p(\mu|x, y) \propto p(y|\mu)\ \mathrm{fid}(\mu|x).$$

However, contrary to Bayes' theorem, the fiducial probability, $p(\mu|x, y)$, depends upon which factor of the likelihood is used for fiducial inference. This is readily understood in terms of Jeffreys' Bayesian model for the fiducial argument. When we create $p(\mu|y)$ by fiducial reasoning, we use the pivotal $y - \nu$ whose Bayesian model requires a uniform ("improper") prior over ν. When, instead, we create $p(\mu|x)$ by fiducial reasoning, we use the pivotal $x - \mu$ whose Bayesian model requires a uniform ("improper") prior over μ. Because μ and ν are nonlinear transformations of the same quantity, it is impossible to have a uniform distribution simultaneously over both. (See Lindley [31] for an important discussion of conditions when fiducial and Bayesian posterior probability agree. Fisher's reply [19] is disappointing, by comparison.) In his 1957 paper, Fisher [16] proposes a modified fiducial argument with inequalities in place of equalities of probabilities, e.g. fiducial conclusions of the form $p(\theta \geq 0) > 0.5$ to replace statements like $p(\theta \geq 0) = 0.5$. This idea relates to current research using sets of probabilities, rather than a single probability, to represent an inductive conclusion. Can ignorance be depicted by a large set of prior probabilities? Explicit connection of this approach with fiducial inference is found in Dempster's [3] work and in Kyburg's [29, 30] novel theory. Perhaps it is premature to say we have seen the end of the fiducial idea!

In a 1963 conference on fiducial probability, Savage wrote [36, p. 926]: "The aim of fiducial probability ... seems to be what I term 'making the Bayesian omelet without breaking the Bayesian eggs'." In that sense, fiducial probability is impossible. As with many great intellectual contributions, what is of lasting value is what we learn trying to understand Fisher's insights on fiducial probability. (See Edwards [4] for much more on this theme.) His solution to the Behrens–Fisher problem, for example, was a brilliant treatment of nuisance parameters using Bayes' theorem. In this sense, "... the fiducial argument is 'learning from Fisher"' [36, p. 926]. Thus interpreted, it certainly remains a valuable addition to the statistical lore.

TEDDY SEIDENFELD

Fieller's Theorem

Fieller's theorem is used in finding a **confidence set** for a ratio of parameters, $\rho = \theta_1/\theta_2$. This problem arises in a variety of biostatistical problems including inverse dose estimation in quantal bioassay (*see* **Quantal Response Models**) [estimation of the LD_{50} (or **median effective dose**) is a special case], estimation of relative potency in **slope-ratio** and **parallel-line** bioassays (see [2]), and the assessment of **bioequivalence**. Other applications include inverse prediction in linear **calibration** and estimation of the point of intersection of two **linear regressions** or the point of extremum in a quadratic regression (*see* **Polynomial Regression**).

In general there are two statistics, $\hat{\theta}_1$ and $\hat{\theta}_2$, which estimate θ_1 and θ_2, respectively. It is assumed that $(\hat{\theta}_1, \hat{\theta}_2)$ follows either exactly or approximately a bivariate normal distribution with mean (θ_1, θ_2) with $\sigma_{11} = \text{var}(\hat{\theta}_1)$, $\sigma_{22} = \text{var}(\hat{\theta}_2)$, and $\sigma_{12} = \text{cov}(\hat{\theta}_1, \hat{\theta}_2)$. An estimate of the covariance matrix is available with $\hat{\sigma}_{ij}$ denoting the estimate of σ_{ij}. In the original, exact form of Fieller's theorem [1] $(\hat{\theta}_1, \hat{\theta}_2)$ is exactly normally distributed with $\sigma_{ij} = \sigma^2 v_{ij}$, where the v_{ij} are known constants, and there is a $\hat{\sigma}$, independent of $(\hat{\theta}_1, \hat{\theta}_2)$, such that $d\hat{\sigma}^2/\sigma^2$ follows a **chi-square distribution** with d **degrees of freedom**. This leads to

$$H(\rho) = \frac{(\hat{\theta}_1 - \rho\hat{\theta}_2)}{(\hat{\sigma}_{11} - 2\rho\hat{\sigma}_{12} + \rho^2\hat{\sigma}_{22})^{1/2}}$$

following exactly a **Student's *t* distribution** with d degrees of freedom. This arises when estimating a ratio of linear combinations in a normal linear model; see [5]. In other contexts $(\hat{\theta}_1, \hat{\theta}_2)$ is only approximately normal and the $\hat{\sigma}_{ij}$s are **consistent estimators** of the σ_{ij}s leading to $H(\rho)$ being approximately t distributed with d degrees of freedom; where $d = \infty$ designates a standard normal distribution.

With $t_{1-\alpha/2}(d)$ denoting the $100(1-\alpha/2)$th percentile of the t distribution with d degrees of freedom,

$$P[H(\rho)^2 \leq t_{1-\alpha/2}(d)^2] = 1 - \alpha. \qquad (1)$$

This holds exactly or approximately according to whether $H(\rho)$ follows exactly or approximately a t distribution, and the resulting confidence set is exact or approximate accordingly. Eq. (1) can be rewritten as $P(Q(\rho) \leq 0) = 1 - \alpha$, where $Q(\rho) = f_0 - 2f_1\rho + f_2\rho^2$ is a quadratic function of ρ, with $f_0 = \hat{\theta}_1^2 - t_{1-\alpha/2}(d)^2\hat{\sigma}_{11}$, $f_1 = \hat{\theta}_1\hat{\theta}_2 - t_{1-\alpha/2}(d)^2\hat{\sigma}_{12}$, and $f_2 = \hat{\theta}_2^2 - t_{1-\alpha/2}(d)^2\hat{\sigma}_{22}$. A confidence set for ρ with confidence coefficient $1 - \alpha$ is given by the set of values c satisfying $Q(c) \leq 0$. Defining $D = f_1^2 - f_0 f_2$, $r_1 = (f_1 - D^{1/2})/f_2$, and $r_2 = (f_1 + D^{1/2})/f_2$, the confidence set for ρ is:

Case 1. A finite interval $[r_1, r_2]$, if $D \geq 0$ and $f_2 \geq 0$.

Case 2. The complement of a finite interval, $(-\infty, r_2] \cup [r_1, \infty)$, if $D \geq 0$ and $f_2 < 0$.

Case 3. $(-\infty, \infty)$ if $D < 0$ and $f_2 < 0$.

It is known that $D < 0$ and $f_2 \geq 0$ cannot occur together; see [4]. Hence we get a finite interval if and only if $f_2 \geq 0$ or equivalently $|\hat{\theta}_2/\hat{\sigma}_{22}^{1/2}| \geq t_{1-\alpha/2}(d)$, which means rejecting $H_0 : \theta_2 = 0$ (*see* **Hypothesis Testing**). When $f_2 < 0$ we do not reject $H_0 : \theta_2 = 0$ and the confidence set is infinite (Cases 2 and 3). Note that if $\theta_2 = 0$, then ρ is ill defined. While such confidence sets have often been dismissed as uninformative or worse (Miller [3] calls them "absurdities") they can have a reasonable interpretation. Fortunately, a finite interval usually results in practice.

One alternative confidence interval uses

$$\hat{\rho} \pm t_{1-\alpha/2}(d)\left[\frac{\hat{\sigma}_{11} - 2\hat{\rho}\hat{\sigma}_{12} + \hat{\rho}^2\hat{\sigma}_{22}}{\hat{\theta}^2}\right]^{1/2},$$

where $\hat{\rho} = \hat{\theta}_1/\hat{\theta}_2$. This results from a **delta method** approximation to the variance of $\hat{\rho}$. While this interval (which is close to $[r_1, r_2]$ from Fieller's theorem for many data sets) is sometimes suitable it can perform badly in terms of achieving the desired confidence coefficient of $1 - \alpha$.

Finite Population Correction

In **simple random sampling** without replacement of n units from a population of N units (*see* **Sampling With and Without Replacement**), the **variance** of an **estimate** differs from that which would have been obtained under simple random sampling *with* replacement by a factor known as the *finite population correction* (fpc). This factor is given by

$$\text{fpc} = \frac{N-n}{N-1}.$$

For example, the variance of a sample **mean**, $\overline{x}$, of a variable, χ, is given under simple random sampling without replacement by the expression:

$$\text{var}(\overline{x}) = \frac{\sigma_x^2}{n}\left(\frac{N-n}{N-1}\right),$$

where σ_x^2 is the variance of the distribution of x. Under simple random sampling with replacement, the variance would be equal to σ_x^2/n without the fpc.

The effect of the fpc on the **standard error** of an estimate is very small in surveys where the sampling fraction, n/N, is low (e.g. below 10%). For sampling fractions that are not small, however, it could produce a sizable reduction in the standard error of an estimate and should not be ignored in the construction of **confidence intervals** or tests of hypotheses (*see* **Hypothesis Testing**). High sampling fractions are most likely to occur in practice when oversampling of relatively small population groups is carried out.

For an *estimated* variance under simple random sampling without replacement, the finite population correction is given by the expression, $(N-n)/N$, and the estimated variance of an estimated sample mean given by:

$$\widehat{\text{var}}(\overline{x}) = \frac{s_x^2}{n}\left(\frac{N-n}{N}\right),$$

where s_x^2 is the sum of the squared deviations about the sample mean divided by $n-1$. The derivation of this is shown in most sampling texts (e.g. Levy & Lemeshow [1]).

Some form of an fpc appears for designs other than simple random sampling that involve sampling without replacement (e.g. **stratified sampling**, single-stage **cluster sampling**, **multistage sampling**). For example, in single-stage cluster sampling, the fpc has the form, $(M-m)/(M-1)$, where M is the number of clusters in the population, and m is the number of clusters in the sample.

PAUL S. LEVY

Fisher Lectures

The major statistical legacy of **R.A. Fisher** is marked by three series of lectures: in North America, in the United Kingdom, and in Australia.

North America

The R.A. Fisher Lectureship was established in 1963 by the **Committee of Presidents of Statistical Societies** (COPSS) to honor both the contributions of Sir Ronald Aylmer Fisher and the work of a present-day statistician for their advancement of statistical theory and applications. The list of Fisher lectures well reflects the prestige that COPSS and its constituent societies place on this lectureship. Biometrics and biostatistics have repeatedly been prominent in the lectures themselves in large part because of Fisher's pivotal contributions to these areas, directly and indirectly. The Fisher Lectureship is a very high recognition of meritorious achievement and scholarship in statistical science and recognizes the highly significant impact of statistical methods on scientific investigations.

The Fisher lecture is intended to be broadbased and emphasizes those aspects of statistics and probability, which bear close relationship to the scientific collection and interpretation of data, areas in which Fisher made outstanding contributions. The lecturer is expected to prepare a manuscript based on the appropriate lecture and to submit it to one of the COPSS society journals.

United Kingdom

The series of Fisher Memorial Lectures in Great Britain is the responsibility of a Committee established in 1965 by representatives of the Royal Society of London, the **Royal Statistical Society**, the Genetical Society, and the British Region of the **International Biometric Society**. The Committee are the trustees of a fund whose purpose is to provide for lectures to be given "on any subject or field of science or learning associated with the name of the late Sir Ronald Aylmer Fisher, namely, the application of mathematics to biology", any residue to be used "to further knowledge and research in any of the said fields".

1966 F. Yates, "Computers, the second revolution in statistics"
1968 R.R. Race, "Blood groups in human genetics"
1969 E.A. Cornish, "Developments from the Fisher–Cornish expansions"
1970 K. Mather, "On biometrical genetics"
1972 G.A. Barnard, "Statistical inference in its historical development"
1974 L.L. Cavalli-Sforza, "Cultural versus biological evolution"
1977 R. Hide, "Motions in planetary fluids"
1978 D.J. Finney, "Bioassay and the practice of statistical inference"
1981 J. Maynard Smith, "The evolution of the sex ratio"
1981 J.H. Bennett, "R.A. Fisher and the genetical theory of natural selection"
1983 S. Karlin, "Kin selection and altruism"
1984 D.R. Cox, "Regression and the design of experiments"
1986 S.M. Stigler, "Francis Galton and the unravelling of the normal world"

Australia

With the impending centenary of Fisher's birth in 1990, the following lectures were given at La Trobe University, Victoria, supported by the Department of Genetics and Human Variation:

1986 Bryan C. Clarke, "The Selective theory of molecular evolution"
1987 R.J. Berry, "Mice and the mess of molecular evolution"

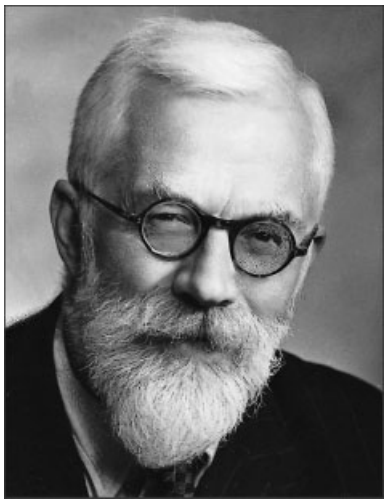
In 1989, Professor P.A. Parsons decided to endow the continuation of this series at the University of Adelaide, where Fisher spent the last two years of his life. The lectures are specified to be "in a field to which Sir Ronald Fisher contributed namely, Genetics, Evolutionary Biology or Statistics". The lectures so far have been given by:

1990 R.S. Holmes, "Ultraviolet light and the cornea: genetic and biochemical aspects of ultra-violet radiation photoreception"
1992 A.W.F. Edwards, "Mendel, Galton, Fisher"
1995 P.A. Parsons, "Conservation strategies: adaptation to stress versus the preservation of genetic diversity"
1995 J.H. Bennett, "Fisher's work on inheritance in the tetrasomic wild plant *Lythrum salicaria* 1935–1959"

1996	Sir Gustav Nossal, "Genetics and vaccination: theoretical and practical aspects"	DOUGLAS G. ALTMAN
1997	Sean B. Carroll, "Living in the past: Xox genes and the evolution of animal body patterns"	

Fisher, Ronald Aylmer

Born: February 17, 1890, in East Finchley, London, UK.
Died: July 29, 1962, in Adelaide, Australia.



Reproduced by permission of the Royal Statistical Society

Ronald Aylmer Fisher achieved original scientific research of such diversity that the integrity of his approach is masked. Born into the era of Darwin's evolutionary theory and Maxwell's theory of gases, he sought to recognize the logical consequences of an indeterministic world, the certainties of which were essentially statistical. His interests were those of **Karl Pearson**, who dominated the fields of evolution, biometry, and statistics during his youth, but his perspective was very different. His ability to perceive remote logical connections of observation and argument gave his conceptions at once universal scope and coherent unity, so that he was little influenced by current scientific vogue at any period of his life.

Fisher was the seventh and youngest child of George Fisher, fine arts auctioneer in the West End, and Katie, daughter of Thomas Heath, solicitor of the City of London. His ancestors had showed no strong scientific bent, but his uncle, Arthur Fisher, was a Cambridge Wrangler.

Already, in childhood, Fisher met the misfortune of poor eyesight and the eye strain that was always to limit his private reading, and he learned to listen while others read aloud to him. His general intelligence and mathematical precocity were apparent early. From Mr Greville's school in Hampstead he went on to Stanmore in 1900, and entered Harrow School in 1904 with a scholarship in mathematics. In his second year there he won the Neeld Medal in mathematical competition with the whole school. To avoid eye strain he received tuition in mathematics under G.H.P. Mayo without pencil, paper, or other visual aids. Choosing spherical trigonometry for the subject of these tutorials, he developed a strong geometrical sense that was greatly to influence his later work. Fisher's interest in natural history was reflected in the books chosen for special school prizes at Harrow, culminating in his last year, in the choice of the complete works of Charles Darwin, in 13 volumes. In 1909 he won a scholarship in mathematics to Cambridge University. In 1912 he graduated from Cambridge as a Wrangler and, awarded a studentship for one year in the Cavendish Laboratory, studied the theory of errors under F.J.M. Stratton and statistical mechanics and quantum theory under J. Jeans.

In April 1912, Fisher's first paper [1] was published, in which the method of **maximum likelihood** was introduced (although not yet by that name). As a result, that summer Fisher wrote to **W.S. Gosset** ("Student") questioning his divisor $(n-1)$ in the formula for the **standard deviation**. He then reformulated the problem in an entirely different and equally original way in terms of the configuration of the sample in n-dimensional space, and showed that the use of the sample **mean** instead of the population mean was equivalent to reducing the dimensionality of the sample space by one; in this way he recognized the concept of what he later called **degrees of freedom**. Moreover, the geometrical formulation immediately yielded **Student's *t* distribution**, which Gosset had derived empirically, and in September Fisher sent Gosset the mathematical proof. This was included in Fisher's paper when, two years later, using the geometrical representation, he derived the general **sampling distribution** of the **correlation** coefficient [2].

Fisher's mathematical abilities were directed into statistical research by his interest in evolutionary theory, especially as it affected man. This interest, already developing at Harrow, resulted in the formation of the Cambridge University Eugenics Society in the spring of 1911, at Fisher's instigation. He served on its Council even while he was chairman

of the undergraduate committee, and he was the main speaker at the second annual meeting of the Society. While famous scientists wrangled about the validity either of evolutionary or of genetic theory, Fisher accepted both as mutually supportive. While the applicability of genetic principles to the continuous variables in man was disputed on biometric grounds, Fisher assumed that the observed variations were produced genetically, and in 1916 [3] justified this view by biometric argument.

In its application to man, selection theory raised not only scientific but practical problems. The birth rate showed a steep and regular decline relative to increased social status. This implied the existence throughout society of selection against every quality likely to bring social success (*see* **Adverse Selection**). Fisher believed, therefore, that it must result in a constant attrition of the good qualities of the population, such as no civilization could long withstand. He considered it important to establish the scientific theory on a firm quantitative basis through statistical and genetic research, and, more urgently, to publicize the scientific evidence so that measures could be taken to annul the self-destructive fertility trend.

Fisher accepted at once J.A. Cobb's suggestion in 1913 that the cause of the dysgenic selection lay in the economic advantage enjoyed at every level of society by the children of small families over those from larger families. Later, he proposed and urged the adoption of various schemes to spread the financial burden of parenthood, so that those who performed similar work should enjoy a similar standard of living, irrespective of the number of their children. In this he was not successful, and the family allowance scheme adopted in Great Britain after World War II disappointed him.

To further these aims, on leaving college he began work with the Eugenics Education Society of London, which was to continue for 20 years. From 1914 he was a regular book reviewer for the *Eugenics Review*; in 1920 he became business secretary and in 1930 vice-president of the Society; and he pursued related research throughout this period. Major Leonard Darwin, Charles Darwin's fourth son and president of the Society from 1912 to 1929, became a dear and revered friend, a constant encouragement and support while Fisher was struggling for recognition, and a stimulus to him in the quantitative research that resulted in *The Genetical Theory of Natural Selection* [12].

In 1913 Fisher took a statistical job with the Mercantile and General Investment Company in the City of London. He trained with the Territorial Army and, on the outbreak of war in August 1914, volunteered for military service. Deeply disappointed by his rejection due to poor eyesight, he served his country for the next five years by teaching high school physics and mathematics. While he found teaching unattractive, farming appealed to him both as a service to the nation and as the one life in which a numerous family might have advantages. When, in 1917, he married Ruth Eileen, daughter of Dr Henry Grattan Guinness (head of the Regions Beyond Missionary Union at the time of his death in 1915), Fisher rented a cottage and smallholding from which he could bicycle to school, and with Eileen and her sister began subsistence farming, selling the excess of dairy and pork products to supply needs for which the family could not be self-sufficient. Their evening hours were reserved for reading aloud, principally in the history of earlier civilizations.

In these years, Fisher's statistical work brought him to the notice of Karl Pearson. In 1915, Pearson published in ***Biometrika*** [2] Fisher's article on the general sampling distribution of the correlation coefficient, and went on to have the ordinates of the error distribution of estimated correlations calculated in his department. The resulting cooperative study was published in 1917, together with a criticism of Fisher's paper not previously communicated to its author. Pearson had not understood the method of maximum likelihood that Fisher had used, and condemned it as being inverse, or **Bayesian**, inference, which Fisher had deliberately avoided. Fisher, then unknown, was hurt by Pearson's high-handedness and lack of understanding, which eventually led to their violent confrontation. Meanwhile, Pearson ignored Fisher's proposal to assess the significance of correlations by considering not the correlation r itself but a remarkable **transformation** $z = \frac{1}{2}\ln[(1+r)/(1-r)]$ that reduced the highly **skewed** distributions with unequal **variances** to distributions which, to a close approximation, are **normal** with constant variance.

Fisher's paper on the correlation between relatives on the supposition of Mendelian inheritance [3] (*see* **Mendel's Laws**), submitted to the Royal Society in 1916, had to be withdrawn in view of the referees' comments (by Pearson and R.C. Punnett). Knowing that Pearson disagreed with his conclusions, Fisher had hoped that his new method, using **analysis of**

variance components, might have been persuasive. In this paper the subject and methodology of biometric genetics were created (*see* **Human Genetics, Overview**). These facts influenced Fisher's decision, in 1919, not to accept Pearson's guarded invitation to apply for a post in his department at University College London.

In September 1919, Fisher started work in a new, at first temporary, post as statistician at Rothamsted Experimental Station, where agricultural research had been in progress since 1843. He quickly became established in this work. He began with a study of historical data from one of the long-term experiments, with wheat on a field known as Broadbalk, but soon moved on to consider data obtained in current field trials for which he developed the analysis of variance. These studies brought out the inadequacies of the arrangement of the experiments themselves, and so led to the evolution of the science of **experimental design**. As Fisher worked with experimenters using successively improved designs, there emerged the principles of **randomization**, adequate replication, **blocking** and **confounding**, and **randomized blocks**, **Latin squares**, **factorial** arrangements, and other designs of unprecedented efficiency. The statistical methods were incorporated in successive editions of *Statistical Methods for Research Workers* (1925) [8], and an 11-page paper on the arrangement of field experiments [9] was expanded into a book, *The Design of Experiments* (1935) [14]. These volumes were supplemented by *Statistical Tables for Biological, Agricultural and Medical Research* (1938) [18], co-authored with **Frank Yates**.

Following up his work on the distribution of the correlation coefficient, Fisher derived the sampling distributions of other statistics in common use, including the variance ratio (called ***F*** in his honor by **G.W. Snedecor**) and the multiple correlation coefficient (*see* **Multiple Linear Regression**). Using geometric representations, he solved, for normally distributed errors, all the distribution problems for the **general linear model**, both when the **null hypothesis** is true and when an **alternative hypothesis** is true [7, 10].

Concurrently, the theory of **estimation** was developed in two fundamental papers in 1922 [5] and 1925 [6]. Fisher was primarily concerned with the small samples of observations available from scientific experiments, and was careful to draw a sharp distinction between sample statistics (estimates) and population values (parameters to be estimated). In the method of maximum likelihood he had found a general method of estimation that had many advantages. It not only provided a method by which to calculate unique numerical estimates for any problem that could be precisely stated, but also indicated what mathematical function of the observations ought to be used to estimate the parameter. His first application of the method of maximum likelihood was in 1922, to the estimation of genetic **linkage** in an example with no fewer than seven parameters.

In 1920, Fisher had compared two different estimators of the standard deviation σ of a normal distribution [4], showing that the sample standard deviation s was not only better but uniquely best, because the distribution of any other measure of spread conditional on s does not involve the parameter σ of interest. Once s is known, therefore, no other estimate gives any further information about σ. Fisher called this quality of s **sufficiency**. This finding led to his introduction of the concept of the amount of **information** in the sample, and to the criteria of the **consistency** and **efficiency** of estimators measured against the yardstick of available information. He exploited the **asymptotic relative efficiency** of the method of maximum likelihood in 1922, and, extending consideration to small samples in 1925, observed that small-sample sufficiency, when not directly available, was obtainable via **ancillary statistics** derived from the **likelihood** function.

Thus, seven years after moving to Rothamsted, Fisher had elucidated the underlying theory and provided the statistical methods that research workers urgently needed to deal with the ubiquitous variation encountered in biological experimentation. Thereafter, he continued to produce a succession of original researches on a wide variety of statistical topics. For example, he initiated nonlinear design, invented k-statistics, and explored **extreme-value** distributions, harmonic analysis, **multivariate analysis** and the **discriminant** function, the **analysis of covariance**, and new elaborations of experimental design and of sample surveys.

In developing his theory of estimation Fisher explored the type of uncertainty expressible precisely in terms of the likelihood, and his ideas on the subject never ceased to evolve. From the beginning he distinguished likelihood from mathematical probability, the highest form of scientific **inference**, which

he considered appropriate only for a restricted type of uncertainty. He accepted classical probability theory, of course, and used **Bayes' theorem** in cases in which there was an observational basis for making probability statements in advance about the population in question, as was often the case in genetics; furthermore, he proposed the **fiducial** argument as leading to true probability statements, at least in one common class of cases.

Fisher introduced the fiducial argument in 1930 [11]. In preparing a paper on the general sampling distribution of the multiple correlation coefficient in 1928, he noticed that in the test of significance the relationship between the estimate and the parameter was of a type that he later characterized as pivotal. He argued that if the one quantity were fixed, then the distribution of the other was determined; consequently, once the observations fixed the value of the observed statistic, the whole distribution of the unknown parameter was determined. Thus, in cases in which a pivotal relationship existed, true probability statements concerning continuous parameters could be inferred from the data provided that exhaustive (fully informative) estimators were available [13].

Controversy arose immediately. Fisher had proposed the fiducial argument as an alternative to the Bayesian argument of inverse probability, which he condemned in all cases in which no objective prior probability could be stated. While **H. Jeffreys** led the debate on behalf of the less restrictive use of inverse probability, in 1934 **J. Neyman** developed an approach to the theory of estimation by deliberately omitting from Fisher's fiducial theory the requirement for exhaustive estimation, thus inaugurating the theory of **confidence intervals**. In some instances this led to numerical results that were different from Fisher's. For many years the debate focused on the case of estimating the difference between two normally distributed populations with unknown variances not assumed to be equal (Behrens's test; *see* **Behrens–Fisher Problem**). Later difficulties with the fiducial argument arose in cases of multivariate estimation because of the nonuniqueness of the pivotals. Fisher did not achieve clarification of the criteria for selection among such alternative pivotals; he was working on the problem at the end of his life.

In proposing the fiducial argument in 1930, Fisher highlighted the main issues of scientific inference and compelled a more critical appreciation of the assumptions made, and of their consequences, in the various approaches to the problem (*see* **Inference, Foundations of**). In reviewing the subject in *Statistical Methods and Scientific Inference* (1956) [17], he distinguished the conditions in which he believed significance tests (*see* **Hypothesis Testing**), likelihood statements, and probability statements each had an appropriate and useful role to play in scientific inference.

In his genetic studies, having demonstrated the consonance of continuous variation in man with Mendelian principles, and having thereby achieved the fusion of biometry and genetics [3], in the 1920s Fisher tackled the problems of natural selection, expressed in terms of **population genetics**, culminating in *The Genetical Theory of Natural Selection* in 1930 [12], which heralded the neo-Darwinian revolution. The book was dictated to his wife during evenings at home; for a while it took the place of the reading and conversation that ranged from all of the classics of English literature to the newest archaeological research.

At home, too, was Fisher's growing family. His oldest son George was born in 1919; then followed a daughter who died in infancy, a second son, and in the end six younger daughters. True to his **eugenic** ideal, Fisher invested in the future, living simply under conditions of great financial stringency while the children were reared. He was an affectionate father, especially with George, who was soon old enough to join him in such activities as looking after genetic mouse stocks. Wherever possible, he brought the children into his activities and answered their questions seriously, with sometimes brilliant simplicity; he promoted family activities and family traditions. Domestic government was definitely patriarchal, and he punished larger offences against household rules, although with distaste. For as long as possible, the children were taught at home, for he trusted in their innate curiosity and initiative in exploring their world rather than in any imposed instruction. In fact, he treated his children like his students, as autonomous individuals from the beginning, assuming that they would act and think on their own responsibility, even when doing so involved danger or adult disapproval.

In 1929, Fisher was elected a Fellow of the Royal Society, as a mathematician. The influence of his statistical work was spreading, and he was already concerned that statistics should be taught as a practical art employing mathematical reasoning, not as self-contained mathematical theory. In 1933 Karl Pearson

retired and his department at University College, London was split; **E.S. Pearson** succeeded his father as head of the statistics department, and Fisher succeeded as Galton Professor of Eugenics, housed in the same building. For both men, it was an awkward situation. While others gave their interpretation of Fisher's ideas in the statistical department, he offered a course on the philosophy of experimentation in his own. After J. Neyman joined the statistics department in 1934, relations between the new departments deteriorated and controversy followed.

Fisher continued both statistical and genetic research. In 1931, and again in 1936, he was visiting professor for the summer sessions at Iowa State University at Ames, Iowa, at the invitation of G.W. Snedecor, director of the Statistical Laboratory. In 1937–1938 he spent six weeks as the guest of **P.C. Mahalanobis**, director of the Indian Statistical Institute in Calcutta. In his own department, where Karl Pearson had used only biometric and genealogic methods, Fisher quickly introduced genetics. Work with mouse stocks moved from the attic at his home, was expanded, and experimental programs were initiated on a variety of animal and plant species; for example, to study the problematic tristyly in *Lythrum salicaria*. Fisher was very eager also to initiate research in human genetics.

Sponsored by the Rockefeller Foundation, in 1935 he was able to set up a small unit for human serologic research under G.L. Taylor, who was joined by R.R. Race in 1937. His hopes that a linkage map of man could be built up using **blood groups** as **genetic markers** with a view to locating disease loci were only to be realized after his death. In 1943, he interpreted the bewildering results obtained with the new *Rh* blood groups in terms of three closely linked loci and correctly predicted the discovery of two new antibodies and an eighth allele. Fisher's enthusiasm for blood-group **polymorphisms** continued to the end of his life, and he did much to encourage studies of associations between blood groups and disease.

In 1927, Fisher proposed a way of measuring selective intensities on genetic polymorphisms occurring in wild populations, by a combination of laboratory breeding and field observation, and by this method later demonstrated very high rates of selective predation on grouse locusts. E.B. Ford was one of the few biologists who believed in natural selection at the time, and in 1928 he planned a long-term investigation of selection in the field, based on Fisher's method. To the end of his life, Fisher was closely associated with Ford in this work, which involved development of **capture–recapture** techniques and of sophisticated new methods of statistical analysis. The results were full of interest, and wholly justified their faith in the evolutionary efficacy of natural selection alone.

Fisher took a continuing delight in computation, introducing an electric calculating machine to Rothamsted and taking pleasure in the neat devices by which he could reduce the labor of computation. He showed little enthusiasm for electronic computers; yet in 1950 he was the first person to publish results in a biological context obtained from the new machines [16].

Forcibly evacuated from London on the outbreak of war in 1939, Fisher's department moved to Rothamsted and, finding no work as a unit, gradually dispersed; Fisher himself could find no work of national utility. In 1943 he was elected Arthur Balfour Professor of Genetics at Cambridge, which carried with it a professorial residence. Lacking other accommodation, he moved his staff and genetic stocks into the residence, leaving his family in Harpenden. Estranged from his wife, separated from home, and deeply grieved by the death in December 1943 of his son George on active service with the Royal Air Force, Fisher found companionship with his fellows at Caius College, and with the serologic unit (evacuated to Cambridge for war work with the Blood Transfusion Service), which planned to join his new department after the war.

There was little support after the war for earlier plans to build up an adequate genetics department. No bid was made to keep the serologic unit. No departmental building was erected. Support for the research in bacterial genetics, initiated in 1948 under L.L. Cavalli (Cavalli-Sforza), was withdrawn in 1950 just as Cavalli's discovery of the first *Hfr* strain of *Escherichia coli* heralded the remarkable discoveries soon to follow in bacterial and viral genetics. Fisher cultivated his garden, continued his research, published *The Theory of Inbreeding* (1949) [15] following his lectures on this topic, and built a group of good quantitative geneticists. He attempted to increase the usefulness of the university diploma in mathematical statistics by requiring all candidates to gain experience of statistical applications by doing research in a scientific department. Speaking as founding president of the **International Biometric**

Society (1947), as president of the **Royal Statistical Society**, and as a member or as president of the **International Statistical Institute**, he pointed out how mathematical statistics itself owes its origin and continuing growth to the consideration of scientific data rather than of theoretic problems.

In 1957, Fisher became involved in the controversy over the interpretation of the association between **smoking** and lung cancer, believing that the inference of **causation** was premature and likely to inhibit the further research that he felt was necessary.

Fisher's own interests extended to the work of scientists in many fields. He was a fascinating conversationalist at any time – original, thoughtful, erudite, witty, and irreverent; with the younger men his genuine interest and ability to listen, combined with his quickness to perceive the implications of their research, were irresistible. He encouraged, and contributed to, the new study of geomagnetism under S.K. Runcorn, a fellow of Gonville and Caius College, of which he was president during the period 1957–1960.

Fisher received many honors and awards: the Weldon Memorial Medal (1928), the Guy Medal of the Royal Statistical Society in gold (1947), and three medals of the Royal Society, the Royal Medal (1938), the Darwin Medal (1948), and the Copley Medal (1956); he was created Knight Bachelor by Queen Elizabeth in 1952.

After retirement in 1957, Sir Ronald Fisher traveled widely, joining E.A. Cornish in 1959 as honorary research fellow of the C.S.I.R.O. Division of Mathematical Statistics in Adelaide, South Australia. He died in Adelaide on July 29, 1962. His ashes are interred in St Peter's Cathedral, beneath a plaque in a side aisle.

Fisher's Exact Test

Fisher's exact test can be used to assess the significance of a difference between the proportions in two groups (*see* **Exact Inference for Categorical Data** for a broader context). The test was first described in independently written articles by Irwin [14] and Yates [25]. Yates used the test primarily to assess the accuracy of his correction factor to the χ^2 test, and attributed the key distributional result underlying the exact test to R.A. Fisher. Fisher successfully promoted the test in 1935, presenting two applications, one to an observational study on criminal behavior patterns [8], and another to an artificial example of a controlled experiment on taste discrimination [9].

Typical recent applications are to the results of simple experiments comparing a treatment with a control. The design must be completely randomized, and each experimental unit must yield one of two possible outcomes (like success or failure). Consider, for example, the study reported by Hall et al. [13]. This was a randomized, double-blind, placebo-controlled study on the effect of ribavirin aerosol therapy on a viral infection (RSV) of the lower respiratory tract of infants. After five days of treatment, each infant was examined for the continued presence of viral shedding in nasal secretions.

There were 26 patients in the randomized trial. For illustrative purposes, the following discussion focuses on hypothetical results from a smaller set of only eight patients. Also, a patient showing no signs of viral shedding in nasal secretions will be said to have recovered. Consider, then, the "results" displayed in Table 1.

All three recoveries were in the treatment group. For a frequency table based on only four treatments and four control subjects, the evidence could hardly be more convincing, but is it statistically significant? Had the experiment included more patients, an approximate P value could have been obtained using the standard χ^2 test (*see* **Chi-square Tests**). But we cannot trust the accuracy of this approximation when it is based on observations on so few patients. Fisher's exact test provides a way around this difficulty.

The reasoning behind the test is as follows. Suppose that the treatment was totally ineffectual, and that each patient's recovery over the subsequent five days was unaffected by whether the treatment were applied or not.

Precisely three patients recovered. If the treatment was ineffectual, then these three, and only these three, individuals would have recovered regardless of whether they were assigned to the treatment or control group. The fact that all three did indeed appear in the treatment group would then have been just a coincidence whose probability could be calculated as follows.

When four out of the eight subjects were randomly chosen for the treatment group, the chance that all three of those destined to recover should end up in the treatment group is given by the **hypergeometric distribution** as

$$\frac{({}_3C_3)({}_5C_1)}{{}_8C_4} = 0.071.$$

This is the standard ***P* value** for Fisher's exact test of the **null hypothesis** of no treatment effect against the one-sided alternative that the treatment has a positive benefit.

Consider the more general setting, as portrayed in Table 2.

The P value for testing the null hypothesis that the treatment has no impact vs. the one-sided alternative that it has a positive value is

$$P = \sum_{y=a}^{\min(n,S)} \frac{({}_SC_y)({}_FC_{n-y})}{{}_NC_n}. \qquad (1)$$

For a two-sided alternative there is no universally accepted definition. The two most common

Table 1 Results from a small, comparative experiment

	Recovered	Not recovered	Totals
Treatment	3	1	4
Control	0	4	4
Totals	3	5	8

Table 2 Notation for a 2×2 frequency table of outcomes from a comparative experiment

	Recovered	Not recovered	Totals
Treatment	a	b	n
Control	c	d	m
Totals	S	F	N

approaches are (i) to double the one-sided P value, or (ii) to extend the above sum over the other tail of the distribution, including all those terms which are less than or equal to the probability for the observed table. The latter strategy is deployed by the major statistical packages, BMDP (Two-Way Tables in [5]), JMP (Contingency Table Analysis in Fit Y by X in [21]), SAS (FREQ procedure in [20]), S-PLUS (function, fisher.test in [17]), SPSS (Crosstabs in [23]), StatXact [6], and Systat (Tables in [24]). Gibbons & Pratt [12] discuss possible alternatives.

The test can be extended to an $r \times c$ **contingency table**, as proposed by Freeman & Halton [11]. It is also used on $r \times 2$ tables for **multiple comparisons**, with the usual controversy over adjustments for simultaneous inferences on a single data set (see [22] and references therein).

Applicability and Power

A major advantage of Fisher's exact test is that it can be justified solely through the randomization in the experiment. The user need not assume that all patients in each group have the same recovery probability, nor that patient recoveries occur independently. The patients could, for example, go to one of four clinics, with two patients per clinic. Two patients attending the same clinic might well have experienced delayed recovery from having contacted the same subsidiary infection in their clinic, but the above argument would still be valid as long as *individuals* were randomly selected without restriction from the group of eight for assignment to the treatment vs. control groups.

If, however, the randomization was applied at the clinic level, with two of the four clinics selected for assignment to the treatment group, then the test would be invalid. Compared with the hypergeometric distribution, the data would most likely be overdispersed (*see* **Overdispersion**).

Similarly, if the randomization was restricted by blocking with respect to clinic, the pair of individuals from each clinic being randomly split between the treatment and control groups, then the test would again be invalid. These alternative designs certainly have their place, particularly in larger experiments with more subjects, but the results would have to be analyzed with another test.

The example also illustrates a major weakness of Fisher's exact test. The evidence for a table based on only four subjects in each of two groups could hardly have been more favorable to the alternative. Yet the P value still exceeds 5%, and most observers would rate the evidence as not statistically significant. It is in general difficult to obtain a statistically significant P value with Fisher's exact test, and the test therefore has low power. The most effective way to increase the power may well be to take quantitative measurements. Suppose, for instance, that all four patients who received the treatment showed reduced nasal shedding of the virus. By quantifying this evidence, and subjecting the quantitative measurements to a test of significance, the experimenter could, in many instances, generate a more powerful test.

One could also, of course, consider running the study on a larger group of patients.

Competing Binomial-model Test

It is also possible to obtain greater power by analyzing the above table with another statistical model. The most commonly used competitor involves assuming that the numbers of recovered patients in each group are independently binomially distributed (*see* **Binomial Distribution**). The test was mentioned by Irwin [14], and promoted by Barnard [2]. Although he soon withdrew his support [3], it has since become a popular alternative. Its increased power has been amply demonstrated by D'Agostino et al. [7] and others. For the above table, the P value is 0.035 vs. the 0.071 for Fisher's exact test. The P value based on this binomial model is typically smaller than the one generated by Fisher's exact test. The main reason for the difference is that the standard definition of the P value contains the probability of the observed table, and this probability is higher for Fisher's exact test than for the binomial model [1, 10, 18]. Thus the null hypothesis is more frequently rejected, and the binomial-model test is more powerful. This test is available in **StatXact** [6].

However, the increased power comes at a cost. To justify the binomial model, one must either assume that all patients within each group have the same recovery probability, or envisage that the patients were randomly sampled from some larger group. The trial must also have been conducted so as to ensure that patient deaths occur independently. They cannot, for example, attend four clinics, with two patients per clinic.

There is another, more subtle problem with the binomial model. Simple calculations show that had fewer than three or more than five patients recovered, then neither P value could possibly have been significant. This puts the researcher in an awkward quandary. For example, had only two patients recovered after 5 days, the researcher would have had an incentive either to present the results after more than five days of treatment when at least one more patient had recovered, or to incorporate more patients into the experiment. One does not win accolades for announcing the results of experiments that are not only statistically insignificant, but also apparently barely capable of ever producing significant results.

These are important complications when it comes to interpreting the results of these sorts of small experiments. Suppose, for example, that in the above experiment the researcher was to have adjusted the five-day reporting time, if necessary, so as to guarantee between three and five recoveries. Then the binomial P value would be invalid. The probability of obtaining a table at least as favorable to the treatment as the above one can be shown to be 0.056, not 0.035, as generated by the standard binomial model.

The Mid-*P* Value

The P value of 0.071 generated by Fisher's exact test is still large compared with the 0.056 figure produced by this modified binomial model. There is yet another alternative with important theoretical and practical advantages (see, for example, [16, 4, 1], and [19]). This is the mid-P value, first introduced in 1949 by Lancaster [15]. In place of the standard definition,

$$P \text{ value} = \Pr(\text{evidence at least as favorable to } H_a \text{ as observed } |H_0),$$

they propose the alternative,

$$\text{mid-}P \text{ value} = \Pr(\text{evidence more favorable to } H_a \text{ as observed } |H_0) + \tfrac{1}{2}\Pr(\text{evidence equally favorable to } H_a \text{ as observed } |H_0).$$

Table 3 summarizes the possible P values for the above example. This table illustrates that the mid-P has the potential to provide a smaller, more significant-looking P value, and to reduce the discrepancy between P values generated by competing models. However, by using a smaller P value, one may reject a valid null hypothesis too frequently. Fortunately, amongst other desirable attributes of the mid-P, its routine use does indeed control a quantity closely related to the type I error rate (see [19], and references therein). The computer package, StatXact [6] facilitates the calculation of the mid-P by providing the probability of the observed table along with the standard P value.

Table 3 Comparison of P values for the data in Table 1

	Fisher's exact test	Binomial model	Modified binomial model
Standard P value	7.1%	3.5%	5.6%
Mid-P value	3.6%	2.0%	3.0%

Conclusion

Fisher's exact test provides a widely applicable way to assess the results of simple randomized experiments leading to 2×2 contingency tables. But it has low power, especially when the standard P value is used. The power can be increased considerably through (i) using the mid-P value, or (ii) carefully constructing a test based at least in part on a binomial model. Further power increases can be generated through (iii) taking quantitative measurements on each subject, or (iv) running the trial with a larger number of patients.

RICK ROUTLEDGE

Fixed Effects

Consider an **explanatory variable** which takes on k possible values in a particular data set and which is to be related to a **response variable** via a **regression** model. Assume that some function of the response variable is related to the linear predictor $\mu + \alpha_i, \ \ i = 1, k-1$; or, equivalently, $\alpha_i, i = 1, k$, where i indexes the possible values of the explanatory variable (*see* **Dummy Variables**). Examples of such explanatory variables are an indicator for clinics in a multiclinic study, school classrooms in a study of school children, different studies in a **meta-analysis**, and blocking factors in **experimental design**. Other explanatory variables may be included in the linear predictor. For example, a single additional variable could be added to define a linear predictor $\mu + \alpha_i + \beta X, \ \ i = 1, k-1$.

If the regression analysis focuses on the estimates of the α_is only for values of the explanatory variable in the data set, then the α_is are referred to as fixed effects. This contrasts with the assumption that the α_is represent a **random sample** from a distribution of effects associated with a wider range of possibilities for the explanatory variable, in which case the α_is are referred to as **random effects**. For general discussions of the distinction and its effect on methods of analysis *see* **Analysis of Variance**.

VERN T. FAREWELL

Fixed Population

A fixed population or fixed cohort is a group of individuals defined by a common fixed characteristic, such as all men in the US born in 1941. Membership in a fixed population does not change over time by immigration or emigration, unlike a **dynamic population**, although members of a fixed cohort may experience the health event under study, or may die or be lost to follow-up.

MITCHELL H. GAIL

Fix–Neyman Process

Fix & Neyman [2] introduced a stochastic model to describe recovery, relapse, death and loss of patients in medical follow-up studies of cancer patients. The model is useful also in other areas of research including compartmental analysis, **survival analysis**, and reliability studies. Some examples of applications of the process are given in Table 1.

The Fix–Neyman process has two transient states, S_1 and S_2, denoting health and illness of patients, and two absorbing states, R_1 and R_2, for causes of death. We shall consider it as a special case of a finite **Markov process** [1] with two states. Generally, the states in a Markov process are communicative: any state in the process can be reached from any other state in the process. This means that we shall consider only the two health states S_1 and S_2 in the process, and derive formulas related to the death states R_1 and R_2 through their relationship with the health states. Since a death state is an absorbing state, the number of death states does not influence the complexity of the process.

Fix & Neyman regarded state S_1 as a health state, and S_2 as an illness state, so that a transition from S_1 to S_2 means onset of illness or a relapse, and a transition from S_2 and S_1 means recovery. In the following discussion, we shall consider illness as a state of health, and allow transitions $S_1 \to S_2$ and $S_2 \to S_1$ to take place without specific designation.

Consider, then, a system consisting of two health states, S_1 and S_2, and two death states, R_1 and R_2. Transitions are possible between the two health states S_1 and S_2 and from either one of the health states to a death state. Each death state is an absorbing state: once an individual enters it, he will remain there for ever. Figure 1 is a graphic description of the transition process; the arrows indicate the directions a transition may take place.

Table 1 Examples of Applications of the Fix–Neyman Process

	S_1	S_2
A person is	employed	unemployed
An elevator is	occupied	unoccupied
A telephone line is	engaged	free
A nuclear particle counting instrument is	free	dead
An automobile is	working	out of order

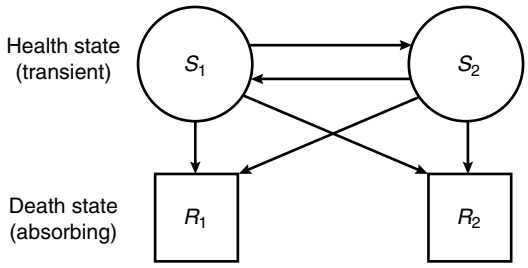

Figure 1 Transitions in the Fix–Neyman process

Transition Probabilities and Intensity Functions

For a time interval (τ, t), we define the *health transition probabilities*

$$P_{\alpha\beta}(\tau, t) = \Pr\{\text{an individual in state } S_\alpha \text{ at } \tau \text{ will be in state } S_\beta \text{ at } t\}, \quad \alpha, \beta = 1, 2, \qquad (1)$$

and the *death transition probabilities*

$$Q_{\alpha\delta}(\tau, t) = \Pr\{\text{an individual in state } S_\alpha \text{ at } \tau \text{ will be in state } R_\delta \text{ at } t\}, \quad \alpha = 1, 2, \delta = 1, 2.$$

At time $t = \tau$, these probabilities will have obvious specific values:

$$P_{\alpha\beta}(\tau, \tau) = \begin{cases} 1, & \beta = \alpha, \\ 0, & \beta \neq \alpha, \alpha, \beta = 1, 2, \end{cases}$$
$$Q_{\alpha\delta}(\tau, \tau) = 0, \quad \alpha = 1, 2, \delta = 1, 2.$$

We assume independence between the transitions in (1). Consider two contiguous time intervals (τ, ξ) and (ξ, t) and two events:

$$A = \{\text{an individual in state } \alpha \text{ at time } \tau \text{ will be in state } \gamma \text{ at time } \xi\}$$

and

$$B = \{\text{an individual in state } \gamma \text{ at time } \xi \text{ will be in state } \beta \text{ at time } t\}.$$

If the events A and B are assumed independent, then we have an important set of Chapman–Kolmogorov equations:

$$P_{\alpha\beta}(\tau, t) = \sum_{\gamma} P_{\alpha\gamma}(\tau, \xi) P_{\gamma\beta}(\xi, t). \tag{2}$$

Transition Intensity Functions

Transition from one health state S_α to another health state S_β is governed by the health intensity function, or transition rate, $\nu_{\alpha\beta}$, and transition from a health state S_α to a death state R_δ is governed by the death intensity function $\mu_{\alpha\delta}$, with the additional definition

$$\nu_{\alpha\alpha} = -\left[\nu_{\alpha\beta} + \sum_{\delta=1}^{2} \mu_{\alpha\delta}\right], \quad \alpha \neq \beta, \alpha, \beta = 1, 2, \tag{3}$$

where $\nu_{\alpha\alpha} < 0, \alpha = 1, 2$. Since these intensity functions are independent of time, the process is time homogeneous.

Differential Equations and Transition Probabilities

For the interval $(\tau, t + \Delta)$ and the two contiguous intervals (τ, t) and $(t, t + \Delta)$, the Chapman–Kolmogorov equations are

$$\begin{aligned} P_{\alpha\alpha}(\tau, t + \Delta) &= P_{\alpha\alpha}(\tau, t) P_{\alpha\alpha}(t, t + \Delta) \\ &\quad + P_{\alpha\beta}(\tau, t) P_{\beta\alpha}(t, t + \Delta), \\ P_{\alpha\beta}(\tau, t + \Delta) &= P_{\alpha\alpha}(\tau, t) P_{\alpha\beta}(t, t + \Delta) \\ &\quad + P_{\alpha\beta}(\tau, t) P_{\beta\beta}(t, t + \Delta). \end{aligned}$$

These equations, as $\Delta \to 0$, lead to the following differential equations:

$$\begin{aligned} \frac{\partial}{\partial t} P_{\alpha\alpha}(\tau, t) &= P_{\alpha\alpha}(\tau, t)\nu_{\alpha\alpha} + P_{\alpha\beta}(\tau, t)\nu_{\beta\alpha}, \\ \frac{\partial}{\partial t} P_{\alpha\beta}(\tau, t) &= P_{\alpha\alpha}(\tau, t)\nu_{\alpha\beta} + P_{\alpha\beta}(\tau, t)\nu_{\beta\beta}, \\ &\quad \alpha \neq \beta, \alpha, \beta = 1, 2. \end{aligned} \tag{4}$$

This is a system of linear, homogeneous, first-order ordinary differential equations with constant coefficients. (Note that, since τ is fixed, the resemblance of (4) to a set of partial differential equations is only formal.) The solution is

$$P_{\alpha\alpha}(\tau, t) = \sum_{i=1}^{2} \frac{\rho_i - \nu_{\beta\beta}}{\rho_i - \rho_j} \exp[\rho_i(t - \tau)]$$

and

$$\begin{aligned} P_{\alpha\beta}(\tau, t) &= \sum_{i=1}^{2} \frac{\nu_{\alpha\beta}}{\rho_i - \rho_j} \exp[\rho_i(t - \tau)], \\ &\quad j \neq i, \ \alpha \neq \beta, \ j, \alpha, \beta = 1, 2, \end{aligned} \tag{5}$$

where

$$\rho_1 = \tfrac{1}{2}\{\nu_{11} + \nu_{22} + [(\nu_{11} - \nu_{22})^2 + 4\nu_{12}\nu_{21}]^{1/2}\},$$

and

$$\rho_2 = \tfrac{1}{2}\{\nu_{11} + \nu_{22} - [(\nu_{11} - \nu_{22})^2 + 4\nu_{12}\nu_{21}]^{1/2}\}$$

are both negative.

The probabilities in (5) depend only on the difference $t - \tau$ but not on τ and t separately; thus the process is *homogeneous with respect to time*, as pointed out earlier. We shall therefore let $\tau = 0$ and let t be the interval length, and write

$$\begin{aligned} P_{\alpha\alpha}(0, t) &= \sum_{i=1}^{2} \frac{\rho_i - \nu_{\beta\beta}}{\rho_i - \rho_j} \exp(\rho_i t), \\ P_{\alpha\beta}(0, t) &= \sum_{i=1}^{2} \frac{\nu_{\alpha\beta}}{\rho_i - \rho_j} \exp(\rho_i t), \quad j \neq i, \\ &\quad \alpha \neq \beta, \ j, \alpha, \beta = 1, 2. \end{aligned} \tag{6}$$

Death Transition Probabilities

The death transition probability $Q_{\alpha\delta}(0, t)$ has a definite relation with the health transition probabilities:

$$Q_{\alpha\delta}(0, t) = \int_0^t P_{\alpha\alpha}(0, \tau)\mu_{\alpha\delta}\, d\tau + \int_0^t P_{\alpha\beta}(0, \tau)\mu_{\beta\delta}\, d\tau. \tag{7}$$

Substitution of (6) into (7), and integration of the resulting expression, gives the formula for the death transition probability:

$$Q_{\alpha\delta}(0, t) = \sum_{i=1}^{2} \frac{\exp(\rho_i t) - 1}{\rho_i(\rho_i - \rho_j)}[(\rho_i - \nu_{\beta\beta})\mu_{\alpha\delta}$$

$$+ \nu_{\alpha\beta}\mu_{\beta\delta}],\ j \neq i,\ \alpha \neq \beta,$$
$$j, \alpha, \beta, \delta = 1, 2. \tag{8}$$

Chapman–Kolmogorov Equation

The Fix–Neyman process described in this article is a Markov process in the sense that the transitions an individual might make in the future are independent of the transitions made in the past. An important consequence of this Markovian property is the Chapman–Kolmogorov equations in (2). Since this process is homogeneous with respect to time, we may rewrite (2) as follows:

$$P_{\alpha\alpha}(0, t) = P_{\alpha\alpha}(0, \tau)P_{\alpha\alpha}(\tau, t) + P_{\alpha\beta}(0, \tau)P_{\beta\alpha}(\tau, t)$$

and

$$P_{\alpha\beta}(0, t) = P_{\alpha\alpha}(0, \tau)P_{\alpha\beta}(\tau, t) + P_{\alpha\beta}(0, \tau)P_{\beta\beta}(\tau, t),$$

for $0 \leq \tau \leq t, \alpha \neq \beta, \alpha, \beta = 1, 2$.

Chapman–Kolmogorov-type equations can be established also for the transition probabilities leading to death:

$$Q_{\alpha\delta}(0, t) = Q_{\alpha\delta}(0, \tau) + P_{\alpha\alpha}(0, \tau)Q_{\alpha\delta}(\tau, t) + P_{\alpha\beta}(0, \tau)Q_{\beta\delta}(\tau, t),$$
$$\alpha \neq \beta,\ \alpha, \beta, \delta = 1, 2.$$

These equations may be verified from (6) and (8).

Expected Duration of Stay

In a study of human health, we may wish to estimate the length of time a person is expected to be healthy. In other studies we may inquire about the length of time an automobile is expected to be in working condition, a person is expected to be employed, or a telephone line is expected to be busy. These inquiries lead to an important concept in the Fix–Neyman process: What is the expected duration of stay in each of the states S_1, S_2, R_1, and R_2 within a time period of length t? This duration depends on the initial state and the corresponding transition probability. For an individual in state S_α at time $t = 0$, let

$$e_{\alpha\beta}(t) = \text{the expected duration of stay in } S_\beta \text{ in the interval } (0, t), \quad \beta = 1, 2,$$

and

$$\varepsilon_{\alpha\delta}(t) = \text{the expected duration of stay in } R_\delta \text{ in the interval } (0, t), \quad \delta = 1, 2.$$

These quantities are related to the transition probabilities by the following equations:

$$e_{\alpha\beta}(t) = \int_0^t P_{\alpha\beta}(0, \tau)\, d\tau$$

and

$$\varepsilon_{\alpha\delta}(t) = \int_0^t Q_{\alpha\delta}(0, \tau)\, d\tau.$$

Substitution from (6) and (8) gives the explicit formulas:

$$e_{\alpha\alpha}(t) = \sum_{i=1}^{2} \frac{\rho_i - \nu_{\beta\beta}}{\rho_i(\rho_i - \rho_j)}(\exp(\rho_i t) - 1)$$

and

$$e_{\alpha\beta}(t) = \sum_{i=1}^{2} \frac{\nu_{\alpha\beta}}{\rho_i(\rho_i - \rho_j)}(\exp(\rho_i t) - 1)$$

for $\alpha \neq \beta, \alpha, \beta = 1, 2$, and

$$\varepsilon_{\alpha\delta}(t) = \sum_{i=1}^{2} \left\{ \frac{1}{\rho_i}[\exp(\rho_i t) - 1] - t \right\} \times \frac{(\rho_i - \nu_{\beta\beta})\mu_{\alpha\delta} + \nu_{\alpha\beta}\mu_{\beta\delta}}{\rho_i(\rho_i - \rho_j)},$$

for $\alpha \neq \beta, \alpha, \beta, \delta = 1, 2$. The sum of the expected durations of stay over all the states is equal to the entire length of the interval:

$$e_{\alpha 1}(t) + e_{\alpha 2}(t) + \varepsilon_{\alpha 1}(t) + \varepsilon_{\alpha 2}(t) = t, \quad \alpha = 1, 2.$$

Limiting Probabilities

Since both ρ_1 and ρ_2 are negative, each of the health transition probabilities in (6) approaches zero as $t \to \infty$:

$$\lim_{t\to 0} P_{\alpha\alpha}(0, t) = \lim_{t\to\infty} \sum_{i=1}^{2} \frac{\rho_i - \nu_{\beta\beta}}{\rho_i - \rho_j} \exp(\rho_i t) = 0,$$

$$\lim_{t\to 0} P_{\alpha\beta}(0, t) = \lim_{t\to\infty} \sum_{i=1}^{2} \frac{\nu_{\alpha\beta}}{\rho_i - \rho_j} \exp(\rho_i t) = 0,$$
$$j \neq i,\ \alpha \neq \beta,\ j, \alpha, \beta = 1, 2,$$

and each of the death transition probabilities in (8) approaches a constant:

$$\lim_{t\to\infty} Q_{\alpha\delta}(0,t) = \lim_{t\to\infty} \sum_{i=1}^{2} \frac{\exp(\rho_i t) - 1}{\rho_i(\rho_i - \rho_j)} \times [(\rho_i - \nu_{\beta\beta})\mu_{\alpha\delta} + \nu_{\alpha\beta}\mu_{\beta\delta}] = \sum_{i=1}^{2} \frac{-[(\rho_i - \nu_{\beta\beta})\mu_{\alpha\delta} + \nu_{\alpha\beta}\mu_{\beta\delta}]}{\rho_i(\rho_i - \rho_j)},$$
$$\alpha \neq \beta,\ \alpha, \beta, \delta = 1, 2.$$

where

$$\sum_{\delta=1}^{2} Q_{\alpha\delta}(0, \infty) = 1.$$

A Time-dependent Fix–Neyman Process

In the above discussion the intensity functions $\nu_{\alpha\beta}$ and $\mu_{\alpha\delta}$ were assumed to be independent of time. If they are replaced by time-dependent functions $\nu_{\alpha\beta}\theta(\xi)$ and $\mu_{\alpha\delta}\theta(\xi)$, with (3) and ρ_1 and ρ_2 unchanged, the formulas for the transition probabilities become

$$P_{\alpha\alpha}(\tau, t) = \sum_{i=1}^{2} \frac{\rho_i - \nu_{\beta\beta}}{\rho_i - \rho_j} \exp\left[\rho_i \int_\tau^t \theta(\xi)\, d\xi\right],$$

$$P_{\alpha\beta}(\tau, t) = \sum_{i=1}^{2} \frac{\nu_{\alpha\beta}}{\rho_i - \rho_j} \exp\left[\rho_i \int_\tau^t \theta(\xi)\, d\xi\right],$$
$$j \neq i,\ \alpha \neq \beta,\ j, \alpha, \beta = 1, 2,$$

and

$$Q_{\alpha\delta}(\tau, t) = \sum_{i=1}^{2} \frac{\exp\left[\rho_i \int_\tau^t \theta(\xi)\, d\xi\right] - 1}{\rho_i(\rho_i - \rho_j)} \times [(\rho_i - \nu_{\beta\beta})\mu_{\alpha\delta} + \nu_{\alpha\beta}\mu_{\beta\delta}]$$

for $\alpha \neq \beta, \alpha, \beta, \delta = 1, 2$.

CHIN LONG CHIANG

Fleiss, Joseph L.

Born: November 13, 1937, in Brooklyn, New York.
Died: June 12, 2003, in Ridgewood, New Jersey.

Joseph L. Fleiss was a statistician whose writings influenced thousands of biomedical researchers in fields ranging from **psychiatry** to dentistry. His most influential contributions were in the analysis of binary and **categorical data**, statistical analysis of diagnostic reliability (*see* **Diagnostic Tests, Evaluation of**), and the design and analysis of **clinical trials**. He wrote more than 200 scientific and statistical papers, as well as two books that are considered classics in biostatistics.

Fleiss received an A.B. cum laude from Columbia College in 1959. While still in college, he worked as a statistical clerk with the Biometrics Research Unit at the New York State Psychiatric Institute (NYSPI). After attending the program in Biostatistics at the University of Minnesota in 1960, he returned to the Columbia School of Public Health where he earned his M.S. degree in Biostatistics in 1961. He received his Ph.D. from Columbia's Department of Mathematical Statistics in 1967, writing a dissertation on "Analysis of variance in assessing errors in interview data". This work was motivated by applied problems that he encountered in the Biometrics Unit, and the progress he made guaranteed his position at NYSPI for many years to come. He worked full time at NYSPI as a Research Scientist and Biostatistician until 1975 and remained affiliated with the institute until 1986.

In 1975, Fleiss was recruited by Columbia University to be Professor and Head of the Division of Biostatistics at the School of Public Health, taking over a program that had been established by John W. Fertig. During Fleiss's tenure as Head of the Biostatistics division, the program grew in stature and size. He established a Ph.D. program in 1977. Over the next 15 years, he recruited a first-class faculty to train new doctoral and master's degree students, generate independent research in biostatistics, and support clinical research initiatives throughout the health sciences at Columbia. Even as the department thrived, Fleiss's health went into a steep decline. A particularly disabling form of Parkinson's disease led to his stepping down as Biostatistics Head in 1992, at the age of 55. He continued to think about biostatistics problems as long as he could but was unable to work beyond the age of 58. His last statistical paper, a commentary on **meta-analysis**, was published in 1995.

Even though Fleiss's career was tragically cut short by illness, his 30 years of productivity had an enormous impact. His first book, *Statistical Methods for Rates and Proportions* [4], addressed the apparently simple issue of using proportions to summarize counts and frequencies. Although this appeared to be a specialized topic, the book attracted a wide readership with its many engaging examples and a thorough, but accessible, discussion of esoteric statistical principles. The book was released in a second edition in 1981. It was particularly influential in the fields of **epidemiology** and psychiatry, where it was used to define acceptable statistical practice for many scientific journals. After Fleiss's death in 2003, a third edition was released by Wiley, through the efforts of his Columbia colleagues Bruce Levin and Myunghee Cho Paik [14].

Fleiss's second book, *The Design and Analysis of Clinical Experiments* [7], was equally influential but with a completely different group of medical researchers. This book reviewed the principles of **experimental design** for experiments on people. Unlike rats in basic science studies, people present experimenters with all sorts of difficulties. They refuse to participate after **randomization**, they drop out, they fail to take the treatment, and

they sometimes misrepresent outcomes. Fleiss's text addressed these issues directly. Instead of simply dwelling on the details of statistical analysis of data already in hand, Fleiss challenged biostatisticians and medical researchers to think carefully about how to plan and interpret studies that used humans as the experimental subjects. This book was so influential that the publisher, John Wiley and Sons, reissued it in the Wiley Classics Library series.

Fleiss began his career in psychiatric research and won acclaim in this field for his many valued publications. His work with colleagues at NYSPI is widely cited as instrumental in the study of measurement and reliability of psychiatric diagnoses [2, 20–23]. A paper with Endicott, Spitzer, and Cohen [2] on the Global Assessment Scale has been especially influential, with over 2000 citations in the literature as of January 2004.

Dentistry also benefited from Fleiss's contributions. In 1983, he was recruited as chairman of the Task Force on Design and Analysis, an independent, not-for-profit organization of biostatisticians and clinical scientists working in dental and craniofacial research. Under Fleiss's leadership, the Task Force promoted the development and use of creative strategies in the conduct and analysis of dental research studies, with major funding provided by commercial sponsors. Over the years, the Task Force has played a key role in the development of basic study designs for oral health trials and techniques for measuring periodontal disease. Fleiss coauthored a number of published manuscripts on the design and analysis of dental research data [1, 10, 15, 16], as well as two Task Force–sponsored guideline papers on conducting clinical trials of treatments for gingivitis and periodontitis [17, 18].

Fleiss was also recognized as a leader in the field of randomized controlled trials. He served as the senior statistical consultant on several important, major randomized trials in **cardiology** and **neurology**. He also produced reader-friendly manuscripts on the history, design, and analysis of clinical trials [6, 8, 9, 11].

Fleiss was a prolific researcher, publishing over 200 journal articles in his curtailed career, as well as numerous book chapters, book reviews, and editorial letters. A number of his articles on statistical methods continue to be influential today. Among his most cited articles are a paper with Cohen and Everitt on large sample standard errors for **kappa** [13], with 458 citations; a paper on measuring nominal scale agreement [3], with 682 citations; another paper with Cohen on kappa [12], with 326 citations; a paper on measuring agreement between two judges (*see* **Agreement, Measurement of**) [5], with 220 citations; and a very frequently referenced paper with Shrout on the use of intraclass correlations in assessing reliability (*see* **Correlation**) [19], with almost 2500 citations (January 2004 data).

Recognized as a leading biostatistician, Fleiss was asked to participate in a number of scientific panels, workshops, and review groups for the **Food and Drug Administration** and the **National Institutes of Health**. He served as a reviewer for many scientific journals and as an associate editor for **Biometrics** (a leading journal in statistical methods for medical, public health, and biological research) from 1975 to 1984. In 1986, Fleiss was elected President of the Eastern North American Region of the **International Biometric Society**.

Fleiss received many honors for his work bridging statistics and medical science. He was elected Fellow of the **American Statistical Association** and won the Mortimer **Spiegelman** Health Statistics Award from the **American Public Health Association** in 1973. In 1988, the Statistics Section of the American Public Health Association (1988) presented him with their Recognition Award. The Departments of Epidemiology and Biostatistics at Harvard University honored him with a Lifetime Contribution Award in 1998.

Fleiss married Isabel Bogorad, whom he met on Columbia University's Morningside campus. They are survived by their three children, Arthur, Elizabeth, and Deborah, and six grandchildren (Amir, Yamit, Eden, Shana, Sarah, and Jesse).

Floating Point Arithmetic

Floating point number representations are a response to the demand to store and manipulate in a computer, using a fixed number of digits, numbers which range widely in magnitude. Most formats that are in common use store the rough equivalent of either 7 or 15 decimal digits. The consequent finite precision of floating point arithmetic has large implications for practical computation, of a kind that we will explore in this article.

Floating point contrasts with the *fixed point* representations that are common on metering devices. For example, a car's dashboard indicators may represent distance to the nearest tenth of a kilometer or of a mile, i.e. with the decimal point fixed one place from the right. In addition to storing the digits of the number, a floating point representation stores an indicator of the position of a varying or *floating* point.

Floating Point Representation

For illustration, assume a computer representation which retains the seven most significant decimal digits in any calculated result. While modern computers typically use a base of 2 or 16, exactly the same principles apply.

On such a computer, 12024 may appear as 0.12024×10^5. The *fraction* $(= 0.12024)$ and *exponent* $(= 5)$ are stored as separate items:

exponent			fraction							
+	0	5	+	1	2	0	2	4	0	0

Note that the number is *normalized*, i.e. stored so that the leading digit in the fraction is nonzero. The number of digits for the fraction determines the *precision* of the representation, while the number of digits for the exponent determines the range of numbers that can be represented.

The square of 12024, calculated in a double-width register, is 144576576. Storage back in a seven-digit register gives

exponent			fraction							
+	0	7	+	1	4	4	5	7	6	6

The relative error from rounding to seven decimal digit precision is largest when a number of the form $0.10000004999\ldots \times 10^z$ is rounded to 0.1×10^z. Thus, the relative error is never more than $u = 0.5 \times 10^{-6}$. The number u, known as the *unit roundoff*, measures the relative *precision* of the numerical representation. Machine epsilon (*macheps*), which is the distance between 1.0 and the next largest exact representation, is twice the unit roundoff.

Observe the contrast between *precision* and *accuracy*. The limited *precision* of the arithmetic restricts the *accuracy* that is possible in any actual calculation. The example that now follows demonstrates how failure to take account of the finite precision of floating point numbers may lead to a catastrophic loss of accuracy.

The Sum of Squares About the Mean

Sums of squares and products about the mean appear in the calculation of variances, covariances, correlations, and a variety of multivariate calculations. We consider the calculation of sums of squares about the mean, i.e. of

$$S = \sum_{i=1}^{n} (x_i - \overline{x})^2. \tag{1}$$

The alternative expression,

$$S = \sum_{i=1}^{n} x_i^2 - \frac{\left(\sum_{i=1}^{n} x_i\right)^2}{n}, \tag{2}$$

allows, in principle, a one-pass calculation of $\sum_{i=1}^{n} (x_i - \overline{x})^2$. With $x_1 = 4007, x_2 = 4008, x_3 = 4009$, on a computer which rounds the result of each pairwise calculation to the seven most significant decimal digits before proceeding, it yields $16056050 + 16064060 + 161072080 - 144576600/3 = 48192190 - 48192200 = -10$.

Table 1 gives the steps at which accuracy is lost in this calculation.

The final subtraction in (2) made obvious a loss of accuracy that had occurred earlier in the formation of each of the quantities $\sum_{i=1}^{n} x_i^2$ and $(\sum_{i=1}^{n} x_i)^2/n$. More generally, the use of the algorithm that is based on (2) for a set of numbers where the mean is $\overline{x}$ and the standard deviation is s can be expected to

Table 1

	Exact	Machine representation
x_1^2	16056049	0.1605605×10^8
x_2^2	16064064	0.1606406×10^8
x_2^3	16072081	0.1607208×10^8
$x_1^2 + x_2^2 + x_3^2$	–	0.4819219×10^8
$(x_1 + x_2 + x_3)^2$	144576576	0.1445766×10^9
$(x_1 + x_2 + x_3)^2/3$	–	0.4819220×10^8

lose around $2 \log_{10} \overline{x}/s$ decimal digits of precision [6, p.12] in the calculated result.

A simple *one-pass* algorithm that is vastly preferable to (2) uses

$$S = \sum_{i=1}^{n} (x_i - x_1)^2 - \left[\sum_{i=1}^{n} (x_i - x_1)\right]^2 \Big/ n.$$

Updating Algorithms

Even better is the use of a formula that updates the mean at each step. It illustrates the

$$\text{new value} = \text{old value} + \text{correction}$$

approach which is often a good starting point for the design of a stable algorithm, i.e. an algorithm that avoids unnecessary loss of accuracy. We include also the extension that allows the calculation of cross-products. For this, we define $\overline{x}^{(k)} = k^{-1} \sum_{i=1}^{k} x_i$, with $\overline{y}^{(k)}$ defined similarly, and

$$s_{xx}^{(k)} = \sum_{i=1}^{k} (x_i - \overline{x}^{(k)})^2,$$

$$s_{xy}^{(k)} = \sum_{i=1}^{k} (x_i - \overline{x}^{(k)})(y_i - \overline{y}^{(k)}).$$

Then

$$\overline{x}^{(k)} = \overline{x}^{(k-1)} + k^{-1}(x_k - \overline{x}^{(k-1)}),$$

$$s_{xx}^{(k)} = s_{xx}^{(k-1)} + (x_k - \overline{x}^{(k-1)})(x_k - \overline{x}^{(k)}),$$

$$s_{xy}^{(k)} = s_{xy}^{(k-1)} + (x_k - \overline{x}^{(k-1)})(y_k - \overline{y}^{(k)})$$

(see [1] and [6, p. 13]).

Implications for Regression Calculations

The least squares regression problem (*see* **Linear Regression, Simple**) determines **b** such that $\mathbf{(y - Xb)'(y - Xb) = ||y - Xb||}_2$ is a minimum. Algebraically, it is equivalent to solving the normal equations

$$\mathbf{X'Xb = X'y}.$$

Whenever the mean of one or more columns of **X** is large relative to its standard deviation, the computed versions of $\mathbf{X'X}$ and $\mathbf{X'y}$ may be inaccurate representations of the data in **X** and **y**.

Floating Point Number Systems

A floating point number system is characterized by the base β, the number of digits t in that base, and the exponent range. Thus, numbers take the form $\pm m \times \beta^{\pm z}$. In the example just given we had a base $\beta = 10$, with $t = 7$ digits stored. Some Hewlett-Packard calculators had $\beta = 10$, $t = 12$, and were able to represent numbers ranging from approximately 10^{-499} to just under 10^{500} with a relative error of no more than $0.5 \times \beta^{1-t} = 0.5 \times 10^{-11}$. The use of base 10 does not take advantage of the simplicity of the numeric representation that is available when the base is a power of 2, typically 2 itself or $2^4 = 16$. While it avoids conversion of numbers between bases at input and output, it slows arithmetic calculations.

The IEEE Standard

The use of the base $\beta = 2$ is now almost universal for computers, with $\beta = 16$ on high-end IBM machines the main exception. The Institute of Electrical and Electronic Engineers (IEEE) standard 754 [4], developed by a working group over several years, has become the accepted international standard for floating point arithmetic. This specifies $\beta = 2$, $t = 24$ binary digits ($\approx$ 7 decimal digits) for single precision, and $t = 53$ ($\approx$ 15 decimal digits) for double precision. Table 2 gives details of selected parameters of IEEE single- and double-precision floating point arithmetic. Most major computer manufacturers now supply processors that implement these standards.

Overflow, i.e. a number that is too large to be represented, or division of a nonzero number by zero, both lead to $\pm\infty$. The operations 0/0, $0 \times$

Table 2 Selected parameters of IEEE single and double-precision floating point arithmetic

	Single-precision	Double-precision
Maximum floating point number	$2^{128} = 3.403 \times 10^{38}$	$2^{1024} = 1.798 \times 10^{308}$
Minimum floating point number[a]	$2^{-126} = 1.755 \times 10^{-38}$	$2^{-1022} = 2.225 \times 10^{-308}$
Unit roundoff (u)	$2^{-24} = 5.96 \times 10^{-8}$	$2^{-53} = 1.110 \times 10^{-16}$
Machine epsilon	$2^{-23} = 1.192 \times 10^{-7}$	$2^{-52} = 2.220 \times 10^{-16}$

[a]This is the smallest number that is stored to full precision.

∞, and $\sqrt{-1}$, all lead to NaN (not a number). Graceful underflow ensures that, whenever possible, leading zeros in the fraction (= *mantissa*) supplement the exponent. Otherwise underflow gives a result of zero.

There are, in addition, IEEE single- and double-extended number formats. The double-extended format must ensure a relative error of no more than 5.42×10^{-20} for numbers in a range of at least $10^{\pm 4932}$. A double-extended IEEE format is supported by the Intel 8087 chip and its successors through to the Pentium and beyond, and by the Motorola 68000 series chips used in Macintosh computers. There are as yet few software systems that take advantage of the double-extended format.

The default rounding mode for IEEE arithmetic is rounding to the nearest representable number, so that unit roundoff is $u = 0.5 \times \beta^{1-t}$, i.e. 5.96×10^{-8} for single-precision and 1.11×10^{-16} for double-precision arithmetic. The standard requires that all arithmetic operations are to be performed as if they were first calculated to infinite precision and then *rounded* to the specified precision. For comments on how this is achieved, see [2] and [3].

The importance of the IEEE standard is that results are accurate and predictable, providing a sound basis on which to build reliable numerical software. Even where IEEE arithmetic is available, compilers do not necessarily allow access to all features. For a detailed discussion of IEEE arithmetic, and comments on the aberrant arithmetics still found on some computers, see [3]. There is a public domain computer program, due in the first place to W. Kahan, which checks out in detail the arithmetic of the computer on which it runs. BASIC, C, FORTRAN, Modula and Pascal versions are available; go to `http://netlib.bell-labs.com/netlib` and search for *paranoia*. In **S-PLUS** the list `.Machine` holds settings of a number of machine arithmetic parameters.

Scaling to Avoid Overflow

Computations can often be reorganized so that the risk of overflow becomes, instead, the possibility of a harmless form of underflow. Consider $a = 10^{20}$, $b = 1$, and assume single-precision IEEE arithmetic. Then evaluation of $a^2 + b^2$ as a first step in the calculation of $r = (a^2 + b^2)^{1/2}$ will lead to overflow. Thus r will be set to $(\infty)^{1/2} = \infty$, with implications for all subsequent calculations that involve r. This is avoided by setting $d = \max\{|a|, |b|\}$ and calculating

$$r = d\left[\left(\frac{a}{d}\right)^2 + \left(\frac{b}{d}\right)^2\right]^{1/2} = 10^{20}(1 + 10^{-40})^{1/2}.$$

Underflow in the attempt to calculate 10^{-40}, so that the result is set to zero, is harmless.

Extreme Fitted Proportions in Logistic and Related Models

A general principle is that one should avoid, or seek a detour around, the computation of intermediate quantities that are incapable of accurate representation. Consider the following logit model for binomial data (*see* **Logistic Regression**):

$$\log \frac{\pi_i}{1 - \pi_i} = \eta_i = \mathbf{x}_i' \boldsymbol{\beta}, \tag{3}$$

where π is the expected value of a binomial proportion p, and $\mathbf{x}_i'$ is the ith row of the model matrix $\mathbf{X}$. This is a Nelder & Wedderburn style **Generalized Linear Model** [7], with logit *link* and binomial *error*.

We consider implications from the finite precision of floating point arithmetic when one or more estimated π_i is very close to one. (Almost inevitably the observed p_i is then one.) Dose–mortality studies with insects or other pests or pathogens, where the highest dose may be designed to achieve a very high

level or mortality, provide examples. Note in passing that when $n_i\pi_i \approx n_i$ for one or more i, the asymptotic theory for the distribution of both deviance and Pearson **chi-square distribution** breaks down.

An iteratively reweighted least squares *scoring* algorithm [7, pp. 40–43] fits this model by solving, successively for $k = 1, 2, \ldots$, the following regression equation:

$$\mathbf{X}'\mathbf{W}\mathbf{X}\boldsymbol{\beta}^{(k)} = \mathbf{X}'\mathbf{W}\mathbf{u}^{(k)}. \tag{4}$$

Here $\mathbf{W}$ has diagonal elements

$$w_i = (\mathrm{var}[p_i])^{-1}\left(\frac{\mathrm{d}\pi_i}{\mathrm{d}\eta_i}\right)^2 = \mathrm{diag}[n_i\pi_i(1-\pi_i)],$$

and $\mathbf{u}^{(k)}$ has elements

$$\begin{aligned} u_i^{(k)} &= \eta_i^{(k-1)} + \frac{\mathrm{d}\eta_i}{\mathrm{d}\pi_i}(p_i - \pi_i^{(k-1)}) \\ &= \eta_i^{(k-1)} + \frac{p_i - \pi_i}{\pi_i(1-\pi_i)}. \end{aligned}$$

Expressions involving η_i and π_i are evaluated at their current estimates $\eta_i^{(k-1)}$ and $\pi_i^{(k-1)}$.

If $\exp -\eta_i$ is less than u = unit roundoff, then

$$\pi_i = \frac{\exp\eta_i}{1+\exp\eta_i} \tag{5}$$

will be calculated as 1. In fact, to retain around d significant decimal digits, $\exp -\eta_i$ must be at least $10^d u$. It is important to calculate $1-\pi_i$, not by subtracting π_i from 1, but as

$$1 - \pi_i = \frac{1}{1+\exp\eta_i}. \tag{6}$$

This allows accurate calculation of $\pi_i(1-\pi_i)$ provided that overflow does not occur in the evaluation of $\exp\eta_i$. This has the much less restrictive requirement that $1-\pi_i > 10^{-308}$ approximately, in order to calculate the result to d significant digits in IEEE double precision arithmetic. A further refinement is to rewrite (5) and (6) in terms of $\exp -(\eta_i/2)$ and $\exp(\eta_i/2)$.

If in place of the model (3), one has the complementary log–log model (*see* **Quantal Response Models**)

$$\log[-\log(1-\pi_i)] = \eta_i = \mathbf{x}_i'\boldsymbol{\beta}, \tag{7}$$

then in (4)

$$\begin{aligned} \mathbf{W} &= \mathrm{diag}\{\pi_i^{-1}(1-\pi_i)[\log(1-\pi_i)]^2\}, \\ u_i^{(k)} &= \eta_i^{(k-1)} - \frac{p_i - \pi_i^{(k-1)}}{(1-\pi_i)\log(1-\pi_i)}. \end{aligned}$$

Here $1-\pi_i$ should be evaluated, using the value of η_i from the previous iterate, as $\exp(-\mathrm{e}^{\eta_i})$.

Even these steps may not be adequate. For the model (7), consider the data $x = 0, 2, 3, 4, 6, 12$; $p = 0.450, 0.837, 0.977, 0.998, 1.0, 1.0$; with $n_i = 1000$, $i = 1, 2, \ldots, 6$. Then $\hat{\eta}_i = 0.5420 + 0.5974x$. For $x_6 = 12$, $\hat{\eta}_6 = 6.627$, so that in IEEE double-precision arithmetic $\exp(-\mathrm{e}^{\eta_6})$ underflows to 0. The crossover is at $\log[-\log(2.25 \times 10^{-308})] \approx 6.563$. Once the current estimate of η_6 exceeds this, it will be necessary to set w_6 and u_6 to their limiting values as $\pi_6 \to 1$, i.e. $w_6 = 0$ and $u_6 = \eta_6$. Similar issues arise when $\hat{\pi}_i \simeq 0$ for one or more i. The aim is to ensure that small and mostly meaningless differences of any $\hat{\pi}_i$ from one or from zero do not prevent calculations from running to completion.

Rounding Errors and Error Analysis

Rounding errors are likely to occur in any extended sequence of calculations that involve floating point numbers. This happens even with carefully designed **algorithms**. A key result for IEEE arithmetic is that

$$\mathrm{fl}(x \text{ op } y) = (x \text{ op } y)(1+\delta), \quad |\delta| \le u$$

where u is the unit roundoff, op is any of the four arithmetic operations $+, -, \times, \div$ [3, p.44], and $\mathrm{fl}(x \text{ op } y)$ denotes the result of the floating point computation of x op y. This forms the basis for error analysis for IEEE arithmetic. It may seem surprising that the result applies to $x - y$ when x and y have the same sign. As happened in the example that followed (2) above, in the calculation of x and y any serious loss of accuracy occurs before the subtraction.

For the two-pass calculation of $S = \sum_{i=1}^{n}(x_i - \overline{x})^2$ that is based on (1), one can show [3, p.38] that, neglecting terms in u^2 or higher powers, the relative error in the calculated value of S is no more than $(n+3)u$, where u is the unit roundoff. This bound is unlikely to be attained in practice. A more realistic bound may be $c(n)^{1/2}u$, where a conservative choice for c might be 1.5. While the error may be of no consequence when n is small, it may become serious

for single-precision calculations with, for example, $n = 10^9$.

The bound $(n + 3)u$ on the error in the computed result is an example of a forward error analysis. It contrasts with backward error analysis which sets bounds on the perturbations needed in the input values so that an exact computation would yield the computed result. For further examples of such analyses, see [3, 8] and [9].

Condition Numbers and Ill-conditioning

Ill-conditioning, i.e. a large condition number, implies that changes that are of the order of the relative precision of representation of x will lead to large relative perturbations in y, making a highly accurate result impossible.

Let $y = f(x)$ be the result of an exact calculation with input value x. A *condition number* relates changes in the elements of y, measured in a manner that is convenient or appropriate, to changes in the elements of x. The calculation of $y = \log x$ provides a simple example. The approximate change, Δy, which results from a small change Δx in x, is $\Delta y \approx f'(x)\Delta x$. Thus

$$\frac{\Delta y}{y} \approx \frac{\Delta x}{x}\frac{1}{\log x}.$$

Any change in x is magnified by a condition number $1/\log x$, which becomes large when x is close to 1. Small changes in x will then lead to large relative perturbations in y, making a highly accurate result impossible. A stable algorithm carries out a computation to the precision allowed by the condition number. It will give an accurate answer to a well-conditioned problem, and do as well as can be expected for an ill-conditioned problem.

Observe that the definition of a condition number is entirely a matter of algebra. An approximate estimate of the relative change in y that results from a relative change $\Delta x/x$ is usually adequate. These ideas have wide application to error analysis in **matrix computations, optimization, numerical integration**, and the numerical solution of differential equations (*see* **Numerical Analysis**).

Condition numbers for vectors or matrices are usually expressed in terms of vector or matrix norms. These are further discussed in the article on **Matrix Computations**.

Follow-up, Active Versus Passive

Disease registers are records of all cases of a disease that have occurred in a known population, and follow-up is the essential process whereby they are kept up-to-date, the most important item being vital status (whether alive or dead).

Cancer registries are the most well-established disease registers, and for them, recording vital status is essential. All registries do this, the means being either active or passive follow-up. The most commonly used is the passive method where registries depend on the national death registration system (*see* **Death Certification**) to inform them about the death of any cancer patient resident in the area covered by the registry. The alternative is active follow-up, where, in addition to passive notification of death, the registry reviews the vital status of all registered patients not known to be dead at regular intervals, say five years, until death.

If the death and cancer registration systems were both perfect, the results of active or passive follow-up should be the same. However, the number of deaths to be matched with cancer registrations is huge. In England and Wales, for example, the list is reduced by notifying cancer registries only of (i) those deaths of residents in their area in which cancer appeared on the death certificate, and (ii) deaths of patients already known to be on a cancer register. Deaths may be missed for a variety of reasons; patient migration after diagnosis, clerical error and computer matching failure, for example. This results in an optimistic view of survival and "immortal" patients who only come to light when they apparently achieve an impossible age.

Active follow-up, if done properly and patients can be traced, should avoid these problems. In addition to passive follow-up, clerks find out from hospitals or from the patient's own doctor or from a central register if one exists, when they were last known to be alive or when they died.

Use of an active follow-up system produces estimates of survival that depend wholly on patients whose vital status is known; after the date they were last known to be alive no assumptions are made about their status and they do not contribute to the estimate of survival (the process of censoring; *see* **Censored Data**). While this method is **unbiased**, there is a loss of precision in proportion to the number of patients lost to follow-up. Estimates of survival at a time after completion of follow-up mean that all living patients will be censored, but since passive notification of death continues, a very pessimistic estimate of survival, depending only on the patients known to have died at the time of the estimate, will result. To avoid this, survival estimates must refer to a time at or before the time of follow-up; if a later date is needed, then the assumptions and methods of passive follow-up must be used.

Active follow-up is more expensive and gives a less **biased** and more truthful estimate of survival, but whether it is worth doing depends on the loss of accuracy and timeliness resulting from a dependence on passive follow-up, and how important this is thought to be.

T. DAVIES & S. GODWARD

Food and Drug Administration (FDA)

The Food and Drug Administration (FDA) is a federal regulatory agency with oversight of a wide range of consumer products: food; medical treatments, devices, and diagnostics (human and veterinary); vaccines; blood and blood products; cosmetics; and other related products. Approximately one-quarter of consumer dollars are spent on products regulated by the FDA. The agency headquarters are in Rockville, Maryland, but field offices are located across the United States and its territories, and an important research unit of the FDA, the National Center for Toxicological Research, is located in Arkansas. More than 9000 individuals are employed by the FDA, including many laboratory and clinical scientists, statisticians, epidemiologists, computer scientists, engineers, lawyers, and others. The FDA is part of the Department of Health and Human Services in the Executive Branch of the federal government.

Although some aspects of federal oversight of health issues can be traced back to the nineteenth century, the first major step in regulating the use of medical products was the passage of the Biologics Control Act of 1902. This legislation, resulting from the deaths of 13 children who received a diphtheria antitoxin that had been contaminated with tetanus, provided for federal oversight of the production of vaccines, serums, toxins, antitoxins, and related products. A few years later, in 1906, the Federal Food and Drugs Act prohibited the sale of adulterated and/or misbranded food and drugs. Additional legislation further clarified and extended regulatory authorities during the early part of the twentieth century, but the next major step in protecting consumers from unsafe products was the passage of the Federal Food, Drug and Cosmetic Act in 1938. As with the Biologics Control Act, the FD&C act was motivated by tragedy; 107 deaths resulted from an elixir that had been manufactured using a toxic substitute for the alcohol that was a routine component of all "elixirs". This Act greatly expanded the regulatory authority of the growing agency, which had been officially designated as the Food and Drug Administration in 1930. It added cosmetics and **medical devices** to the scope of regulated products, authorized factory inspections, required drugs to be labeled for safe use, enhanced enforcement capabilities, and, perhaps most notably, established a drug approval process so that manufacturers would now have to demonstrate a drug was safe before it could be marketed. In 1962, the Act was significantly amended. New provisions included the requirement that drugs be shown to be effective as well as safe before marketing approval could be granted (*see* **Drug Approval and Regulation**). Other additions included the requirement that patients involved in **clinical trials** provide informed consent, the shifting of authority over drug advertising from the Federal Trade Commission to the FDA, and the establishment of good manufacturing practices for the drug industry.

Changes in FDA structure and function continued into the latter part of the twentieth century. In 1971, FDA assumed responsibility for regulating products emitting radiation. In 1972, the regulation of biological products, which had been a function of the National Institutes of Health, was transferred to the FDA, and in 1976, the Medical Device Amendments provided increased and more specific authority for the regulation of medical devices. The 1992 institution of user fees – fees paid by pharmaceutical companies at the time a marketing application was submitted – resulted in an increased workforce in the areas of drugs and biologics and consequent acceleration of product review. User fees were extended to medical devices in 2003.

FDA consists of six centers, each focused on a particular area of FDA responsibility, plus the field offices (Office of Regulatory Affairs) that handle special investigations, consumer complaints, and inspections. The basic structure is shown in Figure 1. The National Center for Toxicological Research (NCTR) is a basic research facility; the other five centers are focused on particular areas within FDA's jurisdiction: drugs, biologics, medical devices/radiology, foods, and veterinary products.

Center for Biologics Evaluation and Research (CBER)

CBER has responsibility for ensuring the safety, purity, potency, and efficacy of biological products used to treat, prevent, or diagnose disease and for ensuring the safety of the nation's blood supply. (Biological products are substances derived from living organisms or produced by biotechnological processes.) This Center regulates vaccines, allergenic

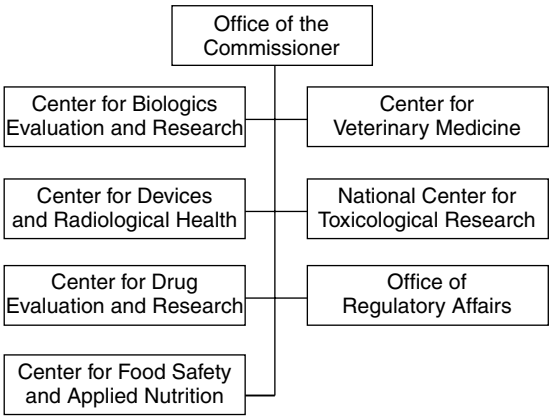

Figure 1 The structure of FDA

extracts, blood and blood products, test kits for donor blood, cellular therapies, tissues, and gene therapies. Biological therapeutics – cytokines such as interferons and interleukins, monoclonal antibodies, and other therapeutic proteins – have also been regulated by CBER, but in 2003, authority for these products was transferred to the Center for Drug Evaluation and Research.

Center for Devices and Radiological Health (CDRH)

CDRH regulates medical devices, ranging from the simplest items such as tongue depressors to pacemakers and cardiac stents, diagnostic imaging devices such as X-ray and mammography machines, computerized axial tomography (CAT) scanners and magnetic resonance imaging (MRI) devices, contact lenses, and computer software used in the diagnosis and treatment of disease. Also regulated in this Center are products that emit radiation that could potentially impact on health, for example, cellular phones, microwave ovens, lasers, and sun lamps.

Center for Drug Evaluation and Research (CDER)

CDER is responsible for drug products, including over-the-counter (nonprescription) drugs and generic drugs. The Center is organized according to disease areas, so that different divisions address **oncology** drugs, cardiovascular and renal drugs (*see* **Cardiology and Cardiovascular Disease**), anti-infectives, antivirals, anti-inflammatory drugs, neuropharmacological drugs, and so on. CDER regulates the vast majority of new medications, including over-the-counter and generic drugs, and plays the lead role within the FDA in regard to policy development relating to drug development and evaluation.

Center for Food Safety and Applied Nutrition (CFSAN)

CFSAN oversees safety of domestic and imported food, with the exception of meat, poultry, and eggs, which are regulated by the Department of Agriculture. Its regulatory oversight also extends to infant formula, dietary supplements, food additives, and cosmetics. CFSAN is directly responsible for safety aspects of food manufacturing, processing, and storage during the distribution process, including development of nutritional labeling, and for developing the guidance and model standards used by states for oversight of restaurants, grocery stores, and other food outlets.

Center for Veterinary Medicine (CVM)

CVM is responsible for ensuring the safety and effectiveness of drugs and food additives (including those derived from biotechnology techniques) approved for use in animals, including companion animals (dogs, cats, and horses), food animals (poultry, cattle, swine), and other species such as honeybees, wildlife, and zoo animals. When drugs are approved for use in food animals, the determination of safety also includes a demonstration that any food derived from these animals treated according to label directions is safe to consume.

National Center for Toxicological Research (NCTR)

NCTR studies issues related to FDA's regulatory needs, particularly with regard to understanding the potential toxicity of FDA-regulated products. Scientists at NCTR collaborate with scientists in other FDA centers as well as in other parts of the government and in academic institutions to better understand the biology underlying safety issues affecting

foods and drugs and to develop methods to improve **risk assessment** in a variety of areas such as food safety and human susceptibility to adverse effects of pharmaceuticals.

Office of Regulatory Affairs (ORA)

ORA is the enforcement arm of the FDA. Most ORA staff work in more than 150 field offices across the United States and in Puerto Rico. To ensure that FDA-regulated products intended for use in the United States meet required standards and that clinical studies of such products are conducted appropriately, ORA staff inspect manufacturing and warehouse facilities in the United States as well as abroad, inspect clinical research sites, and test samples in ORA laboratories. In cases of suspected criminal misconduct relating to these products, ORA takes the lead in determining appropriate legal actions.

To accomplish their respective missions, each center has many components. These may include units focusing on clinical science, laboratory science, statistics, epidemiology, compliance and enforcement, policy development, press and legislative liaison, legal issues, administrative issues (personnel, budget, etc.), staff training, information technology, international activities, and other areas. The Office of the Commissioner coordinates many initiatives in these areas, particularly when more than one center is involved, and oversees all center activities.

The Regulatory Process

The FDA derives its authority from legislation, going back to the FD&C and Biologics Control Acts; amendments to these acts; and additional legislation designed to clarify regulatory authority in specific areas. Regulations specifying required standards for all aspects of product development are developed on the basis of this legislation and are published in the *Federal Register* when issued. Generally, regulations are issued in draft form, with opportunity for public comment to be submitted and considered before a final version of the regulation is issued. Volume 21 of the *Code of Federal Regulations,* published each year by the Government Printing Office, includes all current regulations pertaining to FDA authorities.

In addition to regulations, the FDA issues many guidance documents. These documents are developed to clarify the intent of the regulations and/or to present methodological approaches that are recommended (but not necessarily required) by the agency in specific contexts. Guidance documents are also published in the *Federal Register* and are also usually revised on the basis of public comment, but no compendium of current guidance documents is published yearly, as is done for regulations. All operative regulations and guidance documents are available for reading or printing from the website of the FDA center(s) issuing the document.

Statistics at the FDA

Each FDA component except for the Office of Regulatory Affairs and the Office of the Commissioner has its own statistical group whose work focuses on the particular responsibilities of the center in which it resides. For example, the statisticians in the Center for Food Safety and Applied Nutrition deal substantially with survey and other observational data and risk assessments related to possible food contaminants (*see* **Nutritional Epidemiology**); statisticians at the National Center for Toxicological Research work in the area of **bioassay**; while the statisticians in the centers that evaluate investigational drugs, biologics, and medical devices review data from clinical trials, testing these new products, as well as the study designs that are proposed for such tests. Statistical aspects of postmarketing safety **surveillance**, and risk assessment more generally, are of increasing interest in all centers. FDA statisticians are also often involved in the development of new regulations and guidance documents (*see* **Guidelines On Statistical Methods in Clinical Trials**) that focus on statistical issues or for which statistical considerations are important and frequently publish on methodological issues arising from their review work.

In 2003, there were more than 150 statisticians at the FDA. All FDA statisticians are automatically granted membership in the Food and Drug Administration Statistical Association (FDASA), established in 1995 to provide a focus for cross-center statistical activities. The FDASA cosponsors an annual meeting with the Biopharmaceutical Section of the **American Statistical Association** and plans a yearlong seminar program for FDA statisticians.

In addition to statisticians employed by the FDA, a large number of statisticians from academic institutions and other organizations contribute statistical expertise to FDA decision making, primarily by serving on FDA Advisory Committees. These committees are established by each center to provide expert advice and comment on product submissions, potential risks of regulated products, and other issues. Most Advisory Committees include at least one statistician. Statisticians external to the FDA may also be asked to assist with the review of submissions or development of policy documents that include discussion of statistical issues.

Forecasting

Many data sets in biostatistics arise naturally as **time series**, meaning a set of data collected sequentially through time. Examples include (i) an electrocardiogram trace (ECG), (ii) the number of cases of measles in successive months in a particular country, and (iii) the size of an insect colony on successive days. The analysis of time series data poses special problems because successive observations are usually not independent but are correlated through time. This phenomenon is called *autocorrelation* (*see* **Autocorrelation Function**).

The first step in any time series analysis or forecasting activity is to plot the data against time in a graph called a *time plot*. This sounds a simple task, but, in fact, it may not be easy to choose appropriate scales to present the data. Figure 1 shows two plots of a famous time series called the lynx data. Figure 1(b) has a more compressed vertical scale and may initially seem a less natural way to present the data. However, it does, in fact, allow the viewer to see that the series typically falls faster than it rises. This nonlinear feature cannot be seen in Figure 1(a). An alternative possibility is to plot a transformation of the data such as logarithms. More generally, attention to detail is needed to label the scales carefully, to give the graph a clear self-explanatory title, and so on. Only then will it be possible to interpret the graph safely. Indeed, a good time plot should enable the analyst to get a good idea of the properties of

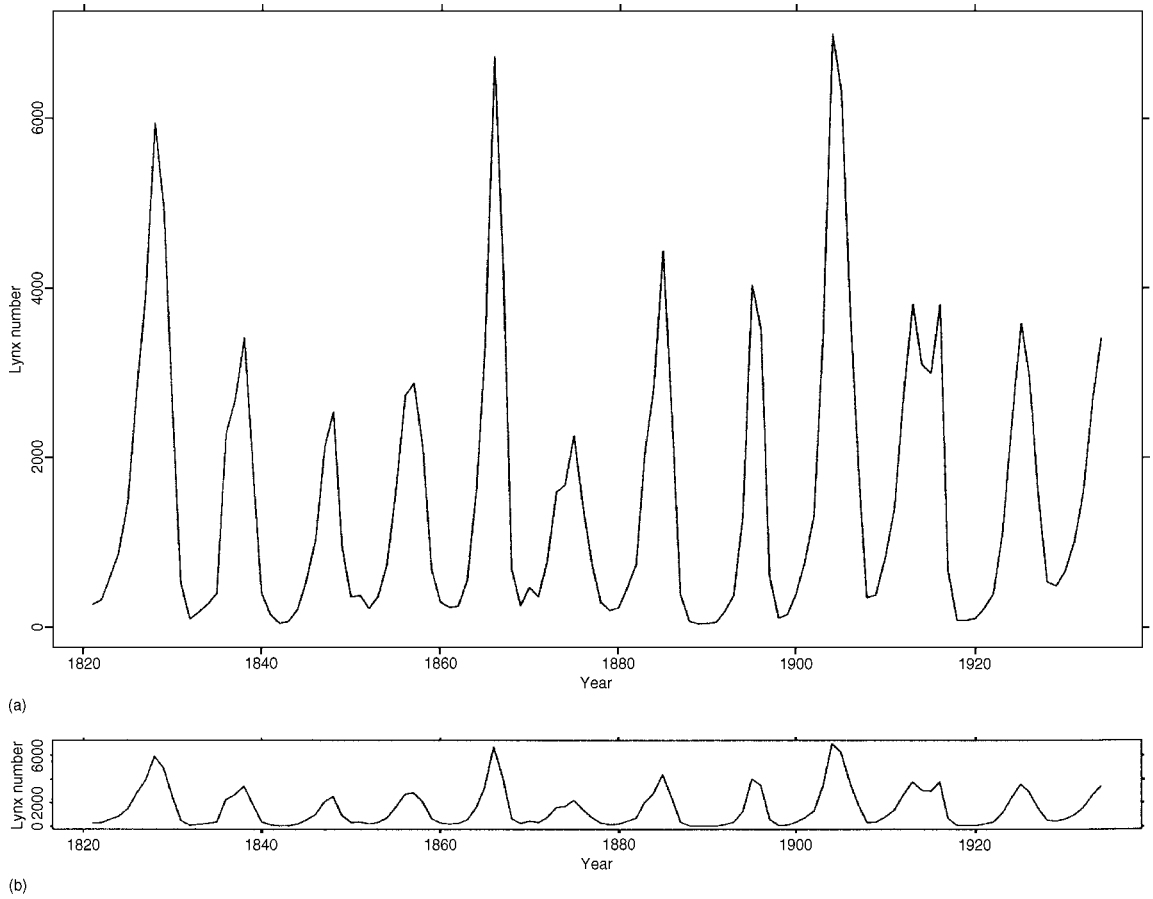

Figure 1 Two time plots of the annual numbers of Canadian lynx trapped in the Mackenzie River district of North-West Canada over the period 1821–1934. Part (b) has a compressed vertical axis that enables the rise and fall of the graph to be more easily assessed. Source: Records of the Hudson Bay Company

the time series, as well as identifying any **outliers** or discontinuities.

Finding an appropriate time series model for a given time series is a complex process that involves looking at a time plot of the data and also at the autocorrelations of the series at different lags. The reader is referred to Diggle [4] for a biostatistical introduction and to Chatfield [3] and Wei [6] for more general introductions. These three books also include introductions to the special time series activity of forecasting, which is the topic of this article (*see* **Spectral Analysis**; **Variogram**).

Denote an observed time series by $x_1, x_2, \ldots, x_n$ and suppose we wish to predict a value at some time in the future, say, x_{n+k}. Here, the integer k is called the *lead time* and the forecast of x_{n+k} made at time n is denoted by $\hat{x}_n(k)$. Most authors use the terms "forecast" and "prediction" interchangeably.

Many different forecasting methods are available and this article can only give a flavor of them. The choice of method depends partly on *clarifying the objectives* of a particular study and finding out exactly how a forecast will be used. The choice also depends on the skill of the analyst; for example, in deciding whether to use a univariate projection forecast, which only uses past values of the given variable, or a multivariate forecast, which incorporates the effects of one or more explanatory variables. This article restricts attention to univariate forecasts, apart from noting that multiple regression can be used to produce multivariate forecasts, but has difficulty in coping with correlated errors and can give spuriously high values of R^2.

Some methods are specifically designed to cope with two sources of variation called *trend* and *seasonality* (*see* **Seasonal Time Series**). Trend may loosely be described as a long-term change in the underlying mean level, while seasonality describes cyclic variation (*see* **Circadian Variation**) that might take place over a period of one day (diurnal variation), one week or one year. For example, the number of (human) deaths is typically higher in winter than summer. Figure 1 shows little evidence of trend in the number of lynx caught, but shows clear evidence of cyclic variation with a period of between nine and 10 years. However, as the period does not appear to be fixed, the variation would generally be described as cyclic rather than seasonal, and is more difficult to model and forecast.

An obvious procedure for forecasting a time series that shows an approximately linear trend is to fit a simple linear regression on time; namely, $x_t = \beta_0 + \beta_1 t + \varepsilon_t$, and substitute the required future value of t – see, for example, [4, Section 7.1]. This procedure emphasizes that forecasting is **extrapolation** in that it involves using the model outside the range of data to which it has been fitted. If the trend changes, forecasts will have poor accuracy. In any case, the trend is unlikely to be *exactly* linear, and a more modern approach is to assume *local linearity* and update forecasts by a procedure such as Kalman filtering and smoothing. Details will not be given here, but we introduce a very simple example of a Kalman filter called *exponential smoothing*, which is more typical of modern time series forecasting methods than linear regression on time.

A general form of linear forecast is to take a linear combination of the observed values; namely,

$$\hat{x}_n(1) = \sum_{j=0}^{n-1} w_j x_{n-j}, \tag{1}$$

where the weights $\{w_j\}$ need to be determined. It is natural to give more weight to more recent observations and to choose a set of weights that sum to unity. One suitable set of weights is given by

$$w_j = \alpha(1-\alpha)^j, \tag{2}$$

where α is a constant such that $0 < \alpha < 1$. These weights do sum to unity as $n \to \infty$ and decay geometrically. However, the real virtue of choosing geometric weights is that (1) incorporating (2) can be rewritten in the recursive form

$$\hat{x}_n(1) = \alpha x_n + (1-\alpha)\hat{x}_{n-1}(1). \tag{3}$$

Thus, as each new observation becomes available, forecasts can readily be updated. The smoothing parameter, α, can be chosen so as to optimize the one-step-ahead forecasts for the data we already have. A higher value of α gives more weight to more recent observations.

Exponential smoothing can readily be generalized to cope with a linear trend (called Holt's linear trend method) and also with seasonality (when it is generally called the Holt–Winters method).

Another class of models that is often used to produce forecasts is that of *autoregressive* (AR) models. (*see* **ARMA and ARIMA Models**). A time series,

X_t, is said to follow an autoregressive process of order p, denoted AR(p), if X_t is a linear function of the preceding p values in the time series, together with an "error" term, ε_t, that is usually assumed to be from an independent sequence of $N(0, \sigma^2)$ variables. Thus, an AR(1) process may be written

$$X_t = \alpha X_{t-1} + \varepsilon_t, \tag{4}$$

where the parameter α has to be chosen such that $|\alpha| < 1$ in order for the process to be stationary. It turns out that AR models can generally be fitted by methods similar to those used for ordinary regression models, except that the explanatory variables are now lagged values of the given variable. Forecasts may be computed in an intuitively obvious way. For example, the AR(1) model gives a one-step-ahead forecast at time n equal to $\hat{x}_n(1) = \alpha x_n$. AR models can be generalized to include lagged values of the "error" terms (called *moving average* terms – a rather misleading terminology) and can also be applied to nonstationary data by suitably *differencing* the data. For example, first-order differencing gives the series $(x_2 - x_1), (x_3 - x_2), \ldots, (x_n - x_{n-1})$ and will remove a linear trend. The large class of models formed in the above way is called the *autoregressive integrated moving average* (ARIMA) class and forms the basis of the *Box–Jenkins* forecasting approach – see [1].

The final approach mentioned here is based on the *state-space* or **structural time series model** – see, for example, [5]. A simple example is given by the so-called *steady* model for which

$$X_t = \mu_t + n_t, \tag{5}$$

where μ_t denotes the unobservable current level and n_t denotes the error term. It is further assumed that μ_t is itself a random variable that evolves through time according to a random walk so that

$$\mu_t = \mu_{t-1} + w_t, \tag{6}$$

where w_t denotes a second error variable independent of n_t. The (unobservable) variable μ_t is called a state variable and the current estimate of it is provided by the updating procedure called the Kalman filter. Given an estimate of μ_t, forecasts of X_t may readily be computed.

Choosing the most appropriate forecasting method for a particular problem is not easy and the reader is referred to [3, Section 5.4].

This article has concentrated on the computation of *point* forecasts. In practice, it is often desirable to calculate an *interval* forecast. The term *prediction interval* is used to describe an interval within which a future value is expected to occur with a specified probability. Some forecasting methods lend themselves more easily than others to the computation of the relevant standard errors that enable prediction intervals to be calculated. However, the possible presence of model uncertainty (the model may change in the future or may have been wrongly identified) means that prediction intervals are typically too narrow. A review of methods for computing prediction intervals is given in [2].

CHRIS CHATFIELD

Forensic Medicine

There are several problems in forensic medicine for which a statistical approach is particularly apt. These include, in particular, estimation of the post-mortem interval, or time since death, the estimation of the age at death, determination of sex from skeletal remains and, amongst the living, the estimation of the quantity of alcohol consumed, as well as issues of **paternity**. Simple summary statistics are used often; for example, in recording variations in relative frequencies amongst **genetic marker** systems in different populations. This issue is extended to a general discussion of problems of forensic identification, with particular reference to DNA profiling, by Dawid & Mortera [2]. Many standard statistical techniques, such as **regression**, are used. Only recently have other techniques, e.g. kernel **density estimation** and **Bayesian methods** been suggested.

Post-mortem Interval

Accurate estimation of the post-mortem interval (PMI) is of obvious importance in the resolution of an investigation involving a corpse. The most common approach is to study factors, such as the temperature of various parts of the body, which vary with PMI, and to determine a suitable relationship between these factors and temperature. In 1962 Marshall & Hoare [9] published the following formula modeling rectal body temperature:

$$\frac{T_{\mathrm{r}} - T_{\mathrm{a}}}{T_0 - T_{\mathrm{a}}} = A\exp(Bt) + (1 - A)\exp\left(\frac{AB}{A-1} \times t\right), \tag{1}$$

where T_{r} denotes rectal temperature at any time, T_{a} denotes ambient temperature, T_0 denotes rectal temperature at death $(t = 0)$, A is a constant that expresses the relative duration of a post-mortem temperature plateau phase, B is a constant that describes the cooling rate for as long as there is a difference between the ambient temperature and that of the body, and t is the time of death. Note, however, that it is a mathematical formula. While no attempt appears to have been made to model the errors implicit in the estimation of the parameters, there have been many empirical studies to determine the magnitude of the errors. Correction factors have been introduced to allow for different environmental factors, for example. Sometimes nomograms are used that relate rectal temperature, ambient temperature and body weight to time since death. The Marshal–Hoare formula measures time since death in the early post-mortem period (i.e. in hours). For longer periods of time, measurement of post-mortem enzyme activity may be used [5].

Age at Death

Gustafson [6] determined age at death on the basis of a regression of adult human age on morphological changes of six characteristics in the structure of teeth. This was based on applying normal **linear regression** techniques to ordinal and categorical data. Gustafson claimed an error of about three to four years, though later estimates of about seven years or even 16 years have been determined. Various Bayesian approaches that account for the data structure and provide results with mean absolute deviations of four to six years are advocated by Lucy et al. [7] and kernel density methods are described by Aykroyd et al. [1].

Sex Determination

Linear **discriminant analysis** is used to aid the determination of the sex of skeletal remains. The high accuracies of discrimination obtained have their basis in the unique form of sexual dimorphism exhibited by the adult human pelvis. One recent study [8] derived a score function, using discriminant analysis, from 122 adults of known sex and applied this to 230 other adults of known sex with 100% correct classification.

Blood Alcohol Measurements

The amount (A) of alcohol consumed based on the blood alcohol concentration (C_t) is calculated using Widmark's [12] formula:

$$A = r \times p \times [C_t + (\beta \times t)], \tag{2}$$

where r is the ratio of the total body ethanol concentration to the blood ethanol concentration, p is the body weight, and β is the ethanol elimination rate constant. Note that r varies between males and females. Various empirical studies have investigated the relationship between predicted and actual

concentrations. The formula is also used for breath alcohol concentration by the substitution of its value for C_t in (2). This introduces another source of error, generally leading to a reduction in the estimated amount of alcohol consumed [4].

Inverse Prediction

Notice that (1) gives an equation for determining rectal temperature from time since death and that (2) gives an equation for determining the amount of alcohol consumed from a blood alcohol concentration. In both cases, the inverse prediction is required. This has been discussed briefly by Aykroyd et al. [1], where age at death is regressed on a score determined from six dental indicators of Gustafson [6].

Paternity

In a paternity case, a male is alleged by the mother of a child to be the father of the child. The truth of the allegation can be partially tested by calculating a so-called "probability of nonpaternity" or "probability of exclusion" (Q, say) in a specific genetic system. The **genotypes** of the mother and child provide information about the true father in that males with certain **genes** are excluded from fatherhood of the child.

Consider a co-dominant system where all genotypes are detectable (in contrast to a dominant/recessive system in which only phenotypes are detectable). Let

$$p_1, p_2, \ldots, p_k, \quad \left(\sum_{i=1}^{k} p_i = 1.0\right)$$

represent the **gene frequencies** associated with a co-dominant system with k alleles, then

$$Q = \sum_{i=1}^{k}[p_i(1-p_i)]^2 + \sum_{j=1}^{k-1}\sum_{i=j+1}^{k} p_i p_j\{[1-p_i]^3 + [1-p_j]^3 + [p_i+p_j][1-(p_i+p_j)]^2\},$$

where the assumption is made that all individuals involved in the paternity case come from a large random mating population at equilibrium [10].

Consider now several loci and let Q_l be the probability of exclusion at locus l. The overall probability of exclusion (i.e. the probability the system will exclude a falsely accused male in a paternity action), Q, follows from being able to exclude the alleged father from at least one locus. Thus, if the loci are independent [11],

$$Q = 1 - \prod_{l}(1 - Q_l).$$

A related approach expresses the probability that the alleged father is the true father (F), given the evidence ($E_1, E_2, \ldots, E_n$) of n phenotypic systems, as follows:

$$\Pr(F|E_1, E_2, \ldots, E_n) = \left\{1 + \frac{\Pr(\overline{F})}{\Pr(F)}\prod_{i=1}^{n}\frac{\Pr(E_i|\overline{F})}{\Pr(E_i|F)}\right\}^{-1},$$

where $\overline{F}$ is the event that the alleged father is not the true father. A particular example of this approach with $\Pr(F) = \Pr(\overline{F})$ is described by Essen-Möller [3].

Forward Search

Introduction

The forward search is a powerful robust statistical method for exploring the relationship between data and fitted models. It is a development of the methods described in the articles on **Residuals** and **Diagnostics** that aids the discovery of clusters of observations and previously unidentified important subsets of the data as well as revealing any groups of outliers.

In this article, we give examples of the use of the forward search for **regression** and **generalized linear models**. These applications, together with the material on **transformations** of data covered in the article **Fan Plot** and the extension to **nonlinear regression**, are described by Atkinson and Riani [1]. We also give an example involving **multivariate** data, a topic extensively covered in [3].

Regression and Residuals

The forward search orders the observations by closeness to the assumed model, starting from a small subset of the data and increasing the number of observations m used for fitting the model. **Outliers** and small unidentified subsets of observations enter at the end of the search.

We write the multiple regression model as

$$ym = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{1}$$

where $\boldsymbol{y}$ is the $n \times 1$ vector of responses, $\boldsymbol{\beta}$ is the $p \times 1$ vector of parameters, and it is assumed that the additive errors of observation ε are independently distributed with constant variance σ^2. Also in (1), $\boldsymbol{X}$ is the $n \times p$ **matrix** of carriers, that is, of **explanatory variables** and perhaps functions of them, such as quadratics and interaction terms.

It is helpful to list the various stages of the forward search.

1. Notation. The vector of p parameters $\boldsymbol{\beta}$ is estimated by **least squares** applied to subsets of the observations. For an arbitrary subset of m observations, the estimate is denoted $\hat{\boldsymbol{\beta}}(m)$. For a subset $S^*(m)$ of size m chosen by the forward search, the estimate is written $\hat{\boldsymbol{\beta}}(m^*)$.

2. Starting the Search. The search starts from a small subset of size m_0; usually $m_0 = p$ or perhaps $p + 1$. To find the starting subset $S^*(m_0)$, we randomly select 1000 subsamples of size m_0. The initial subset $S^*(m_0)$ provides the least **median** of squares estimator $\hat{\boldsymbol{\beta}}(m_0^*)$, that is, it minimizes the median squared residual (Rousseeuw [5]) of the observations over the 1000 samples.

3. Moving Forward in the Search. When the m observations constituting $S^*(m)$ are used in fitting, the fitted values from the estimate $\hat{\boldsymbol{\beta}}(m^*)$ yield n least-squares residuals $\boldsymbol{e}(m^*)$. We order the squared residuals $\boldsymbol{e}^2(m^*)$ and take the observations corresponding to the $m + 1$ smallest as the new subset $S^*(m + 1)$. Usually, this process augments the subset by one observation, but sometimes two or more observations enter as one or more leave. This may also happen at the beginning of the search, where $S^*(m_0)$ is chosen to minimize the median squared residual, not to find the subset yielding the $m_0 + 1$ smallest squared residuals. Because of this very robust starting point and the form of the search, outliers, if any, tend to enter as m approaches n.

4. Monitoring the Search. If any quantity is of interest when it is calculated for the complete set of n observations, we can monitor its evolution during the forward search. In our example, we first look at a forward plot of the residuals $\boldsymbol{e}(m^*)$, scaled by the final estimate of σ. Examples of forward plots of other quantities of interest, such as estimates of the parameters $\boldsymbol{\beta}$ and σ^2 are given by Atkinson and Riani.

The analysis of the data on mandible length [6] in the article on **Goodness of Fit** using simple regression shows appreciable evidence of nonnormality of the residuals. The normal plot of the least-squares residuals in Figure 3 of the article "Goodness of Fit" shows three large negative residuals and two further residuals that are also rather large.

This structure is apparent in the forward plot of the residuals in Figure 1. Units 165, 166, and 149 have large negative residuals throughout the search. Units 146 and 167 also have appreciable negative residuals for much of the search. Working backwards, the last units to join the search are these five, in order 165, 166, 149, 146, and 167. These are the five negative residuals visible in the $Q-Q$ plot in **Goodness of Fit**, which is of the unscaled version of the residuals at the end of the search in Figure 1. The forward search shows that, in this example, the residual plot,

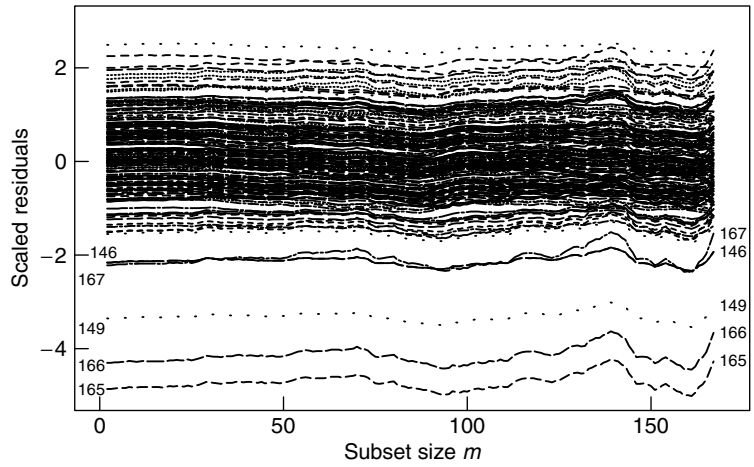

Figure 1 Mandible length data, first-order model: forward plot of scaled residuals. There are five large negative residuals for much of the search, but those for units 146 and 167 are masked at the end of the search

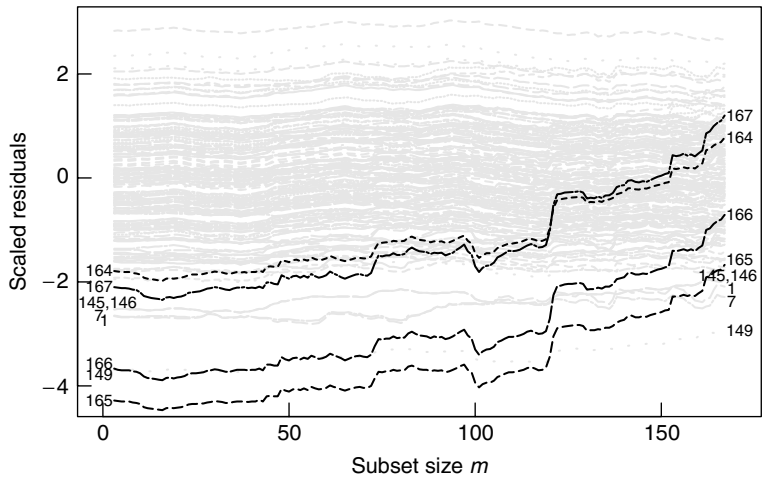

Figure 2 Mandible length data, second-order model, logged response: forward plot of scaled residuals. Four units, 164 to 167, behave differently from the rest, which have an approximately normal distribution

when all observations are fitted, identifies most of the structure of the residuals. The values of $\boldsymbol{x}$ and $\boldsymbol{y}$ for these units is clear from the scatter plot of Figure 5 of the article on **Diagnostics**. If the last three units, which are shown as open circles or crosses in the plot, are excluded, the straight line fitted to the data becomes such that unit 167 has an appreciable negative residual. As the forward plot shows, this residual is reduced when the last three units enter the subset. There is therefore some masking of the outlying nature of this unit.

The units with large residuals identified in this analysis are not all of those plotted with open circles in Figure 5 of the article **Diagnostics**. One reason is that these were identified as being influential observations, rather than having large residuals. A second reason is that that analysis was for a logged response with a second-order model. Figure 2 shows the forward plot of the residuals from this model.

Four units are highlighted in Figure 2. If we ignore them, the forward plot of the residuals is virtually symmetrical throughout the search, with no other

appreciable outliers. The most negative residuals are those for units 149, 7, 1, 145, and 146. But these values do not change much during the search and, as the $Q-Q$ plot in Figure 1 of the article on Diagnostics shows, these are not particularly extreme values when compared with **order statistics** from a normal distribution. The four highlighted units in the figure are units 164 to 167. They are highlighted because their behavior is very different. Initially, they all have large negative residuals, but by the end of the search, the residuals are all appreciably smaller, two having become positive. These units are those for the four oldest fetuses. It seems as if the model toward the end of the search may be being altered by their presence and so produces small residuals. Certainly, this would not be surprising as such extreme points in $\boldsymbol{X}$ space will be leverage points, a property amplified by fitting a quadratic model. Figure 2 of the article on **Diagnostics** shows how extreme these leverage values are. A question we then have to consider is how the evidence for a quadratic model depends on these four units.

Forward Added Variable T Test

If the fitted model and data agree, the parameter estimates should be reasonably constant throughout the forward search. These estimates are **orthogonal** to the residuals used to order the entry of units into the subset $S^*(m)$. The same is not true of the estimate of σ^2, which, being the sum of squared residuals, increases during the search as increasingly outlying observations are included in the subset. As a result, the t tests (*see* **Student's t Distribution**) for the parameters in the linear model decrease dramatically during the forward search. We describe here an alternative form of search that provides information on the inferential effect of the units on the estimated linear model.

If the standard regression model (1) is rewritten as

$$\boldsymbol{y} = \boldsymbol{X\beta} + \boldsymbol{\varepsilon} = \boldsymbol{Q\theta} + \boldsymbol{w}\gamma + \boldsymbol{\varepsilon}, \qquad (2)$$

$\boldsymbol{Q}$ is the $n \times p-1$ matrix of carriers obtained by deleting the column $\boldsymbol{w}$ from $\boldsymbol{X}$. At the end of the search, the t test for the column of $\boldsymbol{X}$ corresponding to $\boldsymbol{w}$ from **multiple regression** on $\boldsymbol{X}$ is identically the added variable test described immediately after equation (11) in the article on **Residuals**. This is found by first regressing $\boldsymbol{y}$ and $\boldsymbol{w}$ on $\boldsymbol{Q}$ and then testing the regression through the origin of the resulting residuals of $\boldsymbol{y}$ on those of $\boldsymbol{w}$.

We adapt the added variable test to the forward search by dropping each column of $\boldsymbol{X}$ in turn to create $p-1$ vectors $\boldsymbol{w}$. We then use regression on each $\boldsymbol{Q}$ to provide a forward search from which $\boldsymbol{w}$ is excluded. We monitor the behavior of the added variable test for each $\boldsymbol{w}$, thus obtaining $p-1$ plots of t statistics from $p-1$ different forward searches: $p-1$ because we are not usually interested in testing hypotheses about the value of the constant in the regression model. Because we exclude $\boldsymbol{w}$ from the search, the t test for $\boldsymbol{w}$ has the correct distribution and increases during the search rather than decreasing. The details are in [2].

We start, in Figure 3, with a forward plot of the added variable t test for regression of untransformed mandible length on **gestational age**. The plot shows a steady upward trend to a very significant value of 35.90. There is no sign of the importance of individual observations such as the units giving large residuals in Figure 1; evidence for the regression is spread throughout the data.

Figure 4, for regression of log $\boldsymbol{y}$ on a quadratic in age is similarly well behaved. The value of t_1, the t test for regression on age, rises steadily to 18.08, while that for t_2 for the quadratic term decreases to -12.55. The leverage points 164 to 167, which are such a notable feature of Figure 2, do not enter at the end of either of the added variable searches on which the plots in Figure 4 are based. The plot shows no evidence that these four units are responsible for the quadratic term in the model. Despite the appearance of Figure 2, the evidence of curvature

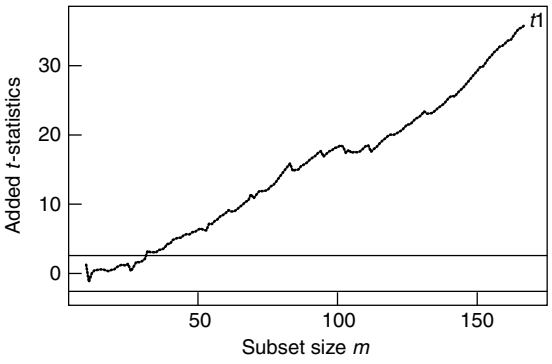

Figure 3 Mandible length data, first-order model: forward plot of added variable t test t_1 for regression on age. Evidence for the regression is spread throughout the data

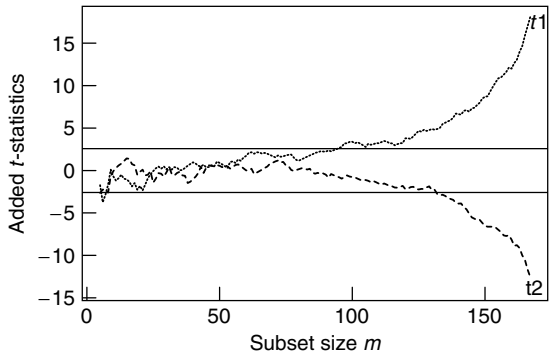

Figure 4 Mandible length data, second-order model, logged response: forward plot of added variable t tests t_1 and t_2 for regression on age and its square. Evidence for the regression is again spread throughout the data

in the relationship with a logged response is spread throughout the data.

Our analysis thus shows that taking a logged response combined with a quadratic model produces residuals, which have an approximately normal distribution, with four leverage points, the residuals for which change appreciably during the search. These four units are not influential for the choice of terms in the linear model. However, they might be influential for the choice of the transformation. But the forward plot of the test for transformation in Figure 5 of the article on the **Fan Plot** shows that this is not the case. Thus, these procedures provide no evidence for the suggestion mentioned by Royston and Altman that the fetuses with an age greater than 28 weeks were different from the younger ones.

Generalized Linear Models

The structure provided by the theory of generalized linear models allows us to apply the forward search to, particularly, **gamma**, **Poisson**, and **binomial** data in a manner analogous to that used for multiple linear regression. Chapter 6 of Atkinson and Riani [1] contains theory and examples.

In generalized linear models, we have a response $\boldsymbol{y}$, a vector of linear predictors with elements $\boldsymbol{\eta} = \boldsymbol{x}^T\boldsymbol{\beta}$, and a link function $g(\boldsymbol{\mu}) = \boldsymbol{\eta}$ connecting the two. In the article on **Residuals**, the deviance D, the analogue of the residual sum of squares in regression, was written as

$$D = \sum_{i=1}^{n} d_i^2, \tag{3}$$

where d_i^2 is the contribution of the ith unit to the total deviance. The deviance residual was then defined as

$$r_{Di} = d_i \text{ sign } (y_i - \hat{\mu}_i). \tag{4}$$

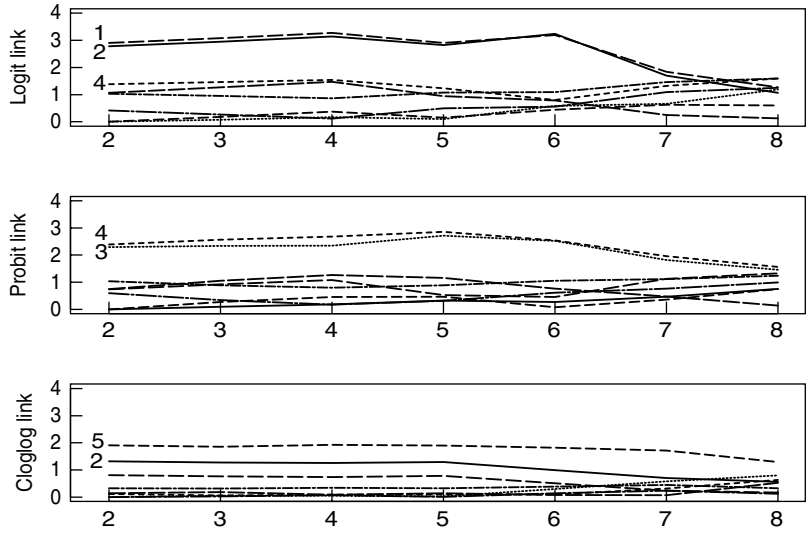

Figure 5 Bliss's beetle data: absolute values of deviance residuals as the subset size increases: (a) logit, (b) probit and (c) complementary log-log links

To extend the forward search to generalized linear models, we replace the least-squares residuals e_i with the deviance residuals r_{Di}. Then, as before, when m observations are used in fitting, the optimum subset $S^*(m)$ yields n deviance residuals $\boldsymbol{r}_D(m^*)$. We order the squared residuals $\boldsymbol{r}_D^2(m^*)$ and take the observations corresponding to the $m+1$ smallest as the new subset $S^*(m+1)$.

For the regression models in the previous sections, we looked at forward plots of residuals and of t tests for components of the linear predictor. As well as problems about individual outliers and the correct form of the linear predictor, there is also a need in generalized linear models to specify the correct form of link function. In the articles on **Goodness of Fit** and **Residuals**, analyses are given of Bliss's beetle data. These are binomial data in which the probability of success θ_i at dose level x_i is modeled by the link function $g(\theta_i) = \eta_i$. The analysis used the **logistic** link

$$g(\theta) = \log \frac{\theta}{1-\theta}. \tag{5}$$

There was evidence that this link was not satisfactory for these data. Alternative links are the probit

$$g(\theta) = \Phi^{-1}(\theta), \tag{6}$$

where Φ is the cdf of the standard normal distribution, and the complementary log–log link

$$g(\theta) = \log\{-\log(1-\theta)\}. \tag{7}$$

(*see* **Quantal Response Models**).

We explore these three possible link functions by looking at forward plots of absolute deviance residuals, which will indicate whether the unsatisfactory nature of the logistic link was caused by a few outliers or whether there is a systematic lack of fit. Figure 5 shows plots of absolute deviance residuals from forward searches for three models in which the explanatory variable is log(dose) and the three links are the logit, probit and complementary log–log. The observations are numbered from the lowest dose level to the highest. For the logit link observations, 1 and 2 are the last two to be included in the forward search. The crossing of the lines at the end of the plot in the top panel of Figure 5 shows that the inclusion of observations 1 and 2 seems noticeably to affect the ordering of the residuals. With the probit link units 3 and 4 (the last two to be included) seem to be different from the rest of the data: they are badly predicted by models in which they are not included. However, the residuals from the forward search with the complementary log–log link in the bottom panel of the figure show no such behavior; all residuals are smaller than two throughout, and relatively constant. Since the scale parameter is not estimated, it is possible to make such absolute comparisons of the residuals across different models, even if they come from different link families.

The conclusion from Figure 5 is that the complementary log–log link is satisfactory and that the other two are not. This conclusion is not dependent on a few observations, but is spread throughout the data. To sharpen and quantify this general impression based on forward plots of residuals, we now consider the goodness of link test, introduced in the article on **Goodness of Fit**. This provides a test for the adequacy of each link from the t test for the inclusion of the constructed variable $\hat{\boldsymbol{\eta}}^2$ in the linear predictor. The constructed variable plot in Figure 8 of the article on **Goodness of Fit** indicates rejection of the logistic link when all observations are used in fitting. We use forward plots of the test statistics to test three links and to see whether the conclusions are based on all observations.

Figure 6 shows a forward plot of the goodness of link test, the order of introduction of the observations, as in Figure 5, being different for the three links. For the logit and probit links, these plots show evidence of lack of fit at the 5% level, which is indicated by the statistic going outside the bounds in the plot. Although, it is inclusion of the last two observations

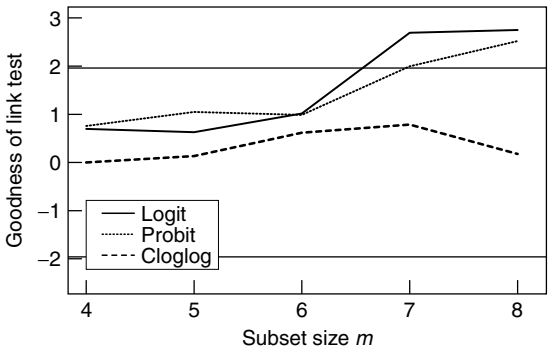

Figure 6 Bliss's beetle data: forward plot of the goodness of link test. Only the complementary log-log link is satisfactory

that causes the values of the statistic to become significant, it is clear from the steady upward trend of the plots that lack of fit is due to all observations. The plot for the complementary log–log link shows no evidence of any departure from this model. This plot also shows that unit 5, which is the one with the biggest residual for the complementary log–log link and the last to be included in this forward search, has no effect on the t value for the goodness of link test.

This analysis shows that, of the three links considered, only the complementary log–log link is satisfactory. The plot of fitted values for the logistic link in Figure 6 of the article on **Residuals** relates this finding to individual observations. The fitted dose response curve for this symmetrical link fits badly in the center of the experimental region, whereas, as Figure 6.36 of Atkinson and Riani [1] shows, the asymmetric complementary log–log link provides an appreciably better fit over the whole range of $\boldsymbol{x}$ values.

Multivariate Data

With multivariate observations, we replace the squared residuals used in the forward search for regression and generalized linear models with the squared **Mahalanobis distances**

$$d_i^2(m^*) = \{\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}(m^*)\}^T \hat{\boldsymbol{\Sigma}}^{-1}(m^*)\{\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}(m^*)\}, \tag{8}$$

where $\hat{\boldsymbol{\mu}}(m^*)$ and $\hat{\boldsymbol{\Sigma}}(m^*)$ are estimates of the mean and **covariance matrix** of the observations based on the subset $S^*(m)$. These distances are used for ordering the observations and for determining how we move forward in the search. We use the robust bivariate boxplots of Zani et al. [7] to determine an initial subset, which is not outlying in any two-dimensional plot of the data. The content of the contours is adjusted to give an initial subset of the required size. Once we have some idea of the structure of the data, we start the search with subsets that seem potentially interesting.

As an example with some expected and some unexpected structure, we look at readings on six dimensions of 200 Swiss bank notes, 100 of which may be genuine, and 100 forged. All notes have been withdrawn from circulation and classified by an expert, so some of the notes in either group may have been misclassified. Also, the forged notes may not form a homogeneous group. For example, there may be more than one forger at work. The data, and a reproduction of the bank note, are given by Flury and Riedwyl [4, pp. 4–8].

Figure 7 is a forward plot of Mahalanobis distances scaled by the estimate of $\boldsymbol{\Sigma}$ at the end of the search. The search starts with 20 observations on notes believed genuine. In the first part of the search, up to $m = 93$, the observations seem to fall into two groups. One has small distances and is composed of observations within or shortly to join the subset. Above these there are some outliers and then, higher still, a concentrated band of outliers, all of which are behaving similarly. The plot clearly shows the difference between the genuine notes and the forgeries. Toward the end of the search, there is evidence that the group of forgeries is not homogeneous.

The structure of the group of forgeries is also readily revealed by the forward search. Figure 8 is a forward plot of the scaled Mahalanobis distances just for the forgeries. In the center of the plot, around $m = 70$, this shows a clear structure of a central group, one outlier from that group and a second group of 15 outliers. As successive units from this cluster enter after $m = 85$, they become less remote and the distances decrease. By the end of the search there is appreciable masking, so that the group of 15 observations is no longer clear from the plot of the Mahalanobis distances. Under such

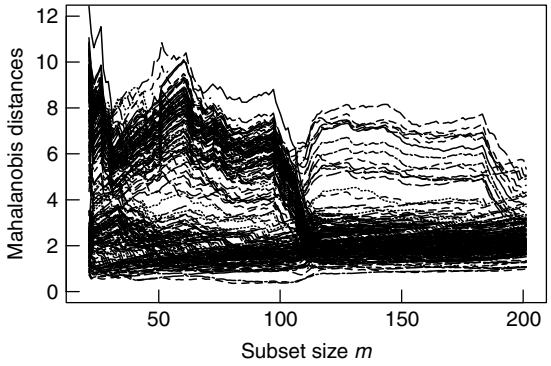

Figure 7 Swiss Banknote Data, all 200 observations: forward plot of scaled Mahalanobis distances starting with 20 notes believed to be genuine. The two groups are clear, but a third group seems to appear toward the end of the search

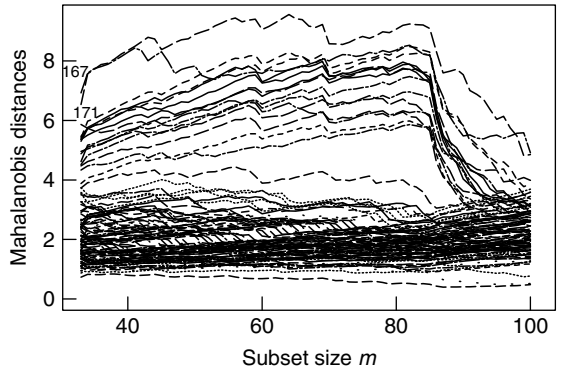

Figure 8 Swiss Banknote Data, 100 notes classified as forgeries: forward plot of scaled Mahalanobis distances. Toward the end of the search, there seems to be a group of 15 observations and a further single outlier

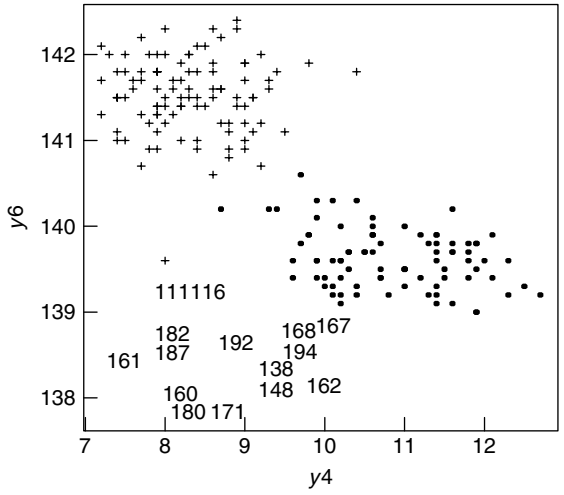

Figure 9 Swiss Banknote Data: scatterplot of y_6 against y_4. The "genuine" notes are marked with crosses; the labeled units are the last 15 to enter the search

conditions, the deletion methods described in the article on **Diagnostics** are likely to fail to reveal the structure.

In this example, the forward search clearly indicates not only the presence of two groups of notes, but also an unexpected subset of 15 observations, showing that the group of forgeries is not homogeneous but consists of two subgroups. Once attention has been drawn to the existence of this structure, it is possible to find it in the data. Figure 9 is one of the 15 different panels of the scatterplot matrix for these six dimensional data and by far the most revealing. The last 15 observations to enter the subset are numbered: the other forgeries are shown by filled circles and the "genuine" notes by crosses. It seems that one genuine note has been misclassified.

The entries in this article show various ways in which the forward search can elucidate the structure of data and, in the case of the third example, reveal unexpected subsets. A fuller analysis of the data on Swiss banknotes, together with numerous other applications of the forward search to multivariate data, are described in [3].

Foundations of Probability

Probability obeys three, basic laws (given below) about which there is little disagreement; and what there is has little effect on their mathematical consequences or on practice. Any quantity obeying these laws is termed a probability and, in contrast to the mathematics, there is considerable disagreement about the interpretation of the quantity. Furthermore, the disagreements over interpretation have important, practical consequences in that an **Inference** made from a data set can vary profoundly as a result of distinct views about probability. Probability is a subject where the foundations really matter. This article begins on the solid ground of the three laws, and then passes to the shifting sands of interpretation.

Probability is a numerical measure of uncertainty about an event. Uncertainty depends on the knowledge available at the time the uncertainty is being quantified. Probability therefore depends on *two* arguments, the uncertain event, A, under consideration and the truth of an event, B, describing the knowledge then possessed. It is written $\Pr(A|B)$ and reads "the probability of A, given B", the vertical line separating the uncertain and given events. [Many writers introduce it as $\Pr(A)$, omitting reference to the second argument, but experience shows that this can be a cause of practical confusion. They then term $\Pr(A|B)$ a **conditional probability**]. The three, basic laws, holding for a suitable collection of events, usually members of a Borel field, are

1. *Convexity*. For all $A, C, 0 \leq \Pr(A|C) \leq 1$ and $\Pr(C|C) = 1$.
2. *Addition*. If the events of a sequence $A_1, A_2, \ldots$ are exclusive, then
$$\Pr(\cup_i A_i|C) = \sum_i \Pr(A_i|C).$$
3. *Multiplication*.
$$\Pr(A \cap B|C) = \Pr(A|C)\Pr(B|A \cap C).$$

(*see* **Axioms of Probability**). Events are exclusive if the truth of any one precludes any of the others being true. $\cup_i A_i$ denotes the union of the events; namely, the event that is true if and only if any one of the individual events is true. In the case of two events, the union is written $A \cup B$. $A \cap B$ is the event that is only true if A and B are both true.

The whole of the rich calculus of probabilities flows from these three laws, or axioms. Yet the laws are merely simple expressions about proportions, as is seen by consideration of an urn containing a number, N, of balls, identical except that they are either white or black, and simultaneously either plain or spotted. Let one ball be drawn at random from the urn, event C above. Let A be the event that the ball is white, then $\Pr(A|C)$ is interpreted as the proportion of white balls w/N. It therefore lies between 0 and 1. Also $\Pr(C|C) = 1$ since some ball is certain to be drawn. This is convexity. To demonstrate additivity, let B be the event that the withdrawn ball is spotted and suppose that there are no white, spotted balls in the urn. This ensures that A and B are exclusive, and that $A \cup B$ is the event that the withdrawn ball is either white or spotted. Then,

$$\begin{aligned}\Pr(A \cup B|C) &= \frac{w+s}{N} = \frac{w}{N} + \frac{s}{N} \\ &= \Pr(A|C) + \Pr(B|C),\end{aligned}$$

where s is the number of spotted balls. For multiplication, suppose that the exclusive condition is removed, so that there are balls that are both white and spotted, r in number, and $A \cap B$ is the withdrawal of such a ball. Then,

$$\begin{aligned}\Pr(A \cap B|C) &= \frac{r}{N} = \left(\frac{w}{N}\right) \cdot \left(\frac{r}{w}\right) \\ &= \Pr(A|C)\Pr(B|A \cap C).\end{aligned}$$

That $r/w = \Pr(B|A \cap C)$ follows, since, in the probability, A, being a white ball, is known to be true and the only uncertainty in B is the additional requirement of it being spotted. It is, therefore, the proportion of spotted balls amongst the white.

Mathematically, probability is very simple, namely just a proportion. It is remarkable that such rich, mathematical consequences follow from such elementary ideas. In performing numerical calculations with probabilities, it is often useful and sensible to think of them as proportions. The addition law has been illustrated for only two events. Using more than two colours of balls, it easily extends to any finite number of events. The only disagreement about the laws of any significance is whether the addition law extends to an enumerable infinity of events.

The minority who say it does not, call probability *finitely-additive*. Otherwise, it is *sigma-additive*, although, this being the majority view, the adjective is usually omitted. Occasionally, the convexity law is extended by replacing $\Pr(C|C) = 1$ by $\Pr(A|C) = 1$ if and only if C logically implies A. This conveniently excludes some zero probabilities, since, equally, $\Pr(A|C) = 0$ if and only if C logically implies the falsity of A. The mathematical foundations of probability are simple, precise and essentially agreed. We now turn to interpretations, of which there are three principal ones.

Interpretations

The Classical View

The mathematical treatment of probability began with games of chance, like the rolling of dice. Here, there are often a number, N, of exclusive possibilities each of which has the same uncertainty. For example, with a single die, $N = 6$ and, if it is well-made and sensibly thrown, each of the six faces has the same chance of occurring. The illustration above, of an urn with a ball drawn at random, means that each ball has the same chance N^{-1} of being drawn. Exactly as in the discussion above, this leads to other probabilities and to the three laws based on the equiprobable cases. In games of chance, the laws may then be used as the basis of mathematical calculations to obtain values of interest, such as the probability of winning a game. Though influential in the early development of the subject, and still valuable in calculations, the classical view fails because it is seldom applicable. Thus, if actuaries want to find the probability of death within a period, there is no obvious set of cases having the same uncertainty.

The Frequentist View

This is currently the most popular interpretation of probability and that used in most biostatistical studies. It finds expression in many forms. The one that is most nearly related to the classical view is to think in terms of a population, usually infinite and often conceptual, where a proportion p of members have a property, A. In a change of language, p is the frequency of A in the population and $\Pr(A) = p$ is the probability that a member of the population has property A. [Here is an example where the second argument of probability is omitted. In this view, $\Pr(A|B)$ is defined, at least when $\Pr(B) \neq 0$, by the multiplication law, as $\Pr(A \cap B)/\Pr(B)$.] Thus, the actuary can think of a population, say, of white females in their 50s in a country, and think of the proportion dying within a year.

Another expression of the frequentist view is illustrated by the repeated tossing, under similar circumstances, of a drawing pin (American: thumb tack), which may either fall with the point up, U, or down, D. Experience shows that the frequency of Us in a long sequence of similar tosses appears to settle down to a limit. This limit is interpreted as $\Pr(U)$ for a single toss. It is not difficult to see that such an interpretation will satisfy the three laws. The concept is of considerable value in science because a good experiment can be thought of as a member of a sequence of similar experiments and the identification of probability with frequency makes sense. Indeed, the ability to repeat a phenomenon under controlled conditions is a hallmark of science. In the usual model for statistical inference, in which data x has probability (or probability density) $f(x|\theta)$ dependent on a parameter θ, the interpretation is the frequency of occurrence of x were the parameter to have the value θ, exhibiting the conditional form used in the formulation of the axioms above.

The classical exposition of the foundations of the frequentist view is by von Mises [13], though the important ideas of **Fisher** [5] have had more influence. For example, we have seen that probability requires the *knowledge* of a population with known frequencies. Fisher pointed out that it is also necessary to have *ignorance*, expressed by our inability to recognize any subpopulation within which different frequencies obtain. This observation has become important in restricting the sample space from all values of a **random variable** X to the subset of those values having a statistic with the value observed in the data. For instance, Fisher claimed that in the analysis of a **contingency table**, the population should be restricted from all tables of a given total size to tables having the same margins as that observed. The idea of recognizable subsets or subpopulations is important in applied work.

Although useful and widely applied, the frequency view has some limitations, the most serious of which is that it typically does not apply to uncertainty about the parameter in $f(x|\theta)$. θ is an uncertain number,

but it is not usually natural to think of it as a member of a population, or as having a frequency in a series. Consequently, in the frequentist position, it is not ordinarily sensible to refer to the probability of θ, given x, despite the fact that the value of the parameter, given the data, may be the principal interest in inference. These, and other difficulties, have largely been overcome by extensive developments this century. For instance, **confidence limits** for θ, based on x, provide an appealing substitute for $\Pr(\theta|x)$. Significance levels for a hypothesis H (*see* **Hypothesis Testing**; ***P* Value**) replace $\Pr(\sim H|x)$, where $\sim H$ is the complement of H.

The Bayesian View

This interpretation is fundamentally different from the other two. It starts with a person, or subject, conveniently referred to as "you". You are uncertain about the truth of an event, A, but have knowledge summarized by B. Then $\Pr(A|B)$ is a numerical measure of your belief that A is true, given B. The key concepts here are "you" and "belief". This interpretation of probability is personalistic, or subjective, and expresses the opinions of a person, or subject, about the uncertain aspects of the world as seen by that person. For the not very sound reason that **Bayes' theorem** plays a more important role when probability is interpreted as belief, rather than frequency, this attitude is called **Bayesian**. It has an immediate advantage over the frequentist view because it is always applicable. In particular, it makes sense to talk about $\Pr(\theta|x)$ or the probability that global warming is taking place. There are, however, some considerable difficulties associated with it.

The first problem is why your beliefs should be capable of being expressed by numbers and, if they are, why they should obey the three laws of probability. This has been answered by several, varied lines of argument that demonstrate that the numeracy and the laws follow from other, simpler axioms. These demonstrations will be discussed later. For the moment, it suffices to remark that there is substantial, logical support for the Bayesian position.

A second problem is that, even if belief can be equated with probability, how are the numbers to be obtained? In the frequency view, data on observable frequencies in finite series are available and only require the conceptual passage to the limit. The probability of death is measured by the frequency of death, or at least by suitable, actuarial treatment of observed frequencies. How are you to measure your belief that you will die within the year? Or, even harder, your belief that the political party you support will win at the next election? This difficulty has not been overcome satisfactorily, although, in many cases studied in frequentist statistics, it presents no serious problem. A valuable, recent reference is [16].

It is often said that a third difficulty with the Bayesian view is its subjectivity. A great strength of science is its claimed objectivity, so that the Bayesian position is often thought inappropriate for scientific inference. There are two responses. In the first it is held that two people with the same information, B in our notation, would, if logical, agree on $\Pr(A|B)$, so that any differences between persons are due either to different information or to false logic. One approach is to introduce situations, B_0, in which probabilities, given B_0, are agreed and then to calculate the general values by Bayes' theorem. B_0 is commonly thought of as a position of ignorance. Whilst substantial progress has been made, difficulties remain. This is sometimes called a "necessary" view: for stated A and B, $\Pr(A|B)$ necessarily follows. The second response is to deny that all of science is objective. Scientists differ strongly in their beliefs concerning global warming. The early stages of a scientific study, which is where inference may be useful, is subjective. Objectivity occurs when enough data have been accumulated and beliefs converge. The sun will rise tomorrow. Additionally, we notice that much of "objective" science is based on probability, or what we will later call "chance". Quantum mechanics and genetics are two examples. A modern, subjective approach is provided in [8].

These are the three, principal, foundational aspects of probability. In the remainder of this article, the frequentist and Bayesian views are explored in greater depth because their practical differences are of importance to biostatisticians.

Justification for the Laws

Ever since the earliest days of probability, the laws have been discussed. They were finally put into a precise, mathematical form in 1933 by **Kolmogorov** [7], essentially that given above. This formulation has provided the basis for the enormous advance in probability, as distinct from scientific inference,

since then. Probability is a field in which the foundations are the laws, and problems of interpretation are often not needed or, if they are, can comfortably be accommodated within the frequentist view. The situation is different in statistics. At about the same time as Kolmogorov, Ramsey [10] took a very different approach. He was concerned with someone, "you", having to choose amongst a number of actions in a world where uncertainty was present and relevant. He asked what principles you might use to decide on one action in preference to others. He developed a number of basic principles that he felt should obviously obtain in decision-making and used these as axioms to construct a calculus. Here is an example of such an axiom. Suppose event A is the only uncertainty present and that, were A to be true, you would prefer action a_1 to action a_2. Suppose that this preference persists were A to be false. Then the axiom says that you would still prefer a_1 to a_2 when A is uncertain for you. This is a form of the "sure-thing" principle; sure, because the status of A is irrelevant.

The calculus of decision making that Ramsey developed had to encompass the uncertainties present, described by beliefs about relevant events. To produce a single number as a measure of uncertainty, he introduced the idea of an ethically, neutral event of probability 1/2: one for which you did not care whether it was true or not, and where the uncertainties of truth and falsity were equal. The toss of a coin that you judge to be fair is an example. This provided a standard by which other uncertainties could be compared. He showed that the axioms implied that beliefs should obey exactly the three laws listed above. In other words, he provided a justification for the Bayesian position by showing that beliefs had to be expressed through probabilities. Ramsey's axioms are at a more fundamental level than Kolmogorov's. The latter's laws are the former's theorems.

It was a startling advance but lay essentially unappreciated until **Savage** [11] independently presented a similar development that attained the level of modern, rigorous mathematics. By then, two other approaches had appeared. In 1939, **Jeffreys** [6], a geophysicist, was concerned with inference in the handling of scientific data and developed axioms for reasonable inferential procedures. Again, the principal deduction from his axioms was that scientific beliefs must obey the probability laws. Unlike other writers, Jeffreys went on to develop practical procedures for treating scientific data. In particular, he developed an original method of testing a hypothesis, H, that addressed $\Pr(H|\text{data})$ directly, rather than through a significance level. Partly because Jeffreys was a physical scientist, and partly because Fisher, working in biological fields, was successfully originating frequentist methods, these Bayesian ideas have had less impact in biostatistics than in other fields.

Meanwhile, two other approaches were being developed by **de Finetti** [4]. Suppose you were asked to describe your belief in the truth of an uncertain event, A, by a number x. Suppose, further, you were told that, were you to state x, you would be given a penalty score $(x-1)^2$ if A were subsequently shown to be true, and x^2 if false. What value of x would you choose? Extend this idea to several events, each with its associated value and consequent score. Finally, the scores are to be added. What properties would the chosen values possess? In some simple and beautiful mathematics, de Finetti showed that your numbers must obey the laws, although, in the case of the addition law, it need only hold for a finite number of events – the finite additivity already mentioned. The procedure for calculating the penalty is called a scoring rule. That above is the quadratic scoring rule. It has subsequently been shown that the result holds for any, reasonable rule.

De Finetti also introduced a second method based on bets concerning an uncertain event, A. Suppose that you were required to post **odds** x against A, in the sense that you would accept a stake s on A, and be prepared to pay out xs (and return the stake) were A subsequently shown to be true, retaining the stake if false. Furthermore, unlike most real betting situations, you were also prepared to have the stake s placed on $\sim A$, returning $x^{-1}s$ if $\sim A$ were true; odds against $\sim A$ being the inverse of odds against A. Suppose that you did this for several events, each with its associated odds. Then he showed that unless the values $(1+x)^{-1}$ obeyed the laws of probability, again with the finite restriction, a person could make a Dutch book against you; that is, the person could place a series of bets that would result in your experiencing sure loss, whatever the truth or falsity of the events. Again, the laws of probability are an inevitable consequence of reasonable requirements.

There have been numerous extensions of these ideas and the position today is that there are many and varied ways, either based on decision-making under uncertainty, or directly on belief as a primitive notion,

that lead to the use of the probability calculus in the expression of beliefs about uncertain events. These all provide a justification for the Bayesian view. It is noteworthy that adherents of the frequentist position have not been prepared to state which of the axioms they object to. This they should do, since implicit acceptance of them implies the Bayesian paradigm. There have been cogent objections raised, but these lead to attitudes that are far removed from those adopted by frequentists. For example, one approach leads to upper and lower probabilities, employing two numbers to describe uncertainty for an event instead of the single probability. These two values obey laws similar in character to, and extensions of, those listed above. Walley [15] is an excellent reference. Shafer [12] has introduced another variant, in "belief functions".

Inference and Action

The approach to uncertainty, leading to probability, used by Ramsey, Savage and some others, is indirect in that it investigates, and treats as fundamental, decision-making, rather than belief (*see* **Decision Theory**). An advantage is that it yields two other dividends besides probability. It demonstrates that the outcome to any action needs to be described by a number describing its worth to you. This is your **utility** for that outcome. Furthermore, the optimum act is that which **maximizes your expected utility**, MEU. The expectation is calculated by reference to the probabilities. Thus, if an act can lead to one of n exclusive and exhaustive outcomes with utilities $u_1, u_2, \ldots, u_n$, having probabilities $p_1, p_2, \ldots, p_n$, the expected utility of that act is $\sum u_i p_i$. Finally, that act is taken of maximum expected utility.

In a modified form, this conclusion has been accepted by the frequentist school. This stems from the work of **Wald** [14]. He used loss in place of utility, so minimizing expected loss instead of MEU, but the change is of no serious content. Wald started from the frequentist approach and adopted loss as a primitive idea in extension of the earlier ideas of losses in connection with errors of the two kinds in hypothesis-testing. Loss, unlike utility, was not deduced from more basic requirements, as with Ramsey. Wald proved a basic, general theorem that essentially showed that only decisions that were MEU could be sensible. Against any other rule, a Dutch book could be made. Wald called such solutions to a decision problem, Bayes' solutions. Because he had no way of determining the probabilities (p_i above), which did not have a meaning within the frequentist paradigm, they were merely positive numbers, adding to one. Wald was unable to recommend a unique decision rule, but only to say that a sensible rule must be a Bayes' solution. He did advocate a rule, **minimax**, which was soon shown to be unsound. Today, frequentists often choose a Bayes' solution, justifying the p's by frequency considerations of how the rule would behave in conceptual repetitions.

The decision-oriented work is important for inference because it supplies perhaps the best answer to the question: what is the purpose of inference? Why do we test hypotheses and estimate parameters? Some might reply that it is carried out in pursuit of an understanding of the world and that it is part of knowledge for its own sake. But knowledge, however "pure" scientists like to think of it, is used to select actions. Knowledge about DNA is used to change plants. The studies we have mentioned show that MEU is the proper method to select an action. It follows, therefore, that our pure knowledge should be stated in a form appropriate to MEU. In particular, scientific inference should be so appropriate. MEU requires, in estimation, probability statements about parameters, $\Pr(\theta|\text{data})$, probabilities that are only available in the Bayesian approach. Confidence intervals are not in a form suitable for MEU. Therefore, according to followers of Savage, they are unsatisfactory as a form of statistical inference. Similarly, in hypothesis-testing, $\Pr(H|\text{data})$ fits with MEU, whereas a significance level does not.

Exchangeability

It often happens that probability as belief differs numerically from probability as frequency. To take a simple example, return to the tossing of a drawing pin mentioned above. After you have tossed it a few times, you will have a belief about the uncertain event of it falling point uppermost at the next toss. This may differ from the limiting frequency of such falls, a value that may be unknown to you. The biometrician, W. F. R. Weldon, had probability 1/6 that a die his research assistant was tossing would show six. After many tosses, the frequency was found to exceed that value. There is, however,

a relationship between the two values of belief and frequency expressed in a result usually ascribed to de Finetti. Consider a sequence of uncertain quantities (random variables is the frequentist terminology) $X_1, X_2, \ldots, X_n$. With the pin or the die, $X_i = 0$ or 1 according to the result of the ith toss. There are many situations in which your beliefs about the sequence are such that they are invariant under permutation of the suffixes. Thus, $\Pr(X_1 = 0, X_2 = 1, X_3 = 1) = \Pr(X_3 = 0, X_1 = 1, X_2 = 1)$, etc. If this is true for all n, the sequence is said to be exchangeable; any X_i can be exchanged for any other as far as your beliefs are concerned. With exchangeable, binary X_i, your probability for any finite sequence of 1's and 0's depends only on r and $n - r$, the numbers of 1's and 0's, respectively, in the sequence. De Finetti's result says that for a binary, exchangeable sequence, the probability of any sequence with r 1's and $n - r$ 0's is

$$\int_0^1 x^r (1 - x)^{n-r} \, \mathrm{d}F(x)$$

for some distribution function $F(\cdot)$ on [0, 1]. Furthermore, r/n tends, with probability one, to a limit, θ say, as $n \to \infty$. There is a similar result for general, exchangeable sequences.

The integral effectively says that you can express your beliefs about the sequence by supposing that there exists a value x such that, given x, the X's are independent and identically distributed with $\Pr(X_i = 1|x) = x$, in other words, a Bernoulli sequence (*see* **Binary Data**). Your belief about x is described by the function $F(\cdot)$. Using the limit result, you, as a Bayesian, can act like a frequentist, having a Bernoulli sequence with parameter θ, but, unlike a frequentist, having a probability distribution for θ. Notice that although to a frequentist θ is a probability, indeed, it is the defining expression; to a Bayesian it is not usually a belief. It would describe a belief were it known, which, being a limiting frequency, it usually is not, as with Weldon. Bayesians often describe θ as a *chance*, to emphasize the distinction. Without the distinction, $\Pr(\theta)$ appears as a probability of a probability, which is nonsense.

Since most situations studied in statistical inference are either based on exchangeable sequences (as with a random sample from a population) or on sequences that are modified from an underlying exchangeable one (as in an autoregressive process (*see* **ARMA and ARIMA Models**), $X_{n+1} = \alpha X_n + \varepsilon_n$ where the ε's are exchangeable), this result is of wide applicability in providing a link between frequentist and Bayesian ideas. It is also important in physics, where the behavior of a set of particles is often judged exchangeable. The probabilities that physicists use are chances in the above terminology, not beliefs.

The Likelihood Principle

It therefore happens that a Bayesian and a frequentist will use the same model of independent and identically distributed random variables, given a parameter θ, but the former will add a probability distribution for θ. Foundationally, the two viewpoints come close together as a result of de Finetti's theorem. However, there is something that pulls them apart and can make their results differ. Repeating what was said above, the foundations of probability really do matter. What separates them are their attitudes towards the likelihood principle.

Let data x be obtained as a result of observing a random variable X having density $f(x|\theta)$ for each parameter value θ. This is the part common to the two schools. As a function of θ for fixed x, $f(x|\theta)$ is called the likelihood of θ (at x). Let $p(\theta)$ be the density for θ adopted by you, as a Bayesian, expressing your beliefs about the parameter based on general knowledge of the situation, but excluding the data. This is usually termed the prior (to x) distribution. The data will change your belief about θ to

$$p(\theta|x) \propto f(x|\theta) p(\theta)$$

by Bayes' theorem. This is the posterior (to x) distribution of θ, given x. The important point here is that the posterior belief about θ depends on X, the quantity observed, only through x, the observed value. In particular, if two values, x and y, have the same likelihood, $f(x|\theta) = f(y|\theta)$ for all θ, then the inferences about θ from x and from y are the same. That statement constitutes a form of the likelihood principle. Bayesians respect and obey the principle in inferences from data, as the above development shows. (The principle does not apply in experimental design or generally in pre-data analysis.) A good reference is [2].

The frequentist does not obey the principle and therein lies a major, practical difference between the two paradigms. For example, a frequentist may use

an unbiased (*see* **Unbiasedness**) estimate $t(x)$ of θ; that is, one satisfying

$$\int t(x) f(x|\theta)\, \mathrm{d}x = \theta,$$

for all θ, where the integral is over the sample space, the range of X. This concept uses, in the integration, values of X other than the observed value x, thereby violating the principle. Often the space is restricted, as we saw above with Fisher's ideas, by confining the range to values of x having common elements with that observed, as with the margins of a contingency table. The key point is that the frequentist requires a space of x-values; the Bayesian does not. By the likelihood principle, the latter restricts the space to one value; that observed. The contrast between the two views is clarified by a slight exaggeration: Bayesians operate in the space of the parameter θ; frequentists in the sample space of X. For example, in contrast to the frequentist's unbiased estimate, the Bayesian might use the posterior mean

$$t(x) = \int \theta p(\theta|x)\, \mathrm{d}\theta,$$

with integration over the whole parameter space.

Here is an example that illustrates the difference. Suppose a drawing pin is tossed a number of times under conditions that lead both the frequentist and the Bayesian to think the sequence exchangeable and therefore, by de Finetti, Bernoulli. Consider two scenarios:

1. An integer n is selected. The pin is tossed n times and is observed to fall point uppermost on r occasions.
2. An integer r is selected. The pin is tossed until is falls uppermost for the rth time. This takes n tosses.

Suppose the values (r, n) are the same in the two scenarios. Then, for a given sequence; that is, including the order of the results, the likelihood for both scenarios is $\theta^r(1-\theta)^{n-r}$ for parameter (chance) θ. The Bayesian will make the same inference in both cases; namely,

$$p(\theta|r, n) \propto \theta^r(1-\theta)^{n-r} p(\theta).$$

However, the frequentist will use the **binomial distribution** ${}^nC_r\theta^r(1-\theta)^{n-r}$ in 1 and the negative binomial ${}^{n-1}C_{r-1}\theta^r(1-\theta)^{n-r}$ in 2. In 1, the unbiased estimate of θ is r/n; in 2, it is $(r-1)/(n-1)$.

The violation of the likelihood principle by frequentists is surprising, since the principle follows logically from the **conditionality principle** and **sufficiency**, usually accepted by frequentists, see [3].

Hypothesis Testing

A common activity in science is that of testing a hypothesis. A null hypothesis is erected as an "Aunt Sally" (American: "Straw man") and data are collected in an attempt to destroy it. Repeated failure to do this leads to its acceptance as part of scientific knowledge. The frequentist approach to testing uses the concept of a significance level. The Bayesian, following Jeffreys, addresses the problem directly through the probability of the null hypothesis, given the data. To illustrate the substantial differences between the approaches, take the case where exchangeable observations $x_1, x_2, \ldots, x_n$ are, given θ and σ^2, normally distributed with mean θ and variance σ^2. Here σ^2 is known but θ is not and the null hypothesis is that $\theta = 0$. Although somewhat specialized, many testing situations resemble it approximately, at least in large samples, and the conclusions derived from it apply rather generally. A more detailed treatment is provided by [1].

The frequentist will use the statistic $t = n^{1/2}\overline{x}/\sigma$, where $\overline{x}$ is the sample mean. On the null hypothesis, this is standard normal with zero mean and unit variance. The significance level of a two-sided test is $P = 2\Phi(-t)$, where Φ is the distribution function of a **standard normal deviate**. Thus, if $t = 1.96$, $P = 0.05$.

The Bayesian will require a prior distribution for θ when $\theta \neq 0$. Suppose this is $\mathrm{N}(0, \tau^2)$. The mean is reasonably at the null value and τ measures the spread of plausible alternatives about the null value. The next stage is to calculate by Bayes' theorem the posterior odds on $\theta = 0$. Odds are chosen in preference to probabilities since the theorem is simpler in terms of them. Under the null, $\overline{x}$, which is sufficient, is $N(0, \sigma^2/n)$. Under the alternative, it is $N(0, \sigma^2/n + \tau^2)$. To pass from prior to posterior odds it is necessary to multiply by the likelihood ratio; namely, the ratio of the probability of $\overline{x}$ when $\theta = 0$, to that when $\theta \neq 0$. This is

$$\frac{n^{1/2}\sigma^{-1} \times \exp[-n\overline{x}^2/2\sigma^2]}{(\sigma^2/n + \tau^2)^{-1/2} \times \exp[-x^2/2(\sigma^2/n + \tau^2)]},$$

which simplifies to

$$(1 + \rho^{-2})^{1/2} \times \exp[-t^2/2(1 - p^2)],$$

where $\rho = \sigma/\tau n^{1/2}$. This is well approximated by its form for a large sample size when $\rho \to 0$;

$$n^{1/2}\tau/\sigma \times \exp(-t^2/2).$$

The posterior odds will therefore be small if, like the P value of the frequentist, $|t|$ is sufficiently large. Both schools therefore agree that $t = n^{1/2}\overline{x}/\sigma$ is the right statistic and that numerically large values cast doubt on the null. But how large does it need to be for significance? The frequentist says larger in modulus than a value that does not depend on n, but only on P. Thus, if $P = 0.05$, it needs to exceed in modulus 1.96 for all n. The Bayesian treatment says it has to be large enough for the posterior odds on $\theta = 0$ to be sufficiently small. Taking logarithms of the approximate value above, this amounts to saying

$$t^2 > \log n + 2\log\left(\frac{\tau}{\sigma}\right) + K, \qquad (*)$$

where K is a constant depending on the critical value selected for the odds. Thus, to compare with the frequentist $P = 0.05$, odds of 19 to 1 against might be selected, when $K = 2\log 19 = 5.89$.

A striking difference between the two schools is now revealed. The frequentist demands for significance that t^2 is greater than a fixed value, whereas the Bayesian demands that it exceeds the value in $(*)$. The latter depends on what alternatives were reasonable a priori as expressed by τ/σ. But, more importantly, it depends on the sample size, unlike the frequentist's value. Either for sufficiently large τ or for a sufficiently large sample, the Bayesian would not declare significance, whereas the frequentist would. It is easier for the frequentist to obtain significance than it is for the Bayesian. The inclusion of the term in $\log n$ in the Bayesian approach, but not in the frequentist, makes for substantial operational differences between the two schools. This conclusion applies not just in this little problem but more widely; for example, in model selection, the logarithm acting like an automatic Occam's razor and deterring the introduction of extra parameters (*see* **Parsimony**).

Fuzzy Logic

Probability is a way of handling uncertainty. It is not the only way that has been suggested. An alternative approach is by fuzzy logic. It is now possible to buy electronic equipment "designed by fuzzy logic". The laws of this logic concern uncertain events, as does probability, but are not based on addition and multiplication, but on minimization and maximization. This results in considerable operational differences between the two methods. One feature that distinguishes fuzzy logic from probability is that the former has no axiomatic justification. The minimization law has not been proved from other, more primitive, assumptions on the lines followed by Ramsey, de Finetti and others. Rather, it has been invented as simple and apparently sensible. A good discussion of the foundational position and its practical effect is given in [9], with discussion.

DENNIS V. LINDLEY

Founder Effect

The "establishment of a new population by a few original founders (in an extreme case, by a single fertilized female) that carry only a small fraction of the total genetic variation of the parental population" was termed the *founder principle* by Mayr [3]. The effect on the descendant population resulting from the small number of **genes** brought by the founders is called the founder effect. The effects are many. First, there is a great reduction in genetic variability compared with the parental population. If **heterozygosity**, averaged over a large number of loci, is used as a measure of genetic variability, then there is a great reduction in heterozygosity. Secondly, there is a high probability of extinction of the descendant population. Thirdly, the effect of random genetic drift is very pronounced, resulting in large fluctuations of allele frequencies in the initial generations. Fourthly, the levels of **inbreeding** are high in the initial generations, which adds to loss of heterozygosity. Compared with the parental population, there is not only a great reduction in average heterozygosity (calculated from allele frequencies at several neutral loci; *see* **Gene Frequency Estimation**) in the small, newly founded population, but the average heterozygosity remains reduced for a very long time even after the descendant population recovers its original parental population size [4]. The frequencies of recessive disease alleles (*see* **Genotype**) and neutral alleles are particularly affected. Some disease alleles are lost through drift, and some alleles that may have been rare in the parental population are pushed to high frequencies. For example, three specific **mutations** in BRCA1 and BRCA2 genes that are responsible for breast cancer are more common in the Ashkenazi Jewish population, whose ancestry can be traced to a small group of founders from central and eastern Europe. Studies indicate that there is a markedly increased prevalence of two mutations in the BRCA1 gene, 185delAG and 5382insC, and one mutation, 6174delT, in the BRCA2 gene, among Ashkenazi Jews than among their ancestral populations, which has been attributed to the founder effect [5–7]. These effects and features are being fruitfully exploited for understanding the architectures of genetic diseases.

Consider a large population, from which a group of individuals moved out and founded a new population. In the large parental population, except for newly arisen ones, disease genes occur on many haplotype backgrounds (*see* **Haplotype Analysis**). That is, if one considers a number of marker loci in the region flanking the disease locus, then the combinations of alleles at these **marker** loci on chromosomes that carry the disease-causing allele are usually many. However, in the newly founded population, because the number of founding individuals is small, the haplotypes of chromosomes carrying the disease-causing allele are much fewer. Thus, individuals who are affected will show a much greater sharing of marker alleles in the genomic region surrounding the disease locus in the descendant population than in the parental population. Therefore, by examining the sharing of haplotypes among affected individuals, one can map more easily the disease locus in the descendant population than in the parental population. This enhances the power of mapping genes in a newly founded population with a small number of founders. This feature has been very successfully exploited to map a gene for a rare autosomal recessive disease, namely benign recurrent intrahepatic cholestasis [2]. This gene was mapped to chromosome 18 by an analysis of shared genomic segments in only four affected individuals belonging to an isolated fishing community, of several thousand individuals, in The Netherlands.

In newly founded populations, dominant disease alleles are lost much more quickly than recessive disease alleles, unless the reduction in fitness due to the dominant disease is negligible. In other words, recessive disease alleles tend to persist longer in small populations compared with dominant disease alleles. However, due to the founder effect, and subsequent genetic drift, different newly founded populations often have different sets of recessive diseases. Therefore, such populations are very useful in mapping genes underlying various recessive diseases.

Unless the initial number of founders is very small, alleles and haplotypes that are common in the parental population are seldom completely absent in a descendant population [8]. Many common diseases are currently thought to be due to actions of common alleles at multiple loci. Furthermore, genotypes at the loci that underlie a common disease also are known to interact with environmental (including cultural) factors (*see* **Gene-environment Interaction**). Populations that are founded by a small number

of individuals often share environmental and cultural factors. Thus, such populations are generally environmentally and culturally homogeneous. This is a nongenetic founder effect, which is currently being exploited by geneticists to map genes underlying common and **complex diseases**. Examples of populations, which are currently being investigated for such purposes, are the Amish of the US and the Bedouins of west Asia. While founder effects can be fruitfully exploited for mapping genes, it is becoming increasingly clear that there are other crucial determinants of the success of such endeavors. Haplotype sharing among affected individuals provides clues to the locations of disease genes. However, when there are multiple genes underlying a disease, such as a common, complex disease, it is harder to discern haplotype sharing. If a disease allele is old, then the region around the disease locus in which marker alleles will be shared among affected individuals is expected to be short. Thus, gene mapping by examination of haplotype sharing is more efficient in newly founded populations. There is currently a major interest in estimating the nature and extent of **linkage disequilibrium** in isolated populations with different founding and demographic histories. The data being generated through individual efforts of researchers and the Single Nucleotide Polymorphism (SNP) Consortium will be of great value in judging the usefulness of population isolates that exhibit strong founder effects [1].

PARTHA P. MAJUMDER

Fractional Factorial Designs

Fractional factorial designs are designs in which only a fraction of the total number of possible factor combinations is used (*see* **Factorial Experiments**). Fractional factorials were introduced by **Fisher** [5] in 1942 for use in agricultural experiments. Unfortunately, these powerful designs were not widely used in medicine or the health sciences until much later. In the biopharmaceutical arena, fractional factorial designs are widely used in exploratory studies of new organic synthesis routes and pharmaceutical formulation development. In addition, fractional factorials are the basis of *matrix designs* used in drug stability studies (see [13]).

Fractional factorials are a very efficient methodology for reducing the number of experimental runs necessary for exploratory studies. When one is interested in many factors, use of a full design would result in a prohibitively large number of runs. For example, suppose one wants to include eight factors in a two-level design; a full factorial would require $2^8 = 256$ runs! Experience has shown that it is reasonable to assume that three-way and higher-order **interactions** are negligible, and hence it is indeed wasteful to use a full factorial for a moderate to large number of factors. With eight factors, there are only eight main effects and 28 two-way interactions, which requires 37 runs not 256 runs.

In this article we will see how to select fractions of full designs so that effects of interest are estimated as efficiently as possible. The focus of the discussion will be directed toward two-level designs; however, other fractional designs are discussed and references are given for the interested reader.

Construction of Fractional Factorials

The construction of general fractional factorials is a challenging combinatorial problem. There is no unique method for construction, and given the characterization of the factorial, many methods have been developed. A variety of construction methods are summarized in Raktoe et al. [15].

Fractional factorials are characterized by the number of levels $r_1, \ldots, r_k$ specified for a set of k factors. Designs are *symmetric* if all factors have the same number of levels, $r_i = r, i = 1, \ldots, k$, and are said to be *mixed* otherwise. *Prime powered* designs have $r_i = p^m$, where p is a prime and m is a positive integer. Construction methods based on group theory and finite geometry have been developed for prime powered symmetric fractional designs. Details are given in Raghavarao [14]. The special subclass of two-level designs is expounded upon in the next section.

An Algorithm for Standard Two-level Designs

A two-level fractional factorial design with k variables is denoted as a 2^{k-p} design, where $1/2^p$ is the size of the fraction and 2^{k-p} is the number of runs. It is easy to construct these designs with a specialized representation of the design and model matrices. The design matrix of a factorial design defines the settings of individual factors over the series of experiments. The model matrix is an extension of the design matrix that includes all terms in the model: main effects and interactions. The first column of the model matrix is a column of 1s, the next k columns comprise the design matrix, and the remaining columns depict any interactions of interest.

We begin with a simple example for three factors. This is for illustration of principles only. The model matrix for a full 2^3 design is given in Table 1. We use both the ± 1 notation and the lowercase letter notation to denote experimental combinations.

Suppose we wish to select four of these eight runs to estimate the main effects of the three factors. Then we need a 2^{3-1} design. The one rule we must always obey is to select runs that result in an **orthogonal design**. An orthogonal design is one in which the sums of all pairwise column products equals zero. This ensures that we have an **optimal design**. One orthogonal run selection is c, b, a, and abc, which

Table 1 A full 2^3 design

Experiment		I	A	B	C	AB	AC	BC	ABC
1	(1)	1	−1	−1	−1	1	1	1	−1
2	c	1	−1	−1	1	1	−1	−1	1
3	b	1	−1	1	−1	−1	1	−1	1
4	bc	1	−1	1	1	−1	−1	1	−1
5	a	1	1	−1	−1	−1	−1	1	1
6	ac	1	1	−1	1	−1	1	−1	−1
7	ab	1	1	1	−1	1	−1	−1	−1
8	abc	1	1	1	1	1	1	1	1

results in the following fractional design matrix:

Run	A	B	C
c	-1	-1	1
b	-1	1	-1
a	1	-1	-1
abc	1	1	1

What are the consequences of use of the four-run vs. the eight-run design? The answer is that less information is available. The reader may verify that, in the fractional design, the interaction effects are such that $BC = A$, $AC = B$, $AB = C$, and $ABC = I$. This phenomenon is called **confounding** and it means that the interactions are not separable from the main effects. Unseparable effects are called *alias sets*. The four orthogonal estimable effects in the fractional design,

$$\delta_1 = \frac{(-c - b + a + abc)}{2},$$
$$\delta_2 = \frac{(-c + b - a + abc)}{2},$$
$$\delta_3 = \frac{(c - b - a + abc)}{2},$$
$$\delta_4 = \frac{(c + b + a + abc)}{4},$$

actually estimate $A + BC$, $B + AC$, $C + AB$, and $I + ABC$, respectively. Thus, if δ_1 is large, then we do not know if it is due to the main effect of A or the interaction BC or both. This is the price we pay. However, this is not serious because designs may be augmented with additional experiments to gather more information if necessary. Even in situations where there is some confounding with two-way interactions, one can intelligently guess which effects are likely to be contributors because experience has shown that real interactions are unlikely when main effects are not present. Suppose, in the above example, only δ_1 and δ_2 are large; then one can postulate that main effects A and B are probably present rather than interactions BC and AC since δ_3 was small. However, confirmatory experiments should always be run!

The general **algorithm** for construction of 2^{k-p} designs is based upon defining design *generators*. Design generators generate the design and identify associated alias sets. We begin with an example of six factors in 16 runs. This is a 2^{6-2} design. The process begins with a full 2^4 design in which columns $A-D$ are designated as usual. We complete the design matrix by assigning two added factors E and F with $E = BCD$ and $F = ACD$ to produce the design matrix in Table 2. All of the resulting confounding relationships are obtained with use of the defining relationships $E = BCD$ and $F = ACD$. The other confounding relationships are identified by use of a convenient multiplicative relationship, $A \odot B = AB$ and $A \odot A = I$. The $\odot$ binary multiplication of uppercase letters corresponds to columnwise multiplication of $\pm$ 1s in the design matrix. We begin by multiplying both sides of defining relationships by the letter on the left. The defining relationships produce $E \odot E = BCD \odot E$ or $I = BCDE$ and $F \odot F = ACD \odot F$ or $I = ACDF$. Both of these imply $I \odot I = BCDE \odot ACDF$ or $I = ABEF$. We now have the design generator sequence:

$$I = BCDE = ACDF = ABEF.$$

A design generator sequence has 2^p effects, where p is the degree of fractionation. The complete alias structure of the design is comprised of 2^{k-p} cosets with p aliased effects in each. A 2^{6-2} design has 16 cosets with four aliases in each. For example, the second coset (take the first coset as the design generator sequence) is $A = ABCDE = CDF = BEF$. The complete alias structure is:

$$I = BCDE = ACDF = ABEF,$$

Table 2 Design matrix for a 2^{6-2} design

Experiment		A	B	C	D	E	F
1	$abcdef$	1	1	1	1	1	1
2	abc	1	1	1	-1	-1	-1
3	abd	1	1	-1	1	-1	-1
4	$abef$	1	1	-1	-1	1	1
5	$acdf$	1	-1	1	1	-1	1
6	ace	1	-1	1	-1	1	-1
7	ade	1	-1	-1	1	1	-1
8	af	1	-1	-1	-1	-1	1
9	$bcde$	-1	1	1	1	1	-1
10	bcf	-1	1	1	-1	-1	1
11	bdf	-1	1	-1	1	-1	1
12	be	-1	1	-1	-1	1	-1
13	cd	-1	-1	1	1	-1	-1
14	cef	-1	-1	1	-1	1	1
15	def	-1	-1	-1	1	1	1
16	(1)	-1	-1	-1	-1	-1	-1

$$A = ABCDE = CDF = BEF,$$
$$B = ABCDF = CDE = AEF,$$
$$C = ABCEF = BDE = ADF,$$
$$D = ABDEF = BCE = ACF,$$
$$E = ACDEF = BCD = ABF,$$
$$F = BCDEF = ACD = ABE,$$
$$AB = ACDE = BCDF = EF,$$
$$AC = ABDE = BCEF = DF,$$
$$AD = ABCE = BDEF = CF,$$
$$AE = ABCD = CDEF = BF,$$
$$AF = ABCDEF = CD = BE,$$
$$BC = ABDF = ACEF = DE,$$
$$BD = ABCF = ADEF = CE,$$
$$ABC = ADE = BDF = CEF,$$
$$ABD = ACE = BCF = DEF.$$

Upon assuming that three-way and higher-order interactions are negligible, we have "clean" main effects and aliasing of two-way interactions with each other. This is a *Resolution IV* design.

Design resolution is categorized as follows:

1. *Resolution III*: main effects are aliased with two-way interactions.
2. *Resolution IV*: main effects are aliased with three-way interactions and two-way interactions are aliased with each other.
3. *Resolution V*: main effects are aliased with four-way interactions and two-way interactions are aliased with three-way interactions.

It is not necessary to generate the entire alias structure to ascertain the resolution of a design because resolution is simply the shortest word length in the generator sequence.

Before proceeding to an example, it is important to note that one should be very careful in the selection of the original defining relationships. It is quite possible to try different defining relationships in the 2^{6-2} design. What about $E = ABCD$ and $F = ACD$ rather than $E = BCD$ and $F = ACD$? The implications of the new assignment with $E = ABCD$ are the design generator sequence $I = ABCDE = ACDF = BDE$, which produces a less efficient Resolution III design.

Tables that provide the highest resolution fractional designs for a given number of runs and factors are available. Extensive tables are listed in the National Bureau of Standards [12] and a shorter list for up to seven factors in eight runs and 15 factors in 16 runs appears in Lochner & Matar [9]. There are also statistical software packages that will generate 2^{k-p} designs. Two relatively inexpensive Windows software packages, ECHIP and SAS JMP, generate the designs, provide the alias structure, and include analysis options. Any statistical package that performs **regression** analysis may used for actual analysis if the user specifies only one member per alias set (*see* **Software, Biostatistical**).

An Example in Preformulation

A 2^{5-1} design was employed to determine the effect multiple components of excipients exerted upon drug stability. Four excipient components and the amount of water added to a wet granulation technique comprised the factors of interest. The example appears in [8]. The first four factors were designated to be filler (lactose, mannitol), lubricant (stearic acid, magnesium stearate), disintegrant (starch, Avicel), and binder (PVP, gelatine). The fifth factor was amount of water added (0, 3%w/w). Samples were prepared and stored at 50°C for 4 weeks to determine the effects of the factors on drug stability. The design and data are given in Table 3, where -1 and 1 correspond to the first and second of the pairs specified in the description of the factors.

Leuenberger & Becher [8] constructed the design by hand with defining relationship $E = ABCD$, that is, the designated level changes for the amount of water added was determined by the four-way interaction of the remaining factors. A Yates analysis scheme (*see* **Yates's Algorithm**) was used to calculate effects.

For the sake of illustration, an example of analysis by SAS JMP is included in the present material. First, the design was created by choosing the Design Experiment Option in the Tables menu of JMP. The two-level designs option was selected to create the Resolution V 16-run design. The design was augmented with the data and we proceeded with the analysis. These data have 15 available **degrees of freedom**, all of which are used to estimate the five

Table 3 Design and results of a drug stability study

Sample	Filler (A)	Lubricant (B)	Disintegrant (C)	Binder (D)	Water (E)	Yield
1	−1	−1	−1	−1	1	59.6
2	1	−1	−1	−1	−1	86.4
3	−1	1	−1	−1	−1	95.0
4	1	1	−1	−1	1	97.0
5	−1	−1	1	−1	−1	83.4
6	1	−1	1	−1	1	53.8
7	−1	1	1	−1	1	93.7
8	1	1	1	−1	−1	99.7
9	−1	−1	−1	1	−1	54.1
10	1	−1	−1	1	1	45.8
11	−1	1	−1	1	1	92.8
12	1	1	−1	1	−1	96.1
13	−1	−1	1	1	1	53.6
14	1	−1	1	1	−1	64.7
15	−1	1	1	1	−1	94.0
16	1	1	1	1	1	96.3

main effects and the 10 two-way interactions. For this reason, we examine the relative size of the effects through the normal plot option (see [1]). The plot is depicted in Figure 1, where sizable effects are labeled. It is evident that lubricant, binder, and water appear to be significant. This is confirmed through the results of an **analysis of variance** on the reduced three-factor model, which is given in Table 4. The cube plot in Figure 2 is a nice graphical depiction of the results.

In summary, stability of drug product is sensitive to moisture, magnesium stearate is clearly superior to stearic acid, and PVP is somewhat preferable to gelatine. Fillers and disintegrants do not affect

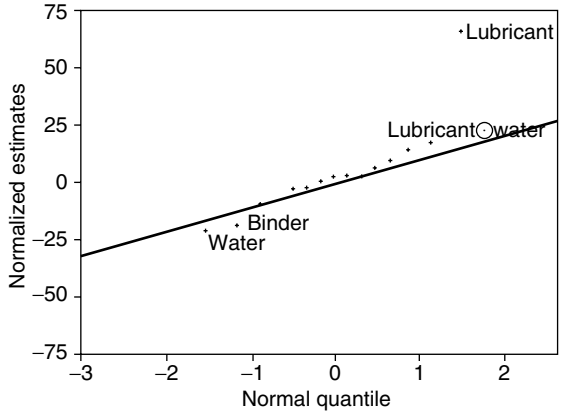

Figure 1 Normal plot of effects

Table 4 Analysis of variance table

Source	df	Sum of squares	F ratio	Pr > F
Lubricant	1	4329.6400	190.0910	<0.0001
Binder	1	316.8400	13.9107	0.0047
Water	1	408.0400	17.9148	0.0022

Binder⊙water	1	100.0000	4.3905	0.0656

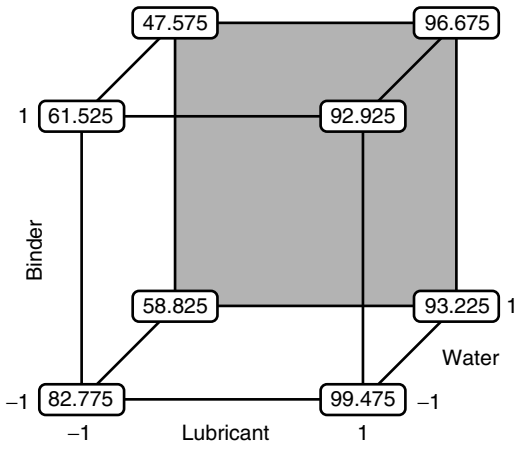

Figure 2 Cube plot of significant factors

the stability and hence the formulator may choose among the four combinations of these two components. Finally, the binder effect depends heavily on

the lubricant used. Use of PVP is clearly indicated in the presence of stearic acid, but either PVP or gelatine provide desirable results in the presence of magnesium stearate. The investigators chose to recommend lactose, mannitol, starch, Avicel, PVP, and magnesium stearate as suitable excipients.

Augmenting Designs to Separate Confounded Effects

Of course, one can visualize instances in which it is impossible to single out aliases that are the real contributors. One of the very important advantages of using a well-designed fractional factorial is that an initial design may be subsequently augmented with additional runs, if necessary, to separate effects without starting over. For example, suppose one alias set of two-way interactions is significant and the aim is to separate the confounded effects in this set. An economic route for separation of m effects is to augment the experiment with a minimum number of $(m-1)$ *complementary runs*. Most software packages that generate designs include an option to augment the design. Details on selection of runs for augmentation are given in [16].

If one wishes to separate some effects in all alias sets, a *foldover design* should be considered. Foldovers are most commonly used to separate two-way interactions from main effects in Resolution III designs. A foldover design is the complementary fraction of the original design. Foldovers are easily generated by simply reversing the signs of the main effects in the initial design.

The alias structure of the combined design follows from examination of the alias structures in complementary fractions. There are 2^p fractions of size 2^{k-p} available from a 2^k design. These fractions may be aligned into complementary pairs. To illustrate, consider a 2^{5-2} design generated with $D = AB$ and $E = AC$, and consequently, $I = ABD = ACE = BCDE$. Three additional fractions may be generated with $D = -AB$ and $E = AC$, $D = AB$ and $E = -AC$, and $D = -AB$ and $E = -AC$. The complete set of four fractions has defining relationships:

$$I = ABD = ACE = BCDE, \quad (1)$$

$$I = -ABD = ACE = -BCDE, \quad (2)$$

$$I = ABD = -ACE = -BCDE, \quad (3)$$

$$I = -ABD = -ACE = BCDE. \quad (4)$$

The generator sequence of a foldover design is such that the sign of words with an odd number of letters is reversed and the sign of words with an even number is the same. Thus, designs (1) and (4) and (2) and (3) are complementary. The contrasts in the A columns of designs (1) and (4), say δ_{A1} and δ_{A2}, estimate $A + BD + CE$ and $A - BD - CE$, respectively. Thus, $(\delta_{A1} + \delta_{A2})/2$ and $(\delta_{A1} - \delta_{A2})/2$ respectively estimate A and $BD + CE$. All other main effects are also separated from their aliased two-way interactions.

Other Fractional Factorial Designs

So far the discussion has been of two-level designs with the number of runs equal to a power of two. There are situations for which this is not the most efficient choice. This is particularly true when one has interest in only main effects such as in **screening** experiments with a large number of factors. For example, suppose one has 10 factors and wishes to detect which subset of these factors is really influential in the outcome of interest. The minimum number of runs necessary for the experiment is 11. The smallest standard design one could use would be a 2^{10-6} design with 16 runs. There are alternative *saturated* designs that may be used. A design for k factors is saturated if the number of runs is $N = k + 1$. Two types of saturated designs are Plackett–Burman and simplex designs.

Plackett–Burman Designs

Plackett–Burman designs are saturated designs for k two-level factors with $N = k + 1$, where N must be a power of four (*see* **Response Surface Methodology**). These designs are equivalent to the standard 2^{k-p} designs when N is a power of two. Construction of Plackett–Burman designs is based on the theory developed around *Hadamard* matrices, which are simply orthogonal matrices with all elements being equal to ± 1s (see [6]). Plackett–Burman designs may be folded over, but the confounding relationships are not easy to obtain. Details are discussed in [4].

Simplex Designs

Simplex designs are also saturated, but N is not restricted to be a multiple of four as in the Plackett–Burman designs. However, the simplex design

only applies to quantitative factors. These designs are often used as sequential searching algorithms to locate optimal domains for a full experimental study. A simplex is a k-dimensional figure constructed so that each vertex has the same Euclidean distance to all other vertices. In two dimensions, a simplex is simply an equilateral triangle. Natural design points are generated with specialized scaled factors that satisfy the equidistant vertices restriction. If we let x_{ij} denote the level of the ith scaled factor on the jth run, then the level of the ith natural factor on the jth run is $u_{ij} = u_i + \delta_i x_{ij}$, where u_i is a selected initial value and δ_i is a selected step size. A four-factor simplex design from Carlson [3] is given in Table 5. The background and application of simplex designs is thoroughly discussed in [2] and [11] (*see* **Simplex Models**).

D-optimal Designs

In general, **optimal designs** are designs for which **variances** of estimated effects are as small as possible. The variance of the vector of estimated effects is $\sigma^2(\mathbf{X}'\mathbf{X})^{-1}$, where $\mathbf{X}$ is the model matrix of the design and σ^2 is the experimental error. Thus, variances may be controlled through selection of $\mathbf{X}$. One mathematical criterion is to maximize the determinant of $\mathbf{X}'\mathbf{X}$, which in turn minimizes the determinant of the inverse. This criterion is deemed D-optimality. Other optimality criteria exist, such as A-, E-, and G-optimality, but in most cases all criteria produce equivalent designs. Kiefer [7] is an excellent source for a rigorous understanding of optimality.

All of the designs we have discussed thus far are D-optimal and can be constructed by hand. In general, D-optimal designs must be constructed by special computer algorithms. In particular, the exchange algorithm developed by Mitchell [10] is widely used in software packages. To obtain a D-optimal design, the number of runs desired, as well as the terms one wishes to estimate, must be specified. The algorithm initially randomly selects a set of N runs. Then an iterative procedure sequentially adds and deletes runs until the determinant of $\mathbf{X}'\mathbf{X}$ is maximized.

A general D-optimal approach is necessary if: (i) some combinations of factors are not reasonable (these may be excluded in algorithmic design searches); (ii) a saturated design with some interactions is desired; (iii) one would like to add complementary runs; and (iv) factors have mixed levels. It must be stressed that the designs obtained are only optimal if the model specified is accurate. The Windows packages ECHIP and SAS JMP use the D-optimality criterion for some choices of designs. A very good software package for choice of optimality criteria, choice of algorithms, and multiple choices of designs is available in PROC OPTEX of the SAS/QC module.

Table 5 A four-factor simplex design

Experiment	Addition time	Reaction time	Ratio of reagents	Amount of catalyst
1	60	180	3.00	0.400
2	32	167	2.78	0.378
3	54	125	2.78	0.378
4	54	167	2.07	0.378
5	54	167	2.78	0.300

FRANCES P. STEWART

Frailty

Introduction

Conceptually, the frailty models are similar to the mixed models, so that conditional on some random variable (which in **survival** data is the term denoted frailty), the observations are independent. Unconditionally, that is, when the frailty is integrated out, the observations are dependent. Thus the frailty generates the dependence between the times. A review is in [13]. Frailty models have been used for univariate data to extend parametric models and to understand the effect of heterogeneity (not accounting for important **covariates**), but they are more interesting in the multivariate case, where the frailty approach makes a completely new class of models.

Basically, there are four types of **multivariate survival** data where frailty models are relevant. The first type is the time to some event (e.g. death) for several individuals, related by family membership (*see* **Familial Correlations**), marriage, exposure to some agent, and so on. Secondly, there are failures of several similar physically related components, like right/left eye or right/left kidney on a single individual. Thirdly, there are recurrent events (*see* **Repeated Events**), where the same event, like myocardial infarction (*see* **Cardiology and Cardiovascular Disease**), **epileptic** seizure, childbirth, or car **accident**, can happen several times for an individual. The fourth type is a **repeated measurements** type, typically the result of a designed experiment, where the time to the same event is studied on multiple occasions for the same individual. There are two further types of multivariate survival data where these models are slightly less relevant. First, there is the study of different events on a single individual, like the times to complication for the eyes, nerves, and kidneys for a diabetic patient. Finally, there are **competing risks** (data on cause of death), where the frailty models are relevant probability models, but where the basic parameters cannot be identified, making them less relevant for statistical inference [13].

These models may be applied in biostatistics to study dependence in lifetimes as well as time to onset of specific diseases in order to evaluate the **clustering** within families. Also, they can be used to quantify the subject differences for recurrent events and may be applied in **actuarial** science to describe a joint insurance for a married couple or for updating the risk of car accidents on the basis of the experience that accumulates for each driver as time goes by. The aim of using frailty models can either be to study the dependence *per se* or to account for the dependence in the evaluation of the effect of explanatory factors (and its uncertainty). Using a model with dependence, with as well as without a given covariate (say, describing a specific gene in a **twin** study), allows for discussing the extent to which the covariate "explains" the dependence seen between the times.

The term frailty was first introduced for univariate data by Vaupel et al. [32] to illustrate the consequences of a lifetime being generated from several sources of variation. However, frailty models have actually been used earlier for recurrent events [9] (*see* **Accident Proneness**) and for describing the dependence between lifetimes of several individuals [6]. To illustrate the idea, consider family data as a standard setup. Suppose there are n independent families, indexed by i. Let $j = 1, \ldots, k$ denote the number of members within families. The number of members could vary between families, without making the problem more complicated. The frailty, say Y_i, is specific to the family. The key assumption is that the lifetimes $(T_{i1}, \ldots, T_{ik})$ are conditionally independent given the family's frailty. Technically, this is obtained by assuming that the **hazard** is

$$Y_i \lambda(t),$$

where t denotes age, and $\lambda(t)$ is a function describing the age dependence. This can be generalized to include known covariates, say a p-vector z_{ij} for individual (i, j), giving a conditional hazard function of $Y_i \exp(\beta' z_{ij})\lambda(t)$. By assigning some distribution to Y_i and integrating it out, we have created a multivariate survival model with dependence between the coordinates.

The frailty is an unobservable quantity. For small groups, we can only obtain limited information on the individual value by observing the time of death or event respectively (*see* **Censored Data**). But we can evaluate the frailty variability by studying a population with many groups.

While most of the literature on frailty models is of the "common frailty" (or "shared frailty") type described above, where all members of a group have the same (constant) value Y_i of the frailty, this may not fully capture the complexity of relationship in all cases. There are a number of ways where the

models can be extended to allow for more general dependence structures; see the section on "Extension to Multivariate Frailty".

Comparison to the Variance Components Model

One can ask why the **normal distribution** models are not applied. There are many simple results and a broad experience with these models. However, they are not well-suited for survival data for three reasons.

1. Data are often censored, meaning that for some observations, it is only known that they exceed some given values, for example, the lifetime of a person alive today is only known to be at least his current age. This makes it difficult to apply a standard **variance components** model, because multivariate distribution functions are needed for the calculations, and simple formulas for them are not available in the normal case.
2. For survival data, it also makes sense to condition on the history up to a certain time point, giving **truncated** data, and this is not well-suited to the normal distribution.
3. The normal distribution gives a very bad fit to survival times, as lifetimes of human beings are left-**skewed** positive variables with a very high variation, and the normal distribution is symmetric and not concentrated on the positive numbers. The standard approach to get positive variables is to apply a normal distribution after a logarithmic **transformation**, but that makes the original variable right skewed, rather than left skewed.

Four other aspects, however, make the analysis of **random effects** more complicated for survival data.

1. The normal distributions satisfy very simple mixture properties, as the sum of two independent normally distributed variables is again normally distributed. The normal distributions are the only distributions with finite variance satisfying this property together with the property that any such distribution can be transformed into any other normal distribution by a linear transformation. The mixture results behind other random effects models necessarily are more complicated. In the frailty model case, both the **gamma** distributions and the positive stable distributions have interesting theoretical properties.
2. Balanced variance components model can be analyzed very simply, by means of the **analysis of variance** (ANOVA) decomposition of the sum of squares, but due to censoring, survival data are rarely balanced, and thus simple analyses are seldom possible.
3. Whereas rather general dependence structures are possible for variance components models, both including many different components and including general linear functions of a few components (**random coefficient** regression models), similar general models are not yet available for survival data; see the section "Extension to Multivariate Frailty".
4. In the normal case, it is simple and natural to evaluate the dependence by means of either the values of the variances or by the **correlation** coefficients of the observations. It is more difficult to quantify the dependence in the survival case.

Distributional Assumptions

Various choices are possible for the distribution of the frailty term. Most applications use a gamma distribution, with density $f(y) = \theta^\delta y^{\delta-1} \exp(-\theta y)/\Gamma(\delta)$. In most models, the scale parameter is unidentifiable, and therefore it is necessary to let $\delta = \theta$ during estimation, giving a mean of 1 and a variance of $1/\theta$ for Y. Let D_{ij} be an indicator of death of individual (i, j). Then, the observed (marginal; integrating over the frailty) likelihood (neglecting index i) is

$$\begin{aligned}
&\int f(y) \Pr(D_1, \ldots, D_k, T_1, \ldots, T_k | y)\, \mathrm{d}y \\
&= \int \frac{\theta^\theta y^{\theta-1} \exp(-\theta y)}{\Gamma(\theta)} \\
&\qquad \times \prod_{j=1}^{k} [y\lambda_j(t_j)]^{D_j} \exp\left[-y \int_0^{t_j} \lambda_j(s)\, \mathrm{d}s\right] \mathrm{d}y \\
&= \frac{\theta^\theta}{\Gamma(\theta)} \prod_{j=1}^{k} \lambda_j(t_j)^{D_j} \int y^{\theta-1+D.} \exp[-y(\theta + \Lambda.)]\, \mathrm{d}y \\
&= \frac{\theta^\theta \Gamma(\theta + D.)}{(\theta + \Lambda.)^{\theta+D.} \Gamma(\theta)} \prod_{j=1}^{k} \lambda_j(t_j)^{D_j}, \qquad (1)
\end{aligned}$$

where $D_\cdot = \Sigma_j D_j$ and $\Lambda_\cdot = \sum_{j=1}^{k} \int_0^{t_j} \lambda_j(s)\,\mathrm{d}s$. The gamma distribution has the further advantage that the conditional distribution of Y, given the survival experience in the family – the integrand in the penultimate expression above – is also gamma, with the shape parameter increased by the number of deaths in the family, that is, with parameters $(\theta + D_\cdot, \theta + \Lambda_\cdot)$ instead of (θ, θ). In a similar manner, the joint survival function can be derived as

$$S(t_1, \ldots, t_k) = \left[\sum_{j=1}^{k} S_j^{1-\theta}(t_j) - (k-1) \right]^{-1/(\theta-1)}, \tag{2}$$

where $S_j(t)$ is the marginal survival function for individual j. Using the marginal survivor functions offers an alternative parameterization of the model as further discussed in the section, "Conditional and Marginal Models".

A positive stable distribution of Y has other nice probabilistic properties [12]. It has one parameter (the stability index) α, $\alpha \in (0, 1]$, where $\alpha = 1$ corresponds to independence and α near 0 corresponds to maximal dependence. If $\lambda(t)$ corresponds to a **Weibull distribution** of shape parameter γ, the unconditional distribution of the lifetime is also Weibull, but of shape $\alpha\gamma$. This result is probably the closest we can come to the variance components model, where the normal distribution appears on all stages of the model. The change from γ to $\alpha\gamma$ corresponds to increased variability. If there are covariates in a **proportional hazards** model, and Y follows a positive stable distribution, the unconditional distributions also show proportional hazards (unlike the gamma model), but the regression coefficients are changed from β to $\alpha\beta$.

Basically, any other distribution on the positive numbers can be applied, but the probability results are not equally simple. The multivariate distribution can be simply formulated by means of the derivatives of the Laplace transform $L(s) = \mathrm{E}\exp(-sY)$. The general density is $(-1)^{D_\cdot} L^{(D_\cdot)}(\Lambda_\cdot) \prod_{j=1}^{k} \lambda_j(t_j)^{D_j}$, where $L^{(p)}(s)$ is the p-th derivative of $L(s)$. The gamma distributions and the positive stable distributions can be unified in a three parameter family; see [11, 31]. The **inverse Gaussian distributions** are also included in this family. The family is called the power variance function (PVF) model because it is characterized by the variance being a power function of the mean, when considered as a natural **exponential family**. The positive stable frailty distributions lead to high dependence initially, whereas the gamma distributions lead to high late dependence [13]. The inverse Gaussian distributions are intermediate. From a practical point of view, it may be difficult to discriminate between the various distribution families because data may be insufficient to estimate two dependence parameters, but from a theoretical point of view, it is interesting to study the different nice properties that the families offer. Another argument for using the more general model is that (particularly with heavily censored data) the estimated degree of dependence is sensitive to the model assumed and thus the use of one of the simpler models may suggest a too precise value for the dependence; instead the two-parameter model may better capture the high variation due to the limited knowledge that follows from the censoring.

Furthermore, **lognormal distributions** have been suggested for the frailty; this allows the use of **restricted maximum likelihood** (REML)-like procedures [21]. The inverse Gaussian and the lognormal distributions are reasonably similar to each other. Oakes [25] reviews various frailty distributions.

Univariate Models

Initially, the frailty models were used to illustrate consequences of hidden heterogeneity, that is, **risk factors** being unknown or unobserved for independent (i.e. univariate) data. In this model, the total variation of a lifetime is split into the effect of known covariates, unknown covariates, and randomness. The effect of unknown covariates is modeled by a proportional hazards frailty model, and the randomness is modeled by the hazard function. One consequence is that even though individual hazard functions increase, the hazard function in the population can decrease due to differences between the individual hazard functions. With a gamma frailty distribution, a conditional proportional hazards model, using a known explanatory variable z, is marginally no longer of the proportional hazards form. Instead, the marginal hazard for a single individual j is

$$\mu(t, \mathbf{z}_j) = \frac{\lambda(t)\exp(\boldsymbol{\beta}'\mathbf{z}_j)}{1 + \theta\Lambda(t)\exp(\boldsymbol{\beta}'\mathbf{z}_j)}, \tag{3}$$

the denominator reflecting the "survival of the fittest" effect, that is, the differential survival implies removal

of the high-risk subjects over time. Although in the presence of known covariates, it is, in principle, possible to estimate the frailty variance using only survival-time data on independent individuals, this estimator depends critically on the proportionality of the hazards conditional on the frailty, an assumption that is unlikely to be strictly true in practice and is inherently untestable. It can be discussed as to the extent to which it should be possible to discriminate between unknown factors and plain randomness. This is analogical to the normal distribution variance components models, where it is not possible to discriminate between variation between and within individuals, unless there are several observations for each individual, with or without known covariates. The positive stable Weibull model is a similar model for survival data. In this model, it is not possible with univariate data to separately determine the influence of unknown covariates and of plain randomness. Aalen [2] reviews univariate frailty models.

Conditional and Marginal Models

Instead of having the hazard in the conditional distribution $\lambda(t)$ as starting point, one may use the hazard in the marginal distribution, say $\mu(t)$, as basis (*see* **Marginal Models for Multivariate Survival Data**). This function has the advantage that it is directly observable, and therefore can be estimated in several different ways. This is particularly relevant when the dependence is not the object of study but a nuisance that has to be accounted for. Such models are considered with the assumption that the marginal distributions are of a specific form, possibly after a transformation. If the marginals are **uniform** (0,1), the multivariate distribution is said to be of **copula** form [8]. In this way, one can separate the inference into that regarding the marginal distribution and that regarding the dependence structure. Liang et al. [20] compare the conditional and marginal approaches. The positive stable frailty distribution is the only one where the two approaches are identical for the proportional hazards model.

Accelerated Failure Time Models

In the case of Weibull models, the frailty models can also be given an **accelerated failure time** formulation, so that the lifetime has a multiplicative expression as $Y^{-1/\gamma}T_0$, where T_0 has a Weibull distribution of shape γ. With covariates, the formula is $Y^{-1/\gamma}T_0\exp(-\eta' z)$, where the relation to the coefficients in the hazards formulation is $\eta = -\beta/\gamma$. In the positive stable frailty model, this implies that the hazard regression parameter β differs between the conditional and the marginal distribution, but the accelerated failure time regression parameters η are the same, and thus they make a better parameterization [16].

Quantifying Dependence

A key problem for quantifying dependence is that standard nonparametric survival analysis assigns no relevance to the variance of the lifetime, making it irrelevant to evaluate correlations and variance components. Some authors have used the variance of the frailty term as a measure of that variance component, but this is inconvenient, as can be illustrated in the Weibull model of shape γ, say with hazard $Y\gamma t^{\gamma-1}$. Conditional on Y, this has mean of $Y^{-1/\gamma}\Gamma(1+1/\gamma)$, say $c_1(\gamma)Y^{-1/\gamma}$ and variance $Y^{-2/\gamma}[\Gamma(1+2/\gamma)-\Gamma(1+1/\gamma)^2]$, say c_2 $Y^{-2/\gamma}$ giving the unconditional variance $\mathrm{Var}(T) = c_1^2\ \mathrm{Var}(Y^{-1/\gamma}) + c_2\mathrm{E}(\mathrm{Y}^{-2/\gamma})$, and a correlation of $\{c_1^2\mathrm{Var}(Y^{-1/\gamma})\}/\mathrm{Var}(T)$ between two individuals with common Y. This shows that the inverse **moments** of Y are more relevant than the ordinary moments. Much simpler formulas are obtained for the logarithm to the time, where the conditional variance is $\pi^2/(6\gamma^2)$, the unconditional variance is $\{\mathrm{Var}(\log Y)+\pi^2/6)\}/\gamma^2$, and the correlation is $\mathrm{Var}(\log Y)/\{\mathrm{Var}(\log Y)+\pi^2/6)\}$, independently of γ, and this may not be well described by the moments on the ordinary scale.

For the nonparametric models, it is more relevant to consider measures that are unchanged by transformations of the time axis, for example, Kendall's coefficient of concordance τ (*see* **Rank Correlation**). This is defined as $\mathrm{Esign}\{(T_{11}\text{-}\mathrm{T}_{21})(T_{12}\text{-}\mathrm{T}_{22})\}$, where (T_{11},T_{12}) and (T_{21},T_{22}) are the lifetimes for two pairs from the distribution. Another possibility is the grade correlation (the theoretical measure underlying the **Spearman** correlation), which has the advantage of an interpretation similar to the standard product moment correlation.

Estimation

The first estimation method for multivariate data with covariates was suggested by Clayton and Cuzick [7], but most applications have rather used an **EM algorithm** [17]. It is also possible to maximize the observed **nonparametric likelihood** function, that is, where the frailties have been integrated out, but including a parameter for each time of event [13]. This method has the advantage of directly giving a variance estimate for all parameters [4]. Instead of using the conditional hazards, one may use the marginal hazards for this evaluation, which has the advantage that the dependence parameters and the hazard parameters are closer to be stochastically independent. An alternative is a **penalized likelihood** approach [29].

The gamma and lognormal shared frailty models can be fitted by means of **S-Plus** [29]. There is no other commercially available software that handles frailty models with nonparametric hazard functions.

Asymptotics

The statistical inference has been performed by doing standard calculations, that is, using **maximum likelihood** estimation and using normal distributions for the estimates, with the variance evaluated as the inverse of (minus) the second derivative of the log likelihood function, the so-called observed **information**. For **parametric models**, this is easily justified. For the bivariate positive stable Weibull model also, the Fisher (expected) information has been calculated for uncensored data [26]. A similar evaluation for the gamma frailty model was made by Bjarnason and Hougaard [5].

For non- and **semiparametric** models, the standard approach also works, although it has been more difficult to prove that it does. For the gamma frailty model with nonparametric hazard, Murphy [22] has found the asymptotic distribution of the estimators and a **consistent estimator** of the asymptotic variance. These results were generalized by Parner [27]. Murphy and van der Vaart [23] show that using the observed nonparametric likelihood as a standard likelihood is correct for testing and for evaluating the variance of the dependence parameter as well as for the explanatory factors.

Extension to Multivariate Frailty

The assumption of the frailty being common for the individuals in the family (the shared frailty model) has been criticized for not being sufficiently flexible, particularly for large pedigrees. One extension is to exchange the scalar Y_i with a multivariate vector $(Y_{i1}, \ldots, Y_{ik})$ with each component connected to one observation. One such trivariate nested model based on the positive stable distribution was suggested by Hougaard [12]. A bivariate model based on dependent gamma variables was suggested by Aalen [1], but this model is complicated to handle, except for some special cases. The simplest model in which exact calculations can be done is to let the multivariate frailty vector be a linear function of independent terms, for example, the so-called correlated frailty model, $Y_{ij} = X_{i0} + X_{ij}$, with all X variables independent [33]. In this case, the Laplace transforms are easily calculated. In the bivariate case, this is not a major extension because the individual terms only modify the marginal distribution and not the dependence structure. It can, however, be useful for combining groups with different degree of dependence into one analysis, for example, monozygotic and dizygotic twins. In the multivariate case, this can be made a real generalization. Korsgaard and Andersen [18] describe an extension of this approach to pedigree data, where each possible line of descent has an associated gamma frailty component. Unfortunately, this approach leads to the number of frailty components growing exponentially with family size.

The multivariate lognormal distribution may, after a few approximations, be used for more complex pedigree data and may thus be much easier to handle than an additive frailty model [19].

Another generalization is to let the frailty change over time, as a **stochastic process** or as piecewise constant values. This allows a dependence, which is more concentrated in time than the shared frailty models, and this may be relevant. As an example, there could be cause-specific frailty terms, like one for accidents and one for heart disease. As accidents have a high influence at young ages, and heart disease at older ages, this apparently leads to a short-term dependence in total mortality.

Applications to Multivariate Data

Hougaard [13] gives a list of references to applications, of which most are to family data.

Guo [10] and Klein [17] study mortality of general families, Nielsen et al. [24] study mortality of adoptive children and their relation to the lifetimes of the biological and adoptive parents, and Hougaard et al. [14] study the dependence in the lifetimes of twins. Thomas et al. [30] study breast cancer concordance in twins using the shared gamma frailty model. Yashin and Iachine [33] study the lifetimes of twins, by means of the correlated gamma frailty model. Pickles et al. [28] study other times than lifetimes, and consider several of the extended models. Aalen et al. [3] have a dental application to the lifetimes of amalgam fillings for a number of individuals.

For recurrent events, Hougaard et al. [15] considered various frailty models for counts of epileptic seizures.

PHILIP HOUGAARD

Framingham Study

When the Framingham Study began, the physical and intellectual apparatus available to assemble and use the data collected was, by today's standards, primitive. This article describes some of the statistical issues and how they were addressed. Topics discussed are: the study design, data handling problems, the development and uses of **logistic regression**, using repeated characterization, subsampling problems, and the injection of new questions into the study.

Study Design

The idea of the Framingham Study is, in retrospect, a fairly straightforward one [4]. A defined population, namely a **random sample** of the population of Framingham, Massachusetts, would be enlisted, examined, and at periodic intervals re-examined, to determine what changes had occurred and how these changes were related to pre-existing characteristics (*see* **Cohort Study**). The primary changes of interest were the development of the first clinical evidence of hypertensive disease, coronary heart disease (CHD), and stroke, but once the study population was under observation, any number of changes and clinical events could be examined.

A number of papers have reported the difficulties encountered in realizing this design [6, 11–13, 14]. This is not the place to recapitulate this story but one issue warrants restating. When the first examination began, the study design was not in place and even as the design developed the details changed. What started out as a purely volunteer population in 1948 was altered during recruitment into a random sample of the Framingham population aged 30–59 as of 1950, and then altered again to a mixed random sample and volunteer group. The purposes of the study were also redefined, so that the study ended up as a relatively clear-cut prospective study of cardiovascular disease.

However, what is obvious a posteriori is not always so clear a priori. For example, if one is interested in the development of hypertensive disease, why include persons with already evident hypertensive disease? If one is interested in the development of coronary heart disease, why include persons with already present coronary heart disease? The answer to the first question is that hypertension may be a factor in the development of coronary heart disease or stroke. Moreover, hypertension is, by definition, the upper end of the blood pressure distribution, so that omitting persons with hypertension amounted to truncating the blood pressure distribution – a statistical nuisance. The answer to the second question is that coronary heart disease may be a factor in the development of stroke and may influence blood pressure levels, and that neither hypertension nor coronary heart disease is necessarily well defined or static. Fortunately, the logical error implicit in excluding persons with pre-existing disease was quickly realized and corrected before the study was well under way.

After specifying the population to study and the diseases to investigate, the next question was: which characteristics should be investigated as possible factors in the development of these diseases? It is difficult to remember that at the time the study began it was not at all clear that cigarette smoking was one of those factors. In fact, the study began without obtaining smoking histories. Only part way through the first examination was this deficiency repaired. Moreover, the standard technique for measuring the concentration of serum cholesterol, the Abell–Kendall method, became available only part way through the initial examination, when it was hastily substituted for a much inferior method. Thus, the beginning of the study was characterized by patching and improvization. While this story has been detailed before, it is well to remember these facts since each of them entailed problems in assembling and analyzing the study results. These have been identified and discussed in a number of early reports [6, 11–13, 15, 16, 18].

Data Handling

It is difficult now to imagine the problems involved in handling large bodies of data when the Framingham Study began. And it was literally "handling". Data were entered on IBM punch cards, which were typically run through a counting sorter or a tabulator, two ingenious pieces of machinery which occasionally would mutilate the punch cards. The trick was to design a coding and punching scheme to put as much information on one card as possible. This entailed a high level of alertness in tabulating the information. It also meant that when the computer became available, transferring the information to tape taxed both

the ingenuity and patience of those responsible. Only gradually did the investigators become comfortable with the computer and only by slow stages were the older techniques for tabulating the data relinquished.

The other major tabulating accessory was the 3×5 card. This was used to enter information about **incident cases**. By using all four corners and the middle, and both sides of the card, a surprising amount of information could be entered. This may seem primitive, but any time one wanted to retabulate, the means to do so were right on one's desk. For those who have prompt turnaround time on their computer this may seem a trivial matter, but immediate computer access is a relatively modern phenomenon and for a long time was simply not a consideration.

Ultimately, the investigators were simply forced to move their data on to the computer, since the counting sorter and tabulator were no longer maintained properly and were finally phased out. The transitional period was painful in the extreme. When the initial computer system was replaced by a better but noncompatible system, the changeover was again painful.

These details may seem trivial but they are at the heart of analytic productivity. It is often assumed that the key to analysis is primarily statistical technique. It is not. The essential key is in the organization of data files and in the maintenance of data quality. Gradually the Framingham investigators developed files that were more and more accessible and more and more trustworthy. Such matters are now managed by software of varying sophistication and which is more or less simple to use (*see* **Software, Biostatistical**). That was not always true. At the beginning of the study it was necessary to cobble together everything necessary to assemble the study files and fit them to the needs of the study (*see* **Data Management and Coordination**).

The Introduction of Logistic Regression

Initially, a major restriction in analyzing the study results was the slow accumulation of new clinical events, but this was compounded by an inability to deal efficiently with the analysis. Suppose one wanted to consider two variables, serum cholesterol and blood pressure. Both of these were continuous variables but they could be dealt with categorically by arbitrarily dividing them into, say, high and not-high. One could, then, examine rates in the four cells obtained by cross-classifying the independent variables. Clearly, as one increased the number of classes and the number of variables – that is, as one got closer to the original data in its full detail and complexity – cross-classification was no longer of much use.

The original publication of the six-year follow-up data dealt with the **multivariate** problem by categorizing events according to whether persons were high on one independent variable, high on two, or high on three [4]. As one went up that scale, the incidence of CHD increased. However, this did not leave one with a measure of the contribution of each of the specific variables. Faced with this problem the investigators appealed to a procedure developed by **Jerome Cornfield**, which used continuous variables as continuous variables and addressed the multivariate question in terms of specific independent variables. The idea he had was the following [2].

Suppose one had two **normal** populations with different **means** but the same **variance**, say a population of cases and a population of noncases. Then it could be shown that the mixture of these two populations led to a logistic regression. In effect this transformed a classification approach, historically dealt with by **discriminant analysis**, into a **regression** approach. If one considered two **bivariate normal distributions** (the variables originally used were serum cholesterol and blood pressure) one could extend this concept to the bivariate case. It was demonstrated that the procedure was quite **robust**, at least where the variables were continuous. Ultimately, Truett et al. [24] extended the model to deal with any number of variables, although robustness in this case was less assured. Logistic regression has since become a mainstay of analysis in prospective studies generally; and while there may be misgivings about some of the uses to which it has been put [7], there is no question it has proved quite useful.

The Cornfield approach to logistic regression assumed, among other things, equal variances in the cases and noncases. Manifestly, that could not be true for dichotomous variables, since a difference in means implied a difference in variances. This difficulty was noted by **Max Halperin** and others, who showed that in the case of dichotomous variables one could sometimes arrive at absurd results using the Cornfield model [19].

In the meantime, another method for estimating the parameters of the logistic regression was

being developed by Walker & Duncan [25]. The study statisticians replaced the estimating procedure suggested by Walker & Duncan with a **maximum likelihood** approach and incorporated this modified Walker–Duncan procedure into the statistical armamentarium of the study. The estimating procedure, however, did not lead to an explicit solution and required successive iterations. The trick was to develop a method that minimized the number of iterations and protected against divergence. Over time the study statisticians were able to devise and refine their own computing program to achieve these *desiderata*. At the same time, the program gave associated statistics to assist in interpreting the results.

There was a problem, however. At the time this iterative computation became available, computer capacity was limited and computer costs per unit of work were quite high. And so the study statisticians looked for a method to estimate the parameters of the logistic regression by maximum likelihood that would minimize costs. When the problem was put to Nathan Mantel he came up with a sampling procedure which led to **unbiased** estimates using all the cases, but only a sample of noncases [22]. The method was ingenious but there was inevitably an increase in sampling error compared with using the full data set. Clearly, if the variables involved were truly normally distributed and the variances for cases and noncases not too dissimilar, then the Cornfield estimation, which was explicit and cheap to compute, was manifestly simpler and better. Before long, computer capacity increased and computer costs decreased, so that ingenuity was no longer necessary. Mantel's procedure, however, led to applications in **case–control studies**. It could be argued that case–control studies are the wrong place for such a procedure; but if the cases and the controls come from the same population, then it is clearly justifiable to treat them by this method, and if they do not come from the same population, then no analytic method is quite safe (*see* **Case–Control Study, Nested**).

One of the hazards in using logistic regression is that the user may confuse it with **linear regression**. In particular, there has been a tendency to ask and answer the question: what proportion of the variance in the dependent variable is accounted for by the independent variables, i.e. the known risk factors? Presumably, it was felt that the larger the proportion explained the more we understand about the causes of the disease – a rather unscientific notion. However, since the dependent variable was either a case or a noncase, it should be obvious that the analogy with **multivariate normal** theory might be hazardous. As Max Halperin pointed out, this is not an easily addressed question; in fact, it does not ordinarily allow for a precise answer [14].

Replication

A key element of the scientific method is replication. In epidemiology one would like to find that similar relations hold in different populations. Logistic regression was used to explore this issue in two ways. One was to apply the parameter estimates derived from the Framingham Study to a number of other populations included in the American Heart Association Pooling Project [23]. It was shown that the estimates derived from the Framingham Study closely predicted the actual incidence of coronary heart disease in all but one of these populations. The Framingham Study parameter estimates were also applied to the CHD experience found in a Yugoslav population. While the estimates for the parameters associated with the independent variables were quite similar for the two groups, the estimates for the constant term were not. Thus, the Framingham Study estimates grossly overstated the CHD incidence actually observed in Yugoslavia [20]. A similar approach was used in comparing data from Honolulu and Puerto Rico with data from Framingham [10].

Prediction

The preceding observations bear on another use made of observations from the Framingham Study. If the findings from Framingham with respect to the relationship between blood pressure, serum cholesterol, and cigarette smoking are generalizable to other US populations, then it made sense to estimate the **risk** of developing CHD as a guide to preventive programs, not only identifying who was at high risk but what their actual risk was. For that purpose the Framingham investigators constructed a set of CHD risk tables for the American Heart Association to use in their public health programs [17]. These tables emphasized two things: first, that the disease, at least so far as **prediction** was concerned, was a multifactorial disease; secondly, that persons were more or less at risk and that it was conceptually wrong to

assert that a person was either a sure case-to-be or was sure never to develop the disease. It was also a fact that for CHD, contrary, say, to lung cancer, there was no really strong predictor, but there were a number of weak predictors. Hence, the more pertinent information one had about the individual the more precisely one could estimate the risk of developing CHD. While this way of looking at disease prediction has not always prevailed in discussions of the etiology of CHD, it seems to have permeated the thinking about this disease.

Using Repeated Characterization

The study design called for repeated examinations of the Framingham cohort (*see* **Longitudinal Data Analysis, Overview**). The primary reason for that was to determine disease incidence and progression, and also to identify changes in factors thought to predispose to disease. Ultimately the interval between examinations came to be two years with a window on either side. Thus, each person returning for examination had a series of observations. How should those repeated observations be used? The method to use depended, of course, on the question to be addressed and the assumptions one was prepared to make.

Take a simple question: What was the incidence of coronary heart disease for each age–sex group? If the cohort of 5209 persons were divided, say, into five-year age groups by sex, then the incidence for each of these groups in, say, two years would be so small that the calculated rates would be subject to very large sampling variability. However, at each examination the entire cohort was, on average, two years older than it was on the previous examination. This meant that any five-year age group would be depleted of some persons (who had moved into the next age bracket) and replenished by other persons recruited from the next younger age group until the entire cohort moved out of the age range. Thus, if one redefined the cohort at each examination in terms of age and disease status, one could simply pool the observations from successive examinations to obtain average incidence rates over the period of observation. This method was extended to other characteristics that were repeatedly observed, e.g. serum cholesterol concentrations and blood pressure. Thus, it was possible to calculate the conditional incidence in a very simple fashion using all of the available data from the successive examinations.

The major assumption in this procedure was that successive subgroups of the total population had the same conditional incidence rate. This is probably true only in an approximate sense. While it was possible to test that assumption, the small sample sizes meant that the **sensitivity** of the test was obviously very low. In some sense what was being presented was an average picture for the various generations included in the cohort.

Obviously this is not the only feasible approach. It was possible to characterize the cohort at entry and follow them for some specified period. That would tell us the **predictive value** of, say, a serum cholesterol observation for the defined period of follow-up. It was also possible to use repeated measurements taking account of the fact that they were made on the same persons [26]. That would obviously give somewhat different conclusions than the pooling procedure. It would also lead to highly complex computation and to necessarily strong assumptions respecting **missing data**. One would hope that no matter how the data were looked at, the subject-matter conclusions would remain consistent. In general, that seemed to be the case, but since each analytic technique really implies a different question, consistency is not necessarily easy to parse.

Subsampling: The Selection Trap

Early in the Framingham Study a sample of the cohort was interviewed to determine what they usually ate, the primary interest being in the relationship between what they ate and their serum cholesterol levels. Since each interview took an experienced dietitian a long time, it was impracticable to interview the entire cohort. A sample was chosen consisting of a random sample supplemented by all persons with either very high or very low serum cholesterol levels. This seemed to be (and in this case, was) an efficient way to address the question at issue.

It was not recognized, however, that linear regressions of serum cholesterol level on various dietary components calculated by the usual **least squares** method would yield estimates that were **biased**, in some instance grossly biased. This, of course, was a consequence of selection on the dependent variable. Dietary data, because of the

intercorrelations among the various elements of the diet, are exceedingly difficult to interpret under the best of circumstances [9] and the **sampling frame** used only added to the difficulty.

The sampling problem was addressed by DeMets & Halperin [5]. They showed that unbiased regressions could be estimated from such data, provided that the necessary supplementary information had been collected, which fortunately had been done. Their solution has proved highly useful to persons concerned with sampling procedures.

Pouring New Wine into Old Bottles

One of the really strong points of a long-running prospective study in which the population is subject to continuing recharacterization is the opportunity to examine new questions as new ideas and new techniques arise. Formally, of course, one is supposed to initiate a study with a well-defined set of questions and methods for addressing them. However, ideas change, new methods become available, and some flexibility, if cautiously administered, is all to the good. There were many instances where the Framingham Study introduced new questions and new methods into their protocol.

From the beginning, the Framingham Study cohort was used to study a variety of chronic diseases and noncardiovascular conditions. The study staff has been receptive to proposals by investigators whose interests lay outside of cardiovascular disease but were anxious to avail themselves of the opportunities for investigations within the study cohort. In the more than 1000 publications based on the Framingham study cohort are papers on a variety of subjects, e.g. nontoxic thyroid nodules, gall bladder disease, eye disease, osteoarthritis, and cancer. But the major innovations over time were in the area of cardiovascular disease. One example may be cited.

The classical lipid measurement included in the Framingham Study was total serum cholesterol, although other lipid measurements were also included. However, serum cholesterol is not a single substance but includes components carried in lipoproteins of varying density. When it was discovered in a cooperative case–control study in which the Framingham Study participated that there was a strong negative relationship between serum cholesterol in the high density lipoproteins and coronary heart disease [1], the Framingham Study was able almost immediately to demonstrate that this was equally true prospectively [8]. In fact, this negative relationship had been demonstrated almost as early as the beginning of the Framingham Study, but discovery and acceptance are two different things. The Framingham investigators were aware of these early findings but, like others, chose to ignore them. However, the confluence of replication in the case–control studies, confirmation in a prospective study, and the application of multivariate analysis techniques which had become a standard in analyzing Framingham Study data, made it clear that this negative relationship between the concentration of HDL cholesterol and CHD was not some kind of artifact. Even with the great weight of evidence that accumulated so quickly, there was considerable covert resistance to accepting this new-old finding, which paralleled the resistance to the initial reports. Resistance was overcome, however, in part because of the authority that the Framingham Study had by then come to command.

Extensions of the Original Study

The Framingham Study has grown dramatically over the years. In 1971 the Framingham Offspring Study began consisting of children of the original cohort and the children's spouses. This consisted of 2489 males and 2646 females with examinations conducted every four years. In addition to all the examination components of the original cohort, new technologies such as carotid ultrasound, heart and brain MRIs and echocardiograms are part of the evaluations. Further, the study often leads the field in collecting new and novel risk factors such as homeostatic (clotting) factors including fibrinogen, inflammatory markers, and infection marker.

In 2002, a sample of over 3500 third generation children (Gen3 Study) and their spouses began. The Framingham Study is unique as a genetics study. Not only is there the risk factor collection (phenotypes) but there is also DNA and cell lines on many of the three cohorts (Original Cohort, Offspring Study, and Gen3 Study). The original study consisted mainly of whites of European extraction. A new substudy, the Omni Study, consisting on nonwhites is now an integral component of the study. Further, a number of ancillary studies evaluating stroke, dementia, arthritis, hearing, vision, sleep apnea, cancer, and nutrition

are major components of the study. Initially, the Framingham Study was the Framingham Heart Study.

Study Validation

The Framingham Study is an epidemiological study consisting mainly of whites of European extraction. The generalization of its results is always a major concern. Other epidemiological studies and clinical trials have repeatedly verified and validated its results (for example, [10]). Recently, a major validation study showed again the validation and transportability of its results to other populations [3]. Its results with minor calibration adjustments are valid even for the entire country of China [21].

Conclusion

The unique thing about the Framingham Study is its continuity and productivity. The continuity arises from its sponsorship since 1948, with one break, by the **National Institutes of Health**. We owe that to the persuasiveness of the first statistician involved in the study, Felix Moore, who cajoled the then National Heart Institute to embrace this study, reluctantly it must be said, and who transformed it into a clearly defined prospective study and set it on its course of methodical data collection. The productivity was a function of the close collaboration between the statisticians and the medical staff but was made possible and fruitful by careful handling and organization of the data files and continuing search for appropriate statistical techniques. It is sometimes forgotten that many epidemiologic studies have failed to realize their potential because the data that got into the medical folders remained in the medical folders. Providing adequate staff and resources for exploring the data is as important as conceiving and operating a prospective study. In this respect, the Framingham Study has been singularly fortunate for the able medical and statistical investigators that have worked together over the years. Both were necessary. Fortunately, both were available.

Closing Comment

The Framingham Study was a bold innovation in epidemiology. It remains unique among epidemiological studies. We can no longer perform such a study. Today we treat blood pressures as low as systolic blood pressure of 140 and diastolic pressures of 85. We treat total cholesterols of 200. These are correct decisions based, in part, on the results of the Framingham Study. Still they render impossible the study of natural history. The Framingham Study is unique in that is has true natural history of the development of coronary and cardiovascular disease. It has this over generations. It is truly unique and precious.

Fraud in Clinical Trials

Scientific research has a long history of fraud [4, 10, 15]. Over 150 years ago, Charles Babbage, the far-seeing inventor of the calculating machine, established a catalog of data manipulations, which he called *trimming* (reducing the variance of the data while preserving their mean by deleting extreme observations), *cooking* (reporting only selected observations: "If a hundred observations are made, the cook must be very unhappy if he cannot pick out fifteen or twenty which will do for serving up") and *forging* (inventing data). Allegations of data tampering have been made against Ptolemy, Galileo, Newton, Dalton, Mendel, and Burt, to name just a few. R.A. Fisher's reanalysis of Gregor Mendel's data on peas is a celebrated example of the use of statistical methods to reveal abnormalities: the agreement between the observed frequencies of certain traits of the peas with the theory was too good to be plausible, which suggested that Mendel or one of his assistants had either manipulated the observations or reported only those results most closely matching theoretical expectations. The fraud perpetrated by Cyril Burt was far worse, since it seems to have involved the complete fabrication of data on identical twins supposedly separated at birth. Here again the fraud was discovered because of numeric anomalies. The number of identical twins reported by Burt (53 pairs) was too large to be plausible and, while the number of pairs increased from less than 20 to more than 50 in a series of Burt's papers, the average correlation of IQ measurements between pairs remained unchanged to the third decimal place! In recent years, scientific journals as well as the lay press have extensively debated over some cases of fraud in clinical trials, thereby fueling suspicions that fraud is a major problem in clinical research [2, 13].

Definitions

Fraud comes in many guises, including some that are well-intended. The boundary between fraud and simple carelessness is often fuzzy, although the former is characterized by a *deliberate* attempt to deceive [10]. The deliberate character of fraud may be very hard to prove in the absence of positive external evidence or confession. Data discrepancies expected as part of the research process, such as transcription errors between the source documents and the case report forms, may potentially be regarded as fraud if they occur in some systematic way or with abnormally high frequency, two circumstances that require a statistical assessment. In many cases, statistical evidence is however likely to reveal misunderstandings and unintentional errors rather than fraud [1].

In the US, the term "fraud" implies injury or damage to victims, therefore the term "misconduct" might be preferred. However "misconduct" also includes practices that fall beyond the scope of this chapter, such as plagiarism, conflicts of interest, misuse of funds, and other questionable research practices. In the UK, a Joint Consensus Conference on Misconduct in Biomedical Research held in October 1999 defined research misconduct as "behaviour by a researcher, *intentional or not*, that falls short of good ethical and scientific standards" [7]. We shall use the term "fraud" specifically to refer to *data fabrication* (making up data values), and *data falsification* (changing or eliminating data values). We are aware that this use of the word is at once far more restrictive than is implied in normal conversation, and less specific than in legal texts, but we prefer the use of this single word for brevity.

Prevalence of Fraud in Clinical Trials

Scientific fraud (in the limited sense of data fabrication or falsification) is, in all likelihood, a rare phenomenon, although other misconduct may well be common [15]. Many authors also believe that fraud is also uncommon in clinical trials [4]. A few cases were uncovered, but they attracted so much media attention that the uncritical observer may have been misled into thinking that the problem was far worse than it actually is. While there may be substantial bias in estimating the actual number of cases of fraud (because of those cases that remain unnoticed or unreported), all systematic investigations carried out to uncover fraudulent data found that the proportion of investigators who had actually committed fraud was less than 1% (Table 1).

Even though serious deficiencies were found in 11% of the audits performed by the US Food and Drug Administration (FDA) between 1977 and 1988, the "for-cause" investigations that followed revealed

Table 1 Incidence of fraud found in random audits performed by several groups

Group	Period	Number of audits	Incidence of fraud
FDA [23]	1977–1988	1955	Incidence of fraud not reported *Note*: 11% of audits showed "serious deficiencies"; 4% required a "for-cause" investigation
South West Oncology Group (SWOG) [20]	1983–1990	1751	No case of fraud = 0%
Pharmaceutical company [18]		1000	Four of 1000 = 0.4% *Note*: fraud affected 438 (6%) of 7000 patients
CALGB [19]	1982–1992	691	Two of 691 = 0.3%
Pharmaceutical company [12]	1990–1994	234	One of 234 = 0.4%

in most cases sloppiness or incompetence rather than fraud. Hence all available estimates point to a low prevalence of fraud. Against these reassuring statistics lingers the possibility that a large number of cases of fraud may have remained completely unnoticed, and that reported cases only constitute the tip of the iceberg. Although this situation remains hypothetical, there have been reports of fraud being detected and then covered up in trials sponsored by pharmaceutical companies as well as in those performed in academic settings. Additionally, audits may be ineffective at detecting fraud, as demonstrated by the fact that an investigational center that passed Cancer and Leukemia Group B (CALGB) audits was subsequently found to have problems [24]. In a recent cross-sectional survey of biostatisticians who were members of the International Society for Clinical Biostatistics in 1998, more than half of the respondents (51%) stated that they knew of a project in which fraud had occurred in the previous 10 years, while almost one-third (30%) of them had been engaged in a project in which fraud took place or was about to take place [16]. All in all we lack reliable data to estimate the true prevalence of fraud, and further prospective investigations in this matter would be very valuable.

Perception of Fraud

Shapiro claims that "scientific misconduct is common enough in investigational drug trials to be a continuing public concern" [15]. Quantitatively, the opposite seems true: fraud in clinical trials is probably rather uncommon and, as we discuss below, it is often inconsequential in multicenter settings. Fraud, however, is so much at variance with the ethics of scientific research that *any* amount of it is deemed utterly unacceptable. The concern with fraud in clinical research may in fact be due to common practices that are scientifically unacceptable, such as data dredging, *post hoc* analyses, selective reporting of the most "interesting" results, nonpublication of negative findings, etc. Although such practices do not constitute fraud in the narrow sense used in this article, they may profoundly bias the results of a study as well as their interpretation. The public may in fact be far more misguided by studies that are poorly designed, wrongly analyzed and inappropriately reported, or not reported at all, than by fraud [1]. Systematic reviews of randomized trials are very important for clinical practice and policy; when important data are not reported this can lead to bias in the overall conclusions.

Intent of Fraud

The major difference between fraud and mere error lies in the "intention to cheat" that defines fraud [10]. This difference must however be qualified by the nature of the intent, as illustrated by the following examples. Consider, first, the case of data falsification. Suppose that at some time point the diastolic blood pressure of a patient is read as equal to 96 mm Hg. If the value is reported as being equal to 100 mm Hg, the discrepancy between the value read and the value reported would constitute a case of data falsification. However, the physician who read the diastolic blood pressure may have reported 100 mm

Hg for simplicity, in recognition of the fact that blood pressure varies substantially in the same patient and that the measurement error is of the order of 5 mm Hg anyway. The reporting of a round number that closely approximates the truth would not *per se* be wrong. If, however, a value of 100 mm Hg made the patient eligible for the trial while 96 mm Hg did not, then the biased reporting would be cause for concern. However, such bias prior to randomization will not affect the overall results of a trial in terms of whether a treatment is efficacious (its internal validity). A much more serious problem arises if this biased reporting took place in a nonblinded trial in order to make the control group worse. Then the charge of fraud and the need for corrective action would be more than justified. The same arguments hold true for data fabrication. Suppose that the level of neutrophils, a required laboratory examination, were truly missing at the last visit of a patient in a certain trial. Any reported value would therefore have had to be fabricated, perhaps by simply carrying over the value of the previous visit. If this had been done in order to avoid a query from the data management center for a safety variable of secondary interest, there would be less cause for concern than if neutrophils constituted the primary endpoint of the trial.

The most serious cases of fraud are those in which there is an expectation of gain in terms of prestige, advancement or money. These cases may involve fabricating complete patients or tampering with the data in order to obtain a desirable result. These cases may also be the easiest to detect statistically, especially in **multicenter** studies, as will be discussed below.

Data Items Frequently Affected by Fraud

Some data items collected in clinical trials seem to be more prone to error and/or fraud than others, as follows.

1. *Eligibility criteria*: data may be "pushed" a little to make a patient eligible for the trial when in fact that patient does not strictly meet the criteria. Many such examples of fraud may have occurred because eligibility criteria were excessively restrictive and widening entry standards is often a good solution (*see* **Eligibility and Exclusion Criteria**).
2. *Repeated measurements*: when the same measurements are requested repeatedly over time (such as, for instance, a battery of laboratory examinations), data may be "propagated" from the previous visit if the measurements are missing for a particular visit. Such imputation of missing values should be reported clearly. Imputation methods may be appropriate at the time of analyzing the data, not at the time of making the observations.
3. *Adverse events*: adverse events are likely to be underreported by some investigators (although such underreporting may reveal a lack of interest or differences in interpretation rather than fraud).
4. *Compliance data*: these data are notoriously unreliable if they are based on the number of medications returned ("pill counts"). Whenever compliance information is deemed important, it is advisable to use objective measurements based on blood or urine tests (*see* **Compliance Assessment in Clinical Trials**).
5. *Patient diaries*: a number of cases of data fabrication have been detected through the color and texture of the pen supposedly used on successive days by the patient, the patient's handwriting, etc. The reliability of information collected in patient diaries can often be questioned.

Preventing Fraud by Making Trials Simple

Some types of fraud could be prevented through a drastic simplification of randomized clinical trials. Two measures might be particularly effective in this respect: a simplification of the eligibility criteria and a reduction in the amount of data requested. These two measures are feasible and desirable in a surprisingly large number of clinical trials, and neither jeopardizes the validity of the trial results. For example, very detailed measurement of large amounts of biochemical tests in late-phase trials is usually unnecessary. In trials requiring prolonged observation of each patient, the follow-up can generally be kept as simple and no more frequent than in routine clinical practice. Simplicity is essential in trials conducted with a public health intent, especially when these are large, but it can be justified even in trials conducted as part of a new drug development program, for there is no regulatory requirement that pivotal trials for drug approval be especially complex. However, the risk of failing

to get approval for a new drug along with the fear of potential litigation may dominate all other considerations of cost or efficiency, and as a result clinical trials may end up being excessively complex. The growing number of regulations governing the conduct of clinical trials, even with approved drugs, may also have the unintended consequence of making trials ever more complex. As mentioned above, such complexity may be counterproductive and may create a situation where an investigator is tempted to fabricate data.

Preventing Fraud by Allowing Missing Data

There is obviously no excuse for making up data, but the temptation will be great for investigators to find ways of avoiding long lists of queries in trials conducted in a fastidious way. It is the responsibility of a competent trial organization to make sure that investigators are not submitted to excessive requests for data clarification. **Missing data** occur in the real world, and thus they should generally be tolerated in clinical trials (except, of course, for the primary endpoint of the trial). While complete data are undoubtedly better than missing data, attempting to collect too much data, and repeatedly demanding complete data on all patients, may be conducive to fraud, even though it does not exonerate the trial participants if they commit it!

Detecting Fraud through Intensive On-site Monitoring

The traditional approach to detect fraud has involved monitoring visits to the clinical centers participating in the trial (*see* **Clinical Trials Audit and Quality Control**). Some such on-site monitoring may be needed and useful, for many types of fraud would remain completely undiscovered if it were not for the careful checks carried out during these visits. However, on-site monitoring is labor intensive and hence expensive, and it too may fail to pick up fraudulent data. Moreover, the law of diminishing returns indicates that it is not **cost-effective** to demand 100% verification of all source data. The approach used for quality control in industrial or laboratory settings can be used so that the monitoring activities are limited to some random selection of the data, with the possible exception of data pertaining to the primary endpoint (*see* **Outcome Measures in Clinical Trials**) of the trial. The random selection can be done at the level of the investigators, the patients or the data items themselves. With such a random sampling scheme, one can estimate the overall data error rate with prespecified precision, and increase the amount of on-site monitoring if the observed rate exceeds some upper limit. Another approach consists of visiting only the centers in which problems, errors or fraud are suspected. Such "for-cause" audits have confirmed major cases of fraud both in multicenter trials and in single institution trials [6, 22]. The major International Conference on Harmonization (ICH) **guidelines** on Good Clinical Practice (GCP) emphasize that a sampling scheme may be appropriate and these can be acceptable to regulatory authorities. It is a major misunderstanding that GCP requires 100% source data verification.

Detecting Fraud through Statistical Checks

Most data entry and data management software used for clinical trials perform basic checks, such as range and consistency checks, but more extensive data checks typically occur at the end of the study along with other statistical analyses, far too late for corrective action. Batteries of checks using standard statistical techniques could also be used early on in the course of a trial without large increases in costs, and could save considerable time if problems are detected and corrected early (*see* **Data Management and Coordination**).

The principles involved in uncovering fraud through statistical techniques rest on the difficulty of fabricating plausible data, particularly in high dimensions [17]. Univariate observations can always be fabricated to fall close to the mean, although preserving their variance is more of a challenge to the inexperienced. Even the astute cheater who takes care to preserve both the mean and the variance may be tripped up by examination of the kurtosis of the distribution. Multivariate observations must in addition be consistent with the correlation structure between their individual components. In general, when data are fabricated to pass certain statistical tests, they are likely to fail on others; Haldane referred to this as "second order" faking [17].

Another way of checking fabricated data is based on the fact that humans are poor random number

generators. Even informed people seem unable to generate long sequences of numbers that pass simple tests for randomness. Digit preference, especially terminal digit preference, or an excess of round numbers may easily reveal data fabrication. Benford's law may also be used to check the randomness of the first digit of all real numbers reported by a single individual (or a single center). This law establishes that the probability of the first significant digit being equal to D ($D = 1, \ldots, 9$) is approximately given by a logarithmic distribution [11]:

$$\Pr(D) \approx \log(D + 1) - \log(D).$$

Hence the frequency of 1's as the first digit should be as high as 30%, the frequency of 2's as the first digit should be close to 18%, while that of 9's should be lower than 5%, a result that runs against intuition. More sophisticated techniques are available to check the randomness of digits in a sequence of data values.

Statistical approaches may also take full advantage of the highly structured nature of clinical trials, which are prospective studies, entirely specified in a written **protocol** and data collection instrument (the "case report form"), usually involving several centers and, when comparative, a randomly assigned treatment. Comparing each center or treatment with the others in terms of the distribution of some variables, either taken in isolation (univariate approach) or jointly (multivariate approach), can detect unusual patterns in the data. Comparisons between centers are particularly informative if there are more than a few observations per center (in which case fraud in any one center may have a sizeable impact on the overall result). Such comparisons are useful with different types of fraud; for instance, the presence of outliers or the consistency in the effect of treatment may reveal fraud aimed at exaggerating the effect, while the presence of "inliers" or underdispersion in the data may reveal invented cases.

Univariate Methods

Beyond range checks and missing data checks, which are performed as part of routine data management, one can use other univariate statistical techniques to inspect the data (Table 2).

Statistical checks may reveal unusual data patterns that are often the mark of fraud (Table 3). Invented or manipulated data tend to have too little variance, no outliers or an abnormally flat distribution [8]. Their distribution may be too close to a simple but

Table 2 Some statistical techniques that may be used to uncover fraud

One variable at a time	Descriptive statistics Box and whisker plot Frequency histogram Stem and leaf plots Tests for slippage
Several variables at a time	Cross-tabulation/scatterplot Correlation/regression Cook's distance Mahalanobis' distance Cluster analysis Discriminant analysis Chernoff faces Star (needle, spike) plots Hotelling's T^2 Tests for treatment contrasts
Repeated measurements	Autocorrelations Profiles Polynomial contrasts Runs tests
Calendar time	Residual plots Cusum Control charts

Table 3 Some patterns that may reveal fraud in clinical trial data

One variable at a time	Digit preference Round number preference Too few or too many outliers Too little or too much variance Strange peaks Data too skewed
Several variables at a time	Multivariate inliers Multivariate outliers Leverage Too weak or too strong correlation
Repeated measurements	Interpolation Duplicates Invented patterns
Calendar time	Breach of randomization Days of week (Sundays or holidays) Implausible accrual Time trends

implausible model, such as a Normal distribution with round numbers for the mean and standard deviation.

Since fraud usually occurs in a single center (except in the unlikely situation of a coordinated fraud across several centers), statistical checks must be performed within each center as well as overall. A comparison of the results reported by different centers may reveal too little variability in one or more centers as compared with the overall variability. Perfect compliance with the protocol, for instance, may be the mark of fraud. Such a comparison may also reveal "slippage" of one or more centers, the null hypothesis being that the means of the variable of interest are equal, but for random fluctuations, to the overall mean [5]. These tests are not informative if there are many centers and few patients per center; on the other hand, grouping small centers could mask a problem in any one of them and is therefore not generally advisable.

Multivariate Methods

Data management usually includes logical checks to ensure the consistency between the values of two or more variables. Multivariate statistical techniques offer more checking possibilities, but they are seldom used in clinical trials, if at all. Multivariate statistical methods include correlations between several patient-related variables as well as comparisons between the randomized groups (Table 2). Simple two-way cross-tabulations or scatter plots for various pairs of variables can be compared across centers, and unusual patterns investigated further. Outlying observations, or outlying groups of observations coming from the same center, can be detected more effectively in multidimensional space than in a single dimension. Moreover, in multidimensional space, "inliers" can be detected through the use of the Mahalanobis' distance just as well as outliers: inliers have an abnormally low Mahalanobis' distance (they fall too close to the multivariate mean), while outliers have an abnormally high Mahalanobis' distance (they fall too far from the multivariate mean) (Table 3). The Mahalanobis' distance is computed by standardizing the variables of interest (subtracting the mean and dividing by the standard deviation), and summing the squares of these standardized variables. The sum approximately follows a χ^2 distribution with N degrees of freedom, if N variables are considered. The detection of inliers may be more useful to detect fraud than the detection of outliers, because fabricated data will tend not to contain outliers which are at higher risk of being detected than are values close to the (multivariate) mean. This method can also be used to see if the N variables of interest are too close to each other for some pair(s) of individuals, in which case one of the individuals in the pair may be a (slightly modified) copy of the other. Robust methods such as using ranks in place of the observations are advisable for the detection of outliers because these can create severe departures from multivariate normality.

Repeated Measures

When, as is often the case, some variables are measured repeatedly over the course of the trial on the same patient, these measures lend themselves well to a variety of checks (Table 2). Here, again, an insufficient variability over time may reveal the propagation of previous values rather than genuine observations (Table 3). Sometimes the fraud involves a mechanism or computer algorithm for making up data.

Calendar Time

In any trial with prolonged patient entry and follow-up, one can use calendar time to perform additional checks on the data (Table 2). Simple checks can be performed on the day of the week, as certain events or examinations are unlikely to have taken place on a Sunday. Time intervals between successive visits and the number of visits per unit time provide further opportunities for checking the plausibility of a sequence of events (Table 3). A comparison of treatment groups by week or month of randomization can reveal suspect periods during which all treatments were not allocated with equal probability. Perfect compliance with the protocol in terms of dates may be a marker, as noted above, but should not be taken on its own as necessarily misconduct. More advanced checks may sometimes be performed, such as the variance of observations over time. An excellent example is provided by an animal study in which the variability of the heart rates of dogs treated consecutively showed far too little variance initially, leading to a strong suspicion of data fabrication in the early stages of the study [3].

Impact of Fraud on the Results of Clinical Trials

The highly publicized case of fraud in the **National Surgical Adjuvant Breast and Bowel Project** (NSABP) provides a framework to examine the impact of such fraud on the results of clinical trials [9]. Briefly, one of the investigators in breast cancer trials systematically altered some baseline patient data so that these patients became eligible for entry into the trials. The data subject to falsification were the dates of surgery and biopsy or estrogen receptor values. For example, in one study, the delay between the surgery and randomization had been set to a maximum of 30 days by the trial protocol, and dates were falsified for a few patients in whom this limit had been exceeded. The fraud clearly was not aimed at distorting the results of the trials one way or another (it could only have done so had the treatment effect been substantially different among the wrongly entered patients than among the others). As a matter of fact, a careful reanalysis of NSABP trials without the data from the fraudulent institution confirmed that the trial outcomes had not been materially affected by the fraud [9]. In another large trial in stroke published recently, all data from one center suspected of fraud were excluded from the analysis, again with negligible impact on the study results. Yet this center had contributed 452 (6.4%) of the 7054 patients randomized in the study, and statistical analysis of the variability of their data supported the belief that no real patients had actually been studied in this center [21]!

Fraud is unlikely to affect the results of a trial if any of the following conditions hold:

- the fraud is limited to one or a few investigators (perhaps one center in a multicenter setting) and/or to a few data items, provided that there are many investigators or centers;
- the fraud bears on secondary variables that have little or no effect on the primary endpoint of the trial;
- the fraud affects all treatment groups equally, and hence does not bias the results of the trial. Fraud committed without regard to the treatment assignments (e.g. prior to randomization or in double-blind trials) generates noise but no bias.

At least one of these conditions frequently holds, and therefore fraud should not be expected to have a major impact on the results of multicenter clinical trials. As a matter of fact, a search of Medline from 1966 to 1997 revealed that 235 articles had been retracted, 86 of which were deemed to be due to misconduct [4]. These numbers do not bear specifically on clinical trial reports, but they are quite small compared with the total number of articles published during the same period.

One caveat is that where an increase in noise occurs, this can make dissimilar treatments appear similar. With a trend towards using **equivalence** or noninferiority trials for licensing purposes this is of concern and could result in ineffective medicines being licensed.

Actions in Cases of Fraud

When fraud is suspected in a center, all analyses can be repeated with and without that center, in order to assess the sensitivity of the trial results to the fraud. Although fraudulent data would in general have to be excluded from the main analysis of the trial, other validated data from the same center might well be kept in the analysis. If a **Data and Safety Monitoring Board** oversees the trial, then it seems appropriate to leave such decisions to their discretion. Biostatistical methods can only point at problems; further investigations and hard evidence are needed to confirm fraud.

Conclusion

Randomized clinical trials constitute, by design, the most reliable type of medical experiment. Their data can be verified using statistical techniques that take advantage of their highly structured nature. Their results are generally robust to occasional cases of data falsification and fabrication at some participating centers. As George put it, "the methodology of clinical trials *de facto* provides a measure of protection against deliberate deception that is generally unappreciated by those not familiar with the methodology" [10]. Claims to the contrary notwithstanding, we are not aware of quantitative evidence that fraud is common in clinical trials. However, fraud is a cause for concern regardless of its prevalence or consequences because the "habit of truth" is the cardinal value in scientific endeavors. Fraud must be fought, but attempts to impose more bureaucracy and heavier

monitoring on clinical trials is the wrong answer to a problem that can be overrated in the media. Fraud can largely be prevented through proper design of the trial protocol and case report form, and detected by statistical procedures and computerized checks that make use of the unique structure of clinical trial data [14].

Frequency Distribution

A frequency distribution is a method of summarizing a set of numerical data in tabular or graphical form. For example, one might summarize the height of individuals, family incomes, or chemical concentrations in blood samples. A frequency distribution is constructed from k nonoverlapping class intervals, usually of equal length. Let $a_0, a_1, \ldots, a_k$ denote the class boundaries. A value, x, is in the jth class interval if $a_{j-1} < x \leq a_j$. A frequency distribution reports the frequency or count of data values falling into each class interval. Let the jth frequency, f_j, denote the number of data values falling into the jth class. The above description can be summarized in tabular form (Table 1).

If numerical observations are from a completely censused population, then the result of the above procedure is a population frequency distribution. When the observations are from a sample of the population, as is usually the case, Table 1 is called a sample frequency distribution.

The procedure can be illustrated with weights of 92 Pennsylvania State University students as reported in Ryan & Joiner [2] (Table 2).

Care and judgment must be exercised in selecting the number of classes and the class boundaries. Whenever possible it is important to keep the class intervals the same length: this maintains the close relationship between the sample frequency table and the underlying population density function. Also, class intervals should be written unambiguously so that each data value falls in exactly one interval. For example, if in the student weight data frequency table the weight classes had been described as 140–150 and 150–160, then the 10 students who self reported their weights as 150 pounds could not be assigned unambiguously to a weight class. In the above frequency distribution the intervals are unambiguous, and also boundaries are kept away from weights that are multiples of 5, i.e. those weights where self-reporting biases are most likely.

Before the advent of modern computing, frequency tables were often used to condense the data before doing time-consuming arithmetic computations: for example, approximate means and variances can be quickly calculated from frequency distributions. Today, however, frequency distributions are primarily used to display and understand data.

Frequency distributions are usually **graphically displayed** as *histograms*. In a histogram each class interval is represented by a vertical bar whose base is the class interval and whose height is the number of observations in the class interval. Figure 1 shows

Table 1 Summary of frequency distribution

Class interval	Class frequency
$a_0 < x \leq a_1$	f_1
$a_1 < x \leq a_2$	f_2
$\cdots$	$\cdots$
$a_{j-1} < x \leq a_j$	f_j
$\cdots$	$\cdots$
$a_{k-1} < x \leq a_k$	f_k
Sum	n

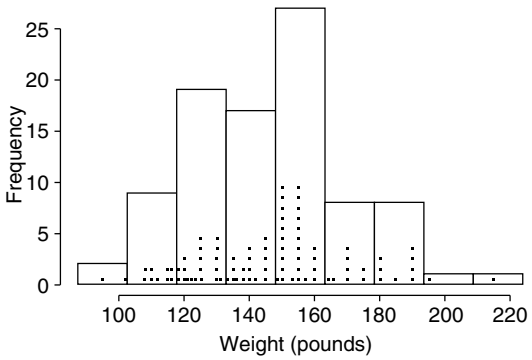

Figure 1 Histogram for student weight data

Table 2 Pennsylvania State University student weight data

Weight in pounds	Frequency	Weight in pounds	Frequency
$87.5 < x \leq 102.5$	2	$162.5 < x \leq 177.5$	8
$102.5 < x \leq 117.5$	9	$177.5 < x \leq 192.5$	8
$117.5 < x \leq 132.5$	19	$192.5 < x \leq 207.5$	1
$132.5 < x \leq 147.5$	17	$207.5 < x \leq 222.5$	1
$147.5 < x \leq 162.5$	27	Sum	$n = 92$

the histogram for the student weights, along with a dot plot representing each of the 92 weights. For unequally spaced intervals the histogram should be modified so that the area of each bar is proportional to the frequency for that class interval.

There are other ways of presenting the same summary information contained in a frequency distribution. The relative frequency distribution reports the proportion of observations falling in each class interval. And the cumulative frequency table reports the number of observations falling in or below each class interval. Kendall et al. [1] give a detailed review of frequency distributions and their extensions.

Frequency Matching

Frequency matching, also known as category matching, is a sampling design used in **case–control studies** that yields **controls** with the same distribution over categories defining levels of potential **confounders** as is observed in the cases. For example, suppose that cases are classified into 20 categories defined by gender and by ten ten-year age intervals, and that the distribution of cases in these categories is observed. A frequency-matched sample of controls with this same distribution could be obtained by sampling as controls a constant multiple of the number of cases in each category. Sometimes, for convenience, one obtains frequency-matched controls that conform to the expected distribution of cases rather than wait to match the on actual distribution of cases.

Frequency matching is also used in **cohort studies** to assure that the control cohort has the same distribution over categorical levels of potential confounders as the exposed cohort.

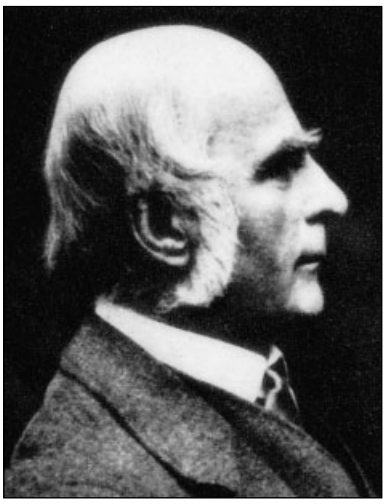
MITCHELL H. GAIL

Galton, Francis

Born: February 16, 1822, in Birmingham, UK.
Died: January 17, 1911, in Haslemere, UK.



Francis Galton was the founder of biometry. The origins of many statistical procedures can be seen in his pioneering efforts. A Victorian polymath, although no mathematician, he influenced the development of mathematical statistics through **Karl Pearson** (who wrote a massive life of him in three volumes), **F. Y. Edgeworth** and, at one remove, **R. A. Fisher**. He was a half-cousin of Charles Darwin (they shared a grandfather in Erasmus Darwin) and throughout his life he enjoyed both private means and a wide circle of intellectual relatives and friends.

A precocious child, he went up to Trinity College, Cambridge, in 1840 to study mathematics and then medicine, but suffered a breakdown which forced him to abandon an honors mathematics degree. Although he almost completed his medical studies he disliked the idea of practising, and with his father's death in 1844 he inherited sufficient wealth to remove the need. In 1853 he married Louisa Butler, daughter of the Dean of Peterborough, whose brother Montagu was later to be Master of Trinity.

Between 1844 and 1853 Galton indulged in African travels, sailing up the Nile and subsequently undertaking extensive explorations in South West Africa, which earned him the 1854 Founder's Medal of the Royal Geographical Society, on whose Council he served for many years. He used his experiences as the basis for a book *The Art of Travel* [1], published in 1855, and the following year he was elected a Fellow of the Royal Society.

In 1861, Galton's statistical inclination showed as he gathered meteorological information from all over Europe from which, on plotting the barometric pressure, he discovered – and named – the "anticyclone". His statistical interests were channeled into questions of heredity by the publication, in 1859, of Charles Darwin's *On the Origin of Species*, coupled very probably with the realization that he and Louisa were likely to remain childless. The result was Galton's first important book, *Hereditary Genius* [2] (*see* **Human Genetics, Overview**).

From the publication of *Hereditary Genius* in 1869 to his death in 1911, Galton occupied himself principally with statistical questions bearing on heredity. In 1874, with the Reverend H. W. Watson, he wrote a paper [7] on the extinction of families, which is regarded as the origin of the statistical theory of **branching processes**. The following year he discovered that a normal mixture of **normal distributions** is itself a normal distribution, about which S. M. Stigler has written "Galton's conceptual use of the result was new and ingenious and represents the most important step in perhaps the single major breakthrough in statistics in the last half of the nineteenth century". The breakthrough continued with Galton's introduction of **regression** in 1877 in connection with the analysis of a genetics experiment that he had planned which was the continuous analog of Mendel's 1865 discrete experiments, and which laid the foundations of biometric genetics (*see* **Genetic Epidemiology**; **Mendel's Laws**).

In 1885, Galton presented his explanation of regression in terms of the geometry of the **bivariate normal distribution**, for which J. Hamilton Dickson of Cambridge provided the mathematics. All of these advances were brought together early in 1889 with the publication of *Natural Inheritance* [3]. After the book had gone to press, Galton realized that if in his regression diagram the two variates were scaled so as to have the same probable error on the paper, then both regression lines would have the same slope (each with respect to its proper axis) which was therefore suitable as an "index of co-relation", or "**correlation** coefficient", as it soon became. In 1899, he invented normal probability paper, a natural extension of his earlier use of the cumulative normal probability

distribution, which he termed an "ogive". In 1901, Galton assisted Pearson and his colleague W. F. R. Weldon in the launch of the journal **Biometrika**, and contributed a short introduction to *Biometry* for the first number.

In 1883, Galton had coined the word "**eugenics**", but it was not until the early years of the twentieth century that he was able to promote his ideas. In 1904 he gave University College money to establish a "Eugenics Records Office", with a Research Fellow and an assistant, later to become the "Eugenics Laboratory" under Pearson. In his will he left University College £45 000 to endow a Chair of Eugenics, initially called the Galton Professorship of Eugenics. The first two holders were Pearson and Fisher (ultimately the Laboratory became the Galton Laboratory and the Professorship one of Human Genetics). In 1907 a "Eugenics Education Society" was formed, and Galton soon agreed to become its Honorary President. The Society flourished, especially under the later presidency of Leonard Darwin, becoming the Eugenics Society (and now the Galton Institute).

Galton was a prolific writer on many subjects, numbering 17 books amongst his 300 publications. Of those not yet mentioned, his pioneering books on fingerprints and their uses (1892 [4] and 1895 [5]) may be recalled.

In 1902 Galton was awarded the Darwin Medal of the Royal Society, and was particularly delighted to be elected an Honorary Fellow of his old Cambridge college, Trinity. Further honors came in extreme old age: he was knighted in June 1909 and received the Copley Medal, the Royal Society's highest award, in October 1910 a few months before he died at the age of 88.

Although Galton was very much a product of his times and his social class, his views were by no means typical. He thought, as did others, that the explorer H. M. Stanley had treated Africans badly; he went out of his way, in *Hereditary Genius*, to express his "grief" that paucity of data prevented him from discussing the influence of mothers on their offspring, which he knew to be as important as that of fathers; and in respect of eugenics he wrote at the end of his autobiography [6]: "Man is gifted with pity and other kindly feelings; he also has the power of preventing many kinds of suffering. I conceive it to be within his province to replace Natural Selection by other processes that are more merciful and not less effective".

Galton–Watson Process

The Galton–Watson process should more accurately be called the Bienaymé–Galton–Watson process; or, better, just the simple **branching process**. Descendants of a single ancestor at generation zero at any given subsequent generation produce offspring, independently of each other and of individuals in preceding generations. The probability distribution of the number of offspring of any one individual is identical with that of the initial ancestor. Denoting by $p_r, r = 0, 1, 2, \ldots$, the probability that any one individual has r offspring, and by Z_n the number of individuals at generation n, we have $p_r = \Pr(Z_1 = r)$. If we write $F(s) = \sum_{r=0}^{\infty} p_r s^r$, $0 \leq s \leq 1$, for the probability generating function (pgf) of Z_1 (*see* **Generating Functions**), then a crucial property is that the pgf of Z_n, $F_n(s)$, is in fact the nth functional iterate of $F(s)$ (i.e. $F_n(s) = F(F_{n-1}(s))$, where $F_0(s) = s$). This is reflected in the fact that if the mean number of offspring per individual is denoted by m (i.e. $m = \sum_{r=0}^{\infty} r p_r = F'(1)$), then the mean number of individuals at time n is m^n (i.e. $\mathrm{E}Z_n = m^n$). If $m > 1$, we thus have "exponential" (Malthusian) average growth with n. However, even in this "supercritical" case, extinction may occur with positive probability. The Criticality Theorem for the process, if the trivial case $p_1 = 1$ is excluded, asserts that if $m \leq 1$ extinction occurs with probability $q = 1$; but if $m > 1$ the probability q of ultimate extinction is the unique root of the equation $F(x) = x$ in the interval $0 \leq x < 1$.

The process and the Criticality Theorem are important because of the breadth of practical applicability [2, 4]. The individuals in the **stochastic process** $\{Z_n\}$ may be (as in the original application to the problem of extinction of surnames) direct male descendants of a single male ancestor; or carriers of copies of a mutant **gene**, electrons in an electron multiplier, neutrons in a nuclear chain reaction, branch units in a polymer molecule [3], or branches emanating from a point of propagation in crack growth. Even though the independence assumptions will tend to break down in practice if numbers become large, particularly in biological applications, the value of q calculated under these assumptions in the case $m > 1$ will nevertheless often provide a good approximation [4]. The structure of the process is easily generalized to several types of individual (the multitype process, with an accompanying Criticality Theorem) which is of very great applicability; for example, in **population genetics** and polymer chemistry. Another important direction of generalization is to permit immigration (e.g. recurrent mutation), in which case when $m < 1$ an equilibrium may result due to a balance between the immigrants and tendency to extinction.

For the simple branching process, I.J. Bienaymé [1] gave a completely correct statement of the Criticality Theorem in 1845. This passed unnoticed until recent decades [5, 7]. The usual designation for the process originates from the partly correct statement of the Criticality Theorem in 1873–1874 by **F. Galton** and H.W. Watson. Kendall [6] gives a vivid history from this starting point.

Gamma Distribution

The gamma density in its general form is

$$g(x; s, a, \rho) = \frac{(x-s)^{\rho-1}}{a^{\rho}\Gamma(\rho)} \exp\left(\frac{s-x}{a}\right)$$
$$(s < x < \infty; a, \rho > 0).$$

It is a Pearson type III density, and includes the χ^2 density (*see* **Chi-square Distribution**); the latter refers to a **"goodness-of-fit"** test based on the sum of squared normed deviations. This in turn relates to the distribution of the sum of squares of **normal** deviates. The distribution may be reverse J-shaped if $0 < \rho < 1$. The basic parameters (s, a, ρ) are associated with origin, scale, and shape; the **skewness** is $\alpha_3 = \sqrt{\beta_1} = \mu_3/\mu_2^{3/2} = 2/\sqrt{\rho}$, and **kurtosis**, $\beta_2 = \mu_4/\mu_2^2 = 3 + 6/\rho$. For normality these two moment parameters take the values 0 and 3, respectively, so that ρ has to be large to decrease the skewness to insignificance. It is well known that the gamma distribution approaches normality very slowly (*see* **Convergence in Distribution and in Probability**). A recent study by Revfeim [7], using a **transformation**, and manipulation of series, relates the distribution and its inverse to the corresponding normal functions.

If we choose $g(\cdot)$ as a suitable model to account for experimental data with some success, then sample size is important. Applications of the gamma distribution are numerous and cover many applied sciences. The reader may refer to the bibliography in Johnson et al. [5], which includes some 300 references. Historically, we may glance at *Karl Pearson's Early Statistical Papers* [6], illustrations relating to the state of the art towards the end of the nineteenth century. Examples are:

1. Range of the barometer; p. 80;
2. Professor Weldon's crab measurements; p. 82;
3. Heights for 25 878 recruits in the US Army (1875); p. 83;
4. Length–breadth index of 900 Bavarian skulls; p. 86;
5. The distribution of 8689 cases of enteric fever received into the Metropolitan Asylums Board Fever Hospitals (1871–1893); p. 88.

Examples of the gamma density are given in Figure 1.

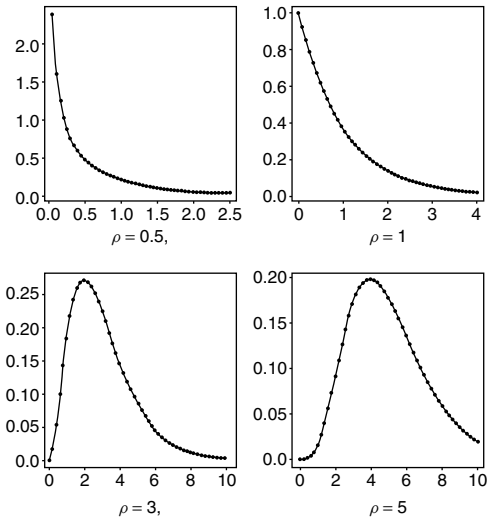

Figure 1 Illustrations of the densities $g(x; 0, 1, \rho)$. Note that for $a > 0$, $g(x; s, a, \rho)$ tends to ∞ as $x \to s$ when $0 < \rho < 1$, but equals unity when $x = s$, and $\rho = 1$

Histograms should be unimodal (*see* **Frequency Distribution**); high density near the origin may lead to estimation problems especially in the estimation of s. A brief account of **simulation** studies for the **maximum likelihood** estimators [1] shows that the distribution of s may be U-shaped if ρ is small (less than unity). If, on the other hand, ρ is large then the distribution may have a large variance. Moreover, in this case it was found that **confidence intervals** for ρ would require sample sizes exceeding 500 to control their variance. Cohen & Whitten [3] have considered modified maximum likelihood estimators including the use of the smallest sample value (*see* **Order Statistics**) to estimate s, and with special attention to cases when ρ is small.

In sampling studies of the estimators (s, a, ρ), given a gamma density (s, a, ρ) with specified sample size, among the great variety of possible forms samples with negative skewness may arise. For example, in sampling from (0, 1, 6) and a sample of 50, there were 20 000 valid solutions with 2157 failures including 432 cases of negative skewness. Similarly for $\rho = 10$, and $n = 50$, there were 182 cases of negative skewness out of some 20 000 trials.

A new parametric form due to Cheng and Traylor [2] avoids the negative skewness syndrome with μ, σ, and λ relating to origin, scale, and shape, the

density being

$$g(x;\mu,\sigma,\lambda) = \frac{1}{\sigma\lambda\Gamma(\lambda^2)}\left\{\lambda^{-2}\left[1+\frac{\lambda(\lambda-\mu)}{\sigma}\right]\right\}^{\lambda^2-1} \times \exp\left\{-\frac{1}{\lambda^2}\left[1+\frac{\lambda(x-\mu)}{\sigma}\right]\right\}$$

$$(\sigma > 0; \lambda \neq 0 \text{ and } 1+\frac{\lambda(x-\mu)}{\sigma} > 0).$$

In our notation

$$\rho = \frac{1}{\lambda^2}, \qquad a = \sigma|\lambda|, \qquad s = \mu - \sigma\lambda^{-1}.$$

Moreover, $\sqrt{\beta_1} = 2/\sqrt{\rho}$ = skewness.

If $\lambda > 0$, then the distribution has positive skewness; if $\lambda < 0$, then the distribution is valid with negative skewness. Hirose [4] has a program for maximum likelihood estimation using a predictor–corrector algorithm. Asymptotic covariances using the Hessian matrix will be available, but caution in finite sample interpretation is advised. Let it be said that in finite samples there is no panacea in maximum likelihood estimation procedures.

In the present context it would be remiss to ignore the link between the gamma distribution and the gamma function. Euler in the eighteenth century used the unnormed gamma density as the integrand and integrated over the range $(0, \infty)$ to define the gamma function. Of course, at that time there was no connection with statistics. This definition, interpreted for complex variables, is to be found in modern textbooks. After Euler, Weierstrass introduced an infinite product formula. Inevitably new forms arose for products of gamma functions such as $\Gamma(x)$, $\Gamma\left(x+\frac{1}{2}\right)$, and $\Gamma(x)\Gamma(1-x)$, as well as the question of approximations for large variables. Stirling's formula (eighteenth century)

$$\ln[\Gamma(x)] = \left(x-\tfrac{1}{2}\right)\ln(x) - x + \tfrac{1}{2}\ln(x\pi) + J(x) \quad (x \to 0, |\arg x| < \pi)$$

plays a role in many asymptotic structures, including, for example, the transition to normality of the **binomial distribution**. The residue $J(x)$ is a divergent power series in odd powers of $1/z$, the coefficients being Bernoulli numbers; these diverge ultimately. A partial sum of the series has an integral form which may be bounded and shown to be valid. Stieltjes [8] produced a convergent continued fraction for the residue and this gives monotonic increasing, and decreasing bounds when the variable is real and positive.

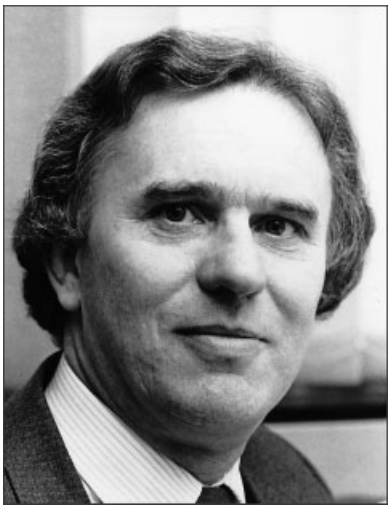
Gardner, Martin John

Born: July 25, 1940, in Essex, UK.
Died: January 22, 1993, in Southampton, UK.



Although Martin Gardner achieved fame for his work at Sellafield, which showed that paternal exposure to ionizing radiation was linked to leukemia in childhood [3] (*see* **Leukemia Clusters**), this discovery came towards the end of a varied and highly productive career in medical statistics. After receiving a first class degree in mathematics he joined the Medical Research Council Social Medicine Unit at the London School of Hygiene and Tropical Medicine. It was there that he became interested in the problem of why the rates of common diseases vary so much between different parts of Britain – an interest to which he returned repeatedly throughout his career. He carried out a series of novel analyses on the geographical links between socioeconomic conditions and coronary heart disease (*see* **Geographic Patterns of Disease**; **Geographic Epidemiology**). Later, at the MRC Environmental Epidemiology Unit in Southampton, he produced two uniquely detailed atlases of mortality in England and Wales [4, 5].

In 1971 Gardner moved to Southampton as a senior lecturer. One of his hallmarks in those early years was his ability to form creative partnerships with doctors. This arose from his facility in grasping medical problems and reducing them to their essence, and from his personality. He was a modest and immensely likeable man, and his promotions to a Readership followed by a personal chair in 1985 were widely welcomed.

He was a gifted teacher of statistical methods. He once gave a lecture on **life tables** that evoked spontaneous applause. Only seldom do lectures on statistics evoke such a response from doctors. He was statistical advisor to the *British Medical Journal* for many years, a position of which he was justly proud. He campaigned vigorously to improve the quality of statistics in medical journals (*see* **Statistical Review for Medical Journals**) and helped to draw up guidelines for statistical analysis. He coordinated the development of statistical checklists for referees, and the production of a series of papers on **confidence intervals**. These were brought together in *Statistics with Confidence* [2]. When refereeing papers Gardner was positive, searching out strengths and scientific importance and not dwelling unduly on weaknesses and errors.

In 1978 Gardner and Donald Acheson published their report on the ill effects of asbestos on health [1]. It was a tribute to Gardner's balanced approach to difficult and contentious issues – a balance that made him much in demand to serve on committees. He rapidly became an expert on control limits for industrial hazards. He was a frequent visitor to the US and through this and his work with the **International Agency for Research Against Cancer** established an international reputation.

Gardner gave time to the scouts, schools, and other local activities. As a schoolboy he had been an exceptional athlete, and sport was a major hobby throughout his life. He and his wife, Linda, whom he met at Berkeley, had three children.

In 1983 Gardner was asked to join the committee, chaired by Sir Douglas Black, examining the excess of childhood leukemia around the nuclear plant at Sellafield in Cumbria. Over the next few years he devised and carried out three major studies together with colleagues in the Environmental Epidemiology Unit. The "Gardner Report" [3], the result of fastidious research, aroused immense public interest and scientific controversy. He handled the media with great skill and addressed the scientific debate with balance and good humor. His career ended all too soon, but on a high note.

DAVID BARKER

Gastroenterology

The specialty of gastroenterology concerns diseases of the digestive tract from the esophagus to the rectum. The biliary tract and pancreas are included, but diabetes is regarded as a subspeciality of **endocrinology**. Often the definition of gastroenterology is widened to include the liver also (*see* **Hepatology**). At one time the internal organs constituting the gastrointestinal tract were directly accessible only at surgery. Nowadays, less invasive investigative techniques include contrast radiography and endoscopy for direct visualization and biopsy. Surgical maneuvers may be effected via endoscopic or minimal-access "keyhole" routes.

Disease taxonomy, though not as problematic as in **psychiatry**, is nevertheless not entirely straightforward. Quite exhaustive investigations fail to demonstrate an organic cause in many cases of abdominal pain. Thus nonspecific acute abdominal pain and irritable bowel syndrome are recognized diagnoses, albeit defined by absence rather than presence of specific diagnostic features.

One important area of ambiguity relates to inflammatory bowel disease (or nonspecific colitis). Crohn et al. [3] described a regional ileitis with granulomatous pathology, yet which in many respects closely resembled the already well-established diagnosis of ulcerative colitis (or idiopathic proctocolitis). Differential diagnosis between ulcerative colitis and Crohn's disease is sometimes clear-cut but is often so problematic that many have debated whether they should be regarded as different diseases. Jones et al. [11] sought to resolve this issue by applying **numerical taxonomy** to a series of patients with nonspecific colitis. Two main clusters emerged, that could be identified with proctocolitis and Crohn's disease, but the latter category was relatively heterogeneous, with several subclusters apparent.

Subsequently Harries et al. [8] pointed out that ulcerative colitis is less frequent in current smokers than in lifelong nonsmokers or ex-smokers; the latter often develop the disease within a year or so of quitting smoking. This observation, contrasting with Crohn's disease, which is slightly commoner in smokers, suggests differences in etiology. Ulcerative colitis shares its nonsmoking epidemiology with a few other conditions, notably the related condition of oral aphthous ulceration, and Alzheimer's and Parkinson's diseases. The possibility of therapeutic use of nicotine is limited by the propensity to cause side-effects. It is thus a particularly appealing option for ulcerative colitis, for which topical administration is feasible.

It was traditionally held as axiomatic that no microorganism could thrive in the highly acidic environment of the stomach. This view was overturned when Warren [17] demonstrated the existence of a hitherto unidentified strain of curved bacilli on the gastric epithelium in patients with chronic gastritis. This organism, now known as *Helicobacter pylori*, is regarded as playing a major role in the etiology of peptic ulceration, and perhaps gastric cancer also. Prospects for identifying and eradicating the organism from symptomatic patients are regarded as good [9]. Guidelines for **clinical trials** of eradicative regimes are given in [18].

Population gastroscopic screening for malignancy is practiced in Japan, where the incidence is much higher than in the West. Evidence from large population-based randomized trials [7, 13, 14] indicates a moderate benefit from **screening** for colorectal cancer using fecal occult blood tests – colonoscopy is also being developed as a screening method. As in other screening contexts, optimizing **sensitivity** and **specificity** is critical, both by avoidance of factors (here, dietary ones) that lead to a false result, and also by choice of test. Studies such as that by Hope et al. [10] point to the great need for methods to compare two tests for both sensitivity and specificity simultaneously. A suitable approach is now available [15].

Gastroenterology has been a major area for development of knowledge-based differential diagnosis systems. de Dombal et al. [5] described a computerized system to assist in the diagnosis of acute abdominal pain (*see* **Computer-aided Diagnosis**), which was able to outperform experienced clinicians. However, one of the greatest benefits was an educative one: as they used the system, clinicians directed their attention towards the factors that were most discriminatory, and their performance improved [6]. Knill-Jones et al. [12] described a model for diagnosis of jaundice. Clamp et al. [2] produced a scoring system for the differential diagnosis of inflammatory bowel disease. Spiegelhalter & Knill-Jones [16] outlined many of the statistical issues involved in scoring systems such as GLADYS (Glasgow Dyspepsia System), which grew out of de Dombal's work. An

excellent review of progress, including a balanced view of the usefulness to clinical practice, is given by de Dombal [4].

Gastroenterological journals are similar to other speciality journals in their statistical content. As an example of process quality improvement, *Gut* has had a statistical advisor for several years, and now has an identified team of some 20 statistical referees. Clinical trials will be required to conform to the CONSORT guidelines with effect from January 1998 [1].

R.G. NEWCOMBE

Gauss, Carl Friedrich

Born: April 30, 1777, in Brunswick, Germany.
Died: February 23, 1855, in Göttingen, Germany.

Described in [1] as "one of the greatest scientific virtuosos of all time", Gauss came from a poor and semiliterate family, and quickly revealed himself as a highly intelligent child and a calculating prodigy. He was supported from 1792 by a stipend from the Duke of Brunswick, which enabled him to study in Brunswick, and later at Göttingen and Helmstedt. During this period he produced a stream of original mathematical and astronomical work, and in 1807 he became director of the Göttingen observatory, where he remained for the rest of his life.

May [1] lists the subjects in which Gauss worked as follows: arithmetic, number theory, algebra, analysis, geometry, probability and statistics, astronomy, geodesy, geomagnetism, mechanics, dioptrics, and physics. In all these he had an enormous international reputation. He was something of a lone worker, with no major mathematical collaborators and little personal contact with other mathematicians. He collaborated to a greater extent in applied work, particularly with an experimental physicist, Wilhelm Weber.

Gauss's importance in statistics rests on his work in the theory of **least squares**, and the central role played in it by the **normal (or Gaussian) distribution**. Least squares had been proposed by A.M. Legendre in 1805 as an intuitively satisfactory way of combining observations. Gauss's account, published in 1809, underpinned the "principle" by a "theory". Using what we should now describe as a **multiple linear regression** model, and a **Bayesian** formulation with **uniform prior** distributions for the parameters, he chose the mode of the posterior distribution (or, equivalently, the **maximum likelihood** (ML) solution). He considered that, for a single sample from a distribution, the arithmetic **mean** was a reasonable estimator, and showed that this implied the use of the normal distribution, which in turn led to the least squares solution to the ML equations. He showed also that, for general error distributions, the least squares solution minimized **mean square error** amongst all linear estimators (the result usually called the Gauss–Markov Theorem). For fuller accounts, see [2] and [3].

May's memoir [1] provides a broad coverage of Gauss's scientific work, and an extensive bibliography.

PETER ARMITAGE

Gavarret, Louis–Denis–Jules

Born: January 28, 1809, in Astaffort, France.
Died: August 21, 1890, in Château de Valmont, France.

Jules Gavarret was born into a middle-class family and initially planned on a military career. To pursue this end, he enrolled in the École Polytechnique in 1829 and was named lieutenant of artillery in 1831; however, he resigned his military position in 1833 to pursue a career in medicine. Subsequently, Gavarret began an extensive collaboration with the eminent Parisian clinician Gabriel Andral with whom he conducted several investigations into the composition of blood. In 1843, Gavarret became a doctor by defending a thesis entitled "De l'Emphysème des Poumons et ses Rapports Avec les Différentes Maladies du Coeur et des Bronches" and ascended to the chair of medical physics in the Paris Faculty of Medicine. During his ensuing 44 year career in academic medicine, Gavarret wrote several more studies that attempted to expand the understanding of how physical principles (heat, electricity, etc.) could be used to explain the functioning of the human body; he retired in 1887 after being awarded numerous honors for his scientific accomplishments.

While still a student of Andral, Gavarret wrote the book that would be his principal legacy to the field of biostatistics: *Principes Généaux de Statistique Médicale, ou Développement des Règles Qui Doivent Présider à Son Emploi* (1840). In this book, Gavarret responded to a debate that had occurred at the Paris Academy of Medicine in 1837 over **Pierre Charles Alexandre Louis's** "numerical method". According to Louis, one should record the numbers of patients who died and recovered from each disease in the hospital wards as well as the types of treatments that each patient received. From these numerical results one could compute the percentage of patients who died after receiving a particular treatment and the percentage of patients who died after not receiving the treatment. If the former percentage was higher than the latter (as was the case for the then-common practice of bloodletting), the procedure should be suspended since it was not truly efficacious. In critiquing Louis's numerical method, Gavarret drew on the probabilistically based work of the contemporary mathematician **Siméon Denis Poisson** to show that the percentages could vary between "limits of oscillation" which depended on the number of cases observed. By applying Poisson's idea to Louis's various numerical conclusions, Gavarret determined, for example, that the average mortality rate from typhoid fever could vary between 26% and 49% on the basis of the 140 cases observed.

Throughout the latter half of the nineteenth century Gavarret's probabilistic analysis of medical statistics was discussed in treatises produced in America, Great Britain, France, and Germany. Although some German commentaries attempted to modify Gavarret's formulas to make them more useful in practice, most accounts did little more than repeat Gavarret's examples verbatim and highlight the "novelty" of applying the "calculus of probabilities" to medical statistics. As a result, few nineteenth-century biostatisticians saw Gavarret's probabilistic concerns as central to their work; nevertheless, Gavarret's approach is still important historically since it foreshadows the probabilistically informed concerns that have become so common within contemporary biostatistical research.

J. ROSSER MATTHEWS

Geisser, Seymour

Born: October 5, 1929 in the Bronx, New York.
Died: March 11, 2004 in St. Paul, Minnesota.

Seymour Geisser was a leading proponent of the importance of **prediction** in the practice of statistics as well as a leading exponent of **multivariate analysis**. He was also a prominent administrator and consultant in the fields of statistics and biostatistics.

Seymour's parents emigrated from Poland to New York City in the early 1920s where they became garment workers. He was a student at Lafayette High School in Brooklyn and received his undergraduate degree in mathematics from the City College of New York in 1950. "It was quite a chore to get up to City College from where I lived", said Geisser, as he remembered his undergraduate days. "City College was up on Convent Avenue and 137th Street and I lived down in Bensonhurst [Brooklyn]. It took almost two hours going and two hours coming back. I spent a lot of time sleeping on the subway."

His interest in statistics arose from conversations with his cousins. His cousin and his cousin's wife (Leon and Dorothy Gilford) were statisticians who assured him that the field provided good opportunities for employment. Dorothy Gilford worked for the Census Bureau and had been trained by **Harold Hotelling** at Columbia University. They suggested that Seymour apply for graduate school at Hotelling's new institution, the University of North Carolina. "When I left City College to go to Chapel Hill, I thought I was entering a country club," reflected Geisser. "It was such a pretty campus." Many of his fellow students went on to prominent careers in statistics. **Ralph Bradley**, Sudish Ghurye, Ingram (Red) Olkin, Milton Terry, Sutton Munroe were already students there. Others, like Don Burkholder, Ted Colton, Fred Descloux, Ed Gehan, Shanti Gupta, Jack Hall, T.V. Narayana, Bill Howe, Jim Pacheres, K.D. Ramachandran, Bill Thompson, John Wilkinson, and Marvin Zelen were contemporaries.

In graduate school, Seymour selected Harold Hotelling as his major professor and wrote a Master's thesis on computing roots and characteristic vectors of matrices (*see* **Matrix Algebra**). His Ph.D. thesis was on the mean square successive difference in statistics. During the summers of 1952 and 1953, while still a graduate student, he worked at the Aberdeen Proving Ground in Maryland. This is where he formulated his Ph.D. thesis problem, which was an extension of the work von Neumann had done there. His Masters and Ph.D. degrees were conferred in 1952 and 1955, respectively.

His first position after graduate school was as an assistant to Herman Chernoff at the National Bureau of Standards (NBS). He worked at a branch of the Operations Research Office located in the Army War College. Others who worked for NBS at the time were Jack Youden, Churchill Eisenhart, Marvin Zelen, Bill Connor, Bill Clatworthy, and Norman Severo. He then joined the Commissioned Officers Corps of the US Public Health Service, with the understanding that he would be assigned to the National Institute of Mental Health, working under **Sam Greenhouse**. **Jerry Cornfield**, **Max Halperin**, **Nathan Mantel**, and **Marvin Schneiderman** also worked at the **National Institutes of Health (NIH)**. Seymour spoke fondly of that time. "We used to eat lunch together and talk about everything from history, to statistics, to religion, to politics. The table talk was really interesting." In those conversations, Jerry Cornfield provided Seymour with his first introduction to **Bayesian** ideas.

His first Bayesian work was in multivariate analysis. In the early sixties, Seymour wanted to see what would happen if he considered the usual multivariate problems from the Bayesian point of view. After looking at **multivariate analysis of variance**, he turned to **classification** and discrimination. Geisser said "It dawned on me that with Bayesian Theory you didn't have to make a [strict] separation for linear discrimination. For example, everything on one side was guilty and the other side innocent, if you like. [A Bayesian] could find the probability of each individual being one or the other. It was a much finer distinction than using, say, the usual Fisher linear discriminant. That really swung me to the Bayesian approach." (*see* **Discriminant Analysis, Linear**).

His appointments at the National Bureau of Standards and the National Institute of Mental Health were from 1955 to 1961. From 1961 until 1965, he was Chief of the Biometry Section at the National Institute of Arthritis and Metabolic Diseases. At this time he also began teaching. From 1960 to 1965, he was a professorial lecturer at George Washington University, teaching in the Statistics Graduate Program at night. Sam Greenhouse and Solomon Kullback were also on the faculty.

In 1965, he became the founding Chair of the Department of Statistics at the State University of New York (SUNY), Buffalo, remaining in that capacity until 1970. During his tenure there, the faculty included Norman Severo, Bill Clatworthy, Marvin Zelen, Manny Parzen, Charles Mode, Jack Kalbfleisch, Ross Prentice, and Peter Enis, who was Seymour's first Ph.D. student at George Washington. When asked about his efforts to build the SUNY, Buffalo department, he said, "Building a group is difficult. There are lots of ups and downs. When you have money, so does everybody else. So you are competing for some very good people. That becomes a difficult chore. And when you don't have money, you can't hire anybody. So a lot of time is spent haggling and fighting with deans about lines, space, money: the usual trinity."

During the 1960s, Seymour developed a strong interest in prediction. This started with his work on classification, which is essentially a prediction problem. His thinking during this period is summarized in [8]. From this point on, his professional efforts were largely driven by his strong belief that the majority of statistical endeavor should be focused on prediction of observables rather than on estimation of unobservable parameters. "It always seemed to me," said Geisser, "that prediction was critical to modern science. There are really two parts, especially for statistics. There is description; that is, you are trying to describe and model some sort of process. [The model] will never be true and, essentially, you introduce lots of artifacts... Prediction is the one thing you can really talk about because what you predict will either happen or not happen and you will know exactly where you stand... Science changes when predictions do not come true." The majority of his work on prediction is summarized in Geisser [12].

In 1971, he became the founding Director of the School of Statistics at the University of Minnesota, remaining in that position until 2001. In the early years, the faculty included Don Berry, Kit [Chris] Bingham, Bob Buehler, Dennis Cook, Somesh Das Gupta, Joe [Morris L.] Eaton, Steven Fienberg, Cliff Hildreth, David Hinkley, F. Kinley Larntz, Bernie Lindgren, David Lane, Frank Martin, Michael Perlman, Milton Sobel, and Sandy Weisberg. During his tenure at Minnesota, there was an emphasis on the foundations of statistics. Geisser commented, "We brought in of a lot of people who were interested in foundations. We had a lot of seminars on it and there was a lot of interesting work that was done on foundations at that time. That was, in a sense, more interesting than methodology. [Without foundations, statistics is] just a trite engineering problem." In this regard, the School held a series of lectures on **R.A. Fisher's** contributions, which led to the monograph, *R. A. Fisher: An Appreciation*, in 1980 [2]. Seymour taught a graduate course called "*Statistical Inference*" for many years. In that course, he discussed the various modes of statistical **inference** and gave thought provoking lectures about the relative advantages and disadvantages of these modes. Recently, he compiled his lecture notes into a manuscript entitled *Modes of Parametric Statistical Inference* [13].

In the late 1980s and early 1990s, Seymour developed an interest in forensic DNA profiling. He was involved as an expert in over 100 litigations involving murder, rape, paternity, and other issues (*see* **Expert Witness, Statistician as**). His experiences in dealing with the FBI throughout these litigations are catalogued in the article "Statistics, litigation and conduct unbecoming," published in [4]. His purpose in these litigations was to point out that statistical calculations displayed in court should be valid. It was his contention that the methods then being used by the prosecution in DNA cases were flawed.

In discussing the people who most influenced his career, in addition to Harold Hotelling and Jerry Cornfield, he mentioned **George Barnard**. "I was particularly influenced by George Barnard. I always read his papers. He had a great way of writing. Excellent prose. And he was trained in philosophy, in logic, at Cambridge." Seymour's favorite statistics books were Fisher's, *Statistical Method in Scientific Inference* [3] and Cramer's, *Mathematical Methods of Statistics* [1]. Seymour chose Cramer for the mathematics of statistics and Fisher for the philosophical underpinnings of statistics. Late in life he said, "I still read those books. There always seems to be something in there I missed the first time, the second time, the third time..."

Seymour authored or coauthored 176 scientific articles, discussions, book reviews, and books over his career. One of his articles, Greenhouse and Geisser [14], is a citation classic. He pioneered several important areas of statistical endeavor. He and Mervyn Stone simultaneously and independently invented the now popular method for validating statistical models called **cross-validation**. Geisser [9] developed the equivalent method of "predictive

sample reuse." He also pioneered the areas of **Bayesian Multivariate Analysis** and discrimination [5, 6, 7, 17], Bayesian diagnostics for statistical prediction and estimation models [15, 16], Bayesian interim analysis [10] and testing for **Hardy–Weinberg equilibrium** using forensic DNA data [11].

Seymour served on many committees of the NIH, **Food and Drug Administration**, National Institute of Statistical Science, and National Research Council. In addition, he was a National Science Foundation Lecturer in Statistics from 1966 to 1969, a member of the National Research Council Committee on National Statistics from 1984 to 1987, Chair of the National Academy of Sciences panel on Occupational Safety and Health Statistics from 1986 to 1987. He delivered the **American Statistical Association** President's Invited Address in 1991.

He held numerous visiting professorships including the University of Tel Aviv, 1971; Stanford University, 1976, 1977, 1988; Harvard University, 1981; the University of Chicago, 1985; the University of Warwick (England), 1986. He was the Lady Davis Visiting Professor, Hebrew University of Jerusalem, 1991, 1994, 1999, and the Schor Scholar, Merck Research Laboratories (2002–2003). He was a Fellow of the Institute of Mathematical Statistics and the American Statistical Association.

Two special conferences were convened to honor his contributions to statistics. The first was organized by Jack Lee and held at the National Chiao Tung University of Taiwan in December of 1995. The second was organized by Glen Meeden and held at the University of Minnesota in May of 2002. In conjunction with the former conference, a special volume entitled *Modeling and Prediction: Honoring Seymour Geisser,* edited by Lee et al., was published in 1996 [18].

Seymour had an avid interest in history, archeology, particularly biblical archaeology, and religion, philosophy, and literature. He was a prolific reader of novels. He studied Latin, French, and German. He enjoyed traveling, especially to wildlife preserves and national parks.

He married his first wife while a graduate student in Chapel Hill. They had four children: Mindy, Dan, Georgia, and Adam. He met his second wife, Anne, while visiting Harvard University. They were married for 22 years. His brother, Martin, was a high school teacher and counselor. He had five grandchildren, Emma, Liam, and triplets Joshua, Eden, and Rachel.

The Department of Statistics at the University of Minnesota has established the Geisser Lectureship in Statistics. Each year, starting in the fall of 2005, an individual will be named the Seymour Geisser Lecturer for that year and will be invited to give a special lecture. Individuals will be selected on the basis of excellence in statistical endeavor and their corresponding contributions to science, both statistical and otherwise. For more information, visit the University of Minnesota Department of Statistics web page, `www.stat.umn.edu`.

RONALD CHRISTENSEN & WESLEY JOHNSON

Gene Conversion

Gene conversion is said to occur when one of the alleles, "A" or "a", at a locus, is converted to the other allele during the process of replication. In diploid species, if the paternal **genotype** at a locus is "AA" and the maternal genotype is "aa", then all offspring are anticipated to have genotype "Aa" under normal circumstances. Occasionally, offspring from this mating are observed to have either genotype "AA" or genotype "aa". This implies that one allele has been replaced or converted by the other into a form like itself. Gene conversion frequently occurs in association with recombination in the flanking sequences, and the prevailing hypothesis is that gene conversion happens as a consequence of recombination and erroneous mismatch repair in the small segment of heteroduplex **DNA** that contains one strand (allele) from each parental molecule. Gene conversion drives the evolution of some genes. Gene conversion events are difficult to detect in species such as humans, where all the products of meiosis cannot be observed, but are easily identified in fungi such as yeast or *Neurospora*, where all the four products of meiosis (*see* **Linkage Analysis, Model-based**) are contained in a 4- or 8-spore ascus.

S. IYENGAR

Gene Expression Analysis

A (protein coding) **gene** is determined to be *expressed* in a cell or group of cells when its transcribed messenger RNA (mRNA) or the resulting protein product is detected (*see* **DNA Sequences**). There is a wide variety of techniques for determining and quantifying gene expression, and many of these have substantial statistical components to them. In this article we review some of the statistical models and methods used in analyzing gene expression data, focusing entirely on approaches quantifying mRNA. Before doing so, we present a small sample of the extensive biological and technological background to gene expression analysis.

Why do we measure gene expression? The most common experiment is *comparative*: we want to compare the mRNA levels of one or more genes in cells from different sources. Comparisons of interest include tumor vs. normal cells, cells from a specific organ in a mutant or genetically modified organism vs. cells from the same organ in a normal organism of the same strain, and cells before and after an intervention such as a drug treatment. Another important class are the time-course experiments, where cells are sampled at different times, e.g. after the administration of a drug, or as the cell cycle or development proceeds, and interest is in temporal patterns of gene expression. Yet other experiments focus on spatial patterns of gene expression. There are many other kinds of gene expression experiments, essentially as many as there are organisms, cell types, and conditions of biological interest.

How do we measure gene expression? As stated above, there are many techniques for doing so, but most rely on DNA–RNA or DNA–DNA *hybridization*. This is the biophysical process through which single-stranded DNA or RNA molecules find and base-pair with their complementary sequences amidst a complex mixture of many molecules of the same kind. The terminology we adopt names the sequence representing a gene of interest, the *probe*, while the pool within which a complementary copy of the probe is sought is named the *target* DNA or RNA. Other terminologies are the reverse of ours.

On what scale do we measure gene expression? Much of the recent interest by statisticians in this area stems from the availability of data sets giving expression measurements on tens of thousands of genes, so-called *microarray* gene expression data. However, nylon membrane filters with thousands of genes spotted on them have been around for over a decade, and smaller-scale quantitative expression data for much longer. We begin with a discussion of the first and simplest method of quantifying RNA, as many of the features of the high-throughput methods are already present here.

Low-throughput Methods

Quantitative Northern Blots

Isolated mRNA is separated according to size by electrophoresis, and transferred by blotting to an immobilizing matrix such as a nylon membrane. A labeled DNA probe is incubated with the blot under conditions that promote annealing, and the probe will then bind to the RNA molecules on the blot complementary to it. This is the hybridization reaction. The result is then imaged, either directly [e.g. by laser scanning or the use of a charge-couple device (CCD) camera], or indirectly, by exposing an X-ray film to the blot.

The amount of RNA can be quantified by measuring the intensity of the signal in the image in regions corresponding to the probe of interest. Usually control RNA is measured at the same time, typically a gene that is thought to be expressed at a more or less constant level, (a "housekeeping" gene), and the expression level of the gene of interest is then given relative to the control gene.

Although this technique has been in use for over 20 years, it has attracted little attention from statisticians. In part this is because low-throughput assays with simple read-outs are usually seen as outside the domain of statistical analysis, apart from simple matters such as analyzing replicate data. This attitude changes when the assay becomes high-throughput, or when much more data are collected on a given unit. These considerations lead naturally into our next topic, which is an important development of the northern blot.

Quantitative PCR, Including Real-time PCR

The polymerase chain reaction (PCR) can be used to estimate the concentration of a particular target RNA relative to a standard. Standards are control sequences

(such as housekeeping genes) that are present in the same preparation of RNA as the target sequence. Quantification is achieved by amplifying the target RNA (and the reference RNA) to a more readily detectable quantity, and by comparing the amount of amplified product generated by the standard and the target sequences.

The method works well if the amplified products are measured during the exponential phase of the chain reaction, if the reference and target sequences are present in approximately equal concentrations, and if they amplify with equal efficiency. More accurate variants involve adding reference molecules in known amounts to a series of amplification reactions.

A more recent technique for quantitating RNA is real-time PCR (RT-PCR) [14], where the target and reference sequences are amplified and detected in the same instrument, and the endpoint is when the reported fluorescence passes a fixed threshold above baseline. There are a number of different protocols, including TaqMan, and a number of different instruments for carrying out this assay. Details can be found in the technical notes from PE Applied Biosystems [24, 25] and Roche Molecular Biochemicals [27]. Rather more statistical research has been devoted to improving quantification methods for RT-PCR; see, for example, [26], but there are still many issues remaining. This is a fertile area for biostatisticians.

High-throughput Methods

Serial Analysis of Gene Expression

Serial analysis of gene expression (SAGE) is a method for comprehensive analysis of gene expression patterns. It is the main quantitative approach to gene expression not based upon hybridization. Three principles underlie the SAGE methodology: (a) a short sequence tag (10–14 bp) contains sufficient information to uniquely identify an mRNA transcript, provided that the tag is obtained from a unique position within each transcript; (b) sequence tags can be linked together to form long serial molecules that can be cloned and sequenced; and (c) a count of the number of times a particular tag is observed provides the expression level of the corresponding transcript.

A typical SAGE experiment would involve two sources of mRNA, say tumor and the corresponding normal tissue. For each source a set (called a library) of (say) 50 000 tags would be derived using the SAGE protocol. In these two libraries there might be 20 000 distinct (termed unique) tags observed, and for each unique tag, the frequency with which that tag appeared in each library could be calculated. The data for this comparative experiment are then two lists of counts, one for each unique tag observed.

The first question a biologist asks here is: Which tags are significantly differentially represented in the two libraries? For any given tag, say tag i, the natural **null hypothesis** here is H_i : the proportions of tag i in the two libraries coincide. Rejection of this null hypothesis leads to the conclusion that the gene corresponding to tag i is differentially expressed between the two sources of RNA.

Making an independence assumption that might be difficult to verify, one current approach to this question starts with the observation that under H_i, the number of times tag i appears in library 1, say, given the total number across the two libraries, is binomial with $p = 1/2$. This is the basis of a test of H_i, and when this is done for all $i = 1, \ldots, 20\,000$, a **Bonferroni** adjustment can be used. The test just described is one of a number in use [2, 21]. There is a range of outstanding questions with these data including: dealing with sequencing errors, which might be of the order of 1%–3% per base in the tags; considering the independence assumption leading to the binomial model; and seeking a valid multiple testing correction less conservative than Bonferroni. The difficulty is that because of the co-expression of genes, different tag counts in a library cannot be regarded as independent. However, the extent to which this matters is not yet clear. When more SAGE libraries accumulate in a given context, questions will undoubtedly arise that lead naturally to classification and cluster analyses; see below in the context of microarray data. As with the technologies outlined above, there seem to be many opportunities for biostatistical research involving SAGE data. A general source on this topic is `http://www.sagenet.org`.

Array-based Approaches

The principal class of high-throughput methods for quantifying gene expression are those based on microarrays, although the term "macroarray" is also used. Broadly speaking there are three basic microarray technologies: nylon membrane arrays, spotted

arrays, and high-density oligonucleotide arrays. The special supplement of *Nature* [23] provides a good overview of the production and utilization of the last two technologies.

We explain each briefly before turning to statistics. There we will attempt to discuss the issues in a general way when applicable to two or more of these technologies, and leave the reader to consult the references for material on topics rather more specific to the different technologies.

Different Array Technologies

Nylon Membrane Filters

This is the oldest array technology, but one that is still widely used around the world. A typical filter microarray has 5000 *complementary DNA* (cDNA) clones, 600–2400 bases in length, spotted in a grid on the membrane. Radio-labeled target cDNA derived from the mRNA of interest is hybridized to the array, and the filter is then exposed to X-ray film and the film imaged. The resulting digital image constitutes the raw data from the experiment.

A very high-density variant of the traditional filter-based microarray is the oligonucleotide filter array, which can have 50 000 spots consisting of pools of 10-mers [22].

Spotted cDNA Microarrays

Introduced in [29], a typical spotted array consists of 5000–20 000 cDNA probes of length 600–2400 bp placed in a regular pattern on a glass microscope slide. The main advantage of the nonporous glass support is that it facilitates miniaturization and the use of fluorescence (rather than radiolabel) based detection. Essentially all spotted arrays use two sources of mRNA. They are converted to cDNA and at the same time labeled with one of two fluorophores having different emission spectra following laser excitation. The labeled cDNAs are mixed in equal quantities and competitively hybridized to the spots on the slide. Following hybridization, laser excitation stimulates the spots to fluoresce, and the photons emitted are collected using band-pass filters tuned to each of the two fluorophores. These are then amplified, converted to digital form, and presented as two digital images of the slide, each quantifying the amount of cDNA on the spots labeled by one of the two fluorophores. These two digital images are the raw data of a spotted microarray experiment. In an obvious sense, each spotted array experiment may be regarded as several thousand paired comparisons.

A variant of the spotted arrays uses as probes long (60–75 bp) oligonucleotides representing part of a gene or expressed sequence tag [15]. These are put onto the glass using an ink-jet printer device, and generally lead to higher quality data. As with the original spotted arrays, a two-color system is used, although the technology may well be good enough to provide reliable single-color quantification.

High-density Oligonucleotide arrays

A quite different technology can be used to place up to 250 000 short (25 bp) oligonucleotide probe pairs on a small glass chip, with 16 or 20 of these probe pairs representing a part or all of a single gene, see [12] and [20]. Each probe pair consists of a perfect match (PM) probe, and a mismatch (MM) probe, the latter being the same as the former apart from a single nucleotide change (A $\leftrightarrow$ G or C $\leftrightarrow$ T) in the middle (13th) position. A tagged target cRNA sample hybridizes with the complementary oligonucleotides on the chip, and detection is via laser excitation followed by the collection of fluorescence emission, as with spotted arrays. As with the approaches already discussed, the image is the starting point of analysis.

Statistical Issues

Design of Experiments

The careful design of microarray experiments is in its infancy. Most work to date concerns spotted array experiments, which require more care by virtue of the paired nature of each experiment. Also, many users of spotted arrays construct the arrays themselves, whereas filter arrays and high-density oligonucleotide arrays tend to be bought "off the shelf". In spotted array experiments, there are two main aspects to the design question: (a) the design of the array itself, i.e. deciding which cDNA probe sequences to print on the slide, whether to use replicated spots and control sequences, and how many and where these should be

printed on the slide; and (b) the allocation of mRNA target samples to the slides, i.e. deciding how the mRNA samples should be paired for hybridization, the dye assignments, and the type and number of replicates.

Proper experimental design is needed to ensure that questions of interest can be answered and that this can be done accurately and efficiently given experimental constraints, such as cost of reagents and availability of mRNA. Designs specifically suited for the question of interest and judicious pairing of mRNA samples for hybridization can greatly improve the efficiency of microarray experiments by ensuring the precise measurement of relevant effects. A number of statisticians have been involved in these questions, but there is little literature so far. For some initial work in this area, see [16]. We can expect much more published research on this topic in the near future.

Image Analysis

As explained above, the "raw data" arising from all microarray technologies are images: of labeled probes on a nylon filter, a glass slide, or a glass chip. There seems little doubt that the results of downstream analyses can be appreciably influenced by the initial image analysis, though few studies of this topic exist at present; see [35] for one such.

Three broad analysis issues can be identified with microarray images, although not all approaches proceed in this way: finding the probe centers (registration); partitioning the pixels in the image into probe and nonprobe regions (segmentation); and assigning summary values to probe intensity and background (quantification). Rather than assign pixels to probe and nonprobe categories, some approaches (especially with nylon filters) use parametric, semiparametric, or nonparametric modeling to determine probe intensity. Once summary values of probe intensities are calculated, there remains the question of combining these to measure absolute or relative gene expression. With nylon filter and spotted arrays, intensity is usually the difference between foreground and background values, and ratios of these quantities are the main vehicle for later analysis. In general there are many ways of carrying out the image analysis, and several commercial and freely available packages for doing so, see [7] for nylon filter arrays [35], and references therein for spotted arrays, and [28] for high-density oligonucleotide arrays. Brandle et al. [5] is a good overall reference, and other articles in that volume can be consulted on this topic, as well as Buhler et al. [6] and Wang [32].

In the case of high-density oligonucleotide arrays, the image analysis does not result in expression values, but in PM and MM probe intensity values. One further analytical step is necessary with this technology before we have a gene (or probe set) expression value: the 16 or 20 PM and MM pairs must be summarized. This is not entirely straightforward and research on it is continuing, but see [18] and [19] for the most thorough published discussion to date.

Preprocessing Tasks: Normalization

As indicated earlier, the most common gene expression experiment is the comparative one. With nylon filter arrays this leads us to compare the images from two hybridizations onto copies of the same basic filter. Sometimes this is done by stripping the results of a first hybridization and re-using the filter, but more commonly a new filter is used. Because the nylon substrate is not solid, there may be warping, and this can make registration across different filters a challenging problem. When this is adequately addressed, interest focuses on comparing the two expression levels for each of the genes spotted onto the array. An entirely analogous situation arises when we have reduced the two images of a single spotted array or two high-density oligonucleotide array experiments to lists of gene expression values. We are back to the same (biologist's) question that we met with SAGE data: Which genes seem to be significantly differentially expressed between the two mRNA sources?

Before we can address this question in the microarray context, however, there is usually a need for normalization. This is a generic term describing the identification and removal of systematic sources of variation, other than differential expression, from the measured gene expression values. Systematic effects can come from different labeling efficiencies, different scanning parameters, and a variety of other causes, see [30] for a good list. These effects can be related to intensity, location on the filter, slide or chip, and other features of the process such as reagent batch and laboratory conditions. The need for normalization can be seen most clearly in

experiments involving two identical mRNA samples hybridized to different membranes or chips, or on the same glass slide, as long as the results are appropriately visualized.

Pairs of gene expression values, say from a treated (T) and a control (C) source, are usually displayed by plotting the $\log_2$ or $\log_{10}$ intensities against one another, e.g. $\log_2 T$ vs. $\log_2 C$. Such plots give an unrealistic sense of concordance between the two sets of intensities and can mask important features of the data. It is better to plot $M = \log_2 T/C$ vs. $A = \log_2 \sqrt{TC}$, which amounts to a rotation of the previous plot and a rescaling of the axes. Assuming, as is almost always the case, that we expect the majority of genes to be expressed at about the same level in both cell samples, regardless of overall intensity, the M vs. A plot should be scattered around the horizontal (A-) axis, in a more or less symmetrical manner, and the histogram of M values should be centered around zero. This is rarely found to be the case.

A standard normalization for nylon filter and spotted array data is to shift the log ratios so that their mean or median is zero. Frequently there is a strong enough intensity dependence that a smoothing of M values along the A-axis defines a better, A-dependent centering. Spatial effects require a modified solution, and there are yet other effects that need to be dealt with from time to time. For a discussion of these issues in the context of spotted arrays, see [34], while [30] is also of interest. Normalization is also relevant to the high-density oligonucleotide technology, but is less well discussed and somewhat more complex, see [18] and [19] for some comments.

Comparative Analyses

Once the log ratios of intensities have been normalized, interest focuses on those that seem to be genuinely different from zero, i.e. that correspond to genes that are differentially expressed. There is no reliable method of assigning statistical significance to log ratios from unreplicated experiments, although a number of model-based approaches claiming to do this can be found in the literature, see [9] for a discussion of this issue in the context of replicated spotted microarrays. For a single comparison, the best approach is probably to apply a careful normalization to the log ratios, rank them, and construct a normal $Q-Q$ plot of them. Typically the plot will not be linear, but an examination of the extremes in conjunction with the M vs. A plot can give a good sense of the outlier log ratios. It is also advisable to carry out a quality examination of the spots corresponding to extreme log ratios. Exactly where to draw the line with ranked log ratios, when determining putatively differentially expressed genes, will depend on a variety of factors, such as the shape of the $Q-Q$ plot, the level of false positive and false negative rates deemed acceptable, and the nature and number of follow-up experiments envisaged. No simple guidelines seem possible, and no formal statistical approach seems available which deals with the question. The situation is different when there are replicate pairs of filters, slides, or chips. We broaden the context somewhat to discuss the issue of multiple testing (*see* **Multiple Comparisons**) more generally.

Multiple Testing

The identification of differentially expressed genes, i.e. genes whose expression levels are associated with a response or covariate of interest, is but one of the testing problems that arise with microarray data. The covariates could be either polytomous, e.g. treatment/control status, cell type, drug type, or continuous, e.g. dose of a drug, time, and the responses could be, for example, censored survival times or other clinical outcomes. The biological question of differential expression can be restated as a problem in multiple hypothesis testing: the simultaneous test for each gene of the null hypothesis of no association between the expression levels and the responses or covariates. As a typical microarray experiment measures expression levels for several thousands of genes simultaneously, we are faced with an extreme multiple testing problem. Special problems arising from the multiplicity aspect include defining an appropriate type I error rate (i.e. false positive rate) and devising powerful multiple testing procedures that control this error rate and account for the joint distribution of the gene expression levels.

A number of recent papers have addressed the question of multiple testing in the context of microarray experiments [10, 13, 31]. However, the proposed

solutions were not cast in the standard statistical framework and do not provide adequate type I error rate control. When going from single to multiple hypothesis testing, several definitions of the type I error rate are possible and include: the per-comparison error rate (PCER), defined as the expected value of (number of type I errors/number of hypotheses); the family-wise error rate (FWER), defined as the probability of at least one type I error; and the false discovery rate (FDR), or expected proportion of type I errors among the rejected hypotheses. In general, for a given multiple testing procedure, PCER $\leq$ FWER and FDR $\leq$ FWER, one should thus decide on an appropriate error rate to control for the problem under consideration. It is important to note that the expectations and probabilities above are conditional on assumptions concerning which hypotheses are true, i.e. on which genes are differentially expressed. A fundamental, yet often ignored distinction in multiple testing is that between strong and weak control of the type I error rate. Strong control refers to control of the type I error rate under *any* combination of true and false hypotheses, i.e. for any combination of differentially and constantly expressed genes. In contrast, weak control refers to control of the type I error rate only when *none* of the genes is differentially expressed, i.e. under the complete null hypothesis that all the null hypotheses are true. In general, weak control without any other safeguards is unsatisfactory. In the microarray setting, where it is very unlikely that none of the genes is differentially expressed, it seems particularly important to have strong control of the type I error rate.

Adjusted ***P* values** provide useful and flexible summaries of the strength of the evidence in favor of differential expression. The adjusted P value for a particular gene reflects the overall false positive error rate for the family of hypotheses when genes with smaller P values are declared differentially expressed. Adjusted P values may also be used to summarize and compare the results from different multiple testing procedures.

In their 1993 book, Westfall & Young [33] proposed resampling-based P value adjustment procedures that are highly relevant in the context of microarray experiments. In particular, these authors defined adjusted P values for multiple testing procedures that control the FWER and take into account the dependence structure between test statistics (their $\min P$ and $\max T$ adjusted P values). In Dudoit et al. [9] these ideas are applied in the context of microarray data. It is clear that this area is undergoing rapid development.

Classification and Clustering

Microarray experiments have revived interest in both cluster and **discriminant analysis** by raising new methodological and computational challenges. In discriminant analysis, also called supervised learning or class prediction, we might have observations on tumor mRNA samples known to belong to prespecified classes, and the task is to build predictors for allocating new observations to these classes. By contrast, in cluster analysis, also called unsupervised learning or class discovery, the classes are unknown a priori and the task is to determine these classes from the data themselves, i.e. to determine the number of classes and assign each observation to one of these classes. Either experiments or genes or both can be clustered, and the commonest approach uses hierarchical procedures based on correlation as a measure of dissimilarity. Clustering of this kind is currently the most popular way of analyzing gene expression data, undoubtedly because of the power of the technique to group co-expressed genes and hence shed light on the function of uncharacterized genes. For some examples see [3, 11] and [1].

The ability successfully to distinguish between tumor classes (already known or yet to be discovered) using gene expression data is an important aspect of this novel genomic approach to cancer classification. There are already many papers on this topic, and almost every technique from the field of machine learning has already been applied to this problem. How do they compare? Are there advantages to the more recent or more elaborate classification techniques? While it is not possible to give a single long-term answer to this question, it is possible to obtain some insights. The study by Dudoit et al. [8] compared a number of familiar methods for classifying tumors based on gene expression data, including nearest neighbor classifiers, linear discriminant analysis, and classification trees. Two recent machine learning devices known as bagging and boosting were also considered. The discrimination methods were all applied to data sets from three recently published cancer gene expression studies, and the main conclusion, for these data sets, was that simple classifiers

such as diagonal linear discriminant analysis and nearest neighbors performed remarkably well compared with more elaborate ones such as aggregated classification trees. These conclusions may change as the size of data sets grows.

Other Topics

When expression levels are measured for thousands of genes in time and space, a challenging problem is to discover and recognize reproducible temporal expression patterns, including those not previously known. Networks of interacting genes that might suggest new biochemical or signaling pathways are of particular interest. Current approaches to this class of questions with microarray data are rather *ad hoc*, usually involving one- or two-dimensional clustering methods. These methods, typified by Eisen's "heat diagrams" [11], rearrange the order of genes and experiments to map the data onto a plane in a more visually compelling way. The hope is that visual examination of the resulting image will identify patterns to which explanations can be attached. Other researchers rely on multi-dimensional scaling, which uses distances between genes or arrays to produce a scatter plot in the plane for subsequent visual examination.

More systematic approaches are clearly needed, with [17] being one such. This are will undoubtedly attract a great deal of biostatistical research in coming years.

TERRY P. SPEED

Gene Frequency Estimation

Gene frequency estimation refers to the estimation of population frequencies of alleles at a given genetic locus or to the estimation of the population frequencies of **haplotypes**. A haplotype, derived from the term "haploid genotype", refers to the particular set of alleles present at a series of linked loci on a chromosome, i.e. alleles at loci that are present relatively close together on a continuous strand of DNA. Each human being has two haplotypes for any given series of linked autosomal loci; one inherited maternally, and the other, paternally. The haplotype transmitted to an offspring of that individual may be identical to one of these two, or may reflect reshufflings due to recombination events. Allele and haplotype frequencies may be estimated from various types of human data, including information from pedigrees, parent–child dyads, or individuals; however, estimation based upon random samples of individuals is emphasized in this article.

Good estimates of gene frequencies are needed for a variety of purposes: they are essential to the generation of valid risk estimates in the context of **genetic counseling**, and form the basis for population descriptions and comparisons and for decisions about genetic screening of populations. Because of their impact upon **power** considerations, sound estimates of gene frequencies are also helpful in planning genetic studies. Marker allele frequencies are required for the application of certain types of **linkage analysis**, such as the Haseman–Elston model-free approach to sib-pair analysis in the absence of parental marker information [7], and the affected-pedigree-member method of Weeks & Lange [15]. Beyond the specifics of gene frequency estimation methodology outlined here, it must always be borne in mind that the sample from which inferences are made must be drawn from the appropriate population according to the needs of the analysis, and must be of a size to achieve the requisite precision. Care must also be taken that purportedly random samples have not been collected in such a way that it is likely that family members have been included.

Allele Frequency Estimation

When all allelic variants corresponding to a particular locus are codominantly expressed, **genotypes** can be fully discerned on the basis of phenotype, and the estimation of allele frequencies becomes a simple matter of "gene counting". Each individual bears two alleles at a particular locus, so that persons expressing only a single allele are known to be homozygous, possessing two copies of that particular allelic variant (*see* **Heterozygosity**). If a random sample of N individuals is collected, and there are X_i copies of allele A_i among the $2N$ alleles, then the estimator of the allele frequency q_i is $X_i/2N$, the **maximum likelihood** estimator. The **variance** is obtained using the standard **binomial** expression, i.e. $q_i(1-q_i)/2N$. However, if dominance relationships govern the phenotypic expression of genotypes at a given locus (for example, one allele masks the expression of another) the situation becomes more complicated. By way of illustration, suppose there are a number of codominantly expressed allelic variants at a given autosomal locus, and also a null allele that results in no detectable product. Then, individuals who are homozygous for a particular codominant allele cannot be distinguished phenotypically from those heterozygotes who have one copy of that allele and a copy of the null allele – both express only a single allele at the phenotypic level. The "gene counting" approach cannot be used in such instances unless haplotype analysis has been used to clarify exactly which alleles are present at all loci concerned; for example, by examination of transmission among family members [16] (*see* **Genetic Transition Probabilities**).

Whatever the nature of these relationships, a maximum likelihood approach may be taken. Suppose that a random sample of individuals is taken from the relevant population, and that there are K distinguishable phenotypes associated with the locus of interest, indexed by $k = 1, 2, \ldots, K$. Generally, an assumption must be made in order to set up the correspondences between genotype and phenotype, expressed via the allele frequencies; most typically, the **Hardy–Weinberg equilibrium** assumption is made so that the population frequency Φ_k of each phenotype can be expressed as a function of the allele frequencies. On the basis of the observation of n_k individuals with the kth phenotype, the **likelihood** of the sample is given by

$$L \propto \prod_{k=1}^{K} \Phi_k^{n_k}$$

and the ln likelihood as

$$\ln L = \sum_{k=1}^{K} n_k \ln(\Phi_k) + \text{a constant.}$$

For example, consider a locus with a codominant alleles $A_1, A_2, \ldots, A_i, \ldots, A_a$ plus a null allele A_x, which cannot be detected, with population allele frequencies $q_1, q_2, \ldots, q_a, q_x$. Then, there are $\binom{k}{2}$ phenotypes of the type $A_i\ A_j$, which occur with population frequency $2q_iq_j$, and k phenotypes of the type that express only a single allele A_i, which may be either A_i homozygotes or heterozygotes involving a null allele and occur with population frequency $(q_i^2 + 2q_iq_x)$, and a phenotype expressing no allele A_x, which occurs with population frequency q_x^2. If we define the sample counts of these phenotypes analogously, we obtain the log likelihood

$$\ln L = \sum\sum_{i<j} n_{ij} \ln(2q_iq_j) + \sum_i n_i \ln(q_i^2 + 2q_iq_x) + n_x \ln(q_x^2).$$

The estimates of the allele frequencies are obtained using standard iterative methods based upon the maximum likelihood approach, and estimates of the **standard errors** can be derived numerically via the Fisher **information** using standard methods. Excellent initial estimates can be obtained using the method of Bernstein [1]; these estimators are also based upon Hardy–Weinberg assumptions. If f_i denotes the proportion of individuals expressing the ith allele, then the Bernstein estimator is $\tilde{q}_i = 1 - (1 - f_i)^{1/2}$ (since under Hardy–Weinberg expectations this is $1 - [(1 - q_i)^2]^{1/2} = q_i$; q_x is generally estimated by subtraction [8]; and additional refinements of the Bernstein method exist [1, 8].

It may be noted that this same maximum likelihood approach is applicable even in the presence of more complex dominance relationships, and the Bernstein estimators generally provide reasonable initial values for iteration. Furthermore, another source of so-called "null" or "blank" alleles is the technical inability to detect particular alleles. For example, in the case of the **HLA system**, specificities were originally detected serologically, utilizing sera from multiparous women; particular alleles could therefore be designated as "blanks" not because they produced no product, but because the reagents that would permit their detection were not yet available. This led to a decreasing frequency of the blank allele as the entire constellation of alleles at a particular locus eventually came to be identifiable. The subsequent application of molecular techniques revealed that at least some serologically determined "alleles" could be further subdivided.

An alternative approach to allele frequency estimation in the presence of dominance relationships, which also yields the maximum likelihood estimate, employs the **EM algorithm** [3]. From this perspective, the genotypes of individuals may not be fully observable, but can be estimated under a specific genetic model with suitable assumptions, utilizing phenotypic data, which can be observed. Given phenotypic counts, and a provisional estimate of the allele frequencies, the expected numbers of genotypes and so of alleles can be obtained (generally under Hardy–Weinberg assumptions), and the gene counting approach used to update allele frequency estimates. Iteration continues in this manner until convergence; this approach is often referred to as "iterative gene counting" for obvious reasons.

Haplotype Frequency Estimation

If haplotyping has been carried out, then all haplotypes in the sample are known, and haplotype frequency estimation is accomplished in a straightforward manner by a process analogous to the gene counting procedure described previously: the number of haplotypes of a given type are counted and standard binomial theory applied to obtain the point estimates and their estimated standard errors [5]. However, in the absence of such information, haplotype frequencies are more typically estimated from observed phenotypic frequency data, based upon a random sample of individuals. Consider estimation of a particular combination of alleles A_i at the A locus and B_j at the B locus. Under equilibrium conditions, the frequency of the haplotype A_iB_j would be equal to the product of their two allele frequencies, p_i and q_j, respectively; however, this is not true in general, and this displacement from equilibrium is measured by the coefficient of disequilibrium $\Delta_{ij} = h_{ij} - p_iq_j$, where h_{ij} is the population frequency of the A_iB_j haplotype. Alternatively, the observation may be made that

$$h_{ij} = p_iq_j, +\Delta_{ij}.$$

This is the basis of one approach to haplotype frequency estimation [2, 11, 12] in which phenotypic data are first used to estimate the coefficient of disequilibrium under Hardy–Weinberg assumptions, as follows:

$$\Delta_{ij} = \sqrt{f}_{--} - [(f_{+-} + f_{--})(f_{-+} + f_{--})]^{1/2},$$

where f_{--} denotes the proportion of persons with neither the A_i nor the B_j allele, f_{+-} denotes the proportion of persons with the A_i but not the B_j allele, and f_{-+} denotes the proportion of persons with the B_j but not the A_i allele. The relevant allele frequencies, p_i and q_j, are then estimated using the phenotypic data as previously described, and the estimated quantities are then substituted into the equation $h_{ij} = p_i q_j + \Delta_{ij}$ to obtain the estimate of h_{ij}. An alternative iterative approach that provides maximum likelihood estimates [17] can also be employed.

It is important to note that the Hardy–Weinberg assumptions are critical to the estimation of haplotype frequencies from phenotypic data in the situations described. The utilization of such methods in an inappropriate context, such as an inbred population (*see* **Inbreeding**), can lead to invalid and misleading results. Kostyu et al. [10] demonstrated the importance of haplotyping in inbred populations and the dangers of inappropriate application of Hardy–Weinberg assumptions in conjunction with phenotypic data, which could seriously impair inferences about the nature of **linkage disequilibrium** and thereby produce erroneous haplotype frequency estimates. Moreover, it should be noted that very large sample sizes are required to achieve reasonable levels of power to detect deviations from Hardy–Weinberg proportions due to inbreeding in human populations [4] even on the basis of fully codominant systems; therefore, it may be unwise to assume that failure to reject Hardy–Weinberg assumptions for such loci implies that they may be safely made in general, particularly when the presence of inbreeding is known or suspected. In studies of inbred populations, the investigator may attempt to study the entire population. Failing that, it may be advisable to strive for both breadth and depth in sampling on the basis of social and anthropological considerations; for example, sampling from a large number of demographic units, such as colonies, and securing information from a large proportion of the members of each such unit. Other approaches have included restriction of the sample to persons of reproductive age and to considerations of persons of a single gender, such as females in a patrilocal system (e.g. where the woman relocates to the colony of her husband) [9, 13].

Although this treatment has emphasized inference based upon random samples from the population of interest, gene frequency estimates may be obtained from other types of data, although appropriate statistical methods must be employed. Allele frequency estimates may be obtained from family data [3, 6, 14, 16] and are typically estimated jointly with other genetic parameters; for example, in the context of **segregation analysis** of pedigrees [6]. However, such estimates are derived mainly from the information provided by persons marrying into the families in the sample; if the sample consists of many small pedigrees or nuclear families, then one would expect better estimates of allele frequencies than if a few large pedigrees were being analyzed. Furthermore, if the pedigrees were brought into the sample because of the presence of one or more affected individuals, the allele frequency estimates may be affected if the correction for **bias** due to **ascertainment** is not accomplished completely.

Gene

The word *gene* has been, and still is, used with various meanings. The genetic material of higher organisms is DNA (deoxyribonucleic acid), a constituent of the 23 pairs of chromosomes a person has. Each DNA molecule has a sequence of many bases along it (*see* **DNA Sequences**), most of which have no known function. About 3% of the bases code for various products, either polypeptide chains or molecules of ribonucleic acid, and a commonly accepted definition of a gene is a combination of DNA segments that together code for one of these functional units. Genes thus occur in pairs at locations, or loci, along the pairs of chromosomes. Different genes that can occupy the same locus are allelic, or alleles, so that there may be many alleles at a given locus in the population – but only two in any one person. Genes that occupy different loci are nonallelic. A common definition of alleles is given as "different forms of the same gene", so that the term "gene" then means the general type of DNA that occurs at a particular locus, as opposed to an allele, which is a specific sequence of DNA that occurs at the locus. It is unfortunate that the word gene is used with either of these two distinct meanings, perhaps better differentiated as "locus" and "allele". A rough analogy can be made with the distinction between "estimator" and "estimate", the latter being a specific instance of the former. English-speaking writers, earlier writers, and population geneticists have tended to use the word gene with the specific ("allele") meaning, whereas non-English writers, more recent writers, and biochemical geneticists tend to use it with the more general ("locus") meaning. (But biochemical geneticists talk of "cloning genes", meaning alleles.) A further disparity occurs when human geneticists speak of there being "two genes at each locus", whereas Drosophila geneticists speak of "two loci for each gene". Just as statisticians are rarely confused when the word estimate is used when estimator might be better (as in the distribution of an estimate), so are geneticists rarely confused by the word gene, whose exact meaning is always clear (to them) by the context.

ROBERT C. ELSTON

Gene-environment Interaction

The interdependent action of **genes** and environment in disease causality is measured by gene–environment interaction. When interaction exists, the combined action of genes and environment can increase or decrease disease risk beyond that due to purely genetic and purely environmental actions. While Haldane [3] first considered gene–environment interaction over half a century ago, evidence continues to emerge that most diseases do not result from entirely genetic or entirely environmental factors, but rather from a complicated interaction of these factors [7]. In fact, Khoury et al. [5] assert that the basis of **genetic epidemiology** comes from the evolving recognition that gene–environment interactions contribute to the etiology of most diseases.

Types of causal interaction include synergism, whereby both factors are needed for disease to occur, and antagonism, where each factor results in disease only when the other is absent [6]. The relation between the recessive gene for Phenylketonuria (PKU) and dietary phenylalanine in mental retardation provides an example of gene–environment interaction. PKU is a genetic disorder in which phenylalanine metabolism is blocked. The interaction between PKU and blood phenylalanine levels produces an increased risk of mental retardation beyond that resulting from either factor alone [10].

We focus here on statistical **interaction**, which does not necessarily imply interaction on the biological or mechanistic level. Statistical interaction is commonly measured by departures from additivity of effects on the chosen outcome scale. Following [8], let R_{ij} be the average risk when $G = i$ and $E = j$, where $G \in (g, \overline{g})$, $E \in (e, \overline{e})$, and $g(\overline{g})$ indicates the presence (absence) of the genetic factor of interest and $e(\overline{e})$ indicates the presence (absence) of the environmental factor of interest. Then one can express additivity on the risk ratio scale (*see* **Relative Risk**) as

$$\frac{R_{ge}}{R_{\overline{ge}}} = \frac{R_{g\overline{e}}}{R_{\overline{ge}}} + \frac{R_{\overline{g}e}}{R_{\overline{ge}}} - \frac{R_{\overline{ge}}}{R_{\overline{ge}}}. \quad (1)$$

That is to say, the risk ratio due to the combined action of the genetic and environmental effects is simply equal to the sum of the risk ratios for the genetic effect and for the environmental effect (minus the null effect). Departures from (1) indicate statistical interaction on an additive risk ratio scale. Lack of departure from (1), however, implies the existence of statistical interaction on a **multiplicative** risk scale [8]. One can express multiplicativity of the risk ratios as

$$\frac{R_{ge}}{R_{\overline{ge}}} = \frac{R_{g\overline{e}}}{R_{\overline{ge}}} \times \frac{R_{\overline{g}e}}{R_{\overline{ge}}}. \quad (2)$$

That is to say, the risk ratio due to the combined action of the genetic and environmental effects is equal to the product of the risk ratios for the genetic effect and for the environmental effect. If the genetic and environmental exposures of interest are associated with disease (i.e. $R_{g\overline{e}}/R_{\overline{ge}} > 1$ and $R_{\overline{g}e}/R_{\overline{ge}} > 1$), then (1) and (2) can never both be true. Specifically, if (1) is true, then the only way (2) can also be true is if $R_{g\overline{e}}/R_{\overline{ge}} = 1$ or $R_{\overline{g}e}/R_{\overline{ge}} = 1$. Clearly, the opposite is also true (i.e. if both g and e have effects and (2) is true, then (1) cannot be true). Hence, the presence or absence of gene–environment interaction depends on the scale used to measure effects, and statistical interaction on the risk scale implies no interaction on the log risk scale and vice versa [8].

One can use stratified analysis (*see* **Stratification**) to assess gene–environment interaction. Cross-classifying the genetic and environmental factors by disease status and applying statistical techniques such as Woolf's test of homogeneity [11] can provide estimates and tests for interaction. Evaluating multiple potential gene–environment interactions simply requires further stratification, but this can lead to problems in sparse data. Instead, one can use a regression approach to assessing interaction. This entails entering into a **regression** model terms for the genetic and environmental factors, plus a product term for the interaction. For example, suppose that in a **case–control study** one collects genetic data x_g, environmental data x_e, and data on disease status. Then one can estimate the coefficients corresponding to the effects of these exposures on disease by fitting a **logistic regression** model,

$$\Pr(\text{disease} \mid x_g, x_e) = \frac{\exp(\beta_0 + \beta_g x_g + \beta_e x_e + \beta_{g\cdot e} x_g x_e)}{1 + \exp(\beta_0 + \beta_g x_g + \beta_e x_e + \beta_{g\cdot e} x_g x_e)}, \quad (3)$$

to the data. Here, β_0 is an intercept term, β_g is the main effect due to genes, and β_e is the main effect of environment. The coefficient $\beta_{g\cdot e}$ of the product $x_g \times x_e$ estimates the gene–environment interaction on the logit scale. One can evaluate this interaction using the likelihood ratio test of a logistic model without the $x_g \times x_e$ product vs. (1) [1]. When $\beta_{g\cdot e} \neq 0$, a departure from odds-ratio multiplicativity (i.e. interaction on the logit scale) exists. If no interaction exists, this model implies that the odds ratio for each factor (genes or environment) is constant across levels of the other factor.

One can evaluate the numerous potential gene–environment (or gene–gene and environment–environment) interactions expected in multifactorial diseases by incorporating additional product terms (including triple products and more complex combinations) into a regression model. The phrase "*n*-order interactions" refers to interactions where the '*n*' is one less than the number of factors involved. However, interpretation of coefficients from models with many interaction terms can be quite complicated. Finally, one should be aware that detecting gene–environment interactions can require substantially larger sample sizes than are necessary for detecting genetic or environmental effects alone [2, 4], and that gene–environment interactions can be **confounded** by **dose–response** relations [9].

General Linear Model

The term "general linear model" refers to a specific model formulation which relates a **response variable**, Y, to a set of **explanatory variables**, $X_1, \ldots, X_k$. The basic relation is written as

$$y = \beta_0 + \beta_1 x_1 + \cdots + \beta_k x_k + e,$$

where y is the observed value of Y corresponding to an observed set of values for the explanatory variables, $x_1, \ldots, x_k$, and the βs are regression coefficients, which are usually to be estimated. It is further assumed that

$$\mathrm{E}(Y) = \beta_0 + \beta_1 x_1 + \cdots + \beta_k x_k$$

and therefore, that $\mathrm{E}(e) = 0$. Note that the linearity of the model relates to the occurrence of the βs and that the x values may represent nonlinear functions of other variables, polynomial terms and standard **transformations**, such as logarithms, being commonly used.

The general linear model is usually written in vector notation as

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{e},$$

where $\mathbf{y}$ represents a column vector of n Y values, $\mathbf{X}$ is a $n \times K$ matrix with rows corresponding to sets of X values, β is a column vector of regression coefficients, and $\mathbf{e}$ is a column vector of values usually called residual or error terms. The term "design matrix" is often used for $\mathbf{X}$. The variance–**covariance matrix** of $\mathbf{e}$, and therefore of $\mathbf{y}$, is nonnegative definite, and is usually denoted by $\mathbf{V} = \mathrm{E}[\mathbf{y} - \mathrm{E}(\mathbf{y})][\mathbf{y} - \mathrm{E}(\mathbf{y})]'$. A common assumption is that all e values have the same variance, σ^2, and that the covariance of all pairs of e values is zero. In this case, $\mathbf{V} = \sigma^2\mathbf{I}$, where $\mathbf{I}$ is the identity matrix.

Estimation of β does not require further distributional assumptions (*see* **Least Squares**) but it is customary to assume that the es are normally distributed to allow **hypothesis testing** and **interval estimation**. Some authors include the assumption of normal distributions as part of the general linear model formulation.

Many standard statistical models fall into the class of general linear models. These include the models used in **linear regression (simple), multiple linear regression, analysis of variance**, and **analysis of covariance**. See the articles on these topics for a description of inference procedures for the general linear model.

The general linear model is a special case of a **generalized linear model**, a term used to refer to a regression model that relates a function of the mean of a response variable to a linear function of explanatory variables.

VERN T. FAREWELL

General Practice

General or family practice – more generically, primary care – is defined as "the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients and practicing in the context of a family and community" [28].

Strictly speaking, *general or family practice* is the medical element of a much wider set of health care services delivered in community settings. The generic term for such services is *primary care*, which is characterized by the fact that patients usually attend for care on their own initiative. General practice is therefore distinguished from secondary (hospital) and tertiary (specialist center) care in that it is immediately available to the population, without the need for referral from other agencies. Although such referrals can and do take place, in the UK about a half of all consultations with doctors in general practice are patient-initiated [34].

It is of course true that the precise nature of effective access to such services (and in particular the funding of it (*see* **Health Care Financing**)) varies from one health care system to another. There are nevertheless a number of common features which are pertinent to the biostatistical issues which arise in the specialty. The most important of these is that the medical conditions which are seen most commonly by family doctors are, quite literally, those that occur commonly in the community (*see* **Community Medicine**). Examples include acute upper respiratory tract infection, low back pain, accidents, and problems associated with the ageing process such as osteoarthritis. In general practice, the old adage of "when you hear the sound of hooves, think of horses not zebras" is particularly apt. The reverse of this coin is that conditions which to specialists appear quite often, such as cancer of the lung or breast and even acute myocardial infarction, are relatively rare in general practice.

The common presenting conditions also include those of a chronic, multifactorial nature. The psychological and social aspects of general practice thus require a multidisciplinary approach to care. They have also led to an emphasis on both organizational issues and on care of the family, rather than just purely medical treatment by doctors for individual patients. Concomitantly, research in general practice is necessarily multidisciplinary, incorporating qualitative as well as quantitative methodologies.

Biostatistical Issues in General Practice

Clearly, many of the biostatistical issues which arise in general practice are the same as in many if not all such areas of application. Even some of these common issues take on a particular flavor, though. For example, consider the importance of estimating the magnitude of differences between groups of subjects using **confidence intervals** rather than just relying on statistical significance (*see* **Hypothesis Testing**) [46]. With the large numbers of individuals often available for community-based studies, confidence intervals are necessary to portray possibly excessive precision (for example, where effects of negligible clinical importance are nevertheless statistically significant; (*see* **Clinical Significance Versus Statistical Significance**) as well as to highlight inadequate **power** when sample sizes are too small. Another example is that the wide variety of sources of (systematic and random) differences between subjects means that the advantage in comparative studies of random allocation (*see* **Randomization**) over nonrandom allocation followed by statistical adjustment for **confounding** effects, is arguably particularly marked in a community setting.

The methodologies discussed in detail here, though, will be a selection of those which have a specific relevance to the specialty, although few if any of them are solely applicable to general practice. First, there is the issue of ascertaining the basic pattern of demand and symptomatology in general practice, and variation in referral to secondary care. Next there are methodological aspects of **clinical epidemiology** – such as **screening** and **diagnostic tests** – which have particular relevance. Lastly, issues in the design and analysis of randomized controlled trials (*see* **Clinical Trials, Overview**) in general practice will be discussed.

Observational Studies

Routine Statistics

The key difficulties are in ascertaining the correct numerators and **denominators** for assessing patterns of demand and levels of morbidity in general

practice [32, 34, 35]. A particular problem has been obtaining valid and reliable estimates of the population at risk. For example, Morrell et al. [34] applied corrections to their observed denominators by using simple **regression** techniques to adjust for changes in registrations, including those who were at risk but not registered with the study practice. The ongoing process of computerization of registers, both practice- and community-based, ameliorates this problem but does not obviate the need for such statistical considerations.

The difficulties are compounded in developing countries, where two-fifths of the population have been estimated to be outside the health care system [10]. In this context, methods based on **cluster sampling** for health **surveys** have been extensively developed and widely used [3, 10, 31].

More recent developments in the use of routine statistics in general practice have included investigations of referrals to (usually expensive) secondary services. These studies have often been based on the assumption of the **Poisson distribution**, both in the context of statistical models for observed data or computer **simulation** techniques [2, 15, 33].

Cluster Sampling

This is a special case of **multistage sampling** [1, 11], where *all* the second stage units (for example, individuals) are selected within the first stage units sampled (such as households). The biostatistical issues relate to the two concepts of *accuracy* (systematic **bias**) and *precision* (sampling error). **Unbiased** estimates are as usual obtained by *equal probability of selection methods* (epsem), which for multistage sampling depends on whether fixed numbers or fixed proportions of second stage units are sampled. For the latter (which is the case in cluster sampling where the sampling fraction is 100% for the second stage units), **simple random sampling** or **stratified sampling** of first stage units is required [1, 37].

The statistical theory of sampling errors in such designs is well established [11, 30]. Whether for sample size planning or for estimating precision and confidence intervals, at issue is the calculation of the **design effect** (or *inflation factor* or *Kish design effect*) to allow for the inefficiency of this design compared with single stage random sampling. There are two general approaches: one requiring an estimate of the **variance** between the clusters [14, 31]; the other requiring an estimate of the *intracluster* (more generally, *intraclass*) **correlation** *coefficient* [3, 22]; for more details, see the section below on Cluster Randomization. In either case, although there is no practical constraint on an estimate of the design effect, in general the consequence is to increase standard errors.

Clinical Epidemiology

Screening and Diagnostic Tests

An example of a methodologic aspect of clinical epidemiology which is particularly relevant to general practice is the effect of the **prevalence** of the condition on the standard performance statistics for screening and diagnostic tests [25, 42]. In particular, the *positive* **predictive value** (probability of disease among subjects with a positive test result) falls as the underlying prevalence decreases, even if the **sensitivity** (ability of the test to detect the disease) and **specificity** (ability of the test to exclude the disease) remain unaltered. For example, a test with 70% sensitivity and 90% specificity for prostatic cancer gave a positive predictive value of 93% for a group of patients with a particular clinical symptom. For patients in a general practice population, however, the same test yielded a positive predictive value below 0.5% [25]. This fundamental point is not altered by employing more sophisticated statistical measures such as **likelihood ratios** for positive and negative test results (used in conjunction with **Bayes' Theorem** to update pre-test to post-test probabilities of disease) and **receiver operating characteristic (ROC) curves** (plots of sensitivity against 1-specificity).

In summary, diagnostic tests which are highly useful in a secondary care environment may well be of no practical value in general practice, where the test conditions are likely to be relatively rare. This is one reason why screening in a general population is often difficult to justify [38].

Agreement

The issue of *interobserver* **agreement** often arises in research in general practice, particularly in the context of **health status** measurement [47]. For continuous variables, simple correlation coefficients are inappropriate as measures of agreement; rather, the

analysis should be based on paired differences [5]. Tests and confidence intervals, for example on (paired) mean differences, assess the "bias" of one assessment relative to the other. Assuming a **normal distribution** for the differences, 1.96 **standard deviations** (of the differences) either side of the mean difference forms a 95% reference range for the paired differences, or *limits of agreement* [5]. A plot of each paired difference against the mean of the respective two measurements portrays the agreement graphically, and may suggest that a logarithmic **transformation** would be worthwhile.

For noncontinuous variables, the most widely used measure of agreement is the **kappa statistic** κ [12]. Specifically, kappa measures chance-corrected agreement, with the option of introducing weights for different levels of disagreement where there are more than two ordered categories [1, 13, 24]. If quadratic weights are employed (that is, weights proportional to the square of the discrepancy on the original scale), then, apart from terms in 1/(sample size), *weighted kappa* is equivalent to the intraclass correlation coefficient [1, 47].

For a **binary** variable, unweighted kappa is equivalent to the intraclass correlation coefficient using scores of 0 and 1 [22, 47]. **McNemar's test** for paired proportions may be used to ascertain whether there is evidence that the discrepancy is in a particular direction, but this is difficult to interpret without also bearing in mind the extent of disagreement overall.

Randomized Controlled Trials

Design

The key biostatistical features of designing randomized controlled trials (RCTs) in general practice are that they should be essentially *pragmatic* rather than *explanatory* [43], and that the unit of randomization is often not the individual but a group of individuals (*see* **Group-randomization Designs**) [21]. In addition, by the nature of the context, selection criteria for entry into such trials should be inclusive rather than exclusive (*see* **Eligibility and Exclusion Criteria**). In more general terms, all aspects of their design should be realistic, recognizing and allowing for the limitations in respect of, for instance, **blinding** and contamination.

Pragmatic RCTs are where the interventions are designed to be as close as possible to the situations in which they would be applied [43]. In this way, the *efficacy* of an intervention (performance under ideal circumstances) which RCTs evaluate is brought as close as possible to *effectiveness* (performance under everyday circumstances) (*see* **Pharmacoepidemiology, Adverse and Beneficial Effects**) [4, 38]. The primary data analyses should be on an **intention-to-treat** basis, comparing the groups as they were randomized. Comparing subjects in terms of intervention actually received (the explanatory approach) will in general be biased since it does not correspond to the random allocation; nevertheless, secondary analyses of this kind will often be worthwhile. Even in the primary analysis the impact of missing outcome data should not be ignored [27], and different assumptions regarding missing values may well need to be the subject of sensitive analyses [41].

The second key feature is allocation of groups rather than individual subjects – that is, *cluster randomization*. As indicated in the section above on Cluster Sampling, the effect of this is to reduce the efficiency of the trial; all other things being equal, then, the sample sizes of such trials will need to be larger. **Sample size determination** for cluster-randomized trials has received considerable attention in epidemiological and statistical journals [14, 16, 22, 45], although it has until recently been relatively neglected in the applied primary care literature [7–9]. In such applications, the cluster is usually the general practice, though it may be individual practitioners. The design is considered as an option because of the likelihood of contamination between the interventions if they are conducted within the same practice.

There has been debate about the importance of removing the effect of contamination in the study design [49]. Cluster randomized trials are, however, likely to remain a reasonable option and the UK Medical Research Council is currently developing guidelines regarding their design, conduct and presentation. Certainly, leaving adjustments for contamination to the analysis has dangers in terms of the ability to estimate and control for it adequately; moreover, any such adjustment for extraneous variables in the primary analysis of the trial runs the risk of interfering with the central principles of an intention-to-treat analysis [27].

As noted above, the two general approaches to sample size planning require prior estimation of either the *intercluster variation* [14, 31] or the *intracluster correlation coefficient* [3, 22]. While the latter is

at least potentially more generalizable, particularly for small clusters, these methods are related [22]. In practice, though, the choice will often depend on the type of prior information available. Basically, each obtains an *inflation factor* as the inverse of the *relative efficiency* of cluster randomization compared with individual randomization. The sample size requirement calculated using standard methods for individual randomization is then multiplied by this inflation factor [16].

The first approach, described by Cornfield [14] for comparing a binary outcome between two interventions, obtains the inflation factor as $\mathrm{IF} = (c\sigma^2)/[p(1-p)]$, where c is the mean cluster size, and p and σ^2 are the mean and (population) variance, respectively, of the cluster-specific proportions. The second, described by Donner et al. [22] for continuous and binary outcome variables, calculates $\mathrm{IF} = 1 + (c-1)\rho$, where c is as before and ρ is the intracluster correlation coefficient [16, 22, 30]. For binary variables, the latter is equivalent to the kappa statistic, κ, described above [12, 24].

From the second approach it is clear that if $\kappa = 0$ (the case of "mavericks" when individuals within clusters are no more similar to one another than individuals randomly selected from the population), then the inflation factor is unity – the cluster design introduces no additional inefficiency over individual randomization. At the other extreme, $\kappa = 1$ (the case of "clones" within clusters) and $\mathrm{IF} = c$; the sample size is then effectively the number of clusters.

In the context of binary outcomes in general practice, the values of κ observed are quite small – for instance, of the order of 0.05 for controlled hypertension [23]. Given the proportional relationship of the **design effect** with cluster size, however, apparently small clustering effects in terms of κ can translate into large design effects when the number of individuals per practice is large. To offset this inefficiency, such designs should almost always be accompanied by features that improve efficiency, such as **stratification** and applications of **factorial** and **Latin square designs** [1]. In fact, the efficiency benefits of stratification are in general even more marked for cluster randomization than for individual randomization [30]. In addition, stratified randomization to ensure balance in respect of key variables is likely to be essential in the (common) situation where the number of clusters is relatively small.

Analysis

It is essential that the statistical analysis of data from RCTs does at least at some point take into account any complex design features such as stratification and cluster randomization [14, 16, 21, 50]. While a simple (unadjusted) analysis may be helpful initially, the effects of adjustments for such characteristics should at some point be ascertained. For instance, having stratified for a variable in the design, only conditioning on this factor in the analysis will achieve both unbiased estimates and maximize efficiency [44].

This can be achieved by the use of either corrections to basic analytic procedures, or **generalized linear models**, with for example fixed effects terms for any stratification variables [17–20]. For variables representing clusters which have been randomized – practices, for example – one approach is to represent these by **random effects** terms in an appropriate model [18]. Whatever the magnitude of the effect of these corrections, the key trial comparisons derived from relatively complex models can be presented (in terms of statistical significance and confidence intervals) just as simply as the corresponding results from unweighted analyses such as t tests (*see* **Student's *t* Statistics**).

The most general approach to all the above analytic issues, though, is by **multilevel modeling** [18, 26, 40]. Such models are, of course, not restricted to studies (experimental or observational) where the clustering is explicitly taken into account in the design. As mentioned earlier, general practice is implicitly characterized by a variety of sources of variation at a number of levels.

Anticipated Developments and Unresolved Problems

The unresolved problems generally take one of two forms. The first is the ascertainment of the magnitude of the benefit which will accrue in general practice research by the application of the more complex of the methods described above. To achieve this, both methodologic work and applied research is needed – for instance, only rarely in the literature are values of intracluster correlation coefficients quoted [123], although this situation is improving [50]. In addition, research is needed into the circumstances in which either Cornfeld's or Donner's approaches to sample size determination is to be preferred, and also into circumstances in which one or both corrections appear

not to be applicable – for example, when an estimated inflation factor is less than unity. Further investigation is also required into whether there are any patterns in the number and nature of the major sources of variation in suitable multilevel models in general practice.

The second general challenge is for research into the relative values of different study designs in evaluating interventions in general practice [4]. This includes the value of large amounts of routinely collected data, particularly as computer technology in general practice becomes more widespread and better developed for this purpose. Clearly, though, the issues of validity and reliability remain even with computerization. Moreover, with observational data (particularly in a context such as general practice with many sources of potentially major variation), comparability in terms of **case mix** will continue to be difficult to establish.

Overall, randomized controlled trials in general practice have met many practical problems – for example, recruitment of practitioners and subjects, objections to **randomization**, and poor subsequent **compliance** [29, 48]. This has led many to question their central role as the **gold standard** for evaluating interventions [39], calling for a role for observational studies [4] and the *patient preference trial*, where patients who express a strong preference are given their choice and only the remainder are randomized [6, 29]. A further possibility is the *comprehensive cohort*, where randomized subjects are nested within a wider cohort of individuals who for one reason or another were not included in the trial [36]. To date, all these alternatives remain either relatively little developed, or controversial, or both. Whilst further methodologic and applied research in general practice will no doubt continue on these and similar approaches, the central role of the pragmatic randomized controlled trial will undoubtedly continue in general practice research.

T.J. PETERS

Generalized Additive Model

In the statistical analysis of **clinical trials** and **observational studies**, the identification and adjustment for **prognostic factors** is an important component. Valid comparisons of different treatments requires the appropriate adjustment for relevant prognostic factors. The failure to consider important prognostic variables, particularly in observational studies, can lead to errors in estimating treatment differences. In addition, incorrect modeling of prognostic factors can result in the failure to identify nonlinear trends or threshold effects on survival.

This article describes flexible statistical methods that may be used to identify and characterize the effect of potential prognostic factors on an outcome variable. These methods are called "generalized additive models", and extend the traditional **general linear model**. They can be applied in any setting in which a linear or **generalized linear model** is typically used. These settings include standard continuous response **regression**, **categorical** or **ordered categorical** response data, count data, **survival** data and **time series**.

One of the most commonly used statistical models in medical research is the **logistic regression** model for **binary data**. We use it here as a specific illustration of a generalized additive mode. Logistic regression (and many other techniques) model the effects of prognostic factors x_j in terms of a linear predictor of the form $\sum x_j\beta_j$, where the β_j are parameters. The generalized additive model replaces $\sum x_j\beta_j$ with $\sum f_j(x_j)$, where f_j is a unspecified ("nonparametric") function. This function is estimated in a flexible manner using a scatterplot smoother (*see* **Graphical Displays**). The estimated function $\hat{f}_j(x_j)$ can reveal possible nonlinearities in the effect of x_j.

We first give some background on the methodology, and then discuss the details of the logistic regression model and its generalization. Some related developments are discussed in the last section.

Smoothing Methods and Generalized Additive Models

The building block of the generalized additive model algorithm is the scatterplot smoother. We will first describe scatterplot smoothing in a simple setting, and then indicate how it is used in generalized additive modeling.

Suppose that we have a scatterplot of points (x_i, y_i) such as that shown in Figure 1. Here y is a **response** or outcome variable, and x is a prognostic factor. We wish to fit a smooth curve $f(x)$ that summarizes the dependence of y on x. If we were to find the curve that simply minimizes $\sum[y_i - f(x_i)]^2$, the result would be an interpolating curve that would not be smooth at all.

The cubic **spline** smoother imposes smoothness on $f(x)$. We seek the function $f(x)$ that minimizes

$$\sum[y_i - f(x_i)]^2 + \lambda \int f''(x)^2 \, \mathrm{d}x. \qquad (1)$$

Notice that $\int f''(x)^2$ measures the "wiggliness" of the function f: linear fs have $\int f''(x)^2 = 0$, while nonlinear fs produce values greater than zero. λ is a nonnegative smoothing parameter that must be chosen by the data analyst. It governs the tradeoff between the **goodness of fit** to the data (as measured by $\sum[y_i - f(x_i)]^2$) and wiggliness of the function. Larger values of λ force f to be smoother.

For any value of λ, the solution to (1) is a cubic spline; that is, a piecewise cubic polynomial with pieces joined at the unique observed values of x in the dataset. Fast and stable numerical procedures are available for computation of the fitted curve. The right panel of Figure 1 shows a cubic spline fit to the data.

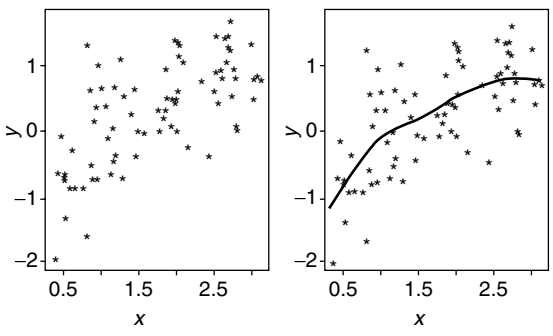

Figure 1 The left panel shows a fictitious scatterplot of an outcome measure y plotted against a prognostic factor x. In the right panel, a scatterplot smoother has been added to describe the trend of y on x

What value of λ did we use in Figure 1? In fact, it is not convenient to express the desired smoothness of f in terms of λ, as the meaning of λ depends on the units of the prognostic factor x. Instead, it is possible to define an "effective number of parameters" or "**degrees of freedom**" of a cubic spline smoother, and then use a numerical search to determine the value of λ to yield this number. In Figure 1 we chose the effective number of parameters to be 5. Roughly speaking, this means that the complexity of the curve is about the same as a **polynomial regression** of degree 4. However, the cubic spline smoother "spreads out" its parameters in a more even manner, and hence is much more flexible than a polynomial regression. Note that the degrees of freedom of a smoother need not be an integer.

The above discussion tells how to fit a curve to a single prognostic factor. With multiple prognostic factors, if x_{ij} denotes the value of the jth prognostic factor for the ith observation, we fit the additive model

$$\hat{y}_i \approx \sum_j f_j(x_{ij}). \tag{2}$$

A criterion such as (1) can be specified for this problem, and a simple iterative procedure exists for estimating the f_js. We apply a cubic spline smoother to the outcome $y_i - \sum_{j \neq k} \hat{f}_j(x_{ij})$ as a function of x_{ik}, for each prognostic factor in turn. The process continues until the estimates $\hat{f}_k$ stabilize. This procedure is known as "backfitting", and the resulting fit is analogous to a multiple regression for linear models.

When generalized additive models are fit to binary response data (and in many other settings), the appropriate error criterion is a penalized log likelihood or a penalized log partial-likelihood (*see* **Penalized Maximum Likelihood**). To maximize it, the backfitting procedure is used in conjunction with a **maximum likelihood** or maximum **partial likelihood** algorithm. The usual Newton–Raphson routine (*see* **Optimization and Nonlinear Equations**) for maximizing log likelihoods in these models can be cast in an IRLS (iteratively reweighted least squares) form (*see* **Generalized Linear Model**). This involves a repeated weighted linear regression of a constructed response variable on the covariates: each regression yields a new value of the parameter estimates which give a new constructed variable, and the process is iterated. In the generalized additive model, the weighted linear regression is simply replaced by a weighted backfitting algorithm. Details can be found in [7, Chapter 6].

The Generalized Additive Logistic Model

Generalized additive models can be used in virtually any setting in which linear models are used. The basic idea is to replace $\sum x_{ij}\beta_j$, the linear component of the model with an additive component $\sum f_j(x_{ij})$.

In the logistic regression model the outcome y_i is 0 or 1, with 1 indicating an event (such as death or relapse of a disease) and 0 indicating no event. We wish to model $p(y_i|x_{i1}, x_{i2}, \ldots, x_{ip})$, the probability of an event given prognostic factors $x_{i1}, x_{i2}, \ldots x_{ip}$. The linear logistic model assumes that the log odds are linear:

$$\log \frac{p(y_i|x_{i1}, \ldots, x_{ip})}{1 - p(y_i|x_{i1}, \ldots, x_{ip})} = \beta_0 + x_{i1}\beta_1 + \cdots + x_{ip}\beta_p. \tag{3}$$

The generalized additive logistic model assumes instead that

$$\log \frac{p(y_i|x_{i1}, \ldots, x_{ip})}{1 - p(y_i|x_{i1}, \ldots, x_{ip})} = \beta_0 + f_1(x_{i1}) + \cdots + f_p(x_{ip}). \tag{4}$$

The functions $f_1, f_2, \ldots, f_p$ are estimated by an **algorithm** like the one described earlier.

To illustrate this, we describe a study on the survival of children after cardiac surgery for heart defects [13]. The data were collected during the period 1983–1988. A pre-operation warm-blood cardioplegia procedure, thought to improve chances for survival, was introduced in February 1988. This was not used on all of the children after February 1988, only on those for which it was thought appropriate and only by surgeons who chose to use the new procedure. The main question is whether the introduction of the warming procedure improved survival; the importance of risk factors age, weight, and diagnostic category is also of interest.

If the warming procedure was given in a randomized manner, we could simply focus on the post-February 1988 data and compare the survival of those who received the new procedure to those who did not. However, allocation was not random, so we can only

try to assess the effectiveness of the warming procedure as it was applied. For this analysis, we use all of the data (1983–1988). To adjust for changes that might have occurred over the five-year period, we include the data of the operation as a covariate. However, operation date is strongly confounded with the warming operation and thus a general nonparametric fit for date of operation might unduly remove some of the effect attributable to the warming procedure. To avoid this, we allow only a linear effect for operation date. Hence we must assume that any time trend is either a consistently increasing or decreasing trend.

We fit a generalized additive logistic model to the binary response death, with smooth terms for age and weight, a linear term for operation date, a categorical variable for diagnosis, and a binary variable for the warming operation. All the smooth terms are fitted with four degrees of freedom.

The resulting curves for age and weight are shown in Figure 2. As one would expect, the highest risk is for the lighter babies, with a decreasing risk over 3 kg. Somewhat surprisingly, there seems to be a low risk age around 200 days, with higher risk for younger and older children. Note that the numerical algorithm is not able to achieve exactly four degrees of freedom for the age and weight terms, but 3.80 and 3.86 degrees of freedom, respectively.

An analysis of deviance (*see* **Generalized Linear Model**) can be carried out for inference from a generalized additive model, analogous to that done for generalized linear models. The only new twist is estimation of the degrees of freedom or effective number of parameters of the fitted model, which was discussed in the previous section. This analysis shows that the warming procedure is strongly beneficial to survival. There are strong differences in the diagnosis categories, while the estimated effect of operation date is not large.

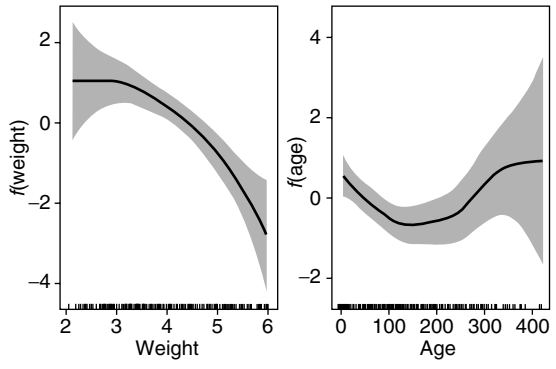

Figure 2 Estimated functions for weight and age for warm cardioplegia data. The shaded region represents twice the pointwise asymptotic standard errors of the estimated curve

Since a logistic regression is additive on the logit scale but not on the probability scale, a plot of the fitted probabilities is often informative. Figure 3 shows the fitted probabilities broken down by age and diagnosis, and is a concise summary of the findings of this study. The beneficial effect of the treatment at the lower weights is evident. As with all nonrandomized studies, the results here should be interpreted with caution. In particular, one must insure that the children were not chosen for the warming operation based on their prognosis. To investigate this, we perform a second analysis in which a **dummy variable** (say, period), corresponding to before vs. after February 1988, is inserted in place of the dummy variable for the warming operation. The purpose of this is to investigate whether the overall treatment strategy improved after February 1988. If this turns out not to be the case, it will imply that warming was used only for patients with a good prognosis, who would have survived anyway. A linear adjustment for operation date is included as before. The results are qualitatively very similar to the first analysis: age and weight are significant, with effects similar to those in Figure 2; diagnosis is significant, while operation date (linear effect) is not. Period is highly significant. Hence there seems to be a significant overall improvement in survival after February 1988. For more details, see [13].

Discussion

The nonlinear modeling procedures described here are useful for two reasons. First, they help to prevent model misspecification, which can lead to incorrect conclusions regarding treatment efficacy. Secondly, they provide information about the relationship between prognostic factors and disease risk that is not revealed by the use of standard modeling techniques. Linearity always remains a special case, and thus simple linear relationships can be easily confirmed with flexible modeling of covariate effects.

The most comprehensive source for generalized additive models is [7], from which the example was

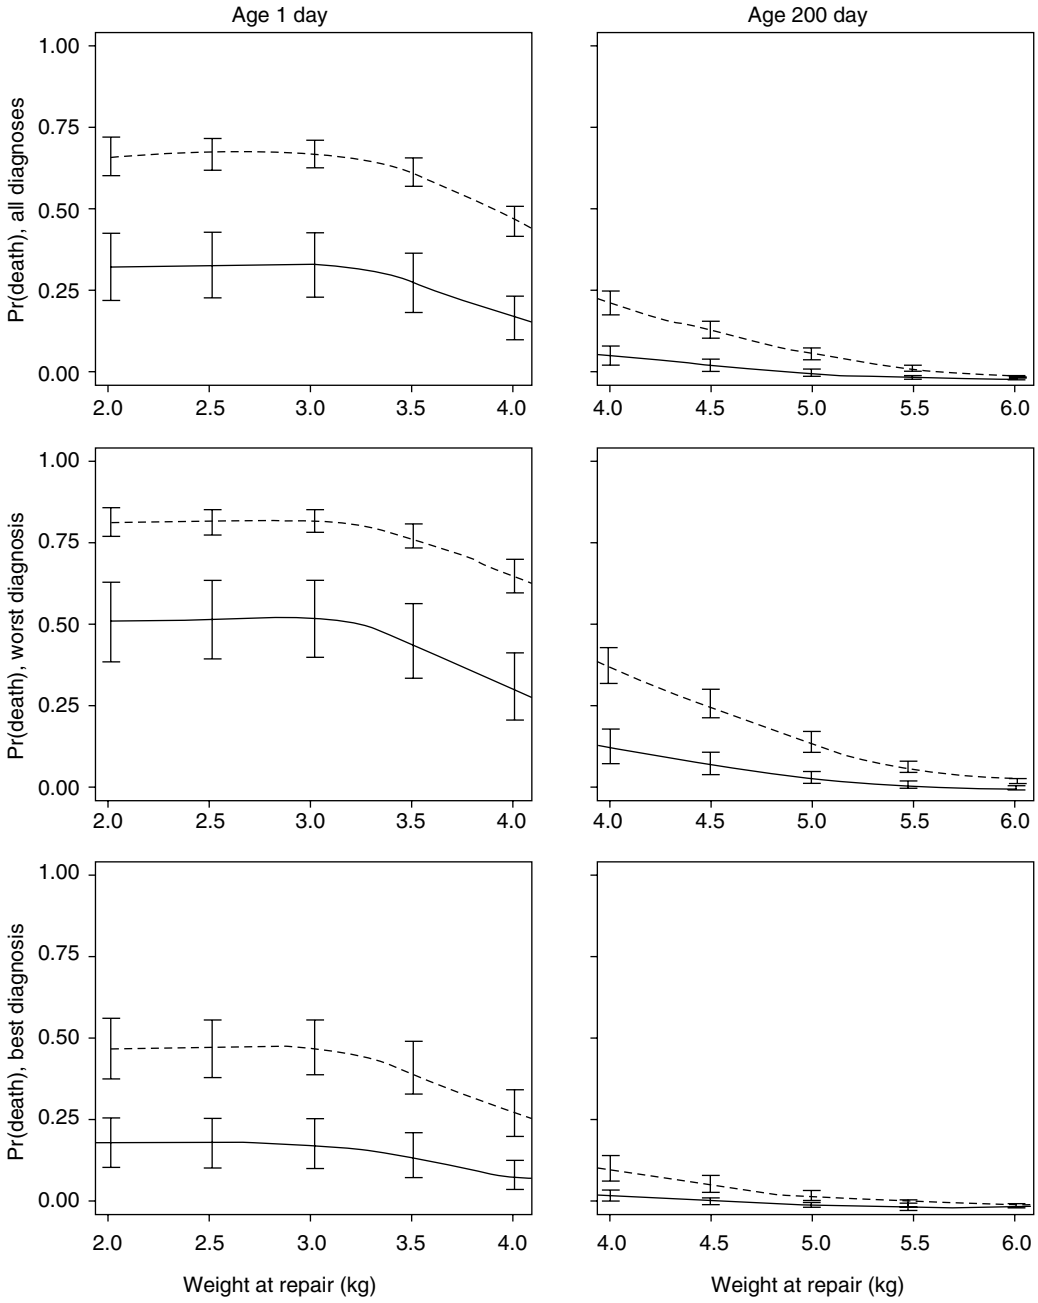

Figure 3 Estimated probabilities for warm cardioplegia data, conditioned on two ages (columns) and three diagnostic classes (rows). The broken line is standard treatment; the solid line is warm cardioplegia. Bars indicate ± 1

taken. A detailed example of the use of generalized additive models in the **proportional hazards** setting is given in [10]. Other medical applications are discussed in [6] and [9]. Penalization and spline models in a variety of settings are discussed in [5], and [12] is a good source for the mathematical background of spline models. See also [3] for an exposition of modern developments in statistics (including generalized additive models), for a nonmathematical audience.

There has been some recent related work in this area. A different method for flexible hazard modeling is described in [11] and a generalization of additive modeling that finds **interactions** among prognostic factors is proposed in [4]. Of particular interest in the **proportional hazards** setting is the *varying coefficient* model [8] (*see* **Semiparametric Regression**), in which the parameter effects can change with other factors such as time. The model has the form

$$h(t|x_{i1}, \ldots, x_{ip}) = h_0(t) \exp \sum_{j=1}^{p} \beta_j(t) x_{ij}. \qquad (5)$$

The parameter functions $\beta_j(t)$ are estimated by scatterplot smoothers in a similar fashion to the methods described earlier. This gives a useful way of modeling departures from the proportional hazards assumption by estimating the way in which the parameters β_j change with time.

Software for fitting generalized additive models is available in the **S/SPLUS** statistical environment [1, 2], in a FORTRAN program called gamfit available at statlib (in general/gamfit at the ftp site `lib.stat.cmu.edu`) and also in the GAIM package for MS-DOS computers, available from the authors.

Generalized Estimating Equations

It is common practice in statistical modeling, as epitomized in the **generalized linear model**, to divide variation in some measure into a systematic part and a random part. The validity of classical **maximum likelihood** inference for such models depends upon the correct choice of model for both parts, including a specific choice of distribution for the random part. Typically, substantive theory guides the construction of the model for the systematic part (*see* **Model, Choice of**). For the random part, although some guidance may be obtained from knowledge of the distributional consequences of a simple and plausible **stochastic process** that might be responsible for this variation, and from experience gained with other comparable data, we rarely have complete confidence in our choice of distribution. This is of especial concern where samples are too small to allow scope for detailed checking of the distributional assumptions, where a **multivariate distribution** must be specified for the random part, and where the available forms of multivariate distribution lack flexibility. This describes well the circumstances that we face with many longitudinal datasets, and where it is often helpful to use "generalized estimating equations" (GEEs) [11]. The GEE approach, while making weaker distributional assumptions than those required for a fully parametric **likelihood**-based model, maintains the properties of **consistency** and asymptotic normality of parameter estimates [8] (*see* **Large-sample Theory**). The description of GEE methods presented here focuses on their use with longitudinal data. However, these methods are also applicable to other forms of multivariate or correlated response data including, for example, studies involving clustered or multistage sampling and the joint analysis of several response features.

Tables 1 and 2 provide simple examples of the kind of longitudinal data at issue. Table 1, from [4], concerns 56 patients from one center (center 1) in a **multicenter** treatment trial for a respiratory disease, with a **binary** self-rated response variable measured at a baseline and on four subsequent occasions. The effects of interest are those for the *time-constant* or *between-subjects* variables for treatment (active

vs. placebo), and age of the subject and the *time-varying* or *within-subjects* effect of time. Table 2, from [34], gives data of a very similar structure, but here concerned with a 59 patient treatment trial (0 = placebo, 1 = progabide) for epilepsy, where the response measure is a count reflecting the number of seizures within four successive intervals of 2 weeks. In both datasets a pretreatment baseline measure of the response was also taken. In models fitted later in this article this baseline measure has been included as an additional **covariate**, in the style of **analysis of covariance** (*see* **Baseline Adjustment in Longitudinal Studies**).

The **multivariate normal distribution** provides the basis of many methods for analyzing longitudinal continuous responses. Since the normal distribution can be linked to a binary response through its cumulative distribution function, the probit, it is not surprising that methods based on the multivariate probit likelihood have been proposed for multivariate binary data, such as that of Table 1 (*see* **Quantal Response Models**). However, the probit does not have a closed form, and requires the use of moment-based approximations typically requiring large samples (e.g. [25]) or computationally intensive numerical quadrature (e.g. [9]). The probit scale also lacks some of the desirable properties of the log **odds** scale, for example the ability to estimate the same effect from both retrospective **case–control studies** and prospective **cohort studies**. However, multivariate generalizations of the logistic distribution lack the flexibility of the multivariate normal.

For the **multinomial distribution** the same parameters occur in both the first and higher-order **moments** of the distribution, and no model exists that can simultaneously produce simple expressions, in terms of model parameters, for the joint, marginal, and conditional distributions [15]. Similar considerations often apply with other types of data with which we are faced. Thus, an important

preliminary consideration before embarking on longitudinal analysis of discrete data is to decide which effects should be directly parameterized in the model, and which represented only by more complex functions of those parameters or treated as a nuisance. This is the rationale underlying the GEE approach, which for the most part is concerned with how to make inference about the marginal regression parameters of a generalized linear model (GLM), and to a lesser extent with the association among responses.

Generalized Linear Models

GLMs cover a range of models in common use in medical statistics, including Gaussian **linear regression**, **logistic regression**, and **loglinear models** for count data. As described in **Generalized Linear Model**, the general class of model requires the specification of a link function that relates the mean response to a vector of covariates $\mathbf{X}_i$ and a variance function that relates the variance of the response to the mean. Then, for any response with a distribution that is a member of the **exponential family**, the likelihood L_i can be expressed as $L_i = f(y_i) = \exp\{[y_i\theta_i - b(\theta_i)]/a(\phi) + c(y_i, \phi)\}$, where in canonical form $\theta_i = \eta_i = \mathbf{X}_i\boldsymbol{\beta}$, $\mathrm{E}(y_i) = \mu_i = b'(\theta_i)$, and $\mathrm{var}(y_i) = b''(\theta_i)a(\phi)$. In the case of binary logistic regression $b(\theta_i) = \log(1 + \mathrm{e}^{\theta_i})$ and $\phi = 1$, while **Poisson regression** for a count response has $b(\theta_i) = \mathrm{e}^{\theta_i}$ again with $\phi = 1$.

For any members of this wide class of models, maximum likelihood estimates of the regression coefficients $\boldsymbol{\beta}$ can be obtained by an iterative weighted least squares solution (*see* **Generalized Linear Model**) to the score equations (the derivatives of L_i with respect to the regression parameters)

$$U(\boldsymbol{\beta}) = \sum_{i=1}^{n} \left(\frac{\partial \mu_i}{\partial \boldsymbol{\beta}}\right)^{\mathrm{T}} v_i^{-1}\{Y_i - \mu_i(\boldsymbol{\beta})\} = 0, \quad (1)$$

where $\{v_i^{-1}\}$ are weights derived from the variance function $v_i = \mathrm{var}(Y_i)$. The large sample **covariance matrix** of the parameter estimates is given by the inverse of the Hessian $\mathbf{H}_1(\boldsymbol{\beta})$

$$\hat{\mathbf{H}}_1(\boldsymbol{\beta}) = \sum_{i=1}^{n} \left(\frac{\partial \mu_i}{\partial \boldsymbol{\beta}}\right)^{\mathrm{T}} v_i^{-1} \left(\frac{\partial \mu_i}{\partial \boldsymbol{\beta}}\right). \quad (2)$$

Huberized/Sandwich Estimator of a Sample Covariance Matrix

The validity of the covariance matrix based on (2) depends upon the correctness of the specification of the variance function. An alternative estimator for the covariance matrix that provides a consistent estimate even when the specification of the variance function is incorrect is the so-called "sandwich" estimator $\mathbf{H}_1^{-1}(\boldsymbol{\beta})\mathbf{H}_2(\boldsymbol{\beta})\mathbf{H}_1^{-1}(\boldsymbol{\beta})$, where

$$\hat{\mathbf{H}}_2(\boldsymbol{\beta}) = \sum_{i=1}^{n} \left(\frac{\partial \mu_i}{\partial \boldsymbol{\beta}}\right)^{\mathrm{T}} v_i^{-1}\{Y_i - \mu_i(\boldsymbol{\beta})\} \times \{y_i - \mu_i(\boldsymbol{\beta})\}^{\mathrm{T}} v_i^{-1} \left(\frac{\partial \mu_i}{\partial \boldsymbol{\beta}}\right). \quad (3)$$

The "bread" of the sandwich is the standard covariance matrix estimator and the sandwich is the cross-product of the empirical scores [13, 37, 38]. This is also known as the **robust** or "heteroscedastic consistent" covariance estimator, or the "variance correction".

The sandwich estimator plays an important role in GEE methodology, but its appropriateness should not be accepted uncritically. For comparison purposes Drum & McCullagh [6] consider the simple case of a difference of means test for two independent samples, for which the conventional estimate of the variance of the group difference would be $s^2(1/n_1 + 1/n_2)$, whereas the sandwich estimate is $s_1^2[(n_1 - 1)/n_1^2] + s_2^2[(n_2 - 1)/n_2^2]$. These correspond to the alternative forms of the two-sample t test that use pooled or separate variance estimates (*see* **Student's *t* Statistics**). Where one or both samples is small, the loss of power in using the latter form is substantial, and should not be accepted lightly. With medium to large samples the loss of power is likely to be slight [1].

Bias in this estimator for unbalanced designs is also considered by Chesher & Jewitt [3]. Such considerations have prompted some criticism of the use of the label "robust" for the sandwich estimator.

Independence Working Models

Combining generalized linear models and the robust estimator for var($\boldsymbol{\beta}$) provides a very simple means of analyzing repeated measures data. Individuals now provide a response vector $\boldsymbol{\mu}_i = (\mu_{i1}, \mu_{i2}, \ldots, \mu_{iT})$ and the score equations take the form

$$U(\boldsymbol{\beta}) = \sum_{i=1}^{n} \mathbf{D}_i^{\mathrm{T}} \mathbf{V}_i^{-1} \{y_i - \mu_i(\boldsymbol{\beta})\} = \mathbf{0}, \qquad (4)$$

where $\mathbf{D}$ is a vector of partial derivatives $\partial\mu/\partial\beta$ and $\mathbf{V}_i$ is a covariance matrix for the Ys. The solution to these equations provides consistent estimates of $\boldsymbol{\beta}$ even where the $\mathbf{V}_i$ matrix has been specified incorrectly. Appropriate standard errors can be obtained for such a misspecified model by using the sandwich estimator. If, for estimation purposes, V_i is specified to by $\boldsymbol{\Delta}_i = \mathrm{diag}[\mathrm{var}(Y_{i1}), \ldots, \mathrm{var}(Y_{iT})]$, in other words the responses are naively assumed to be independent (an *independence working model* or IWM), then estimation can proceed using standard GLM software with each subject contributing as many records as repeated measures. The operational simplicity of this approach is hard to exaggerate. Of course, these estimates are not **efficient**, but the loss of efficiency is often not great [10].

Table 3 gives the parameter estimates from a logistic regression fitted to the respiratory disease data of Table 1, in which each subject contributes a set of four records. Three forms of **standard error** are shown together with their associated test statistic: (i) the classical standard error that is based on the false assumption that the four records within a set are independent; (ii) the "robust/sandwich" standard error; and (iii) one based on **bootstrap** resampling of subjects. The bootstrap estimate is always closer to the robust/sandwich estimate than the classical estimate, which, for between-subjects effects, is much too small. However, in the case of the within-subjects effect for the time trend, it is the robust and bootstrap estimates that are smaller. Assuming independence is not always anticonservative.

Table 3 Logistic regression estimates for respiratory data

Marginal vs. Conditional Estimation

Before describing potentially more efficient use of generalized estimating equations for longitudinal data it is worth considering the interpretation of the parameters that we have just obtained. We have estimated a **cross-sectional model** simultaneously to each of the four measurement occasions. The fit is to the four univariate margins and not to any joint distribution of responses as such. Moreover, unlike in a **random effects** model for repeated data there is no *subject-specific* effect. Estimates for the effects of covariates, whether time-dependent or not, are thus not conditional upon any such subject-specific effect, but instead relate to effects averaged over individuals.

The two alternative measures of the effect of a covariate are the same in the case of linear link models with additive subject-specific effects and log link models with multiplicative subject effects. For a logistic link, as with the other link functions, the average effect coincides with the subject-specific effect only for no effect or no subject-specific variance. Where subject-specific effects are substantial, Figure 1 illustrates how the marginal response curve is obtained from averaging the subject-specific curves which, if each was logistic, results not only in a marginal curve of smaller slope but one that is not even logistic in form. Zeger et al. [41] discuss the relationship among these different estimates of the regression coefficients. The broad consensus is that average effects are often of interest from a public health point of view, but may not be so pertinent where interest lies in scientific investigation of the individual-level process or in individual-level prediction. It is also of interest that **marginal models** rarely provide descriptions of the data that fully specify a possible data-generating mechanism as would be required, for example, to specify a **Monte Carlo** simulation.

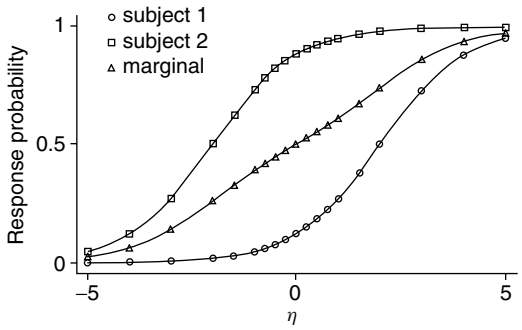

Figure 1 Logistic subject-specific and marginal effects

For comparison, Table 3 presents the estimates and standard errors from a random effects logistic model [24] applied to the respiratory data. As expected, these subject-specific regression coefficients are larger than the corresponding marginal parameters, but so too are the standard errors, resulting in comparable test statistics.

Quasi-likelihood

Wedderburn [35] pointed out that the GLM score equations (1) could be solved for any choice of link and variance function even where the integral of the score equations – a likelihood-type function given the name **quasi-likelihood** – did not actually correspond to a member of the exponential family nor even to a known parametric distribution. McCullagh [22] showed that the regression estimates obtained from solving such *quasi-score functions* were approximately normal with mean $\boldsymbol{\beta}$ and variance still given by (2).

Medical statisticians frequently encounter counts and proportions data where perhaps, through geographic, social, or genetic proximity, the several units contributing to each response are not independent. Such data then typically possess greater variance than expected under the ordinary GLM. In the case of count data, in place of a GLM specified with $\mathrm{var}(Y_i) = \mathrm{E}(Y_i)$ as appropriate to **Poisson** distributed counts, a model in which $\mathrm{var}(Y_i) = \phi \mathrm{E}(Y_i)$ might be estimated with $\phi > 1$ to account for the extra variance or **overdispersion**. Although in this instance this does not change the estimated regression coefficients, the estimated parameter variances increase by the factor ϕ.

Simple moment estimators for this scale parameter ϕ were proposed [23] on the basis of the Pearson **residuals** $\hat{r}_i = \{y_i - b'(\hat{\theta}_i)\}\{b''(\hat{\theta}_i)\}^{-1/2}$, of the form $\phi = \sum_i \hat{r}_i^2/(N-p)$. Firth [7] examined the relative efficiency of such quasi-likelihood estimators concluding that greater efficiency can only be obtained by making assumptions about higher-order **moments**.

Wei & Stram [36] consider a direct application of this kind of approach to longitudinal data in which a separate occasion-specific quasi-likelihood equation is estimated for each time point after which a special parameter covariance matrix covering all

the parameters is estimated and used as the basis of subsequent tests. This represents a special case of the IWM approach described previously (see [4]).

Table 4 presents the results from fitting overdispersed Poisson regression models to the epilepsy data using the IWM approach. For illustrative purposes, the fitted model includes simple main effects and a common pattern of overdispersion, though Thall & Vail [34] find some evidence for a more complicated structure. The estimated dispersion parameter based on the Pearson residuals is 5.1, showing that the variability in these data is well in excess of those for Poisson counts, for which it would be 1. Again the standard errors derived using the sandwich estimator are larger than the naive estimates for the between-subjects effects but is smaller for the within-subjects effect of time. We have again provided estimates from a random effects model for comparison. This model assumes a **gamma distributed** random effect uncorrelated with included regressors, acting multiplicatively on the Poisson rate parameter. Unlike the logistic model there is no consistent increase in the parameter estimates over those from the marginal model.

Generalized Estimating Equations

Liang & Zeger [16] and Zeger & Liang [40] extended the quasi-likelihood approach to consider a multivariate mean vector and suggested that improved efficiency could be obtained by simultaneously estimating parameters in the covariance matrix of the response vector. This corresponds to taking the estimating equations (3) and, where previously we have considered using a diagonal matrix as the working matrix for $\mathbf{V}_i$, now using something which begins to approximate the off-diagonal covariance. An obvious form is

$$\mathbf{V}_i = \frac{\boldsymbol{\Delta}_i^{1/2}\mathbf{R}_i(\alpha)\boldsymbol{\Delta}_i^{1/2}}{\phi},$$

where $\mathbf{R}_i(\alpha)$ is a $T \times T$ "working **correlation** matrix" with parameter vector α. Typical possibilities for $R_i(\alpha)$ are:

1. An identity matrix – equivalent to the IWM approach of the previous section.
2. An **exchangeable** correlation matrix with a single parameter, similar to that which underlies repeated measures analysis of variance in which $\text{corr}(Y_{ij}, Y_{ik}) = \alpha$, $j \neq k$.
3. An *AR-1 autoregressive* correlation matrix, also with a single parameter but in which $\text{corr}(Y_{ij}, Y_{ik}) = \alpha^{|k-j|}$, $j \neq k$ (*see* **ARMA and ARIMA Models**).
4. An unstructured correlation matrix with $T(T-1)/2$ parameters, similar to that underlying **multivariate analysis of variance**, in which $\text{corr}(Y_{ij}, Y_{ik}) = \alpha_{jk}$.

If V_i is correctly specified, then the covariance matrix for the fitted regression coefficients could be obtained

Table 4 Overdispersed Poisson regression estimates for the epilepsy data

from the inverse of the **information matrix** $\mathbf{H}_1(\beta)$:

$$\sum_{i=1}^{n} \hat{\mathbf{D}}_i^{\mathrm{T}} \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i.$$

However, although we should have regard to possible loss of **power**, it is in general safer to use a robust sandwich variance estimator with a construction that parallels that already described.

In the first applications of non-IWM GEE estimation, Liang & Zeger [16] followed the pattern set in quasi-likelihood estimation of using moment estimators (*see* **Method of Moments**) for both the scale parameter, ϕ, and for the correlations, α. With observation-specific Pearson residuals, the scale parameter $\hat{\phi}$ is first estimated by $1/\{\sum_i \sum_j \hat{r}_{ij}^2/(N-p)\}$ and then $\hat{\alpha}$ is estimated by $\hat{\phi} \sum_i \sum_{k>j} \hat{r}_{ij}\hat{r}_{ik}/\{\sum_i [n_i(n_i-1)/2] - p\}$ for the exchangeable model, or by the regression slope of $\log(\hat{r}_{ij}\hat{r}_{ik})$ on $\log(|j-k|)$ for the AR-1 model. In the case of the unstructured or saturated form of the covariance matrix for balanced data the (jk)th element can be estimated by $\hat{\phi} \sum_i \hat{r}_{ij}\hat{r}_{ik}/(N-p)$. This last form is typically only practicable with large samples or with few observation occasions. Whichever form is chosen, the estimation process consists of an iteration between iterative weighted least squares estimation of the regression parameters for a given estimate of the association parameters followed by recalculation of the estimates of the association parameters based on the residuals from the current estimates of the regression parameters.

Of course the correlation matrix need not be parameterized directly. Indeed, since multivariate discrete distributions give rise to complex constraints on the feasible correlation matrices there may be some advantage in not doing so. In the case of binary data Lipsitz et al. [19] suggested using the pairwise marginal **odds ratios** γ_{ijk} for $j = 1, T-1$ and $k = j+1, T$ where

$$\gamma_{ijk} = \frac{\mathrm{E}(Y_{ij}Y_{ik})\mathrm{E}[(1-Y_{ij})(1-Y_{ik})]}{\mathrm{E}[Y_{ij}(1-Y_{ik})]\mathrm{E}[(1-Y_{ij})Y_{ik}]}. \qquad (5)$$

Although these estimators for the association parameters α may suffice where scientific interest lies in the estimation of the regression coefficients, they are not especially good estimators of the association parameters themselves. Moreover, it is sometimes appropriate to consider the association, for example as characterized by the correlation matrix, as depending explicitly on covariates or experimental or sampling design variables. Prentice [26] proposed extending the **estimating equation** approach to the estimation of the association parameters. A second set of equations is estimated for which the "observed data" are the cross-products over measurements of the time-specific residuals $s_{ijk} = r_{ij}r_{ik}$. As was the case for the score equations for the regression coefficients, this involves a choice of some "working covariance matrix". In simple cases the estimates obtained correspond to the simple moment estimates already described.

These two sets of estimating equations can be combined [28, 42] as follows:

$$\sum_i \begin{pmatrix} \dfrac{\partial \mu_i}{\partial \beta}, & \dfrac{\partial \mu_i}{\partial \alpha} \\ \dfrac{\partial \sigma_i}{\partial \beta}, & \dfrac{\partial \sigma_i}{\partial \alpha} \end{pmatrix}^{\mathrm{T}} \begin{pmatrix} \mathrm{cov}(y_i), & \mathrm{cov}(y_i, s_i) \\ \mathrm{cov}(y_i, s_i), & \mathrm{cov}(s_i) \end{pmatrix}^{-1} \times \begin{pmatrix} y_i - \mu_i \\ s_i - \sigma_i \end{pmatrix} = \mathbf{0},$$

where $\sigma_{ijk} = \mathrm{E}(s_{ijk})$. Liang et al. [17] present a similar set of estimating equations for the mean and marginal odds ratios. In either case, the score functions for β and α are solved together using a modified Fisher scoring algorithm (*see* **Generalized Linear Model**). If the equations for α and β are assumed orthogonal, then the off-diagonal elements of the first two matrices (for derivatives and weights, respectively) are assumed zero and these are referred to as *first-order estimating equations* and the estimation method as GEE1. If these matrix elements are nonzero and the two sets of equations are solved jointly, then this corresponds to a *second-order estimating equations* approach or GEE2. GEE1 gives consistent estimates of β when the model for α is misspecified. GEE2 does not share this "robustness" but can give more efficient estimates. In practice (e.g. [17]), there is little or no gain in efficiency for β in the use of GEE2, but there can be substantial gains for the association parameters α.

As with the estimation equation for β, these estimating equations for α now involve the specification of a "working" covariance matrix for $\mathrm{cov}(s_i)$ (for GEE1 and GEE2) and $\mathrm{cov}(y_i, s_i)$ (for GEE2 only). These involve third and fourth moments of the data about which most applied statisticians will have little intuitive grasp and which may be subject to complex constraints. (In theory, the estimating equation approach could be extended further to estimate these

higher-order moments as well.) In addition, for large numbers of repeated measures the size of this covariance matrix can make it difficult to invert.

In the discussion of Liang et al. [17], Prentice & Pepe [27] suggested a reparameterization in terms of conditional residuals, which, tending to be less correlated than unconditional residuals, might provide greater efficiency. Carey et al. [2] (but see also [5]) proposed a simple iterative schema involving conditional residuals for the special case of odds-ratio association models with multivariate binary data. They suggested estimating a common odds ratio $\alpha_{ijk} = \alpha$ [see (4) above] from the following logistic regression:

$$\text{logit } \Pr(Y_{ij} = 1 | Y_{ik} = y_{ik}) = \alpha y_{ik} + \log\left(\frac{u_{ij} - \mu_{ijk}}{1 - \mu_{ij} - \mu_{ik} + \mu_{ijk}}\right),$$

where $\mu_{ijk} = \Pr(Y_{ij} = Y_{ik} = 1)$ and the second term on the right-hand side is an *offset*. Since μ_{ijk} and hence the offset depends upon the values of α and β, iteration is required between the offset logistic regression for α and the GEE logistic regression for β, giving rise to the name *alternating logistic regression* (ALR). The approach can be extended to allow variation in the degree of association with covariates by replacing y_{ik} in the above equation by $x_{ijk} y_{ik}$ with a corresponding change in α to a vector of regression-type coefficients.

This last approach exploits the robustness properties of GEE1 estimation with respect to the β regression parameters but typically achieves almost as good efficiency in the estimation of the odds-ratio association parameters α as the much more complex GEE2 method, and at the same time substantially reduces the matrix inversion problem. Lipsitz & Fitzmaurice [18] consider the conditional residual approach where the association is modeled using correlations. They report similarly good performance for autoregressive correlation structures, and more generally where there are missing data.

Recently Wild & Yee [39] have adapted the GEE approach to allow for the fitting of **generalized additive models** (GAMs rather than GLMs) of the sort described by Hastie & Tibshirani [12].

In practice, the GEE estimation algorithms described above do not always converge. Lipsitz et al. [20] considered restricting the estimation process to one step. Starting from an IWM solution, the association parameters are estimated using the IWM residuals and the regression coefficients are re-estimated once more. They concluded that where the fully iterated method failed to converge, the one-step estimator could well be adequate. They found no discernible differences in power or bias among IWM logistic regression, one-step or iterated GEE1. In addition, efficiency was comparable except where the correlation over time was high and the variable time-varying.

Comparative Results from GEE Models

Table 5 presents results of logistic regressions with exchangeable, AR-1, unstructured, and ALR estimates, with classical and robust standard errors. Table 6 gives the lower triangle of the estimated correlation matrices from each of these models. The estimated correlations from the unstructured model look to be closer to those of an exchangeable structure than the autoregressive structure, but regression estimates and standard errors from the three models are all very similar, as also are the classical and robust standard errors from within the same model (where any differences might have suggested possible model misspecification).

Table 7 presents results from the epilepsy data with exchangeable, overdispersed exchangeable, AR-1, and unstructured models, again with standard and robust standard errors. As expected, allowing for overdispersion in the exchangeable model does not result in different parameter estimates nor in different estimates of the robust standard errors. Differences do arise in the case of the classical standard errors, reflecting the fact that for these data allowing for the correlation alone is not sufficient to avoid a misspecified model, a fact indicated by the substantial differences between classical and robust standard errors. Once allowance is also made for overdispersion the two forms of standard error are much more comparable. Inspection of the estimated correlation matrix under the unstructured model shown in Table 8 might suggest the autoregressive structure as the more appropriate of the structured models.

Missing Data, Weighted Estimating Equations, and Complex Sampling Designs

In general, under the assumption of data *missing completely at random* (MCAR) [21], marginal model

specification together with an appropriate parameterization of the covariance matrix requires the occasion-wise subsets of data to be complete for the modeling of each response measurement, but does not require complete data across all measurement occasions (*see* **Nonignorable Dropout in Longitudinal Studies**). Moreover, GEE methods typically provide estimates of parameters whose interpretation is not dependent upon the pattern of MCAR missing data. However, the occurrence of missing data complicates the estimation of the totally unspecified correlation matrix since the estimate obtained from the nonmissing data is not guaranteed to be positive definite.

Robins et al. [30] describe how weighting the estimating equations by the weights given by the inverse of the response probabilities can extend the missing data properties of GEE estimation to the case of data *missing at random* (MAR). This approach also allows the application of the GEE methodology to multiphase designs and other designs involving the use of **surrogate** measurement. **Multistage sampling** designs are considered by Qaqish & Liang [29].

Specialized methods are required for the application of GEE methodology in the presence of *nonignorable* missing data.

Discussion

The field of GEE continues to be one of rapid development, particularly in respect of efficient estimation of the structure of association among observations.

[a]Allowing for overdispersion.

This will further enhance the value of these methods for longitudinal data. As with other model fitting methods for longitudinal data, special care needs to be taken in the interpretation of results where predictor variables include those that may be endogenous. This can include baseline measures of the type used in the illustrations.

Programs for GEE model fitting are available for **software** platforms such as **S-PLUS** [33], with a suite of such programs and data exploration and management tools specifically for longitudinal data being provided by OSWALD [31]. With the more recent availability of basic GEE methods in more popular packages (e.g. the SAS macros of [14]; Stata V.5.0 [32]) widespread application of these methods is assured.

Generalized Linear Mixed Models

Introduction

Generalized linear mixed models (GLMMs) are an extension of the class of **generalized linear models** in which **random effects** are added to the linear predictor. This modification extends the broad class of generalized linear models to accommodate **correlation** via random effects, while retaining the ability to model nonnormal distributions and allowing nonlinear models of specific form. The class of GLMMs includes the special cases of **linear mixed models**, **random coefficient models**, random effects **logistic regression**, and random effects **Poisson regression**, to name a few.

The incorporation of random effects is a natural way to model or accommodate correlation in the context of a nonlinear model for nonnormal data. It generates a rich class of correlated data models that would be difficult to specify directly. Readily available, flexible, **multivariate distributions** analogous to the **multivariate normal distribution** do not exist for most nonnormally distributed data.

Inferences for these models can be of the usual variety, that is, modeling the effect of predictors on the mean, in which case the random effects and correlation are "nuisance" features of the model. In other situations, however, both estimation and testing of the **variances** of the random effects, as well as prediction of the realized values of the random effects, may be of interest (*see* **Variance Components**).

We will illustrate several of our points using as an example the **longitudinal** study of physicians and their patients described by Korff et al. [8]. This study classified 44 primary care physicians in a large HMO according to their practice styles in treating back **pain** management (low, moderate, or high frequency of prescription of pain medication and bed rest), and followed an average of 24 patients per physician for 2 years (1 month, 1 year, and 2 year follow-ups) after the index visit. Outcome variables included functional measures (e.g. Did you experience moderate to severe activity limitation?), patient satisfaction (e.g. "After your visit with the doctor, did you fully understand how to take care of your back problem?"), and cost.

Generalized Linear Mixed Models: A Definition

Generalized linear mixed models constitute a class of models for describing the stochastic relationship of an n-dimensional outcome vector $\boldsymbol{Y}$ to an $(n \times p)$-dimensional matrix of **covariates** $\boldsymbol{X}$, with rows $\boldsymbol{x}_i'$.

The construction of generalized linear mixed models begins with the specification of a generalized linear model conditional on a vector $\boldsymbol{u}$ of random effects. That is, given a vector $\boldsymbol{u}$ (often with components specific to a subject or cluster), the conditional density of Y_i is of the **exponential family** form $f(y_i|\boldsymbol{u}) = \exp[\{y_i\theta_i - b(\theta_i)\}\phi + c(y_i, \phi)]$, where b and c are functions of known form. In addition, one assumes that $E(Y_i|\ \boldsymbol{u}, \boldsymbol{x}_i) = g^{-1}(\boldsymbol{x}_i'\boldsymbol{\beta} + \boldsymbol{z}_i'\boldsymbol{u})$, where $\boldsymbol{z}_i$ is a specified vector of covariates, analogous to $\boldsymbol{x}_i$. Given $\boldsymbol{u}$, the model additionally assumes that the responses Y_i are independent. The function g links the linear predictor to the expected value of the response. The model further assumes that the random effects $\boldsymbol{u}$ follow a distribution G, typically (but not necessarily) multivariate normal with mean vector $\mathbf{0}$ and **covariance matrix** $\boldsymbol{\Sigma}(\boldsymbol{\gamma})$, where $\boldsymbol{\gamma}$ is a vector of (co)variance parameters, for example, variances and correlation coefficients.

Thus, the model assumes that the linear predictor consists of two portions: the fixed effects portion $\boldsymbol{x}_i'\boldsymbol{\beta}$, and the random effects portion $\boldsymbol{z}_i'\boldsymbol{u}$, for which a distribution is assigned to $\boldsymbol{u}$. Just as with linear mixed models, the assumption of a distribution for the random effects induces correlations among observations. Finally, the assumptions underlying GLMMs specify the multivariate distribution of $\boldsymbol{Y} = (Y_1, \ldots, Y_n)'$, so that one can base inference with these models on **likelihood** methods.

The specification of covariate effects conditional on random effects determines the interpretation of the fixed effects parameters $\boldsymbol{\beta}$. For example, considering the activity limitation outcome in the back pain study, GLMMs would measure how the risk of activity limitation in a particular patient of a particular physician changes over time, and how that change relates to the practice style of the physician. Using GLMMs, one can also directly relate changes in **explanatory variables** within an individual subject to changes in the expected value of the subject's response.

To be more specific, we consider the simple and common case in which the data are correlated in clusters, where $i = 1, \ldots, m$ indexes the clusters (e.g.

patients) while $j = 1, \ldots, n_i$ indexes units within clusters (e.g. different time points) (*see* **Cluster Sampling**). In a GLMM with a single fixed effect, the parameter β measures the change in the conditional expectation of Y corresponding to a unit increase in the covariate within the ith cluster,

$$\beta = g[E(Y_{ij}|x_{ij} + 1, \boldsymbol{u}_i)] - g[E(Y_{ij}|x_{ij}, \boldsymbol{u}_i)], \quad (1)$$

where $\boldsymbol{u}_i$ is a cluster-specific vector of random effects. This contrasts with **marginal models**, where one specifies the marginal or population-averaged (PA) distribution of the response of the jth unit in the ith cluster, integrated over the distribution of $\boldsymbol{u}$, together with some working (hypothesized) covariance structure for the n_i responses in the ith cluster to account for intraclass correlation. For the single fixed effect example, marginal models measure the change in the marginal expectation $\mathrm{E}(Y_{ij}|x_{ij})$, unconditional on the random effects, associated with change in the covariate. Such covariate effects are exactly those one would estimate with a single response per subject; the cluster structure thus plays no role in the interpretation of the model regression coefficients.

In addition to estimates of the effects of covariates on the expected value of the response, GLMMs can provide estimates of the dependence of responses within clusters, such as subjects. Measures such as the intraclass correlation coefficient, $\mathrm{corr}(Y_{ij}, Y_{ij'})$, depend on the random effects distribution G, along with its parameters $\boldsymbol{\gamma}$; using estimates of $\boldsymbol{\gamma}$ one can construct estimates of intraclass correlation.

As well as modeling within-cluster response dependence and estimates of its magnitude, GLMMs allow consideration of the individual random effects, which themselves may be of interest. For example, in the back pain study, we would include random effects to describe both the physician and patient effects on each of the outcomes. We might be interested in obtaining predicted values for the random effects of each physician to help indicate which physicians had better outcomes and/or lower costs, after adjusting for fixed effects of model covariates. The random effects in a GLMM are best predicted by their conditional expectations given the data, $E(\boldsymbol{u}|\boldsymbol{Y})$. However, this expectation is unknown since it depends on the unknown parameters $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$. Hence, one typically estimates $E(\boldsymbol{u}|\boldsymbol{Y})$ using estimates of these parameters. The estimated values of $E(\boldsymbol{u}|\boldsymbol{Y})$ are *shrinkage* estimates and "borrow strength" across the data set in order to improve estimates of individual random effects, especially when data incorporating a particular random effect are sparse (*see* **Shrinkage Estimation**).

Inference and Estimation

Maximum likelihood (ML), or variants such as **restricted maximum likelihood** (REML), are standard methods of estimation for linear mixed models and generalized linear models (e.g. logistic regression). Evaluation of the likelihood and hence likelihood inference with GLMMs is computationally difficult, however, because the random effects on which the likelihood is conditioned must be integrated out of the distribution prior to maximization as a function of the fixed effects. Although several useful computational methods currently exist, the development of new methods for GLMMs continues to be an active research area.

To illustrate the inherent complexity, consider a general mixed logistic regression model for binary data. The marginal likelihood takes the form

$$\int \cdots \int \exp\left\{\sum_i Y_i(\boldsymbol{x}_i'\boldsymbol{\beta} + \boldsymbol{z}_i'\boldsymbol{u})\right\} \times \prod_i \{1 + \exp(\boldsymbol{x}_i'\boldsymbol{\beta} + \boldsymbol{z}_i'\boldsymbol{u})\}^{-1} \, \mathrm{d}G(\boldsymbol{u}), \quad (2)$$

where G is the distribution function of the random effects and the integration is of a dimension equal to the dimension of $\boldsymbol{u}$. For most choices of G, the integral cannot be evaluated in closed form although, for simple cases like random intercept and/or random slope models, (1) reduces to a product of lower-dimensional integrals amenable to numerical integration. **Numerical integration** becomes inaccurate for three or more dimensions, but simulation-based methods such as **Markov Chain Monte Carlo** [3], in particular, Gibbs sampling, and Monte Carlo **EM** [13] have proven useful in these settings. Such methods can also handle complications such as crossed random effects.

If ML estimation is feasible, then the usual inferential methods are available. In particular,

- ML estimators are asymptotically normal, with standard errors available from second derivatives of the log likelihood.

- One can carry out hypothesis tests using **likelihood ratio**, score, or Wald procedures.
- One can calculate best-predicted values as expected values of the random effects conditional on the data, substituting ML or REML estimates for unknown parameters. Typically, one cannot evaluate the conditional expected values in closed form, so these calculations involve numerical integration.
- One can test whether variances of random effects are zero using the likelihood ratio statistic. As with linear mixed models, the asymptotic null distribution involves a mixture of chi-square distributions rather than the null **chi-square distribution** usual in fixed effects models [15].

For the case of random intercepts only, several authors have proposed a **semiparametric** mixed model approach that jointly estimates the regression parameters and the (**nonparametric**) mixing distribution G. These methods are given in several papers, including [1, 2, 9, 10, 11]. This approach provides consistent estimation of the effects of all covariates and of G under conditions of **identifiability** [7].

Although GLMMs require specification of the random effects distribution G, several studies of the performance of logistic models with random intercepts show that estimates of the fixed effects parameters $\boldsymbol{\beta}$ are robust to **misspecification** of G. For example, using both approximations and **simulations**, Neuhaus et al. [14] showed that incorrectly assuming that G was Gaussian produced fixed effects covariate effect estimates with very little bias (*see* **Unbiasedness**). Heagerty and Kurland [5] corroborated these findings but pointed out that more severe model misspecifications, such as the failure to model interactions of covariates and random effects, could yield biased estimates of covariate effects.

Contrasting the Marginal and Conditional Approaches

We return to the special case of correlated clusters and the notation used previously to describe them. Many investigators have considered alternative methods for clustered data that focus on models for the marginal expectation of the response,

$$E(Y_{ij}|\,\boldsymbol{x}_{ij}) = \int y \left[\int \cdots \int f(y|\boldsymbol{x}_{ij}, \boldsymbol{u}_i)\, \mathrm{d}G(\boldsymbol{u}_i) \right] \mathrm{d}y, \quad (3)$$

where $\boldsymbol{x}_{ij}$ is the vector of covariate values associated with Y_{ij}. Some approaches, such as **Generalized Estimating Equations** (GEEs), do this without fully specifying the functional form of the joint distribution of the responses $Y_{i1}, \ldots, Y_{in_i}$ within the ith cluster.

GLMM and marginal models are similar in that both parameterize the mean and covariance matrices of correlated groups of observations, and both base inferences on **marginal likelihoods** or marginal **quasi-likelihoods** of the observed data. However, the implications of modeling the response distribution conditional on random effects, as do GLMMs, rather than averaged over random effects, as do marginal models, are profound. With a nonlinear link function, the impact of a conditional main effect in the linear predictor varies, on the scale of $\mathrm{E}(Y)$, with the values of accompanying fixed and random effects. Hence, in contrast with the linear case, when averaging over the random effect distribution, the mean linear predictor does not correspond (transform to) to the marginal conditional expectation $\mathrm{E}_{\boldsymbol{u}_i}[\mathrm{E}(Y_{ij}|\boldsymbol{x}_{ij}, \boldsymbol{u}_i)]$. Similarly, linear predictors based on within-group covariate means do not transform to means of the response within the corresponding groups. Hence, as stated earlier, marginal approaches measure conceptually and numerically different covariate effects than do GLMMs. In some cases, scientific interest and inferential goals of a problem lead one clearly to the marginal or conditional specification of a model; in other cases, the appropriate direction is less clear. Since the distinctions between marginal models and GLMMs are commonly blurred in practice, it is useful to contrast them further.

Marginal models are most helpful when correlation among observations cannot be ignored, but neither the nature of the clustering that generates such correlations, nor the individual clusters themselves, are otherwise of particular scientific interest. This characterization often applies when public health impact is the focus of an investigation. From that perspective, there may be little concern with either intracluster factors or with predictions about the specific units, such as families observed cross-sectionally or individuals observed over time, that generate the

measurement clusters. In the back pain study mentioned earlier, in which practice style was constant within subjects over time, marginal modeling would be natural to study a presumed homogeneous effect of practice style across subjects and times, and any population time trend. (However, it would not be useful for quoting the **odds** of reduction over time in, say, the risk of activity limitation for an individual patient.)

In such circumstances, for example, where longitudinal observation is used for logistical reasons or statistical efficiency, and correlations are nuisance parameters in analysis, then, there is technical advantage in bypassing a conditional model (*see* **Efficiency and Efficient Estimators**). For example, GLMMs that mistakenly assume random effects that are homoscedastic can produce biased estimators [5, 6]. In contrast, estimates of marginal model parameters obtained using GEE are **consistent**, even if the association structure is misspecified.

In other circumstances, however, marginal models may not measure covariate effects of primary scientific interest, for example, in longitudinal studies in which explanatory variables change over time *within a subject* and interest is in how *individuals respond* to such changes. In the back pain study, investigators were interested specifically in assessing patterns of change over time in individual subjects. In such situations, GLMMs are more ambitious than marginal models in attempting to (i) parse, using explicit random effects and predicted values for them, sources of variation that produce correlated observations, and to (ii) portray and predict, for instance, shapes of individual longitudinal disease trajectories, vulnerabilities of individual litters to teratogenesis, breeding values of individual bulls, and susceptibilities of individual families to inheritable diseases. The price of this ambition is paid in more stringent assumptions, and in greater complexity of the model fitting process and computations.

If one is willing to pay such a price, then GLMMs may be used to make inferences about marginal distributions, even when purely marginal methods would be adequate. Marginal modeling, however, without such assumptions *does not* allow conditional inference, for example, about longitudinal trajectories typical of individual subjects. More specifically,

- Variations of **Simpson's paradox** and the **ecologic fallacy** may apply at several levels. The marginal distribution may be of a different form from any conditional distribution and, indeed, the form of a conditional mixing distribution required for common marginal models may be quite unusual [17]. In extreme cases, features in every conditional model may be absent in the marginal model, for example, the marginal effect averaged across 2×2 conditional tables might be opposite in direction to those in each conditional table. More commonly, however, population average effects may simply understate the strengths of effects on individuals [18].
- GEE for marginal models may not estimate the variance–covariance structure efficiently and does not allow, without further assumptions, prediction of random effects. However, see [4, 16, 18] for developments in these directions.

For a more detailed critique of marginal modeling, see [12].

Summary

During the past decade, GLMMs have become an important statistical tool and now see heavy use for modeling correlated, nonnormally distributed data. Software for fitting GLMMs is starting to mature, and much experience has contributed to better appreciation of both the utility and pitfalls of the currently available techniques. GLMMs are a natural modeling approach for longitudinal data when changes within subjects are of interest.

Generalized Linear Model

The term *generalized linear model* was first introduced in a landmark paper by Nelder & Wedderburn [23], in which a wide range of seemingly disparate problems of statistical modeling and inference (**analysis of variance** (ANOVA), **analysis of covariance** (ANCOVA), Gaussian, binomial, and **Poisson regression**, and so on) were cast in an elegant unifying framework. The flexibility and power of the generalized linear model are perhaps best illustrated by initial consideration of the simple Gaussian linear model (*see* **Linear Regression, Simple**). Let Y_i be a random **response variable** and let x_i denote an **explanatory variable**. In the Gaussian linear model, we assume that

$$Y_i = \beta_0 + \beta_1 x_i + \sigma E_i, \quad i = 1, 2, \ldots, n,$$

where $E_1, E_2, \ldots, E_n$ are errors that are independently and identically distributed standard **normal** random variables. An equivalent way of writing the model is as $Y_i \sim \mathrm{N}(\mu_i, \sigma^2)$, $i = 1, 2, \ldots, n$, where $Y_1, Y_2, \ldots, Y_n$ are independently, but not identically, distributed and $\mu_i = \beta_0 + \beta_1 x_i$, $i = 1, 2, \ldots, n$. The objective of this model is to use the explanatory variable to characterize the variation in the mean of the response distribution across observational units, and hence to learn about the relationship between the explanatory and response variables.

Frequently, interest lies in the formulation of **regression** models for responses with other continuous or discrete distributions. In such settings, while the objective is typically to model the mean of the distribution, it must be modeled indirectly via the use of parameter transformations. In a generalized linear model this is done through the introduction of a link function $g(\cdot)$ and the model assumption, which, in the case of a single explanatory variable, takes the form

$$g(\mu_i) = \beta_0 + \beta_1 x_i.$$

The error distribution must also be generalized, usually in a way that complements the choice of link function. This leads to a very broad class of regression models.

This unifying theory has impacted the way such statistical methods are taught, has provided greater insight into the connections between various statistical procedures, and has led to considerable further research. McCullagh & Nelder [22] provide a comprehensive lucid account of the theory and applications which involve generalized linear models. Dobson [12] serves as an excellent introduction to the topic. In the following exposition, we draw primarily on the former.

The Generalized Linear Model (GLM)

The Exponential Family

Let Y be a random response variable of interest, and let y denote its corresponding realized value. The random variable Y has a distribution in the **exponential family** if

$$f_Y(y; \theta, \phi) = \exp\left\{\frac{\theta y - b(\theta)}{a(\phi) + c(y, \phi)}\right\}, \qquad (1)$$

where $f_Y(y; \theta, \phi)$ is a probability density or mass function, if Y is a continuous or discrete random variable respectively, $a(\cdot)$, $b(\cdot)$, and $c(\cdot, \cdot)$ are known functions, and ϕ is known. The parameter θ is often referred to as the canonical parameter or natural parameter, and ϕ is called the dispersion parameter. When ϕ is unknown, it is considered a **nuisance parameter** and (1) may or may not be a member of the exponential family. For simplicity, we will initially assume that ϕ is known, and we will subsequently denote its specified value as ϕ_0.

The function $a(\phi_0)$ typically takes the form ϕ_0/w, where w is a fixed weight that may vary from observation to observation. The importance of the weight function arises in the analysis of grouped data, where it is often the group size. The function $b(\cdot)$ is termed the cumulant function, since it plays a central role in the determination of the cumulants (*see* **Characteristic Function**), and $c(\cdot, \cdot)$ is an arbitrary function of (y, ϕ_0), and possibly the weight w.

With $\phi = \phi_0$, the log likelihood arising from (1) takes the form

$$l(\theta; y) = \frac{\theta y - b(\theta)}{a(\phi_0)} + c(y, \phi_0). \qquad (2)$$

Since $\mathrm{E}\{\partial l/\partial\theta\} = 0$ it follows that $\mathrm{E}\{Y\} = \mu = \partial b(\theta)/\partial\theta = b'(\theta)$. Furthermore, since $\mathrm{E}\{\partial^2 l/\partial\theta^2\} + \mathrm{E}\{(\partial l/\partial\theta)^2\} = 0$, it follows that $\mathrm{var}\{Y\} = V = a(\phi_0)b''(\theta)$. To make the dependence of the variance V on μ explicit, we will sometimes write it as

$\text{var}\{Y\} = a(\phi_0)v(\mu)$, where $v(\cdot)$ is called the variance function.

Formulation of a Regression Model

Let $Y_1, Y_2, \ldots, Y_n$ be a set of random response variables in which Y_i, the response for the ith unit, has a distribution governed by

$$f_{Y_i}(y_i; \theta_i, \phi_0) = \exp\left\{\frac{\theta_i y_i - b(\theta_i)}{a_i(\phi_0)} + c_i(y_i, \phi_0)\right\}. \tag{3}$$

In (3), $a_i(\cdot)$ and $c_i(\cdot, \cdot)$ are all assumed to have the same functional form across responses; the subscripts are introduced only to accommodate varying weights across responses (e.g. $a_i(\phi_0) = \phi_0/w_i$). The cumulant function is assumed to be common for all observations, and the subscript on θ accommodates different expectations for the different responses. The dispersion parameter is considered to be fixed and common.

We then let $y_1, y_2, \ldots, y_n$ represent a sample of size n arising from the corresponding n random variables, which we write more compactly in vector form as $\mathbf{y} = (y_1, y_2, \ldots, y_n)'$. Let $\mathbf{x}_i = (x_{1i}, x_{2i}, \ldots, x_{pi})'$ denote a $p \times 1$ vector of explanatory variates arising from the same unit on which y_i is observed, with $x_{1i} = 1$, and let $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_p)'$ be a $p \times 1$ vector of regression coefficients. For convenience we let $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)'$ denote the $n \times p$ matrix of covariate vectors. The inner product $\mathbf{x}_i'\boldsymbol{\beta} = \eta_i$ consists of a linear combination of the regression parameters and hence is termed the linear predictor for the ith observation. Thus $\mathbf{X}\boldsymbol{\beta} = \boldsymbol{\eta} = (\eta_1, \eta_2, \ldots, \eta_n)'$ is an $n \times 1$ vector of linear predictors. The objective in forming a generalized linear model is to relate these linear predictors to the corresponding means, and to model the variation in the mean from one observation to the next, using the explanatory variates and the regression parameters. For estimability, interpretability, and to serve the central purpose of data reduction, $p < n$.

The link function is a monotonic differentiable function that typically maps the parameter space for the mean $\mu_i = b'(\theta_i)$ on to the real line. The role of the link function is to make explicit the nature of the relationship between the linear predictor and the mean. That is, we typically select a link function $g(\cdot)$ and let

$$g(\mu_i) = \eta_i = \mathbf{x}_i'\boldsymbol{\beta}.$$

A wide variety of link functions are often suitable, but several criteria are available to guide their selection. First, while it is not essential, link functions that map on to the real line are generally preferred to avoid numeric difficulties in estimation that arise since the linear predictor is unconstrained. Secondly, certain link functions lead to regression parameters that have attractive properties in terms of their interpretation. Thirdly, for each member of the exponential family there exists a so-called canonical link function that leads to inference for $\boldsymbol{\beta}$ based solely on **sufficient statistics**. Canonical link functions arise by equating the canonical parameter to the linear predictor; substitution of $\theta_i = \eta_i$ into a **likelihood** based on (3) gives $\mathbf{X}'\mathbf{y}$ as a sufficient statistic for $\boldsymbol{\beta}$. Fourthly, using procedures for model **diagnostics** one can consider the **goodness of fit** of various link functions to guide the choice.

Examples

Before proceeding, it is perhaps worthwhile to consider some particular members of the exponential family with a view to gaining better insight into the current model formulation. In each of the following cases, we begin with a probability density or mass function in its usual form, rewrite it in the form of (1), identify the canonical and dispersion parameters as well as the functions $a(\cdot), b(\cdot)$, and $c(\cdot, \cdot)$, and finally consider possible link functions. For convenience, we drop the subscript i on the response variable and the vector of explanatory variables.

Example 1: the GLM for Poisson Responses

Suppose that Y is a **Poisson** random variable with mean $\mu > 0$. Then

$$\Pr(Y = y; \mu) = f_Y(y; \mu) = \frac{\mu^y e^{-\mu}}{y!}, \quad y = 0, 1, 2, \ldots .$$

This can be rewritten as

$$f_Y(y; \theta, \phi_0) = \exp[(\theta y - e^{\theta}) - \log(y!)],$$

where $\theta = \log \mu$, $a(\phi_0) = 1$, $b(\theta) = e^{\theta}$, and $c(y, \phi_0) = -\log(y!)$. The dispersion parameter ϕ_0 can in fact

be taken as one, and since there are no weights involved, we obtain the particularly simple form of $a(\cdot)$. Note that $\mathrm{E}\{Y\} = \mu = b'(\theta) = \mathrm{e}^{\theta}$ and $\mathrm{var}\{Y\} = a(\phi_0)b''(\theta) = v(\mu) = \mathrm{e}^{\theta}$. Thus $v(\mu)$ is an identity function and the mean equals the variance, as one would expect for a Poisson random variable.

The log link is the canonical link and is the standard link function for **Poisson regression**. It generates the familiar **loglinear model**

$$\log(\mu) = \beta_1 + \beta_2 x_2 + \cdots + \beta_p x_p.$$

Note that covariate effects that are additive on the log scale have multiplicative effects on the mean of the distribution. However, any link functions that map the positive real line on to the entire real line are also possible.

Example 2: the GLM for Binomial Responses

Suppose that $mY \sim \mathrm{bin}(m, \pi)$ with $\mathrm{E}\{Y\} = \mu = \pi$. Then

$$\begin{aligned}\Pr(Y = y; \pi) &= f_Y(y; \pi) \\ &= \binom{m}{my} \pi^{my}(1-\pi)^{m-my}, \\ & \qquad y = 0, \frac{1}{m}, \frac{2}{m}, \ldots, 1.\end{aligned}$$

This can be rewritten as

$$f_Y(y; \theta, \phi_0) = \exp\left[\frac{\theta y - \log(1+\mathrm{e}^{\theta})}{m^{-1}} + \log\binom{m}{my}\right],$$

where $\theta = \log(\pi/(1-\pi))$, $a(\phi_0) = 1/m$, $b(\theta) = \log(1+\mathrm{e}^{\theta})$, and

$$c(y, \phi_0) = \log\binom{m}{my}.$$

Again since the variance is a function solely of the mean, the dispersion parameter may be set to one. The function $a(\phi_0) = 1/m$ then takes the familiar form, with the number of Bernoulli trials forming the **binomial** sample serving as the weight. Note that $\mathrm{E}\{Y\} = \mu = b'(\theta) = \exp\{\theta\}/(1+\exp\{\theta\}) = \pi$ and $\mathrm{var}\{Y\} = a(\phi_0)b''(\theta) = a(\phi_0)v(\mu) = \exp\{\theta\}/(m(1+\exp\{\theta\})^2) = \pi(1-\pi)/m$, as one would expect.

The canonical link leads to the specification of a **logistic regression** model, which is perhaps the most widely used for binomial data. Reasons include those discussed earlier in the context of canonical links, the fact that the regression coefficients may be interpreted as log **odds ratios**, and the resulting attractive features for the regression analysis of retrospective data [22] (*see* **Retrospective Study**). We obtain

$$\log\left[\frac{\pi}{(1-\pi)}\right] = \beta_1 + \beta_2 x_2 + \cdots + \beta_p x_p.$$

In particular contexts, other link functions are routinely adopted, the basic requirement being that they map the interval [0, 1] on to the entire real line. For example, in **dose–response** studies the probit link, given by $g(\pi) = \Phi^{-1}(\pi)$, where $\Phi(\cdot)$ is the cumulative distribution function for a standard normal random variable, is commonly used [14]. In applications involving discrete time **survival data** the complementary log–log link ($g(\pi) = \log(-\log(\pi))$) has connections to **proportional hazards** models, and so is also frequently adopted [22] (*see* **Quantal Response Models**).

Example 3: the GLM for Gaussian Responses

Suppose that $Y \sim \mathrm{N}(\tau, \sigma^2)$ with σ^2 known, giving the usual Gaussian probability density function

$$f_Y(y; \tau, \sigma^2) = \frac{1}{(2\pi)^{1/2}\sigma}\exp\left[\frac{-(y-\tau)^2}{2\sigma^2}\right], \quad -\infty < y < \infty.$$

This can be rewritten as

$$f_Y(y; \theta, \phi_0) = \exp\left\{\left(\frac{\theta y - \theta^2}{2}\right)\Big/\phi_0 - \frac{1}{2}\left[\frac{y^2}{\phi_0} + \log(2\pi\phi_0)\right]\right\},$$

where $\theta = \tau$, $\phi_0 = \sigma^2$, $b(\theta) = \theta^2/2$, $a(\phi_0) = \phi_0$, and $c(y, \phi_0) = -\frac{1}{2}$ $[y^2/\phi_0 + \log(2\pi\phi_0)]$. Here the mean and variance are functionally independent and hence the variance function can be taken as $v(\mu) = 1$. The weights are all taken to be unity.

Note that $\mathrm{E}\{Y\} = \mu = b'(\theta) = \theta = \tau$ and $\mathrm{var}\{Y\} = a(\phi_0)b''(\theta) = a(\phi_0)v(\mu) = \phi_0 = \sigma^2$.

The canonical link function is the identity link function, giving $g(\mu) = \mu = \eta$, or

$$\mu = \beta_1 + \beta_2 x_2 + \cdots + \beta_p x_p,$$

which is the deterministic part of the usual **multiple linear regression** model.

Other examples of distributions within the exponential family include the **gamma** and **inverse Gaussian** distributions. Details regarding the formulation of related regression models are provided in McCullagh & Nelder [22].

Estimation

The Fisher Scoring Algorithm

We now consider maximum likelihood as a method for obtaining an estimate of the regression parameter vector $\boldsymbol{\beta}$. In the following derivations, it will be useful to bear in mind the role of the following mappings:

$$\theta \xrightarrow{b'(\cdot)} \mu \xrightarrow{g(\cdot)} \eta.$$

We now reintroduce the subscripts to distinguish between observations within the sample. Consider a log likelihood arising from n observations, each with a probability distribution governed by the density or mass function of the form given in (3) with specified ϕ_0. Letting $l_i(\theta_i; y_i) = \log[f_{Y_i}(y_i; \theta_i, \phi_0)]$, we obtain

$$l(\boldsymbol{\theta}; \mathbf{y}) = \sum_{i=1}^{n} l_i(\theta_i; y_i) = \left\{ \sum_{i=1}^{n} [\theta_i y_i - b(\theta_i)] \big/ a_i(\phi_0) + \sum_{i=1}^{n} c_i(y_i, \phi_0) \right\}.$$

Given a covariate vector and upon specification of a link function, a transformation from $\boldsymbol{\theta}$ to $\boldsymbol{\beta}$ is defined indicating that the log likelihood can be written in terms of $\boldsymbol{\beta}$ as $l(\boldsymbol{\beta}; \mathbf{y})$. The **maximum likelihood** estimate is the solution to a system of p score equations of the form $\partial l / \partial \boldsymbol{\beta} = \mathbf{0}$. One strategy for solving this system is to employ the Fisher scoring methods, which can be thought of as a standard Newton–Raphson search in which the matrix of second derivatives is replaced by its expectation (*see* **Optimization and Nonlinear Equations**).

Specifically, note that by the chain rule the contribution to $U_j(\boldsymbol{\beta}) = \partial l / \partial \beta_j$ from the ith subject may be written as

$$\frac{\partial l_i}{\partial \beta_j} = \frac{\partial l_i}{\partial \theta_i} \frac{\partial \theta_i}{\partial \mu_i} \frac{\partial \mu_i}{\partial \eta_i} \frac{\partial \eta_i}{\partial \beta_j}, \tag{4}$$

where

$$\frac{\partial l_i}{\partial \theta_i} = \frac{y_i - b'(\theta_i)}{a_i(\phi_0)}, \qquad \frac{\partial \theta_i}{\partial \mu_i} = \frac{1}{b''(\theta_i)}, \quad \text{and} \quad \frac{\partial \eta_i}{\partial \beta_j} = x_{ij}.$$

Substituting into (4), we obtain

$$\frac{\partial l_i}{\partial \beta_j} = \frac{y_i - b'(\theta_i)}{a_i(\phi_0)} \frac{1}{b''(\theta_i)} \frac{\partial \mu_i}{\partial \beta_j} = x_{ij}.$$

Noting that $\mu_i = b'(\theta_i)$ and $V_i = a_i(\phi_0)b''(\theta_i)$, we can write

$$U_j(\boldsymbol{\beta}) = \sum_{i=1}^{n} \frac{(y_i - \mu_i)}{V_i} \frac{\partial \mu_i}{\partial \eta_i} x_{ij}. \tag{5}$$

The complete score vector is given by $\mathbf{U}(\boldsymbol{\beta}) = (U_1(\boldsymbol{\beta}), \ldots, U_p(\boldsymbol{\beta}))'$.

The contribution from the ith subject to the (j, k)th element of the observed **information matrix** $\mathbf{I}(\boldsymbol{\beta})$ is given by $\partial^2 l_i / \partial \beta_j \partial \beta_k$ and may be written

$$[y_i - b'(\theta_i)] \frac{\partial}{\partial \beta_k} \left[\frac{1}{a_i(\phi_0)b''(\theta_i)} \frac{\partial \mu_i}{\partial \eta_i} x_{ij} \right] + \left[\frac{1}{a_i(\phi_0)b''(\theta_i)} \frac{\partial \mu_i}{\partial \eta_i} x_{ij} \right] \frac{\partial}{\partial \beta_k} [y_i - b'(\theta_i)]. \tag{6}$$

The use of the expected (Fisher) information obviates the need to derive an expression for the derivative in the first term, since $\mathrm{E}\{y_i - b'(\theta_i)\} = 0$. Therefore, if $[\mathcal{I}(\boldsymbol{\beta})] = \mathrm{E}\{[\mathbf{I}(\boldsymbol{\beta})]\}$ is the expected information matrix, the (j, k)th entry is given by

$$[\mathcal{I}(\boldsymbol{\beta})]_{jk} = \sum_{i=1}^{n} \frac{1}{a_i(\phi_0)b''(\theta_i)} \left(\frac{\partial \mu_i}{\partial \eta_i} \right)^2 x_{ij} x_{ik}. \tag{7}$$

The Fisher scoring method involves iterating according to

$$\tilde{\boldsymbol{\beta}}^{(h)} = \tilde{\boldsymbol{\beta}}^{(h-1)} + [\mathcal{I}(\tilde{\boldsymbol{\beta}}^{(h-1)})]^{-1} \mathbf{U}(\tilde{\boldsymbol{\beta}}^{(h-1)}), \tag{8}$$

where $\tilde{\boldsymbol{\beta}}^{(h)}$ denotes the value of $\boldsymbol{\beta}$ after h steps. Typically, iteration is continued until the distance between successive estimates becomes less than some tolerance level.

Note that when the canonical link is used, $\partial\mu_i/\partial\eta_i = \partial b'(\theta_i)/\partial\theta_i = b''(\theta_i)$, indicating that the first term in (6) vanishes even for the observed information matrix. Therefore, since the second term in (6) is not random, for canonical links the Fisher scoring procedure coincides with a standard Newton–Raphson search.

Iteratively Reweighted Least Squares

The Fisher scoring method is sometimes referred to as "iteratively reweighted least squares" and it is of interest to consider the reason for this. Multiplying both sides of (8) by $\mathcal{I}(\tilde{\boldsymbol{\beta}}^{(h-1)})$ gives

$$[\mathcal{I}(\tilde{\boldsymbol{\beta}}^{(h-1)})]\tilde{\boldsymbol{\beta}}^{(h)} = [\mathcal{I}(\tilde{\boldsymbol{\beta}}^{(h-1)})]\tilde{\boldsymbol{\beta}}^{(h-1)} + \mathbf{U}(\tilde{\boldsymbol{\beta}}^{(h-1)}). \tag{9}$$

The expected information matrix given by (7) can be expressed as

$$\mathcal{I} = \mathbf{X}'\mathbf{W}\mathbf{X},$$

where $\mathbf{X}$ is the matrix of covariates as before, and $\mathbf{W}$ is an $n \times n$ diagonal matrix with (j, j)th entry

$$[\mathbf{W}]_{jj} = \frac{(\partial\mu_j/\partial\eta_j)^2}{V_j}. \tag{10}$$

Also note that the score vector $\mathbf{U}$ may be rewritten using this notation as $\mathbf{X}'\mathbf{W}\mathbf{D}$, where $\mathbf{D} = (D_1, \ldots, D_n)'$ with $D_j = (y_j - \mu_j)\partial\eta_j/\partial\mu_j$. Thus, if $\mathbf{W}^{(h-1)}$ is the matrix formed by (10) evaluated at $\tilde{\boldsymbol{\beta}}^{(h-1)}$, (9) may be rewritten as

$$\begin{aligned}\mathbf{X}'\mathbf{W}^{(h-1)}\mathbf{X}\tilde{\boldsymbol{\beta}}^{(h)} &= \mathbf{X}'\mathbf{W}^{(h-1)}\mathbf{X}\tilde{\boldsymbol{\beta}}^{(h-1)} \\ &\quad + \mathbf{X}'\mathbf{W}^{(h-1)}\mathbf{D}^{(h-1)} \\ &= \mathbf{X}'\mathbf{W}^{(h-1)}\mathbf{Z}^{(h-1)},\end{aligned}$$

where $\mathbf{D}^{(h-1)}$ again indicates evaluation at $\boldsymbol{\beta}^{(h-1)}$, and $\mathbf{Z}^{(h-1)} = (Z_1^{(h-1)}, \ldots, Z_n^{(h-1)})'$ with

$$Z_j^{(h-1)} = \mathbf{x}_j'\tilde{\boldsymbol{\beta}}^{(h-1)} + D_j^{(h-1)}.$$

Therefore the iterative step given by (8) can equivalently be written as

$$\mathbf{X}'\mathbf{W}^{(h-1)}\mathbf{X}\tilde{\boldsymbol{\beta}}^{(h)} = \mathbf{X}'\mathbf{W}^{(h-1)}\mathbf{Z}^{(h-1)}. \tag{11}$$

Because the expression above is reminiscent of the equations of estimation for weighted least squares, the resulting algorithm is sometimes referred to as "iteratively reweighted least squares".

Alternative Methods of Estimation

For hierarchical **loglinear models**, **iterative proportional fitting** is another approach for maximum likelihood estimation [10]. In this approach, the parameter estimates are iteratively modified until the fitted values for the sufficient statistics are as close as possible to the observed values. See Agresti [1] or Bishop et al. [3] for details.

Other methods such as minimum chi-square, modified minimum chi-square, and minimum discrimination algorithms [1] are feasible, but do not in general provide maximum likelihood estimates, and so are not commonly used (*see* **Ban Estimates**).

Assessing Model Fit

A central question in fitting generalized linear models relates to quality of fit. That is, it is important that the model adequately reflect the variation and trends in the data before much stock is placed in the parameter estimates and related inferences. Issues pertaining to model fit may be broadly classified as based on the assessment of a particular model, or the assessment of one model relative to another.

Omnibus Goodness-of-fit Statistics

A natural basis on which to judge the quality of fit of a model is how closely the model-based estimates for the expected values, or fitted values, approximate the observed data. These fitted values are typically computed as

$$\hat{\mu}_i = \mu_i(\hat{\boldsymbol{\beta}}) = g^{-1}(\hat{\eta}_i),$$

where $\hat{\eta}_i = x_i'\hat{\boldsymbol{\beta}}$, $i = 1, \ldots, n$. To facilitate such an assessment it is instructive to conceptualize a so-called saturated model in which the observed data are reproduced exactly by the fitted values. Such a model can be obtained by allowing the number of parameters in the linear predictor to equal the number of observations and by judicious choice of the covariate vector. Note that while such a model

is attractive in that it reproduces the data, it does not serve the purpose of data reduction, and so is not particularly useful apart from as a benchmark for model assessment.

Let $\boldsymbol{\beta}^{\text{sat}}$ denote the $n \times 1$ vector of regression coefficients arising from the saturated model, and $\boldsymbol{\beta}^{\text{red}}$ denote the $p \times 1$ regression parameter of our reduced model ($p < n$). Again, we let $\hat{\boldsymbol{\beta}}^{\text{sat}}$ and $\hat{\boldsymbol{\beta}}^{\text{red}}$ represent the corresponding maximum likelihood estimates. Since the **likelihood ratio test** statistic

$$g_{\text{D}} = 2[l(\hat{\boldsymbol{\beta}}^{\text{sat}}) - l(\hat{\boldsymbol{\beta}}^{\text{red}})]$$

measures the "distance" or deviance between the saturated and reduced models on the likelihood metric, and because it plays an important role in what follows, it is referred to as the scaled deviance statistic". To be specific, we let G_{D} and g_{D} denote the random variable and realized value of the scaled deviance respectively. The (unscaled) deviance statistic simply refers to $\phi_0 g_{\text{D}}$.

An alternative intuitive omnibus measure for the quality of fit is the Pearson **chi-square statistic**, which takes the form

$$g_{\text{P}} = \sum_{i=1}^{n} \left[\frac{(y_i - \hat{\mu}_i)^2}{\hat{V}_i} \right] = \sum_{i=1}^{n} \left[\frac{(y_i - \hat{\mu}_i)^2}{a_i(\phi_0)v(\hat{\mu}_i)} \right].$$

A variety of other types of goodness of fit statistics are available. In fact, Cressie & Read [5] show that both the scaled deviance and Pearson chi-square statistics are members of a broader class of measures in the power divergence family. Here we restrict consideration to the scaled deviance and Pearson chi-square statistics.

For the Gaussian linear model with a known variance, g_{D} and g_{P} are the error sum of squares divided by the variance parameter, and so, subject to correct model specification are exactly chi-square distributed on $n - p$ degrees of freedom, In this context, values of g_{D} or g_{P} near $n - p$ are typically thought to represent an adequate fit of the model to the data, with large values suggesting that a substantial reduction in the quality of fit is incurred in using the reduced model vs. the saturated model. This judgment may be formalized and made somewhat more rigorous by exploiting the relevant **chi-square distribution** on $n - p$ **degrees of freedom**. That is, one can test with size α the **null hypothesis** of an adequate fit with the scaled deviance and claim an inadequate fit if $\Pr(T > g_{\text{D}}) < \alpha$, where T is a generic $\chi^2(n - p)$ random variable. Usually, however, in the Gaussian linear model, the dispersion parameter ϕ is unknown. It can be eliminated from the goodness-of-fit assessment by the use of the standard $\boldsymbol{F}$ **test** [12].

There is considerable debate over the role of the scaled deviance and Pearson statistics in the assessment of the overall fit of a non-Gaussian linear model. A key issue of debate is the adequacy of the approximation involved in adopting a chi-square reference distribution for these quantities. For concreteness and convenience, we illustrate the following points in the context of binomial data and subsequently make remarks specific to other distributions in the exponential family. Let the data consist of pairs $(y_i, \mathbf{x}_i)$, where $Y_i \sim$ bin $(m_i, \pi_i), i = 1, \ldots, n$ with $\log[\pi_i/(1 - \pi_i)] = \mathbf{x}_i'\boldsymbol{\beta}$. Then $\text{E}(Y_i) = \mu_i = m_i\pi_i$, which is estimated as $\hat{\mu}_i = m_i\hat{\pi}_i = m_i \exp(\mathbf{x}_i\hat{\boldsymbol{\beta}})/[1 + \exp(\mathbf{x}_i'\hat{\boldsymbol{\beta}})]$, where $\hat{\boldsymbol{\beta}}$ is the maximum likelihood estimate. If interest lies in the asymptotic behavior of a function of the estimated means, it is important to recognize that there are two ways in which the total amount of data may increase. The chi-square approximation of the deviance statistic under the binomial distribution is based on the behavior as m_i (and hence μ_i) tends to infinity, $i = 1, \ldots, n$, with the total number of binomial samples, n, fixed. In this case G_{D} is approximately independent of $\hat{\pi}_i, i = 1, \ldots, n$, and hence is a reasonable measure of goodness of fit. In contrast, McCullagh & Nelder [22] demonstrate that, as $n \to \infty$, if $m_i\pi_i(1 - \pi_i)$ is bounded, not only is the chi-square approximation to the distribution of G_{D} poor, but G_{D} is not independent of $\hat{\boldsymbol{\beta}}$. This latter point suggests that larger values of G_{D} need not reflect poor fit, but could simply arise due to a particular value of $\hat{\boldsymbol{\beta}}$. If $\hat{\mu}_i$ or $m_i - \hat{\mu}_i, i = 1, \ldots, n$ are relatively small, then one is faced with so-called sparse data. The Pearson statistic shares the degeneracy properties of the deviance statistic arising with very sparse data, which were considered by McCullagh & Nelder [22]. Thus caution is warranted for the use of either measure in these settings. Further studies of the asymptotic behavior of G_{D} and G_{P} for multinomial data, reviewed by Cressie & Read [6], suggest that the same considerations apply in this context. For Poisson data, the sparse data setting arises when $\hat{\mu}_i = \exp(\hat{\eta}_i)$ are small for some $i, i = 1, \ldots, n$. Hence the asymptotic chi-square approximations for Poisson models improve as $\mu_i \to \infty$ for each $i, i = 1, \ldots, n$.

A second consideration relates to the interpretation and the particular type of lack of fit that these statistics are designed to detect. Pierce & Schafer [24] suggest that in general the deviance provides a more meaningful measure of lack of fit than the Pearson statistic, and that given the inadequacy of the chi-square approximation for the distribution of G_D, efforts to provide a better approximation to its distribution, or to develop modifications to the deviance that maintain its attractive features, would be worthwhile. In particular, computer-intensive exact methods can be utilized to enumerate the distribution of G_D or G_P under an assumed model [6]. Alternatively, McCullagh [20, 21] suggests that the effect of the estimates on the distribution of G_D and G_P may be addressed by relying on estimates of the conditional **moments** of a goodness-of-fit statistic. Thus, rather than relying on approximate chi-square distributions, moments of the distribution of G_D, conditional on the sufficient statistics for $\boldsymbol{\beta}$, should be derived. Having derived the conditional means and variances, a normal approximation can then be employed to compute approximate significance levels for testing goodness of fit. To date, this proposal has received relatively little attention. See Firth [16] and the article on **Goodness of Fit** for further details.

Model Selection

Since parsimony is a major consideration in model selection, given a model with q covariates, it is often desirable to test whether a model with fewer covariates (say, $p < q$) would suffice. Let $\boldsymbol{\beta}_q = (\beta_1, \ldots, \beta_p, \beta_{p+1}, \ldots, \beta_q)'$ and $\boldsymbol{\beta}_p = (\beta_1, \ldots, \beta_p)'$ and suppose that interest lies in testing H_0: $\beta_{p+1} = \beta_{p+2} = \cdots = \beta_q = 0$. It is natural to carry out such a test by computing the corresponding likelihood ratio statistic $2[l(\hat{\boldsymbol{\beta}}_q) - l(\hat{\boldsymbol{\beta}}_p)]$, which is approximately chi-square distributed on $q - p$ degrees of freedom. Note that this may equivalently be thought of as the difference in the scaled deviance statistics for the model with q and p regression parameters.

For this reason one can think of tests of this sort as being directed at comparing the quality of fit of the reduced and fuller models and doing so based on the change in deviance. Specifically, we do this by examining whether the simpler model significantly reduces the quality of fit relative to the full model. If $G_D^{(q)}$ represents the deviance of a model with an $q \times 1$ vector $\boldsymbol{\beta}$, and if

$$\Delta G_D^{(q,p)} = G_D^{(q)} - G_D^{(p)},$$

then we reject $H_0 : \beta_{p+1} = \beta_{p+2} = \cdots = \beta_q = 0$ with size α if

$$\Pr(T > \Delta g_D^{(q,p)}) < \alpha,$$

where T is a generic $\chi^2(q - p)$ random variable and $\Delta g_D^{(q,p)}$ represents the realized change in deviance.

We remark that while the asymptotic chi-square approximation for the distribution of the scaled deviance may be questionable in many practical situations, the validity of the approximation for the comparison of nested unsaturated models, as described here, is typically quite good.

Residual Analyses

Residual analyses provide another means by which to investigate issues pertaining to quality of fit. We consider three types of residuals here, and cite Pierce & Schafer [24] for further details. The first two types are closely related to the scaled deviance and Pearson statistics previously discussed.

Note that the scaled deviance may be written as

$$g_D = \sum_{i=1}^{n} 2[l_i(\hat{\boldsymbol{\beta}}^{\text{sat}}) - l_i(\hat{\boldsymbol{\beta}}^{\text{red}})] = \sum_{i=1}^{n} d_i,$$

where d_i is the contribution from the ith subject to the overall statistic. The (scaled) deviance residual is taken as the signed square root of d_i and is denoted

$$r_{D_i} = (-1)^{I(y_i - \hat{\mu}_i < 0)}(d_i)^{1/2},$$

where $I(A)$ is an indicator function (*see* **Dummy Variables**) taking the value 1 if A is true and zero otherwise. These residuals have a limiting (i.e. $\mu_i \to \infty$) standard normal distribution, but the approximation for modest sample sizes can be improved by adopting an adjusted deviance residual of the form

$$r_{AD_i} = r_{D_i} + \delta(\hat{\boldsymbol{\beta}}),$$

where $\delta(\hat{\boldsymbol{\beta}}) = E[(Y_i - \mu_i)^3/6\hat{V}_i^{3/2}]$ [24].

The second type of residual is the Pearson residual, which takes the form

$$r_{P_i} = \frac{y_i - \hat{\mu}_i}{[V_i(\hat{\mu}_i)]^{1/2}}.$$

It is the signed square root of the contribution to g_P from the ith observation, and also has an asymptotically standard normal distribution.

Another class of residuals may be formed by considering **transformations** to the data such that the distribution of the residuals, linear in the transformed data, is more closely represented by the standard normal distribution. These transformations are generally derived to reduce the skewness of residuals taking the form

$$r_{A_i} = \frac{T(y_i) - \hat{E}[T(Y_i)]}{\{\text{var}[T(Y_i)]\}^{1/2}}.$$

Wedderburn is credited [2] with showing that, for likelihoods in the exponential family under a generalized linear model, the appropriate transformation $T(\cdot)$ is given by

$$T(\cdot) = \int \frac{d\mu}{v^{1/3}(\mu)}.$$

The particular form of such residuals will clearly depend on the family of distributions, and **numerical integration** may be required to find the appropriate form of $T(\cdot)$. Having obtained, analytically or numerically, the form of $T(\cdot)$, the approximate mean and variance terms necessary to compute r_{A_i} may be approximated by Taylor series expansion.

For discrete distributions, Pierce & Schafer [24] recommend adopting continuity corrected versions of the above residuals by replacing y_i with $y_i - 1/2$ if $y_i > \mu_i$ or with $y_i + 1/2$ if $y_i < \mu_i$. A detailed study suggests that the adjusted deviance residual, with continuity correction applied as appropriate, appears to be the most attractive since its sampling distribution is well approximated by the standard normal distribution, at least for binomial and Poisson data [24].

For further definitions of residuals, and a discussion of useful diagnostic procedures based on residuals, see the articles on **Residuals** and **Diagnostics**.

Assessment of the Link Function

When several link functions are available for use, it is desirable to consider the implications of link function **misspecification**, and to explore which link function provides the best fit to the data. On the former point, there exists a general theory of misspecified models [32]. With regard to generalized linear models, Fahrmeier & Tutz [13] make pertinent comments, and further related references are contained in this text.

The objective of discriminating between several link functions can be facilitated by casting these link functions into a broader parametric family. Thus, having specified a distribution from the exponential family and a set of covariates, a model may be specified with a parametric link $g(\mu; \boldsymbol{\gamma}) = \eta$, where $\boldsymbol{\gamma}$ is an $r \times 1$ parameter vector indexing members of the family of link functions. Typically, $r = 2$ forms a sufficiently rich class that it may contain relevant links, and even this has been argued by some to require a great deal of data to enable identification of suitable links. Specific two-parameter families have been proposed for various members of the exponential family, but applications to binomial data have received the most attention [8, 27, 29]. Prentice [26] and Pregibon [25] present quite general approaches.

There are several options available in terms of analyses involving such families. Perhaps the most obvious is to maximize the enriched log likelihood $l(\boldsymbol{\beta}, \boldsymbol{\gamma}; \mathbf{y})$ with respect to all parameters. It may be desirable, however, to identify which of the more commonly used link functions are supported by the data. In this case, examination of the **profile likelihood** of $\boldsymbol{\gamma}$ (in which $\boldsymbol{\beta}$ is a nuisance parameter) provides insight into the most plausible values of $\boldsymbol{\gamma}$. If $\boldsymbol{\gamma}_{10}$ and $\boldsymbol{\gamma}_{20}$ are specific values of $\boldsymbol{\gamma}$ corresponding to two commonly used links, likelihood ratio tests can in principle be performed to help determine which is more appropriate. An alternative strategy is to fit a model with a specific link given by $\boldsymbol{\gamma}_0$, and to carry out a score test of the hypothesis H_0: $\boldsymbol{\gamma} = \boldsymbol{\gamma}_0$ [27, 29] (*see* **Likelihood**).

Pregibon [25] describes the following convenient way in which to carry out approximate tests for the adequacy of a given link. If $g(\mu; \boldsymbol{\gamma}_0)$ is the specified link and $g(\mu; \boldsymbol{\gamma})$ is the correct link, note that by a first-order Taylor series expansion one can write

$$g(\mu; \boldsymbol{\gamma}_A) \simeq g(\mu; \boldsymbol{\gamma}_0) + \boldsymbol{\gamma}_*' \mathbf{D}(\mu; \boldsymbol{\gamma}_0),$$

where $\boldsymbol{\gamma}_* = (\boldsymbol{\gamma} - \boldsymbol{\gamma}_0)$ and $\mathbf{D}(\mu; \boldsymbol{\gamma}) = \partial g(\mu; \boldsymbol{\gamma})/\partial \boldsymbol{\gamma}$. Given the fitted value $\hat{\mu}$ obtained under the specified link, one can then evaluate $\mathbf{D}(\hat{\mu}; \boldsymbol{\gamma}_0)$. The approach then involves thinking of $\mathbf{D}(\hat{\mu}; \boldsymbol{\gamma}_0)$ as a vector of supplementary covariates to be added to the linear predictor. Fitting a revised model with $\boldsymbol{\gamma} = \boldsymbol{\gamma}_0$ and

$$\mathbf{x} = [x_1, x_2, \ldots, x_p, D_1(\hat{\mu}; \boldsymbol{\gamma}_0), \ldots, D_r(\hat{\mu}; \boldsymbol{\gamma}_0)]',$$

and testing the significance of $\boldsymbol{\gamma}_*$ via the change in deviance, is an approximate test of $H_0 : \boldsymbol{\gamma} = \boldsymbol{\gamma}_0$.

Pregibon [25] indicates that this method of testing may be thought of as equivalent to a test based on the first iteration of the method of Fisher scoring for the full likelihood approach with starting values given by $\hat{\boldsymbol{\beta}}_0$ (the MLE under the null model) and $\boldsymbol{\gamma}_0$.

Inference

Interval Estimation and Hypothesis Testing

Upon obtaining the maximum likelihood estimate $\hat{\boldsymbol{\beta}}$, it is natural to consider **hypothesis testing** and **interval estimation**. Here we discuss various options for interval estimation. Related procedures for hypothesis tests follow directly.

We consider the multiparameter case and, with only a slight loss of generality, suppose that interest lies in the first $r < p$ elements of $\boldsymbol{\beta}$. Full generality may be immediately achieved by reordering the elements of $\boldsymbol{\beta}$ such that the r parameters of interest are listed first, and by rearranging the information matrix conformably with this parameter vector. Let $\boldsymbol{\beta}_{(1)} = (\beta_1, \beta_2, \ldots, \beta_r)'$, $\boldsymbol{\beta}_{(2)} = (\beta_{r+1}, \beta_{r+2}, \ldots, \beta_p)'$, and hence $\boldsymbol{\beta} = (\boldsymbol{\beta}_1', \boldsymbol{\beta}_2')'$. Let $\mathcal{I}_{(1,1)}$ and $\mathcal{I}_{(2,2)}$ denote the $r \times r$ and $(p-r) \times (p-r)$ submatrices of $\mathcal{I}$ corresponding to $\boldsymbol{\beta}_{(1)}$ and $\boldsymbol{\beta}_{(2)}$ respectively, and let $\mathcal{I}_{(1,2)}$ and $\mathcal{I}_{(2,1)}$ denote the upper and lower off-diagonal submatrices, respectively, giving

$$\mathcal{I} = \begin{bmatrix} \mathcal{I}_{(1,1)} & \mathcal{I}_{(1,2)} \\ \mathcal{I}_{(2,1)} & \mathcal{I}_{(2,2)} \end{bmatrix}.$$

Furthermore, let

$$\boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{(1,1)} & \boldsymbol{\Sigma}_{(1,2)} \\ \boldsymbol{\Sigma}_{(2,1)} & \boldsymbol{\Sigma}_{(2,2)} \end{bmatrix}$$

denote the inverse of the expected information matrix partitioned conformably with $\mathcal{I}$.

From standard likelihood theory, $(\hat{\boldsymbol{\beta}}_{(1)} - \boldsymbol{\beta}_{(1)})' [\boldsymbol{\Sigma}_{(1,1)}]^{-1} (\hat{\boldsymbol{\beta}}_{(1)} - \boldsymbol{\beta}_{(1)})$ is an approximate $\chi^2(r)$ pivotal quantity (*see* **Fiducial Probability**) if $\boldsymbol{\Sigma}_{(1,1)}$ is evaluated at $(\hat{\boldsymbol{\beta}}_1, \hat{\boldsymbol{\beta}}_2)$. Hence one can construct an approximate joint **confidence** region for $\boldsymbol{\beta}_{(1)}$ with simultaneous coverage probability $100(1-\alpha)\%$, by finding all values of $\boldsymbol{\beta}_{(1)}$ for which

$$(\hat{\boldsymbol{\beta}}_{(1)} - \boldsymbol{\beta}_{(1)})' [\boldsymbol{\Sigma}_{(1,1)}]^{-1} (\hat{\boldsymbol{\beta}}_{(1)} - \boldsymbol{\beta}_{(1)}) < \chi^2_{1-\alpha}(r), \tag{12}$$

where $\boldsymbol{\Sigma}_{(1,1)}$ is evaluated at $(\hat{\boldsymbol{\beta}}_1, \hat{\boldsymbol{\beta}}_2)$.

As an alternative, score-based confidence intervals may be derived as follows. Let $\hat{\boldsymbol{\beta}}_{(2|1)}$ denote the profile likelihood estimate of $\boldsymbol{\beta}_{(2)}$ for specified $\boldsymbol{\beta}_{(1)}$. Furthermore, let $\mathbf{U}_{(1)}(\boldsymbol{\beta}_{(1)}, \hat{\boldsymbol{\beta}}_{(2|1)})$ denote the first r elements of $\mathbf{U}$ evaluated at $\boldsymbol{\beta}_{(1)}$ and $\hat{\boldsymbol{\beta}}_{(2|1)}$. Then an approximate $100(1-\alpha)\%$ score based joint confidence region for $\boldsymbol{\beta}_{(1)}$ is constructed by finding all values of $\boldsymbol{\beta}_{(1)}$ such that

$$\mathbf{U}_{(1)}'(\boldsymbol{\beta}_{(1)}, \hat{\boldsymbol{\beta}}_{(2|1)}) [\boldsymbol{\Sigma}_{(1,1)} - \boldsymbol{\Sigma}_{(1,2)} \boldsymbol{\Sigma}_{(2,2)}^{-1} \boldsymbol{\Sigma}_{(2,1)}]^{-1} \times \mathbf{U}_{(1)}(\boldsymbol{\beta}_{(1)}, \hat{\boldsymbol{\beta}}_{(2|1)}) < \chi^2_{1-\alpha}(r), \tag{13}$$

where all elements of $\boldsymbol{\Sigma}$ are evaluated at $(\boldsymbol{\beta}_{(1)}, \hat{\boldsymbol{\beta}}_{(2|1)})$.

Finally, an approximate joint likelihood based confidence region with simultaneous coverage probability $100(1-\alpha)\%$ is given by all values of $\boldsymbol{\beta}_{(1)}$ for which

$$2[l(\hat{\boldsymbol{\beta}}_{(1)}, \hat{\boldsymbol{\beta}}_{(2)}), -l(\boldsymbol{\beta}_{(1)}, \hat{\boldsymbol{\beta}}_{(2|1)})] < \chi^2_{1-\alpha}(r). \tag{14}$$

Under fairly standard regularity conditions, the asymptotic approximations involved for Wald and score-based intervals are $O_p(n^{-1/2})$, while those for likelihood ratio-based intervals are $O(n^{-1})$. High-order improvements in the former are available via the use of corrections from Edgeworth expansions (*see* **Skewness**), but the performance of likelihood ratio-based intervals is generally quite good even for relatively small samples [22].

Let $\boldsymbol{\beta}_{(10)}$ denote a specific value of $\boldsymbol{\beta}_{(1)}$. Approximate tests of the hypothesis H_0: $\boldsymbol{\beta}_{(1)} = \boldsymbol{\beta}_{(10)}$ can be carried out by evaluating the approximate pivotal quantities in (12)–(14) at the null value and computing the corresponding significance level. Specifically, Wald, score, and likelihood ratio based P values are derived by computing

$$P_W = \Pr(T > (\hat{\boldsymbol{\beta}}_{(1)} - \boldsymbol{\beta}_{(10)})' [\boldsymbol{\Sigma}_{(1,1)}]^{-1} \times (\hat{\boldsymbol{\beta}}_{(1)} - \boldsymbol{\beta}_{(10)})),$$

$$P_S = \Pr(T > \mathbf{U}_{(1)}'(\boldsymbol{\beta}_{(10)}, \hat{\boldsymbol{\beta}}_{(2|1)}) [\boldsymbol{\Sigma}_{(1,1)} - \boldsymbol{\Sigma}_{(1,2)} \times \boldsymbol{\Sigma}_{(2,2)}^{-1} \boldsymbol{\Sigma}_{(2|1)}]^{-1} \mathbf{U}_{(1)}(\boldsymbol{\beta}_{(10)}, \hat{\boldsymbol{\beta}}_{(2|1)})),$$

and

$$p_L = \Pr(T > 2[l(\hat{\boldsymbol{\beta}}) - l(\boldsymbol{\beta}_{(10)}, \hat{\boldsymbol{\beta}}_{(2|1)})]),$$

where $\hat{\boldsymbol{\beta}}_{(2|1)}$ now represents the maximum profile likelihood estimate of $\boldsymbol{\beta}_{(2)}$ at $\boldsymbol{\beta}_{(10)}$, and T is a generic $\chi^2(r)$ random variable.

The Dispersion Parameter

Implication of an Unknown Dispersion Parameter

Note that, thus far, we have assumed that the dispersion parameter ϕ was a known fixed parameter, and hence that the likelihood was a function only of the regression parameters in the linear predictor. As indicated earlier, this is entirely appropriate for binomial and Poisson responses with no **overdispersion** when the dispersion parameter is defined to be one. For other distributions in the exponential family, however, this parameter will also require estimation.

It would be natural to wonder how this might impact the methods of estimation and inference considered thus far. Fortunately, both the score vector and information matrix are scaled by ϕ and hence the Fisher scoring algorithm is unaffected by unknown ϕ; the maximum likelihood estimate for $\boldsymbol{\beta}$ arising from (8) is unaffected by unknown ϕ.

In terms of the interval estimates arising from (12)–(14), if an estimate $\tilde{\phi}$ is obtained, suitable adjustments are made by replacing ϕ_0 in $\mathcal{I}(\hat{\boldsymbol{\beta}})$ and $\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}})$ with $\tilde{\phi}$. Asymptotically, the methods for interval estimation and testing previously described will maintain their frequency properties.

Estimation of the Dispersion Parameter

A convenient, consistent and approximately unbiased estimate of ϕ is obtained by noting that if

$$G_{\mathrm{P}} = \sum_{i=1}^{n} \left[\frac{(y_i - \hat{\mu}_i)^2}{\hat{V}_i} \right]$$

is approximately chi-square distributed on $n - p$ degrees of freedom, then $\mathrm{E}(G_{\mathrm{P}}) = n - p$. However if $V_i = \phi v(\mu_i)/w_i$, a moment-type estimate (*see* **Method of Moments**) can be obtained by substituting this expression into G_{P}, equating this to its expected value, and solving for ϕ to give

$$\tilde{\phi} = \sum_{i=1}^{n} \frac{(y_i - \hat{\mu}_i)^2}{v(\hat{\mu}_i) w_i^{-1} (n - p)}. \qquad (15)$$

Note, for example, that in linear regression models with Gaussian residuals, (15) gives $\tilde{\phi}$ as the usual sample variance estimate based on the **mean square error**.

Overdispersed Data

One might elect to estimate a dispersion parameter even when one is not part of the specified distribution function. Distributions for which the variance is functionally determined by the mean (and possibly a weight) are potentially too restrictive for some applications. The binomial and Poisson distributions are two such distributions in which, even after control of all appropriate covariates, deviance statistics, residual plots, and other diagnostic procedures may demonstrate a nonnegligible lack of fit. If this apparent lack of fit is not limited to a small fraction of exceptional observations but, rather, appears to be a general inadequacy of the model, it is common to describe this feature as **overdispersion**, meaning that there is greater variability in the data than that expected based on the model.

In such situations, it is common to generalize the standard variance function $v(\mu) = \mu(1 - \mu)$ for binomial data and $v(\mu) = \mu$ for Poisson data) by the introduction of a dispersion parameter. The variance function is extended in the usual way, taking the form $V = \phi v(\mu)/w$.

The revised expected information matrix becomes $\mathcal{I}/\phi$, leading to information-based large-sample variance estimates inflated by a factor ϕ. This in turn leads to tests that are appropriately more conservative and confidence intervals for the regression coefficients that are correspondingly wider. The dispersion parameter is estimated again as in (15).

Alternative strategies for accommodating overdispersion are increasingly common. Mixed models may be formulated in which a latent **random effect** may be thought of as mimicking the explanatory role of one or more missing covariates that would explain the outlying observations. Such mixed models have seen a great deal of application in clustered/longitudinal data where, conditional on the random effect, the responses follow a distribution from the exponential family. The resulting marginal likelihoods sometimes have a closed form (as in a Poisson regression model with canonical link and a random intercept, $\exp(\beta_1)$, following a **gamma distribution**), but generally do not. See Fahrmeier & Tutz [13] for a good discussion of modeling, estimation, and inference issues related to mixed generalized linear models.

Applications

Example 4: Beetle Mortality Data

Bliss [4] provides data from a toxicology study in which beetles were assigned to one of eight groups and subsequently exposed to a specified dose of carbon disulfide. The response of interest relates to survival over a five hour exposure period, and can be summarized at the group level simply as the fraction of the entire sample of beetles at that dose group that survived. The dose, x_i, is measured as the logarithm (base 10) of the concentration of carbon disulfide (mg/l). If m_i is the number of beetles assigned to the ith dose group, then we assume that Y_i has a binomial probability mass function as in Example 2. The data are summarized in Table 1.

The fitted values which arise from fitting regression models with three different link functions are also given in Table 1, the corresponding maximum likelihood estimates are given in Table 2, and the corresponding Pearson residual plots are given in Figure 1. The deviance residuals give a similar plot. Note that the fitted values and residual plots indicate considerable variation in the quality of fit for the different link functions. In particular, since the residuals are much closer to zero on average, it appears that the model with the complementary log–log link fits the data better than either the logistic or probit models (*see* **Quantal Response Models**). This statement is not contradicted by the scaled deviance and Pearson chi-square statistics, suggesting that there is no need to accommodate overdispersion. On this basis it is most reasonable to base inference on the complementary log–log link model.

We can therefore claim that there is a very highly significant dose–response effect. An approximate Wald-based 95% confidence interval for β_2 is (18.52, 25, 56).

Example 5: Cellular Differentiation Data

Consider an *in vitro* biomedical study with the objective of investigating the tendency for two agents [tumor necrosis factor (TNF) and interferon (INF)] to induce cellular differentiation, and their tendency to act in a synergistic manner. In a study reported by Trinchieri et al. [30], cells were grouped and received one of 16 combination doses of TNF and IFN according to a two-way **factorial design**. We take as the response of interest

Table 1 Data and fitted values for beetle mortality data

Observation	Dose, x_i	Number, m_i	Dead, y_i	Fitted value, $\hat{\mu}_i$		
				Logit	Probit	CLL
1	1.691	59	6	3.457	3.358	5.589
2	1.724	60	13	9.842	10.722	11.281

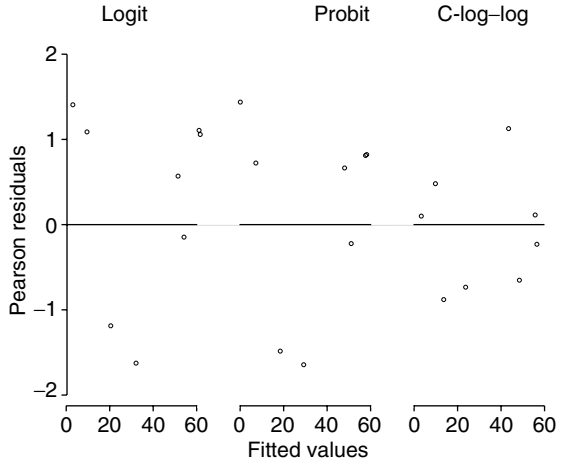

Figure 1 Residual plots for binary models with various link functions

Y_i, the number of cells showing evidence of cellular differentiation after exposure, and model this according to a Poisson process, as in Fahrmeier & Tutz [13].

Since a central question relates to the possible **synergism** of the two agents, we fit a Poisson regression model with the two main effects and a first-order interaction. The results are given in Table 3 and appear to indicate synergism. Examination of various types of residuals (plots not shown here) reveal serious lack of fit of this model to the data. Since no other covariates are available, we elect to introduce a dispersion parameter into the model. Using the moment estimate for ϕ given by (15), we obtain $\tilde{\phi} = 140.82/(16-4) = 11.735$. The revised large sample standard errors for the regression coefficients are then computed from the revised large sample covariance matrix $(11.735)^{1/2} \times [\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}})]^{1/2}$ and are also given in Table 3. An approximate 95% confidence interval for β_4 is given by $(-1.472 \times 10^{-4}, 3.383 \times 10^{-5})$, and suggests that there remains little evidence of a synergistic effect after addressing the lack of fit of the Poisson model via the introduction of the additional dispersion parameter.

Quasi-likelihood

Wedderburn [31] used the term **quasi-likelihood** to describe objective functions that can be used to generate estimates of a linear regression model in a somewhat more general context than has been discussed thus far. The approach is based on the fact that the score vectors and information matrices arising from a generalized linear model from the exponential family rely solely on the first and second moments of the assumed distributions. This suggests more general models may be formulated subject to specification of mean and variance functions (and a dispersion parameter as appropriate).

To this end, let $y_1, y_2, \ldots, y_n$ denote a sample of observations, where associated with y_i is a $p \times 1$ vector of explanatory covariates $\mathbf{x}_i$. Let $\mathrm{E}(Y_i) = \mu_i$ and $\mathrm{var}(Y_i) = V_i = \phi v(\mu_i)/w_i$ and $g(\mu_i) = \mathbf{x}_i'\boldsymbol{\beta}$ as before, where $\boldsymbol{\beta}$ is a $p \times 1$ vector of regression parameters and $g(\cdot)$ is a link function. The generalization originates from the fact that $v(\mu_i)$ can be a somewhat arbitrary variance function and is not necessarily determined by a particular distribution in the exponential family.

Equations of the form

$$U_j(\boldsymbol{\beta}) = \sum_{i=1}^{n} \frac{(y_i - \mu_i)}{\phi w_i^{-1} v(\mu_i)} \frac{\partial \mu_i}{\partial \beta_j} = 0, \quad j = 1, 2, \ldots, p,$$

may be solved to obtain a consistent estimate of $\boldsymbol{\beta}$. This solution may be aided as before, by a modified

Table 3 Maximum likelihood estimates for cellular differentiation data

Parameter	Poisson		Overdispersed Poisson	
	$\hat{\beta}_j$	$\{[\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}})]_{jj}\}^{1/2}$	$\hat{\beta}_j$	$\{\tilde{\phi}[\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}})]_{jj}\}^{1/2}$

Newton–Raphson procedure in which the variance of $\mathbf{U}(\boldsymbol{\beta})$ is estimated by the expected value of $\mathrm{E}\{\partial\mathbf{U}(\boldsymbol{\beta})/\partial\boldsymbol{\beta}\}$ which is a $p \times p$ matrix with (j,k)th element

$$\mathcal{I}_{jk}(\boldsymbol{\beta}) = \sum_{i=1}^{n} \frac{\partial\mu_i/\partial\beta_j \partial\mu_i/\partial\beta_k}{\phi w_i^{-1} v(\mu_i)}.$$

Specifically,

$$\hat{\boldsymbol{\beta}}^{(h)} = \hat{\boldsymbol{\beta}}^{(h-1)} + [\mathcal{I}(\hat{\boldsymbol{\beta}}^{(h-1)})]^{-1}\mathbf{U}(\hat{\boldsymbol{\beta}}^{(h-1)}).$$

Again, by equating the Pearson statistic to its degrees of freedom, the dispersion parameter may be estimated as

$$\tilde{\phi} = \sum \frac{(y_i - \hat{\mu}_i)^2}{v(\hat{\mu}_i) w_i^{-1}(n-p)}, \tag{16}$$

and the large sample covariance matrix for $\hat{\boldsymbol{\beta}}$ is given by $[\mathcal{I}(\hat{\boldsymbol{\beta}})/\tilde{\phi}]^{-1} = \tilde{\phi}\boldsymbol{\Sigma}(\hat{\boldsymbol{\beta}})$.

The term "quasi-likelihood" comes from the fact that $\mathbf{U}(\boldsymbol{\beta})$ behave in many respects like score vectors from a bona fide likelihood function from the exponential family, and thus may be thought of as quasi-score equations. Furthermore, one can construct a **quasi-likelihood function** $Q(\boldsymbol{\beta}, \phi; y)$ by integrating

$$Q(\boldsymbol{\beta}, \phi; y) = \int_y^{\mu} \frac{(y-t)}{\phi w_i^{-1} v(\mu)} \frac{\mathrm{d}\mu}{\mathrm{d}\beta}\, \mathrm{d}t.$$

This can in turn be used to define quasi-likelihood ratio statistics which behave similarly to genuine likelihood ratio statistics, although the distributional approximations are of lower order [19].

A variety of other quasi-likelihood approaches have been proposed for use when the variance function does not have the form $\mathrm{var}(Y_i) = \phi v(\mu)/w_i$. Scenarios for which this is not a viable assumption include most mixed models, autoregressive models (*see* **ARMA and ARIMA Models**), and very general **multivariate** responses. Liang & Zeger [18] adopted a quasi-likelihood approach for estimation in the context of longitudinal/clustered data and coined the term **generalized estimating equation**. In this context the variance functions are arranged in matrix form and, with arbitrary specification, the estimating equations yield consistent estimators for the regression parameters. Various estimates for the covariance parameters under particular formulations may be defined based on Pearson-type residuals.

Crowder [7], Firth [15], and Godambe & Thompson [17] discuss quadratic estimating equations in which improved efficiency of estimation can be achieved by specification of higher-order moments of the response (*see* **Estimating Functions**). Prentice & Zhao [28] motivate joint estimating equations for mean and covariance parameters from quadratic exponential models. For further comments, see Dean [9] and Zhao & Prentice [33]. For textbook treatments of the subject, refer to Fahrmeier & Tutz [13] and Diggle et al. [11].

Software

There are now numerous statistical **software** packages available for fitting generalized linear models. Fahrmeier & Tutz [13] contains an annotated appendix devoted to the discussion of software packages and so serves as a useful reference.

The package GLM is specialized for fitting generalized linear models and there is now a "glm" function in **S-PLUS**. SAS has various procedures available for fitting particular types of generalized linear model, and a generic procedure is currently under development. SPSS and BMDP also have routines that facilitate fitting many types of linear models from the exponential family, but no generic procedures are currently available.

RICHARD J. COOK

Generalized Linear Models for Longitudinal Data

Generalized linear models [8] have unified **regression** analysis for discrete and continuous, *independent* responses. In **longitudinal** studies, however, we observe repeated observations on each of many independent persons. It is likely that repeated responses for the same person are **autocorrelated** with one another. This correlation must be taken into account to draw valid and efficient inferences about parameters of scientific interest.

With a single observation on each subject, the only available target of estimation is $E(Y)$, the marginal mean or cross-sectional average value among persons with the same value of x. For example, in a **cross-sectional study** of alcohol use, this might be the prevalence of reported use in the population sample under study. With repeated observations on each person, there are additional possible targets, including the conditional mean given past responses, or the conditional mean given underlying latent variables (*see* **Random Coefficient Repeated Measures Model**). Approaches to longitudinal data analysis can be distinguished by their target of estimation. Different targets also correspond to different assumptions about the source of autocorrelation.

It is possible to formulate linear models for correlated responses so that the interpretation of regression parameters is insensitive to the particular target or model for **correlation**. With nonlinear models such as **logistic regression**, distinct targets have regression parameters with distinct interpretations. This article contrasts three approaches to longitudinal data analysis: **marginal**, **random effects**, and **transition** models, each with its own target of estimation and implied autocorrelation structure.

To illustrate the ideas, we focus on data from a Johns Hopkins Prevention Research Center (PRC), randomized community trial [5] in which first grade youths in Baltimore City received in 1986 either a behavioral or reading intervention and were visited at least once a year to monitor their mental health development. We consider data on reported alcohol use and level of psychiatric distress in a subset of 692 youths who had complete data for the years 1991–1994. In 1991 the youths were between the ages of 10 and 14. A question we address is whether youths with higher levels of distress as measured by a 14-item questionnaire are more likely to self-report having ever used alcohol.

Psychiatric distress was measured by administering 14 items asking the youth whether or not he: worries a lot, is afraid a lot, has trouble sleeping, worries that bad things will happen, is sad, has nothing that makes him/her happy, is afraid to go outside, wants to hurt himself, worries parents will never come back, is tired all the time, and does not feel like eating. Each item is rated on a four-point scale with higher score indicating greater psychiatric distress. An age-standardized mean score was used as the predictor variable in this analysis. The response variable is a self-report of whether or not the youth had ever consumed alcohol. Note that in the absence of reporting errors, having reported use in one year would determine the outcome in subsequent years. But this is not the case here because of the substantial inconsistencies in the reported records.

Approaches to Modeling

In this section we consider model formulation and interpretation for the three kinds of generalized linear model: marginal, random effects, and transition models, each with a unique target of estimation. To illustrate the differences between the three approaches, we focus in each case on the problem of relating a **binary** response, Y, such as alcohol use, and a single explanatory variable, x, for example psychiatric distress score. The standard generalized linear model for this problem when the responses are mutually independent is the logistic linear regression model,

$$\text{logit } \Pr(Y = 1) = \beta_0 + \beta_1 x, \qquad (1)$$

where $\text{logit } \Pr(Y = 1) = \log[\Pr(Y = 1)/\Pr(Y = 0)]$ is also called the log **odds**.

For longitudinal data, repeated observations on the same subject are typically correlated. The three kinds of model discussed below differ in their target of estimation and in the way they introduce correlation structure, and this has implications for the correct interpretation of the regression parameter β_1.

Notation

We use Y_{ij} to denote the jth of n_i responses on the ith of m subjects. Each Y_{ij} is associated with a unique time t_{ij} at which the response is measured. Associated with each response Y_{ij} is a vector $\mathbf{x}'_{ij} = (x_{ij1}, \ldots, x_{ijp})$ of explanatory variables. We write $\mu_{ij} = \mathrm{E}(Y_{ij})$ and $V_{ij} = \mathrm{var}(Y_{ij})$.

A classical generalized linear model [8] assumes that the complete set of responses Y_{ij}, $j = 1, \ldots, n_i$, $i = 1, \ldots, m$ are mutually independent, with means and variances determined as follows:

$$h(\mu_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta}, \text{ for some known } \textit{link function } h(\cdot);$$
$$V_{ij} = \phi V(\mu_{ij}), \quad \text{for some known } \textit{variance function } V(\cdot).$$

We call the above a *cross-sectional* generalized linear model, to distinguish it from a *longitudinal* generalized linear model, in which we retain this basic structure but relax the independence assumption.

Marginal Models

In a marginal model the target of estimation is the population-average or cross-sectional mean response, μ_{ij}. We model the relationship of this marginal mean and the explanatory variables $\mathbf{x}_{ij}$ separately from the within-subject correlation. Specifically, a marginal model makes the following assumptions:

$$h(\mu_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta},$$
$$V_{ij} = \phi V(\mu_{ij}),$$
$$\mathrm{corr}(Y_{ij}, Y_{ik}) = \rho(\mu_{ij}, \mu_{ik}; \boldsymbol{\alpha}), \quad \text{where } \rho(\cdot) \text{ is a known function.}$$

The first two of these assumptions are exactly the assumptions made in a cross-sectional generalized linear model. It follows that the marginal regression coefficients, $\boldsymbol{\beta}$, have the same interpretation as coefficients from a cross-sectional analysis.

In the PRC study, we express the log odds of alcohol use as a function of age and psychiatric distress score. From (1) we see that the regression parameter β for distress score represents the change in the log odds of reporting having ever used alcohol per unit increase in the explanatory variable x. By construction, this change is averaged over the whole population. A marginal regression model does not address questions concerning heterogeneity between subjects. Nor, in the longitudinal setting, does it address questions concerning the possible effect of a subject's previous responses on their current response.

Random Effects Models

In a random effects generalized linear model, the target of estimation is the mean of Y_{ij}, conditionally on the values of unobserved (latent) **random variables**, $\mathbf{U}_i$, specific to person i. For example, when the outcome is a binary indicator of alcohol use, the latent variable might represent the youth's predisposition to use and/or report the use of alcohol. Specifically, for each i let $\mathbf{U}_i$ denote a vector of random variables of dimension q, representing the ith subject, and let $\mathbf{d}_{ij}$ denote an associated vector of q explanatory variables. The $\mathbf{U}_i$ are assumed to be mutually independent with a common underlying **multivariate distribution**, usually multivariate Gaussian (*see* **Multivariate Normal Distribution**), and the assumptions of the cross-sectional generalized linear model are modified to

$$h(\mu^{\mathrm{c}}_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta}^* + \mathbf{d}'_{ij}\mathbf{U}_i,$$
$$V^{\mathrm{c}}_{ij} = \phi V(\mu^{\mathrm{c}}_{ij}),$$

where μ^{c}_{ij} and V^{c}_{ij} denote the conditional mean and variance of Y_{ij}, given $\mathbf{U}_i$. We use $\boldsymbol{\beta}^*$ rather than $\boldsymbol{\beta}$ to emphasize that the substantive meaning of the regression parameter is different from that of $\boldsymbol{\beta}$ in a marginal model. The random vector $\mathbf{U}_i$ represents a set of unobserved, or latent, characteristics of the ith subject which influence the mean response; for example, if $\mathbf{d}'_{ij} = (1, t_{ij})$, then the elements of $\mathbf{U}_i$ correspond to the intercept and slope of a subject-specific time trend in the mean response.

In the specific case of a simple logistic regression and scalar Gaussian U_i, the random effects GLM reduces to

$$\text{logit } \Pr(Y_{ij} = 1|U_i) = \beta^*_0 + \beta^*_1 x_{ij} + \alpha U_i, \qquad (2)$$

where $U_i \sim \mathrm{N}(0,1)$. Note that the restriction to a **standard normal** distribution for U_i implies no loss of generality, as any other mean and/or variance of U_i could be absorbed into the model parameters β^*_0 and α. In (2), the regression parameter β^*_1 again represents a change in the log odds per unit change in x, but this is now conditional on the subject's own value of

U_i. It is instructive to derive the marginal properties of the random effects model (2). This requires us to integrate out the dependence on the unobserved $\mathbf{U}_i$. For example, the unconditional mean response is

$$\Pr(Y_{ij}=1) = \int \Pr(Y_{ij}=1|u) f(u)\ \mathrm{d}u$$
$$= \int \frac{\exp(\beta_0^* + \beta_1^* x_{ij} + \alpha u)}{1+\exp(\beta_0^* + \beta_1^* x_{ij} + \alpha u)} f(u)\ \mathrm{d}u,$$

where $f(\cdot)$ is the standard Gaussian density function. This integral is not easily expressible in closed form, but a good approximation is available. Zeger et al. [15] show that for the model (2),

$$\text{logit}\ P(Y_{ij}=1) \approx (c^2\alpha^2+1)^{-1/2}(\beta_0^* + \beta_1^* x_{ij}), \tag{3}$$

where $c = 16(3)^{1/2}/(15\pi)$, from which it follows that

$$\boldsymbol{\beta} \approx (c^2\alpha^2+1)^{-1/2}\boldsymbol{\beta}^*, \tag{4}$$

where $c^2 \approx 0.346$. This **shrinkage** effect is also easily demonstrated by **simulation**. Figure 1 illustrates a simulation of the model (2) when $\beta_0^* = -1$, $\beta_1^* = 1$, and $\alpha = 1.5$. The solid lines show $\Pr(Y_{ij}=1|U_i)$ as functions of x for each of 25 subjects whilst the dotted line shows $\Pr(Y_{ij}=1)$, calculated as the average of all 25 subject-specific functions. The dotted line, which is in effect what we would be estimating in a marginal model, is very well approximated by a linear logistic, but with the regression parameter β_1 substantially smaller than β_1^*, as predicted by (4). Note that α is a measure of the degree of heterogeneity between subjects, because the subject-specific intercepts are $\beta_0 + \alpha U_i; i = 1, \ldots, m$, and the U_i have a standard Gaussian distribution.

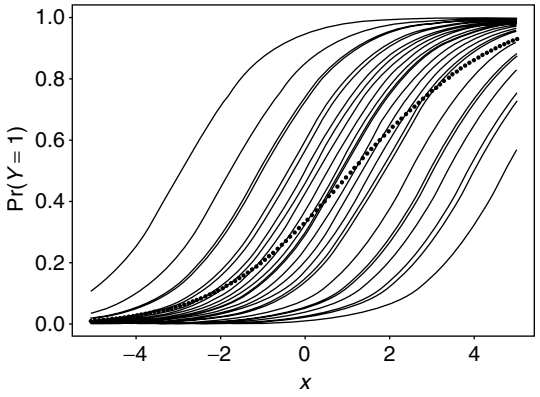

Figure 1 Simulation of the probability of a positive response in a random intercept model logit $\Pr(Y_{ij}=1|U_i) = -1.0 + x_{ij} + 1.5U_i$, where U_i is a standard normal random variable. The dotted line is the average over all 25 subjects

Incidentally, if we replace the logit link in (3) by the probit we can derive an exact expression for the shrinkage of the regression parameter. We now have

$$\Pr(Y_{ij}=1) = \int \Phi(\beta_0^* + U_i + \beta_1^* x_{ij}) f(u)\ \mathrm{d}u, \tag{5}$$

where $\Phi(\cdot)$ is the standard Gaussian distribution function. Using the threshold interpretation of the probit model and the property that the sum of two Gaussian random variables is itself Gaussian, (5) becomes

$$\Pr(Y_{ij}=1) = \Phi[(1+\alpha^2)^{-1/2}(\beta_0^* + \beta_1^* x_{ij})]. \tag{6}$$

In particular, the marginal regression parameter in this random effects model is $\beta_1 = (1+\alpha^2)^{-1/2}\beta_1^*$.

Transition Models

In a transition GLM, the target of estimation is the conditional mean at a fixed time given the history of responses to that point. Hence we model the mean and variance of Y_{ij}, conditionally on past responses $Y_{i,j-k}$, for $k \geq 1$. For example, we might replace the assumptions of a cross-sectional GLM by

$$h(\mu_{ij}^{\mathrm{t}}) = \mathbf{x}_{ij}'\boldsymbol{\beta}^{**} + \sum_{k=1}^{r} \alpha_k y_{i,j-k},$$
$$V_{ij}^{\mathrm{t}} = \phi V(\mu_{ij}^{\mathrm{t}}),$$

where now μ_{ij}^{t} and V_{ij}^{t} are the expectation and variance of Y_{ij} conditional on all $Y_{i,j-k}$ for $k \geq 1$, and the notation $\boldsymbol{\beta}^{**}$ emphasizes that the regression parameters again differ in their substantive meaning from the regression parameters in the analogous marginal or random effects models. The integer r is called the *order* of the model. Note that, strictly, the above assumptions do not determine the joint distribution of $Y_{i1}, \ldots, Y_{in}$, but only the conditional distribution of $Y_{i,r+1}, \ldots, Y_{in}$ given $Y_{i1}, \ldots, Y_{ir}$. This reduces the practical usefulness of transition models when n, the number of observations per subject, is small.

A simple example of a transition logistic regression GLM is the first-order model in which

$$\text{logit } \Pr(Y_{ij} = 1 | Y_{i,j-k} : k \geq 1) = \beta_0^{**} + \beta_1^{**} x_{ij} + \alpha Y_{i,j-1}. \quad (7)$$

The transition model (7) is superficially similar to the random effects model (2), in the sense that both include a stochastic term in the linear predictor for the conditional mean response. However, the effect of the stochastic term is somewhat different for two reasons: first, the "random intercept" $\beta_0^{**} + \alpha Y_{i,j-1}$ takes one of only two possible values according to whether $Y_{i,j-1} = 0$ or 1; secondly, and perhaps more importantly, the random intercept for a given subject changes over time and has a reinforcing effect over time because for $\alpha > 0$, a realized value of $Y_{ij} = 1$ increases the conditional probability that $Y_{i,j+1}$ will also equal 1. Note also that, in contrast to the analogous random effects model (2), the physical meaning of the parameter α depends on the time separation between $t_{i,j-1}$ and t_{ij}. The model as defined therefore makes no sense either for data collected at irregularly spaced times, or for data in which the set of measurement times is not common to all subjects.

Simulation again provides a convenient way to illustrate the kind of relationships that can arise between the transition regression parameter β_1^{**} in (7) and the corresponding marginal regression parameter. Figure 2 shows a simulation of the model (7) in which $\beta_0^{**} = -1, \beta_1^{**} = 1, \alpha = 1.5$, and measurements are taken on each of 1100 subjects at times $t_j = j - 6; j = 1, \ldots, 11$. Part (a) uses $x_{ij} = t_j$ for each subject to represent an increasing time trend in the probability of a positive response, whereas part (b) uses $x_{ij} = x_i$ to correspond to a time-independent explanatory variable, and with 100 of the 1100 subjects assigned to each of 11 equally spaced values of x_i to span the range -5 to 5. The solid lines show the two conditional probabilities $\Pr(Y_{ij} = 1)$ given $Y_{i,j-1} = 0$ and given $Y_{i,j-1} = 1$, each as a function of x. The dots show the observed proportions of positive responses amongst the 100 responses associated with each of the 11 values of x. In both cases this marginal proportion increases more rapidly with x than do either of the two conditional proportions, that is, the marginal regression parameter of (7) is $\beta_1 > \beta_1^{**}$. In these simulations we generated initial observations Y_{i0} at time $t_0 = -6$ by sampling from

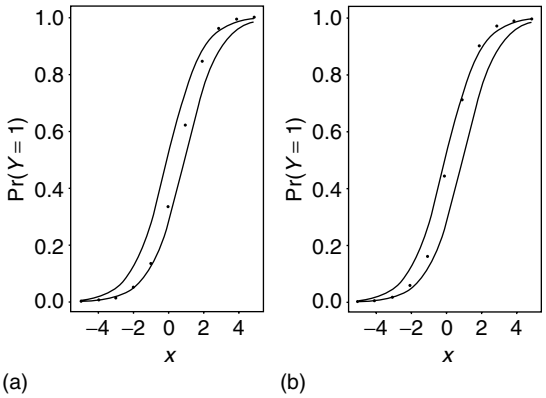

Figure 2 Simulation of the probability of a positive response in a transition logistic regression model $\text{logit } \Pr(Y_{ij} = 1 | Y_{i,j-k} : k \geq 1) = -1.0 + x_{ij} + 1.5 Y_{i,j-1}$, $j = 1, \ldots, 11, i = 1, \ldots, 1100$. Part (a) $x_{ij} = j - 6$ for each subject; Part (b) uses $x_{ij} = x_i$, to correspond to a time-independent explanatory variable with 100 of the 1100 subjects assigned to each of 11 equally spaced values of x_i to span the range -5 to 5. The solid lines show the two conditional probabilities $\Pr(Y_{ij} = 1)$ given $Y_{i,j-1} = 0$ and given $Y_{i,j-1} = 1$, each as a function of x. The dots show the observed marginal proportions of positive responses amongst the 100 responses associated with each of the 11 values of x

independent Bernoulli distributions with

$$\text{logit } \Pr(Y_{i0} = 1) = \beta_0^{**} + \beta_1^{**}[(x_{i1} - (x_{i2} - x_{i1})] + 0.5\alpha,$$

which is equivalent to extrapolating the time trend in the explanatory variable for each subject and taking a notional value of 0.5 for a fictitious observation at time $t_{-1} = -7$.

Inference

With random effects and transitional extensions of the GLM, it is possible to estimate unknown parameters using traditional **maximum likelihood** methods.

For random effects models, the likelihood of the data, expressed as a function of the unknown parameters, is given by

$$L(\boldsymbol{\beta}^*, \boldsymbol{\alpha}; \mathbf{y}) = \prod_{i=1}^{m} \int \prod_{j=1}^{n_i} f_{ij}(y_{ij} | \mathbf{u}) f(\mathbf{u}; \boldsymbol{\alpha}) \, \mathrm{d}\mathbf{u}, \quad (8)$$

where $\boldsymbol{\alpha}$ represents the parameters of the random effects distribution. The likelihood is the integral over the unobserved random effects of the joint distribution of the data and the random effects. Except in the special case of a Gaussian linear model, **numerical integration** techniques are usually necessary to evaluate the likelihood (8).

Transition models can also be fitted using a version of maximum likelihood. The joint distribution of the responses $Y_{i1}, \ldots, Y_{in_i}$ can be written in the form

$$\begin{aligned} f(y_{i1}, \ldots, y_{in_i}) = {} & f(y_{in_i}|y_{i,n_i-1}, \ldots, y_{i1}) \\ & \times f(y_{i,n_i-1}|y_{i,n_i-2}, \ldots, y_{i1}) \ldots \\ & f(y_{i2}|y_{i1}) f(y_{i1}). \end{aligned} \tag{9}$$

In a first-order Markov model (*see* **Markov Chains**)

$$f(y_{ij}|y_{i,j-1}, \ldots, y_{i1}; \boldsymbol{\beta}^{**}, \boldsymbol{\alpha}) = f(y_{ij}|y_{i,j-1}; \boldsymbol{\beta}^{**}, \boldsymbol{\alpha})$$

so the **likelihood** contribution from person i simplifies to

$$\begin{aligned} & f(y_{i1}, \ldots, y_{in_i}; \boldsymbol{\beta}^{**}, \boldsymbol{\alpha}) \\ & \quad = f(y_{i1}; \boldsymbol{\beta}^{**}, \boldsymbol{\alpha}) \prod_{j=2}^{n_i} f(y_{ij}|y_{i,j-1}; \boldsymbol{\beta}^{**}, \boldsymbol{\alpha}). \end{aligned} \tag{10}$$

One difficulty that arises with (10) is that the marginal distribution of Y_{i1} often cannot be determined from the conditional distributions $f(y_{ij}|y_{i,j-1})$ without additional assumptions. A simple alternative is then to maximize the *conditional likelihood* of $Y_{i2}, \ldots, Y_{in_i}$ given Y_{i1}, which is obtained by omitting $f(y_{i1})$ from the equation above (*see* **Conditionality Principle**). Conditional maximum likelihood estimates can be found using standard GLM **software**, treating functions of the previous responses as explanatory variables. Inferences conditional on Y_{i1} are less efficient than maximum likelihood estimators but are all that is available without additional assumptions about $f(Y_{i1})$. The need to condition on the initial response from each subject makes it clear why these models are of limited value for short series, and the problem is exacerbated for transition models of higher order.

In the marginal model described above, we need only specify the first two **moments** of the responses for each person. With Gaussian data, the first two moments fully determine the likelihood, but this is not the case for GLM models in general. Hence, to use likelihood-based inference, additional assumptions about higher order moments must also be made. Examples for binary data are given by Prentice & Zhao [10], Fitzmaurice & Laird [2], and Liang et al. [7].

Even if additional assumptions are made, the likelihood is often intractable and involves many nuisance parameters in addition to $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ which must be estimated. For this reason, in applications for which the marginal regression parameters address the questions of primary scientific inference, a better approach may be to use **generalized estimating equations** or GEE. This is a multivariate analog of **quasi-likelihood**, with the same feature that it leads to **consistent** inferences about mean responses without requiring specific assumptions to be made about second and higher-order moments. Here, we give only a brief outline. For more detailed accounts, see Liang & Zeger [6], Zeger & Liang [14] and Prentice [9].

In the absence of a convenient likelihood function, the GEE method estimates $\boldsymbol{\beta}$ by solving a multivariate analog of the quasi-score function [12]:

$$\mathbf{S}_\beta(\boldsymbol{\beta}, \boldsymbol{\alpha}) = \sum_{i=1}^{m} \left(\frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}} \right)' \mathrm{var}(\mathbf{Y}_i)^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i) = \mathbf{0}. \tag{11}$$

In the multivariate case there is the additional complication that $\mathbf{S}_\beta$ depends on $\boldsymbol{\alpha}$ as well as on $\boldsymbol{\beta}$ since $\mathrm{var}(\mathbf{Y}_i) = \mathrm{var}(\mathbf{Y}_i; \boldsymbol{\beta}, \boldsymbol{\alpha})$. This can be overcome by replacing $\boldsymbol{\alpha}$ in the equation above by an $m^{1/2}$-consistent estimate, $\hat{\boldsymbol{\alpha}}(\boldsymbol{\beta})$. Liang et al. [7] and Gourieroux et al. [3] show that the solution of the resulting equation is asymptotically as **efficient** as if $\boldsymbol{\alpha}$ were known.

The correlation parameters $\boldsymbol{\alpha}$ may be estimated in a similar fashion by simultaneously solving $\mathbf{S}_\beta = \mathbf{0}$ and

$$\mathbf{S}_\alpha(\boldsymbol{\beta}, \boldsymbol{\alpha}) = \sum_{i=1}^{m} \left(\frac{\partial \boldsymbol{\eta}_i}{\partial \boldsymbol{\alpha}} \right)' \mathbf{H}_i^{-1} (\mathbf{W}_i - \boldsymbol{\eta}_i) = \mathbf{0}, \tag{12}$$

where $\mathbf{W}_i = (Y_{i1}Y_{i2}, Y_{i1}Y_{i3}, \ldots, Y_{i,n_i-1}Y_{in_i}, Y_{i1}^2, Y_{i2}^2, \ldots, Y_{in_i}^2)'$, the set of all products of pairs of responses and squared responses, and $\boldsymbol{\eta}_i = \mathrm{E}(\mathbf{W}_i; \boldsymbol{\beta}, \boldsymbol{\alpha})$ [9].

The choice of the weight matrices, $\mathbf{H}_i$, in (12) will affect the efficiency of the resulting estimators, and good choices are problem-dependent. When the

parameters $\boldsymbol{\alpha}$ are not of direct interest, we can use simple models for the within-subject correlation leading to a *working variance matrix*, $\mathbf{W}_i$. Substituting this for var(Y_i), gives the estimating equations

$$\mathbf{S}_\beta(\boldsymbol{\beta}) = \sum_{i=1}^{m} \left(\frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}} \right)' \mathbf{W}_i^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i) = 0. \quad (13)$$

The solution, $\hat{\boldsymbol{\beta}}$, of (14) is asymptotically Gaussian [6], with variance consistently estimated by

$$\left(\sum_{i=1}^{m} \mathbf{D}_i' \mathbf{W}_i^{-1} \mathbf{D}_i \right)^{-1} \left(\sum_{i=1}^{m} \mathbf{D}_i' \mathbf{W}_i^{-1} \mathbf{V}_{0i} \mathbf{W}_i^{-1} \mathbf{D}_i \right) \times \left(\sum_{i=1}^{m} \mathbf{D}_i' \mathbf{W}_i^{-1} \mathbf{D}_i \right)^{-1} \quad (14)$$

evaluated at $\hat{\boldsymbol{\beta}}$, where

$$\mathbf{D}_i = \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}$$

and

$$\mathbf{V}_{0i} = (\mathbf{y}_i - \boldsymbol{\mu}_i)(\mathbf{y}_i - \boldsymbol{\mu}_i)'.$$

This *empirical* variance estimate [4, 13] is consistent as the number of individuals contributing to each element of the matrix goes to infinity. For example, in an **analysis of variance** problem, the number of units in each treatment group must get large.

GEE estimators enjoy two properties. First, $\hat{\boldsymbol{\beta}}$ is nearly efficient relative to the maximum likelihood estimates of $\boldsymbol{\beta}$ in many practical situations provided that the working variance matrices, $\mathbf{W}_i$, are reasonable approximations to var($\mathbf{Y}_i$) (e.g. [6] and [7]). In fact, GEE is equivalent to maximum likelihood for multivariate Gaussian data and for binary data from a **loglinear model** when var($\mathbf{Y}_i$) is correctly specified [2]. Secondly, $\hat{\boldsymbol{\beta}}$ is consistent as $m \to \infty$, even if the covariance structure of $\mathbf{Y}_i$ is incorrectly specified. When marginal regression coefficients are the scientific focus, it may be reasonable to sacrifice a small amount of efficiency in return for robustness against possible misspecification of the second and higher moment structure.

The robustness of the inferences about $\boldsymbol{\beta}$ can be checked in particular applications by fitting a final model using different covariance assumptions and comparing the two sets of estimates and their robust standard errors. If these differ substantially, then a more careful treatment of the covariance model may be necessary [1].

Example

To illustrate the main ideas above, we use each of the three approaches to describe a different aspect of the dependence of alcohol use on the reported level of psychiatric distress. In the marginal approach, the target of estimation is the prevalence (or log odds) of reporting ever having used alcohol and its dependence on psychiatric distress score and time. In a marginal analysis, we must also specify a model for the association among the four repeated responses for each youth. After preliminary analyses, we assume that the association, measured by the log odds ratio for Y_{ij} and Y_{ik}, is a linear function of the difference between and the mean of the two observation times. Hence, the model specification is

$$\text{logit } \Pr(Y_{ij} = 1) = \beta_0 + \beta_1 t_{ij} + \beta_2 x_{ij},$$
$$\log \text{OR}(Y_{ij}, Y_{ik}) = \alpha_0 + \alpha_1 |t_{ij} - t_{ik}| + \frac{\alpha_2 (t_{ij} + t_{ik})}{2},$$

where x_{ij} is the psychiatric distress score for youth i at visit j.

The parameter estimates, model-based and empirical standard errors, obtained using GEE, are shown in Table 1. There is evidence of increasing prevalence of reporting ever having used alcohol in older children and significantly higher reported use among children with higher distress. The population odds of use is estimated to be 19% [= exp(5 × 0.0345) − 1] higher

Table 1 Results from marginal logistic regression analysis of alcohol use data

Variable	Estimate	Standard errors	
		Model-based	Empirical
Mean model			
Intercept (β_0)	−0.243	0.0702	0.0701
Time (β_1)	0.228	0.0293	0.0294
MH score (β_2)	0.0345	0.00723	0.00707
Association model			
Intercept (α_0)	1.66		0.328
Time lag (α_1)	−0.225		0.0823
Average time (α_2)	0.118		0.111

in one subgroup with psychiatric distress score that is five points higher than another (95% CI: 11%, 28%). The odds ratio between repeated observations on a subject decreases with increasing lag from 4.3 for observations one year apart to 2.8 at three years apart. At a fixed lag, the estimated odds ratio increases toward the later years of the study, but the evidence for this increase is weak.

A random effects model was fit to these same data to estimate a youth's predisposition of reporting ever having used alcohol and to examine the dependence of this risk on psychiatric distress. The approximate likelihood approach of Stiratelli et al. [11] was used for estimation. The results for the following random intercept logistic model are shown in Table 2:

$$\text{logit } \Pr(Y_{ij} = 1|U_i) = \beta_0^* + \beta_1^* t_{ij} + \beta_2^* x_{ij} + \alpha U_i.$$

In this model it is assumed that the random effects U_i are an independent sample from a Gaussian distribution with mean 0 and variance 1 and that given U_i, the repeated binary responses for youth i are independent of one another. Given the cumulative nature of the outcome, this assumption is unlikely to be valid.

Using the random intercept model, we estimate that a youth's odds of reporting ever having used alcohol increases by 27% $[= \exp(5 \times 0.0473) - 1]$ if his distress score increases by five points (95% CI: 16%, 38%). The standard deviation, α, of the random intercept is estimated to be 1.64 so that roughly 95% of youths would have log odds of reporting ever having used alcohol within $\pm$ 3.3 of the mean value. Note this is an extreme level of heterogeneity, indicating strong association among repeated observations on each youth. This also reflects, if less directly, the consistency of reports across time by a youth.

The coefficients for the random effects model are larger than those from the marginal model owing to the attenuation that results from averaging personal risks of reported use to obtain prevalences. Note that the degree of attenuation is similar for all coefficients and is roughly equal to the value given in (3).

Finally, the following transition model can be estimated from these data:

$$\text{logit } \Pr(Y_{ij} = 1|Y_{i,j-1}) = \beta_0^{**} + \beta_1^{**} t_{ij} + \beta_2^{**} x_{ij} + \alpha_1 Y_{i,j-1} + \alpha_2 Y_{i,j-1} x_{ij}.$$

Note that we have allowed the log odds of reporting ever having used alcohol in one year to depend on whether or not the youth reported use in the prior year and have included an interaction between psychiatric distress score and prior report. In this way we estimate a separate effect of psychiatric distress on a new report of alcohol use given no reported use at the prior visit β_2^{**}, and on the confirmation of a prior report of ever using alcohol, $\beta_2^{**} + \alpha_2$. The results are shown in Table 3.

The strongest predictor of reported use at a given visit is having reported use at the prior visit with an odds ratio of 5.5 (95% CI: 4.5, 6.7). This indicates a reasonably high degree of consistency in repeated assessments of ever use. Psychiatric distress score is positively associated with the outcome among those with no prior reported use, the odds being 25% higher for children whose score is five points higher (95% CI: 12%, 38%). The indication from these data is that the effect of psychiatric distress is smaller among those who reported having used alcohol at the prior visit; a five point higher distress score is associated with only a 10% higher odds of consistently reporting use in this case.

Acknowledgment

The data for our example were gathered with a National Institute on Drug Abuse research grant (DA04392), for which James C. Anthony is Principal Investigator. The authors also gratefully acknowledge support from the National Institute of Mental Health grants MH38725-11 (Dr P. Leaf, PI) and MH56639 (Dr S. Zeger).

Table 2 Results of random intercept model for the alcohol use data

Variable	Estimate	Standard error

Generalized Maximum Likelihood

Many interpretations of the phrase "generalized maximum likelihood" are possible. A few such, which are to be found in the literature, are listed here, in no particular order. These methods have been studied by many authors, but here, for brevity, we quote only one or two references for each from which other work can be traced. Also, discussion will be restricted to the fully parametric case, so that semiparametric methods such as Cox's **partial likelihood** for the **proportional hazards** model (*see* **Cox Regression Model**), and nonparametric estimators such as that of **Kaplan and Meier** for the survivor function, are not covered. Throughout, "**maximum likelihood**" is abbreviated to ML.

Maximum Probability Estimators

Weiss & Wolfowitz [12] drew attention to the overly simplistic, in their view, assumptions made in order to construct "regular" likelihood theory. In particular, they were concerned with the common restriction to estimators which have asymptotic normal distributions (*see* **Large-sample Theory**).

Let the data be D_n, where n represents the sample size or some similar quantity, and let $f_n(\cdot;\theta)$ be the density or probability function of D_n depending on a parameter θ. The ordinary ML estimator is found by maximizing $f_n(D_n;\theta)$ over θ. It is assumed that a normalizing sequence $k_n \to \infty$ for the family $f_n(D_n;\theta)$ can be found somehow such that: there exists an estimator T_n and $m(\theta) > 0$ such that

$$\liminf_{n\to\infty} \Pr_{\theta}[k_n|T_n - \theta| < m(\theta)] > 1 - \varepsilon,$$

for every $\varepsilon > 0$. In addition, it is assumed that if k_n is replaced by a sequence k_n' tending to infinity faster than k_n, $k_n'|T_n - \theta|$ is not bounded in this way for any T_n, so the above probability then tends to zero instead of being close to 1. Thus, k_n is the maximal rate, and T_n is a **consistent estimator** tending to θ at this rate. In the "regular" likelihood case, k_n can be taken as $n^{1/2}$ (or as $3n^{1/2}$ or $n^{1/2} + \log n$, etc.) and T_n as $\hat{\theta}_n$, the ML estimator (or as $\hat{\theta}_n + 3/n^2$, etc.).

A maximum probability (MP) estimator is defined as the θ value that maximizes

$$I_n(\theta) = \int_{\theta - r/k_n}^{\theta + r/k_n} f_n(D_n;t)\,\mathrm{d}t,$$

r being some specified positive constant. As $n \to \infty$, the interval $(\theta - r/k_n, \theta + r/k_n)$ shrinks towards its midpoint θ. The MP estimator is chosen so that the average value of $f_n(D_n;\theta)$ over this interval; namely, $I_n(\theta) \div (2r/k_n)$, is maximized. When $f_n(D_n;t)$ is continuous in t, $I_n(\theta) \div (2r/k_n) \to f_n(D_n;\theta)$ as $r/k_n \to 0$, and then MP estimation becomes equivalent to ML estimation. In this sense, MP estimation is a kind of smoothed version of ML estimation, and is asymptotically equivalent to it in the regular case. Weiss & Wolfowitz actually defined MP estimation more generally with the integral over a shrinking set $\{t: k_n(t - \theta) \in R\}$, where R is a specified bounded subset of the real line.

The MP estimate has an optimality property: roughly speaking, $k_n(T_n - \theta_0)$ is asymptotically smallest in probability when T_n is the MP estimator, θ_0 being the true parameter. This maximum efficiency of the MP estimator was explained by Weiss & Wolfowitz by interpreting it as being asymptotically equivalent to a certain Bayes estimator with respect to a **prior distribution** uniform on $(\theta - r/k_n, \theta + r/k_n)$. Various other technical properties and extensions, including that to vector parameters, were discussed by Weiss & Wolfowitz. The main thrust is that the MP estimator is not restricted to the regular cases which support the standard theory of ML estimation. Some further results are given in [1, Section 3.3].

Maximum Probability of Spacings

Let $x_1, \ldots, x_n$ be an ordered random sample from a continuous univariate distribution with distribution function $F(x;\boldsymbol{\theta})$ and density $f(x;\theta)$ on (α_1, α_2). The end points α_1 and α_2 may be known or unknown; in the latter case they are included as components of the parameter vector θ.

Define $d_i(\theta) = F(x_i;\theta) - F(x_{i-1};\theta)$ for $i = 1, \ldots, n+1$, taking x_0 as α_1 and x_{n+1} as α_2. Under θ, the $d_i(\theta)$ are the "uniform spacings" derived from the x-sample, with $\sum d_i(\theta) = 1$. The maximum product of spacings (MPS) method of Cheng & Amin [3]

chooses as the estimator of θ that value which maximizes

$$G(\theta) = \prod_{i=1}^{n+1} d_i(\theta).$$

Note that $G(\theta) \leq (n+1)^{-(n+1)}$, this maximum possible value being attained when the $d_i(\theta)$s are all equal to $(n+1)^{-1}$. The MPS estimator is thus the θ value which makes the sample spacings most nearly uniform.

Cheng & Amin pointed out that, in "regular" situations, the remainder term $r(x_i, x_{i-1}; \theta)$ in

$$d_i(\theta) = f(x_i; \theta)(x_i - x_{i-1}) + r(x_i, x_{i-1}; \theta)$$

becomes negligible as $n \to \infty$, and $(x_i - x_{i-1})$ does not depend on θ. Then, maximizing $\prod d_i(\theta)$ is asymptotically equivalent to maximizing $\prod f(x_i; \theta)$, the likelihood function, and so MPS estimation is asymptotically equivalent to ML estimation. In nonregular situations this equivalence can break down, and Cheng & Amin gave examples in which MPS yields better estimates than ML, the latter method sometimes failing altogether.

Corrected Likelihood

Let $x_1, \ldots, x_n$ be a random sample from a continuous univariate distribution with distribution function $F(x; \theta)$ and density $f(x; \theta)$, and let

$$H(\theta) = \prod_{i=1}^{n} [F(x_i + h_i; \theta) - F(x_i; \theta)],$$

where the h_i are small positive quantities. This would be the **likelihood** function appropriate to **grouped data** in which the ith observation is only known to lie in the interval $(x_i, x_i + h_i]$; it has been argued that, because all measurement is of limited accuracy, this form of likelihood is more realistic in practice. Cheng & Iles [4] described the standard approach in which one makes the approximation

$$H(\theta) \doteqdot \prod_{i=1}^{n} [f(x_i; \theta) h_i],$$

where $f(x; \theta)$ is the density function, and then ignores the h_i since they do not involve θ. Thus, the standard likelihood function is defined as $L(\theta) = \prod f(x_i; \theta)$.

Consider, as an example, the **Weibull distribution** function $F(x; \theta) = 1 - \exp[-(x - \alpha)^\beta]$ on (α, ∞) with $\theta = (\alpha, \beta)$, α being the lower endpoint and β the shape parameter. It is known that when $\beta < 1$ there is no consistent solution of the likelihood equation $\partial \log L(\theta)/\partial\theta = 0$, so the usual ML theory fails. Cheng & Iles identified the source of the problem as follows. For $\beta < 1$, $L(\theta)$ is an increasing function of α, so $\hat{\alpha} = \min(x_1, \ldots, x_n) = x_m$, say. The contribution to $H(\theta)$ from x_m when $\theta = (\hat{\alpha}, \beta)$ is

$$F(x_m + h_m; \theta) - F(x_m; \theta) = 1 - \exp(-h_m^\beta) \doteqdot h_m^\beta.$$

In contrast, the corresponding contribution in the approximated version is

$$f(x_m; \theta) h_m = h_m \beta (x - x_m)^{\beta - 1} \exp[-(x - x_m)^\beta] = \infty.$$

Their suggestion was to use $H(\theta)$ as the "corrected" likelihood. In regular cases, this will be equivalent to using $L(\theta)$. In the Weibull example, only h_m will have any effect, and Cheng & Iles make some suggestions for its choice.

General Estimating Functions

Perhaps the most general definition of an estimator is simply that it is some function of the data, and that of a generalized ML estimator is that it results from maximizing some function of the data, this function deputizing for the likelihood. In the above, this function is $I_n(\theta)$ for MP estimation, $G(\theta)$ for MPS estimation, and $H(\theta)$ for "corrected likelihood" estimation. These three methods assume that the parametric distributional form for the data is known, and the generalization focuses upon extending the theory beyond the usual regularity restrictions. Other suggestions in the literature are more concerned with **robustness**: the deputizing function is chosen to avoid critical dependence on the parametric form adopted for the likelihood. Such proposals include: **least squares** [7]; conditional least squares [10]; Gaussian estimation [6, 13]; M-estimators [8]; maximum **quasi-likelihood** [11]; and minimum chi-square [2]. General asymptotic theory for estimating functions has been given by Huber [9] and Crowder [5].

Generating Functions

Biostatistical information usually comes in the form of a sample of observed values, e.g. serum cholesterol levels in a group of 30 students. Often a hypothesis is constructed concerning the distribution of the values in the population from which the sample (group) is drawn. This may be specified by a formula for its probability density function (pdf) for a continuous distribution, or by its probability mass function (pmf) for a discrete distribution. Pdfs and pmfs are, however, often less informative than the **moments** of a distribution. Moments can be summarized by a **moment generating function**.

A generating function is similar to an alphabetical list – it is a single piece of documentation about a sequence of items. When a moment generating function for a distribution is expanded into a series, it gives the values of all the moments as the coefficients of successive terms in the series. The first term gives the mean, the second tells us about the variability, the third about the **skewness**, etc.

Another type of sequence that occurs in biostatistics is a sequence of probabilities, for instance the probabilities of $0, 1, 2, \ldots$ spina bifida births in a region per month. The coefficients in a probability generating function (pgf) provide a sequence of probabilities.

Suppose that $a_0, a_1, a_2, \ldots$ is an infinite sequence of real numbers all of which are finite. Then the power series

$$H(s) = a_0 + a_1 s + a_2 s^2 + \cdots = \sum_{r=0}^{\infty} a_r s^r$$

turns the sequence into the function $H(s)$ [given a finite sequence, $a_0, a_1, \ldots, a_n$, then the corresponding function is $H(s) = \sum_{r=0}^{n} a_r s^r$]. $H(s)$ is called the generating function of the sequence and s is called the generating variable (s is a mathematical artifact – it has no statistical interpretation and is not a random variable). When the sequence is infinite, the restriction that all the a_r are finite ensures that $H(s)$ exists and has a finite sum, provided that s is not too large. Two sequences that are identical have the same power series generating function. Less obviously, if two generating functions are identical, then so are the sequences that they generate; this property of uniqueness is important.

A second form of generating function somewhat resembles an exponential series and is called an exponential generating function. The connection between an infinite sequence and its exponential generating function is

$$h(t) = \sum_{r=0}^{\infty} \frac{a_r t^r}{r!};$$

for a finite sequence the exponential generating function is $h(t) = \sum_{r=0}^{n} a_r t^r / r!$. Even if the a_r increase with r without bound, $h(t)$ will exist if $a_r / r!$ is finite for all r. An exponential generating function also has the property of uniqueness.

Generating functions are useful not only as generators of formulas for the individual items in a sequence. They give recurrence relations when the mathematical expressions for the a_r are complicated and they can provide good approximations. In discrete distribution theory they are particularly valuable for combining sequences of probabilities in various ways.

Moment Generating Functions

The rth uncorrected moment, μ'_r, of the **random variable** X is the expected value of X^r, where r is a positive integer, i.e. $\mu'_r = \mathrm{E}(X^r)$. If $\mu'_r / r!$ is finite for all r, then

$$\begin{aligned} U_X(t) &= \mathrm{E}\left(1 + Xt + \frac{X^2 t^2}{2!} + \frac{X^3 t^3}{3!} + \cdots\right) \\ &= \sum_{r \geq 0} \frac{\mu'_r t^r}{r!} = \mathrm{E}[\exp(Xt)] \end{aligned} \tag{1}$$

is the uncorrected-moment generating function (umgf). It is an exponential generating function. By successive differentiation

$$\begin{aligned} \mu'_1 &= \left[\frac{\mathrm{d}U_X(t)}{\mathrm{d}t}\right]_{t=0}, \\ \mu'_2 &= \left[\frac{\mathrm{d}^2 U_X(t)}{\mathrm{d}t^2}\right]_{t=0}, \ldots, \\ \mu'_r &= \left[\frac{\mathrm{d}^r U_X(t)}{\mathrm{d}t^r}\right]_{t=0}, \ldots. \end{aligned} \tag{2}$$

Example 1: Uncorrected Moments of the Binomial Distribution

Suppose that bacteria in a particular culture have fixed and independent probabilities p of being mutant and that n of them are examined under a microscope. Assume that the number of mutants has a **binomial distribution** with probability mass function (pmf) $\binom{n}{x}p^x(1-p)^{n-x}$, where n is a positive integer, $0 < p < 1$, $x = 1, 2, \ldots, n$. Then

$$\begin{aligned} U_X(t) &= \mathrm{E}[\exp(Xt)] \\ &= \sum_{x=0}^{n} \frac{n!p^x(1-p)^{n-x}}{x!(n-x)!} \cdot \mathrm{e}^{xt} \\ &= (1-p+p\mathrm{e}^t)^n \\ &= 1 + \frac{np(\mathrm{e}^t-1)}{1!} \\ &\quad + \frac{n(n-1)p^2(\mathrm{e}^t-1)^2}{2!} + \cdots \\ &= 1 + np\left(t + \frac{t^2}{2!} + \frac{t^3}{3!} + \cdots\right) \\ &\quad + \frac{n(n-1)p^2}{2!}\left(t^2 + \frac{2t^3}{2!} + \cdots\right) + \cdots . \end{aligned}$$

The uncorrected moments are therefore $\mu_1' = np$, $\mu_2' = np + n(n-1)p^2$, etc. A quicker way to find them is to set $t = 0$ in

$$\begin{aligned} \frac{\mathrm{d}U_X(t)}{\mathrm{d}t} &= n(1-p+p\mathrm{e}^t)^{n-1}p\mathrm{e}^t, \\ \frac{\mathrm{d}^2U_X(t)}{\mathrm{d}t^2} &= n(n-1)(1-p+p\mathrm{e}^t)^{n-2}p^2\mathrm{e}^{2t} \\ &\quad + n(1-p+p\mathrm{e}^t)^{n-1}p\mathrm{e}^t, \text{ etc.} \end{aligned}$$

The variable $X + c$ has the distribution of X shifted c units to the right of the origin. Because $\mathrm{E}\{\exp[t(X+c)]\} = \exp(ct)\mathrm{E}[\exp(tX)]$, we have

$$U_{X+c}(t) = \mathrm{e}^{ct}U_X(t); \tag{3}$$

this relates the moments of a shifted distribution to those of the original distribution.

Example 2: Uncorrected Moments of the Two- and Three-parameter Gamma Distribution

Let the survival time after a particular surgical procedure have an (unshifted) two-parameter **gamma distribution** with parameters a and b. Then the probability density function (pdf) for survival time is $f(x) = a^b\exp(-ax)x^{b-1}/\Gamma(b)$, $0 < a$, $0 < b$, $0 \le x < \infty$. The umgf is therefore

$$\begin{aligned} U_X(t) &= \int_0^\infty \frac{a^b\mathrm{e}^{-ax}x^{b-1}\mathrm{e}^{xt}}{\Gamma(b)}\,\mathrm{d}x \\ &= \left(\frac{a}{a-t}\right)^b \int_0^\infty \frac{\mathrm{e}^{-y}y^{b-1}\,\mathrm{d}y}{\Gamma(b)}\,\mathrm{d}x, \\ &\quad \text{where } y = x(a-t), \\ &= \left(\frac{a}{a-t}\right)^b \\ &= 1 + \frac{bt}{a} + \frac{b(b+1)t^2}{a^2 2!} \\ &\quad + \frac{b(b+1)(b+2)t^3}{a^3 3!} + \cdots, \end{aligned}$$

and the uncorrected moments are $\mu_1' = b/a$, $\mu_2' = b(b+1)/a^2$, $\mu_3' = b(b+1)(b+2)/a^3$, etc. Note that as a becomes large, the uncorrected moments tend to zero and the distribution tends to a degenerate distribution at the origin.

Suppose now that there is an initial constant length of time, c, during which the patient is kept alive in intensive care. Assume, then, that the distribution is shifted by an amount c to the right of the origin. This gives a three-parameter gamma distribution with umgf

$$\begin{aligned} U_{X+c}(t) &= \exp(ct)\left(\frac{a}{a-t}\right)^b \\ &= \left[1 + ct + \frac{(ct)^2}{2!} + \cdots\right] \\ &\quad \times \left[1 + \frac{bt}{a} + \frac{b(b+1)t^2}{a^2 2!} + \cdots\right], \end{aligned}$$

and its uncorrected moments are $\mu_1' = c + b/a$, $\mu_2' = c^2 + 2cb/a + b(b+1)/a^2$, etc. As a gets large, the new umgf tends to $\exp(ct)$, showing that the distribution tends to a degenerate distribution at $x = c$.

Some distributions have moments for which $\mu_r'/r!$ is unbounded and so the umgf does not exist. The **characteristic function** (cf) exists for all distributions, however. For a continuous distribution this is

$$\varphi_X(t) = \mathrm{E}[\exp(itX)] = \int_{-\infty}^{\infty} \exp(itx)\,\mathrm{d}F(x), \tag{4}$$

where $i = \sqrt{(-1)}$ and t is real; for a discrete distribution on 0, 1, 2, ... it is

$$\varphi_X(t) = \mathrm{E}[\exp(itX)] = \sum_{x\geq 0} \exp(ixt)\Pr(X = x). \tag{5}$$

When the umgf exists, $U_X(t) = \varphi_X(-it)$.

The rth moment about the mean of a distribution is $\mu_r = \mathrm{E}((X-\mu)^r)$, where μ is the mean; it is called the rth corrected moment (or the rth central moment). The first central moment, μ_1, is always zero. The second central moment, μ_2, is the variance, $\mathrm{var}(X)$. The central-moment generating function (cmgf) is

$$\begin{aligned} M_X(t) &= \mathrm{E}\left(1 + (X-\mu)t + \frac{(X-\mu)^2t^2}{2!} + \cdots\right) \\ &= 1 + \sum_{r\geq 2} \frac{\mu_r t^r}{r!} = \mathrm{E}\{\exp[(X-\mu)t]\}. \end{aligned} \tag{6}$$

Shifting a distribution leaves its central moments unaltered, since

$$M_{X+a}(t) = \mathrm{E}\{\exp[(X+a-\mu-a)t]\} = M_X(t). \tag{7}$$

Example 3: Central Moments of the Normal Distribution

The concentration of the antibiotic in tubes of chloramphenicol gel is assumed to have a **normal distribution** with parameters μ, σ^2 and pdf $f(x) = \exp[-(x-\mu)^2/2\sigma^2]/[\sigma(2\pi)^{1/2}]$, $-\infty < x < \infty$. The cmgf is

$$\begin{aligned} M_X(t) &= \mathrm{E}\{\exp[t(X-\mu)]\} \\ &= \int_{-\infty}^{\infty} \frac{\exp\left[\dfrac{-(x-\mu)^2}{2\sigma^2}\right]}{\sigma\sqrt{2\pi}} \\ &\quad \times \exp[(x-\mu)t]\,\mathrm{d}x \\ &= \frac{\exp\left(\dfrac{\sigma^2t^2}{2}\right)}{\sigma\sqrt{2\pi}} \\ &\quad \times \int_{-\infty}^{\infty} \exp\left[-\frac{(x-\mu-\sigma^2t)^2}{2\sigma^2}\right] \mathrm{d}x \\ &= \exp\left(\frac{\sigma^2t^2}{2}\right) \\ &= 1 + \frac{\sigma^2t^2}{1!2} + \frac{\sigma^4t^4}{2!2^2} + \frac{\sigma^6t^3}{3!2^3} + \cdots. \end{aligned}$$

The odd central moments, μ_{2r+1}, are zero and the even ones are $\mu_r = (2r)!(\sigma^2/2)^r/r!$.

The relationship between the cmgf and the umgf is

$$M_X(t) = \mathrm{E}\{\exp[(X-\mu)t]\} = \exp(-\mu t)U_X(t); \tag{8}$$

therefore

$$\begin{aligned} \sum_{r\geq 0} \frac{\mu_r t^r}{r!} &= \left[1 - \mu t + \frac{(\mu t)^2}{2!} - \frac{(\mu t)^3}{3!} + \cdots\right] \\ &\quad \times \sum_{r\geq 0} \frac{\mu'_r t^r}{r!} \end{aligned} \tag{9}$$

and

$$\begin{aligned} \sum_{r\geq 0} \frac{\mu'_r t^r}{r!} &= \left[1 + \mu t + \frac{(\mu t)^2}{2!} + \frac{(\mu t)^3}{3!} + \cdots\right] \\ &\quad \times \sum_{r\geq 0} \frac{\mu_r t^r}{r!}. \end{aligned} \tag{10}$$

Because two sequences that are identical have the same generating function, we can equate the coefficients of $t^r/r!$ on the two sides of (9) to give

$$\mu_r = \sum_{j=0}^{r} (-1)^j \binom{r}{j} \mu'_{r-j}\mu^j, \tag{11}$$

i.e. $\mu_1 = -\mu'_1 + \mu = 0,$

$\mu_2 = \mu'_2 - \mu^2,$

$\mu_3 = \mu'_3 - 3\mu'_2\mu + 2\mu^3,$ etc.

Also, from (10), we have

$$\mu'_r = \sum_{j=0}^{r} \binom{r}{j} \mu_{r-j}\mu^j, \tag{12}$$

i.e. $\mu'_1 = \mu,$

$\mu'_2 = \mu_2 + \mu^2,$

$\mu'_3 = \mu_3 + 3\mu_2\mu + \mu^3,$ etc.

Example 1 continued: Central Moments of the Binomial Distribution

From Example 1 and the relationship between the cmgf and the umgf, (8), the cmgf of the **binomial distribution** is

$$M_X(t) = \left[1 - \mu t + \frac{(\mu t)^2}{2!} - \cdots\right]\left\{1 + npt + \frac{[np + n(n-1)p^2]t^2}{2!} + \cdots\right\},$$

where $\mu = np$. Hence $\mu_1 = 0$, $\mu_2 = np(1-p)$, etc.

The well-known binomial and exponential expansions were used in Examples 1 and 2. A standard way to create an unknown expansion is via a Maclaurin series:

$$h(t) = [h(t)]_{t=0} + \left[\frac{\mathrm{d}h(t)}{\mathrm{d}t}\right]_{t=0}\frac{t}{1!} + \left[\frac{\mathrm{d}^2h(t)}{\mathrm{d}t^2}\right]_{t=0}\frac{t^2}{2!} + \left[\frac{\mathrm{d}^3h(t)}{\mathrm{d}t^3}\right]_{t=0}\frac{t^3}{3!} + \cdots.$$

This gives $\mu_1 = [\,\mathrm{d}M_X(t)/\,\mathrm{d}t]_{t=0}$ (= 0 always), $\mu_2 = [\,\mathrm{d}^2U_X(t)/\,\mathrm{d}t^2]_{t=0}$, and so on.

Example 1 continued again: Central Moments of the Binomial Distribution

Here $h(t) = M_X(t) = \exp(-\mu t)(1 - p + pe^t)^n$, so

$$\frac{\mathrm{d}M_X(t)}{\mathrm{d}t} = -\mu M_X(t) + \frac{nM_X(t)pe^t}{1-p+pe^t},$$

$$\frac{\mathrm{d}^2M(t)}{\mathrm{d}t^2} = -\frac{\mu\,\mathrm{d}M_X(t)}{\mathrm{d}t} + \frac{n\,\mathrm{d}M_X(t)/\,\mathrm{d}t}{1-p+pe^t} + \frac{nM_X(t)pe^t}{1-p+pe^t} - \frac{nM_X(t)p^2e^{2t}}{(1-p+pe^t)^2}.$$

Therefore $\mu_1 = [\,\mathrm{d}M_X(t)/\,\mathrm{d}t]_{t=0} = -\mu + np = 0$ and $\mu_2 = [\,\mathrm{d}^2M_X(t)/\,\mathrm{d}t^2]_{t=0} = np - np^2$, as before.

An important property of the umgf is that if X, Y, Z, etc. are independent random variables, then

$$U_{X+Y}(t) = U_X(t)U_Y(t),$$

$$U_{X+Y+Z}(t) = U_X(t)U_Y(t)U_Z(t), \text{ etc.},$$

and

$$U_{X-Y}(t) = U_X(t)U_Y(-t).$$

Similarly, for the cmgf,

$$M_{X+Y}(t) = M_X(t)M_Y(t),$$

$$M_{X+Y+Z}(t) = M_X(t)M_Y(t)M_Z(t), \text{ etc.},$$

and

$$M_{X-Y}(t) = M_X(t)M_Y(-t).$$

These formulas give the moments of sums and differences of independent variables in terms of the moments of the individual variables.

Cumulant Generating Function

The cumulant generating function (cgf) of a distribution, $K(t)$, is sometimes simpler to handle than the umgf or cmgf. It is the logarithm to base e of the umgf. Expanding it as an exponential generating function gives the cumulants κ_r of the distribution, i.e.

$$K_X(t) = \ln U_X(t) = \ln\left(\frac{1 + \mu_1' t + \mu_2' t^2}{2!} + \cdots\right) = \sum_{r\geq 1}\frac{\kappa_r t^r}{r!}; \tag{13}$$

Expansion of the logarithm shows that there is no term in t^0 in (13) and that $\kappa_1 = \mu_1' = \mu$.

Example 4: Cumulants of the Poisson Distribution

The response in quanta of acetylcholine released per stimulus of a nerve cell has a **Poisson distribution** with parameter λ and pmf $e^{-\lambda}\lambda^x/x!$, $0 < \lambda$, $0 \leq x < \infty$. The umgf is

$$U_X(t) = \sum_{x=0}^{\infty}\left[\frac{e^{-\lambda}\lambda^x}{x!}\right]e^{xt} = \exp[\lambda(e^t - 1)],$$

so

$$K_X(t) = \lambda(e^t - 1) = \lambda + \lambda t + \frac{\lambda t^2}{2!} + \frac{\lambda t^3}{3!} + \cdots.$$

The cumulants of the Poisson distribution are all equal to the mean λ.

The cgf is an exponential generating function and so if need be the cumulants can be obtained as $\mu_1 = [\,\mathrm{d}K_X(t)/\,\mathrm{d}t]_{t=0}$, $\mu_2 = [\,\mathrm{d}^2K_X(t)/\,\mathrm{d}t^2]_{t=0}$, etc.

Because $K_{X+a}(t) = \ln[\exp(at)U_X(t)] = at + K_X(t)$, the coefficients of $t^r/r!$ in $K_{X+a}(t)$ and in $K_X(t)$ are the same for $r \geq 2$. This implies that when a constant is added to X, only κ_1 is changed; this is why the cumulants are sometimes called semi-invariants.

Consider

$$K_{X-\mu}(t) = \ln M_X(t) = \left(\frac{\mu_2 t^2}{2!} + \frac{\mu_3 t^3}{3!} + \frac{\mu_4 t^4}{4!} + \cdots\right) - \left(\frac{\mu_2^2 t^4}{(2!2!2)} + \cdots\right) + \cdots.$$

Equating the coefficients of t^r in $K_{X-\mu}(t)$ and $\ln M_X(t)$ shows that for $r \geq 2$ the cumulants are functions of the central moments

$$\kappa_2 = \mu_2, \quad \kappa_3 = \mu_3, \quad \kappa_4 = \mu_4 - 3\mu_2^2, \text{etc.} \tag{14}$$

Example 4 continued: Central Moments of the Poisson Distribution

Because $\kappa_r = \lambda$ for all r for the Poisson distribution, the mean is $\mu_1' = \lambda$ and, from (14), $\mu_2 = \lambda$, $\mu_3 = \lambda$, $\mu_4 = \lambda - 3\lambda^2$.

Let $X = X_1 + X_2 + \cdots + X_n$, where the X_js are independent random variables. The umgf of X is the product of the individual umgfs, and therefore the cgf of X is the sum of their cgfs

$$K_X(t) = \sum_{j=1}^{n} K_{X_j}(t). \tag{15}$$

Thus the kth cumulant of a sum is the sum of the individual kth cumulants.

Joint Moments and Cumulants

When X_j, $j = 1, 2, \ldots, m$, are not independent we need to look at their joint distribution. The uncorrected moments of a joint distribution are quantities like $\mathrm{E}(\prod_{j=1}^{m} X_j^{r_j})$; they are denoted by $\mu'_{r_1 r_2 \ldots r_m}$ and are called product moments about zero. The central product moments are

$$\mu_{r_1 r_2 \ldots r_m} = \mathrm{E}\left(\prod_{j=1}^{m} [X_j - \mathrm{E}(X_j)]^{r_j}\right). \tag{16}$$

For a bivariate distribution the central product moment, μ_{11}, is the covariance, cov (X_1, X_2).

The joint umgf of $X_1, X_2, \ldots, X_m$ is a function of m generating variables $t_1, t_2, \ldots, t_m$:

$$U_{X_1,\ldots,X_m}(t_1, t_2, \ldots, t_m) = \mathrm{E}\left[\exp\left(\sum_{j=1}^{m} t_j X_j\right)\right], \tag{17}$$

the joint cmgf is

$$\mathrm{E}\left(\exp\left\{\sum_{j=1}^{m} t_j [X_j - \mathrm{E}(X_j)]\right\}\right) = \exp\left\{-\sum_{j=1}^{m} t_j \mathrm{E}(X_j)\right\} \times U(t_1, t_2, \ldots, X_m), \tag{18}$$

and the joint cgf is $\ln U_{X_1 \ldots X_m}(t_1, t_2, \ldots, t_m)$. Their use is similar to that for univariate distributions.

Example 5: Moments of a Bivariate Gamma Distribution

Pairs of tumors were initiated at the same time, one on each side of the back of a mouse. Suppose that the sizes, X and Y, of the two tumors after one month's growth are not independent but have the joint pdf

$$f(x, y) = \begin{cases} a^2\{\mathrm{e}^{-ay} - \mathrm{e}^{-a(x+y)}\}, & 0 \leq x < y, \\ a^2\{\mathrm{e}^{-ax} - \mathrm{e}^{-a(x+y)}\}, & 0 \leq y < x, \end{cases}$$

$0 < a$. Then the marginal distribution of X has the pdf

$$f(x) = \int_0^y a^2\{\mathrm{e}^{-ay} - \mathrm{e}^{-a(x+y)}\}\,\mathrm{d}x + \int_y^\infty a^2\{\mathrm{e}^{-ax} - \mathrm{e}^{-a(x+y)}\}\,\mathrm{d}x = a^2 y \mathrm{e}^{-ay}$$

(a particular sort of gamma distribution); the marginal distribution of Y is similar. The joint umgf is

$$U_{X,Y}(t_1, t_2) = \int_0^\infty \int_0^y a^2\{\mathrm{e}^{-ay} - \mathrm{e}^{-a(x+y)}\}$$

$$
\begin{aligned}
&\times \exp[t_1 x + t_2 y]\,\mathrm{d}x\,\mathrm{d}y \\
&+ \int_0^\infty \int_y^\infty a^2\{\mathrm{e}^{-ax} - \mathrm{e}^{-a(x+y)}\} \\
&\times \exp[t_1 x + t_2 y]\,\mathrm{d}x\,\mathrm{d}y \\
&= a^2 \int_0^\infty \left[\frac{\exp[-(a - t_1 - t_2)y]}{t_1} \right. \\
&+ \frac{\exp[-(a - t_1 - t_2)y]}{(a - t_1)} \\
&\left. - \frac{\exp[-(a - t_1)y]}{t_1} - \frac{\exp[-(a - t_2)y]}{a - t_1} \right] \mathrm{d}y \\
&= a^3 (a - t_1)^{-1} (a - t_2)^{-1} (a - t_1 - t_2)^{-1}.
\end{aligned}
$$

The joint cgf is

$$
\begin{aligned}
K_{X,Y}(t_1, t_2) &= \ln[U_{X,Y}(t_1, t_2)] \\
&= -\ln\left(1 - \frac{t_1}{a}\right) - \ln\left(1 - \frac{t_2}{a}\right) \\
&\quad - \ln\left(1 - \frac{t_1}{a} - \frac{t_2}{a}\right) \\
&= \frac{2t_1}{a} + \frac{2t_2}{a} + \frac{2t_1^2}{a^2 2!} + \frac{t_1 t_2}{a^2 1!1!} \\
&\quad + \frac{2t_2^2}{a^2 2!} + \cdots,
\end{aligned}
$$

showing that $\mathrm{E}(X) = \kappa_{1,0} = 2/a$, $\mathrm{E}(Y) = \kappa_{0,1} = 2/a$, $\mathrm{var}(X) = \kappa_{2,0} = 2/a^2$, and $\mathrm{cov}(X, Y) = \mathrm{E}(XY) - \mathrm{E}(X)\mathrm{E}(Y) = \kappa_{1,1} = 1/a^2$.

Probability Generating Function

The probability generating function (pgf) is a very useful tool for studying discrete distributions; it is not applicable to continuous distributions. Let X be a discrete random variable X taking the values $0, 1, 2, \ldots$ with nonzero probability mass function (pmf) $p_x = \Pr(X = x)$. Then the pgf of the distribution is

$$
G_X(z) = \sum_{x=0}^{\infty} p_x z^x = \mathrm{E}(z^X). \tag{19}
$$

The conditions for $G_X(z)$ to be a pgf are

$$
G_X(0) \geq 0,
$$

$$
G_X(1) = 1 \text{ and } \left[\frac{\mathrm{d}^r G_X(z)}{\mathrm{d}z^r} \right]_{z=0} \geq 0, r > 0. \tag{20}
$$

Note that whereas the umgf, cmgf, and cgf are exponential generating functions where the a_r are the coefficients of $t^r/r!$, the pgf is a power-series generating function and the p_x are the coefficients of z^x. If probabilities are obtained via a Maclaurin series, then it is important to remember that $p_r = (r!)^{-1}[\,\mathrm{d}^r G_X(z)/\,\mathrm{d}z^r]_{z=0}$.

The pgf, cf, umgf, cmgf, and cgf of a discrete distribution are closely related. We have

$$
\begin{aligned}
G_X(z) &= \mathrm{E}(z^X), \\
\varphi_X(t) &= \mathrm{E}[\exp(itX)] = G(\mathrm{e}^{it}) \\
U_X(t) &= \mathrm{E}[\exp(tX)] = G(\mathrm{e}^t), \\
M_X(t) &= \mathrm{E}\{\exp[t(X - \mu)]\} \\
&= \mathrm{e}^{-\mu t} G(\mathrm{e}^t), \\
K_X(t) &= \ln \mathrm{E}[\exp(tX)] = \ln G(\mathrm{e}^t).
\end{aligned}
$$

Example 6: Probability Generating Function of an Exponentially Mixed Poisson Distribution (a Geometric Distribution)

Suppose that the number of schistosome ova per specimen has a Poisson distribution with parameter λ, where λ varies from patient to patient according to an exponential distribution with pdf $c\mathrm{e}^{-\lambda c}\,\mathrm{d}\lambda$. Then the resultant distribution of the number of ova per specimen, X, has the pmf

$$
\begin{aligned}
\Pr(X = x) &= \int_0^\infty \frac{\mathrm{e}^{-\lambda}\lambda^x}{x!} \cdot c\mathrm{e}^{-\lambda c}\,\mathrm{d}\lambda \\
&= \frac{c}{(1 + c)^{x+1}}, \quad x = 0, 1, \ldots.
\end{aligned}
$$

This is the pmf for a **geometric distribution**. Consider now the pgf. In Example 4 we saw that the umgf of the Poisson distribution is $\exp[\lambda(\mathrm{e}^t - 1)]$, so its pgf is $\exp[\lambda(z - 1)]$. Integrating over λ using an exponential distribution gives the pgf of X as

$$
\begin{aligned}
G_X(z) &= \int_0^\infty \mathrm{e}^{\lambda(z-1)} \times c\mathrm{e}^{-\lambda c}\,\mathrm{d}\lambda \\
&= \frac{c}{c + 1 - s}.
\end{aligned}
$$

The uniqueness property of pgfs ensures that this is the pgf of the same (geometric) distribution.

Let $X_1, X_2, \ldots, X_k$ be k independent random variables with pgfs $G_1(z), G_2(z), \ldots, G_k(z)$ and set

$X = \sum_{j=1}^{k} X_j$. Then

$$G_X(z) = \mathrm{E}(z^{X_1+X_2+\ldots X_k}) = \prod_{j=1}^{k} \mathrm{E}(z^{X_j}) = \prod_{j=1}^{k} G_j(z); \tag{21}$$

this method of combining distributions is called *convolution*. The pgf for the difference of two random variables, X_1 and X_2, is

$$G_{X_1-X_2}(z) = G_{X_1}(z)G_{X_2}(z^{-1}). \tag{22}$$

Consider now a "damage" process. If we have x items initially and each item has an independent probability $(1-\alpha)$ of removal, then the probability that k of them remain is $\binom{x}{k}\alpha^k(1-\alpha)^{n-k}$. When the initial number, X, is a random variable with pgf $G_X(z) = p_0 + p_1 z + p_2 z^2 + \cdots$ and R is the number remaining, then

$$\Pr(R = r) = p_r^* = \sum_{x \geq r} p_x \binom{x}{r} \alpha^r (1-\alpha)^{x-r} \tag{23}$$

and the pgf for R is

$$\begin{aligned} G_R(z) &= \sum_{r\geq 0} p_r^* z^r = \sum_{r\geq 0}\sum_{x\geq r} p_x \binom{x}{r} \alpha^r (1-\alpha)^{x-r} z^r \\ &= \sum_{x\geq 0}\sum_{r\leq x} p_x \binom{x}{r} \alpha^r (1-\alpha)^{x-r} z^r \\ &= \sum_{x\geq 0} p_x (1-\alpha+\alpha z)^x \\ &= G_X(1-\alpha+\alpha z). \end{aligned} \tag{24}$$

A similar but rather more complicated way of combining two distributions is illustrated in the next example.

Example 7: A Compound Process for the Negative Binomial Distribution

Suppose that each year brain fluid is sampled from anencephalic infants from a varying number of hospitals. If the number of anencephalics per hospital, X, has a logarithmic distribution with pgf $\ln(1-\theta z)/\ln(1-\theta)$ and the number of cooperating hospitals per year, N, has a Poisson distribution with pgf $\exp\lambda(z-1)$, then the total number of specimens collected per year, Y, has the distribution with pgf

$$\begin{aligned} G_Y(z) &= \sum_{x=0}^{\infty} \frac{\mathrm{e}^{-\lambda}\lambda^x}{x!} \left[\frac{\ln(1-\theta z)}{\ln(1-\theta)}\right]^x \\ &= \exp\left\{\lambda\left[\frac{\ln(1-\theta z)}{\ln(1-\theta)} - 1\right]\right\} \\ &= \left(\frac{1-\theta}{1-\theta z}\right)^{-\lambda/\ln(1-\theta)} \end{aligned}$$

(the sum of x independent variables with the same pgf, $h(z)$, has the pgf $[h(z)]^x$). The outcome is a **negative binomial distribution**. This is a random-stopped sum distribution with a pgf of the form $G_1[G_2(z)]$, sometimes called a compound or a generalized distribution (these terms have other meanings as well).

There are also bivariate and multivariate pgfs. Given k dependent discrete variables $X_1, X_2, \ldots, X_k$, their joint pgf is

$$G_{X_1,X_2,\ldots,X_k}(z_1, z_2, \ldots, z_k) = \mathrm{E}\left(\prod_{j=1}^{k} t_j^{X_j}\right). \tag{25}$$

Factorial Moment Generating Functions

For a discrete distribution the factorial moment generating function (fmgf) is often easier to handle than other types of moment generating functions. The term "factorial moment" nearly always refers to a descending factorial moment; the rth descending factorial moment of X is

$$\mu'_{[r]} = \mathrm{E}\left[\frac{X!}{(X-r)!}\right] = \sum_{x\geq r} \frac{p_x x!}{(x-r)!}. \tag{26}$$

(The rth ascending factorial moment of X is $\mathrm{E}[(X+r-1)!/(X-1)!]$.) In the past other notations have been adopted for the $\mu'_{[r]}$; these are still used occasionally.

The fmgf is an exponential generating function. We have

$$\begin{aligned} \sum_{r\geq 0}\sum_{x\geq r} \frac{\mu'_{[r]} t^r}{r!} &= \sum_{x\geq 0}\sum_{r\leq x} \frac{p_x x!}{(x-r)!}\frac{t^r}{r!} \\ &= \sum_{x\geq 0} p_x (1+t)^x = G_X(1+t), \end{aligned} \tag{27}$$

where $G(z)$ is the pgf. So

$$\mu'_{[r]} = \left[\frac{\mathrm{d}^r G_X(1+t)}{\mathrm{d}t^r}\right]_{t=0} = \left[\frac{\mathrm{d}^r G_X(z)}{\mathrm{d}t^r}\right]_{z=1}. \tag{28}$$

A joint fmgf for a multivariate distribution with pgf $G_{X_1,X_2,\ldots,X_k}(z_1, z_2, \ldots, z_k)$ is defined similarly as $G_{X_1,X_2,\ldots,X_k}(1+t_1, 1+t_2, \ldots, 1+t_k)$.

The relationships between the univariate factorial moments and the uncorrected moments are

$$\begin{aligned}
\mu'_1 &= \mu'_{[1]} = \mu,\\
\mu'_2 &= \mu'_{[2]} + \mu'_{[1]},\\
\mu'_3 &= \mu'_{[3]} + 3\mu'_{[2]} + \mu'_{[1]}, \text{ etc.}
\end{aligned}$$

and

$$\begin{aligned}
\mu'_{[2]} &= \mu'_2 - \mu'_1,\\
\mu'_{[3]} &= \mu'_3 - 3\mu'_2 + 2\mu'_1, \text{ etc.}
\end{aligned} \tag{29}$$

Stuart & Ord [7] give further details and formulas. A particularly useful equation is

$$\mu_2 = \mu'_{[2]} + \mu - \mu^2. \tag{30}$$

The factorial cumulant generating function (fcgf) is the logarithm of the (descending) fmgf. It is an exponential generating function and the rth factorial cumulant, $\kappa_{[r]}$, is the coefficient of $t^r/r!$ in its expansion, i.e.

$$\ln G(1+t) = \sum_{r\geq 1} \frac{\kappa_{[r]} t^r}{r!}. \tag{31}$$

The formulas connecting $\{\kappa_r\}$ and $\{\kappa_{[r]}\}$ are analogous to those connecting $\{\mu'_r\}$ and $\{\mu'_{[r]}\}$, i.e.

$$\begin{aligned}
\kappa_1 &= \kappa_{[1]} = \mu,\\
\kappa_2 &= \kappa_{[2]} + \mu,\\
\kappa_3 &= \kappa_{[3]} + 3\kappa_{[2]} + \mu, \text{ etc.}
\end{aligned} \tag{32}$$

Examples 1 and 7 continued: The Factorial Moment Generating Functions and the Factorial Cumulant Generating Functions for the Binomial and Negative Binomial Distributions

In Example 1 the number of mutants had a binomial distribution. The pgf is $\sum_{x=0}^{n} \binom{n}{x} p^x (1-p)^{n-x} z^x = (1-p+pz)^n$; the fmgf is therefore

$$\begin{aligned}
G_X(1+t) &= (1+pt)^n\\
&= 1 + npt + \frac{n(n-1)p^2t^2}{2!}\\
&\quad + \frac{n(n-1)(n-2)p^3t^3}{3!} + \cdots
\end{aligned}$$

and the factorial moments are $\mu'_{[1]} = np$, $\mu'_{[2]} = n(n-1)p^2$, $\mu'_{[3]} = n(n-1)(n-2)p^3$, etc. The fcgf is $\ln G_X(1+t) = n\ln(1+pt)$.

In Example 7 the number of specimens collected per year, Y, had a negative binomial distribution. Setting $\pi = \theta/(1-\theta)$ and $l = -\lambda/\ln(1-\theta)$ enables the pgf to be restated as $G_Y(z) = (1+\pi-\pi z)^{-l}$. Thus the fmgf is $(1-\pi t)^{-l}$, giving $\mu'_{[1]} = l\pi$, $\mu'_{[2]} = l(l+1)\pi^2$, $\mu'_{[3]} = l(l+1)(l+2)\pi^3$, etc. The fcgf is $-l\ln(1-\pi t)$.

Bibliography

Historical aspects of the development and use of generating functions in probability theory are discussed in [6] and the book on the history of probability theory and statistics by Hald [3]. A number of authors on probability theory and its applications give lucid accounts of generating functions in probability theory and statistics at a level that asks for only a moderate background in mathematics. The books by Feldman & Fox [2] and Port [5] can be recommended. Stuart & Ord [7] give a thorough treatment of all kinds of moments and their generating functions. Wilf's [8] lively and lucid text on the mathematics of generating functions is aimed at advanced undergraduate and postgraduate students. Douglas [1] gives a full discussion of the relationships between the various types of moments and cumulants in the context of discrete distribution theory. The book by Johnson et al. [4] on discrete distribution theory gives the probability generating function a central role and demonstrates its many uses.

Genetic Correlations and Covariances

Fisher [3] devised a theoretical basis for making inferences about genetic and environmental causes of variation in continuous traits. This provided a synthesis of Mendelian inheritance (*see* **Mendel's Laws**) with the Darwinian theory of evolution through selection, and overcame serious problems associated with the theory of blending inheritance, a concept that Darwin had relied on despite recognizing that it presented a major obstacle for his theory of evolution.

Definitions

Genetic Variances

Consider a genetic locus defined by two alleles, A_1 and A_2. Assume that a population is in **Hardy–Weinberg equilibrium** and that mating within this population occurs at random. Specifically, if the frequency of A_1 is p, the frequencies of A_1A_1, A_1A_2, and A_2A_2 are $p^2, 2p(1-p)$, and $(1-p)^2$, respectively.

Suppose this genetic locus is the only factor that causes variation in the trait Y, and let $Y = G = \mu_{ij}$ for individuals with **genotype** A_iA_j. The mean of Y, μ, is therefore given by $p^2\mu_{11} + 2p(1-p)\mu_{12} + (1-p)^2\mu_{22}$, and the variance, σ^2, by $p^2(\mu_{11} - \mu)^2 + 2p(1-p)\ (\mu_{12} - \mu)^2 + (1-p)^2(\mu_{22} - \mu)^2$. Now $\sigma^2 = \sigma_g^2$ can be decomposed as $\sigma_a^2 + \sigma_d^2$, where

$$\begin{aligned}\sigma_a^2 &= 2p(1-p)[p\mu_{11} + (1-2p)\mu_{12} - (1-p)\mu_{22}]^2 \\ &= 2p(1-p)[p(\mu_{11} - \mu_{12}) + (1-p) \\ &\quad \times (\mu_{12} - \mu_{22})]^2 \end{aligned} \tag{1}$$

is called the *additive* component of variance, and

$$\sigma_d^2 = \{p(1-p)[\mu_{11} - 2\mu_{12} + \mu_{22}]\}^2 \tag{2}$$

is called the *dominance* component of variance. Note that if $\mu_{12} = (1/2)(\mu_{11} + \mu_{22})$ – i.e. the heterozygote is the average of the two homozygotes – then $\sigma_d^2 = 0$.

These genetic variance components, σ_a^2 and σ_d^2, have an interpretation. If the values μ_{11}, μ_{12}, and μ_{22} are plotted against the number of A_2 alleles, and a straight line fitted by weighted **least squares** with weight proportional to frequency, the mean squared deviation about the mean μ is σ^2, and σ_a^2 is the variance "explained" by the straight line, in the usual **linear regression** sense. This line represents the effects of alleles under the additive assumption that the effect of two A_2 alleles is twice that of one A_2 allele; hence, σ_a^2 is called the additive genetic variance. Note that, by considering the ratio of σ_a^2 to σ_d^2, if either p or 1-p is small, then most of the genetic variance is additive.

The variance not explained by the linear association, and therefore attributed to nonlinear effects of alleles, is the residual sum of squares about the straight line, σ_d^2; R.A. Fisher called this the dominance variance [3].

Note that dominance variance and dominant inheritance do not refer to the same concept. If a trait takes just two values, and is solely determined by a single gene expressed in a dominant fashion, then $\mu_{12} = \mu_{22} \neq \mu_{11}$, say, and then $\sigma_a^2 = 2p^3(1-p)(\mu_{11} - \mu_{22})^2 \neq 0$, so that σ_d^2 does not account for the total variance.

Genetic Covariance between Relatives

Assume as above that the trait is determined solely by a single genetic locus, and consider now a pair of genetically related individuals, such as a mother and her son. By summing over the three possible genotypes of the father, the genetic covariance between mother and son is $p^3{\mu_{11}}^2 + 2p^2(1-p)\mu_{11}\mu_{12} + p(1-p){\mu_{12}}^2 + 2p(1-p)^2\mu_{12}\mu_{22} + (1-p)^3{\mu_{22}}^2 - \mu^2$, which can be shown to be equal to $1/2\sigma_a^2$. This same expression, $1/2\sigma_a^2$, holds for *all* parent–offspring pairs.

For sibling pairs, including dizygotic (DZ) twins (*see* **Zygosity Determination**), if the summation is made over all nine possible genotypes of mother and father under the assumption that maternal and paternal genotypes are independent, the genetic covariance between siblings is found to be $(1/2\sigma_a^2 + 1/4\sigma_d^2)$.

The above procedure can be extended to determine the genetic covariance between any pair of relatives. For second-degree relatives, such as grandparent and grandchild or uncle and nephew, the genetic covariance is $1/4\sigma_a^2$, and for third degree it is $1/8\sigma_a^2$, and so on, the covariance being multiplied by a factor of 1/2 for each extra generation. For genetically

identical (monozygotic, MZ) twin pairs, obviously the covariance is $\sigma^2 = \sigma_g^2 = \sigma_a^2 + \sigma_d^2$. Apart from appearing in expressions for the covariance between sibling (including twin) pairs, the term σ_d^2 occurs only when there is **inbreeding**. Nonindependence between parents, or **assortative mating**, induces extra covariation.

The **genetic correlation** is the genetic variance divided by the total variance.

Genetic Covariance in Terms of Identity Coefficients

Let G_i and G_j represent the genotype of two individuals i and j. In general, under Hardy–Weinberg equilibrium and no inbreeding (unless $\sigma_d^2 = 0$), the genetic covariance can be expressed as

$$\text{cov}(G_i, G_j) = 2\phi_{ij}\sigma_a^2 + K_{2ij}\sigma_d^2, \qquad (3)$$

where ϕ_{ij}, the kinship coefficient or coefficient of coancestry, is the probability that a **gene** drawn at random from a given locus of i is identical by descent with a gene drawn at random from the same locus of j, and K_{2ij} is the probability that both genes at a given locus are identical by descent in i and j. Under random mating, for MZ twin pairs, $\phi_{ij} = 1/2$. In the absence of inbreeding, $\phi_{ij} = 1/4$ for first-degree relatives (parent–offspring and sibling pairs), 1/8 for second-degree relatives (such as grandparent–grandchild), and so on, the coefficient being halved for each successive generation separating the pair. For MZ pairs, $K_{2ij} = 1$, and for sibling pairs, $K_{2ij} = 1/4$. Otherwise, $K_{2ij} = 0$, except for pairs such as double-first cousins, in which case, $K_{2ij} = 1/16$, and for offspring of related persons; for example, of sib-matings, in which case $K_{2ij} = 7/32$ (*see* **Identity Coefficients**).

Genetic Covariance under Polygenic Inheritance

Assume G now represents a **polygenic** factor, i.e. the combined effect of a number of genetic factors $G_i, i = 1, 2, \ldots, n$, at different loci. Let

$$G = G_1 + G_2 + G_3 + \cdots + G_1 \odot G_2 + G_1 \odot G_2 \odot G_3 + \cdots + G_1 \odot G_2 \odot \cdots \odot G_n, \qquad (4)$$

where each G_k has variance $\sigma_k^2 = \sigma_{ak}^2 + \sigma_{dk}^2$ as above, and the $\odot$ notation represents interaction between the loci (epistasis). There may be interactions between the additive components of loci, between the dominance components of loci, and between additive and dominance components of loci. It can be shown that in this case (3) must be extended by including a term for each interaction of a different type; see [1]. An interaction between pairs of additive components involves a variance component, σ_{aa}^2 say, multiplied by $(2\phi_{ij})^2$, and between triples of additive components a term $(2\phi_{ij})^3\sigma_{aaa}^2$, and so on. Similar comments apply to dominance components, with the coefficient K_{2ij} replacing $2\phi_{ij}$. These interaction components all contribute fully to the covariance between MZ twin pairs, because the coefficients $2\phi_{ij}$ and K_{2ij} are both unity, but contribute far less to the covariance for other relationships. Therefore, while dominance contributes to sibling covariance but not to parent–offspring covariance, epistasis can contribute to both parent–offspring and sibling covariances.

Provided the G_i are independent, which is a reasonable assumption for unlinked loci, the additive genetic variance is the sum of additive variances at each loci. The same holds for the total variance. In the absence of epistasis, the genetic correlations between relatives in terms of additive and dominance variance components are the same for a polygenic factor as for a single locus.

If G represents a large number of genetic loci, each having a small additive impact on the trait, multivariate **central limit theorems** for the distribution of G across groups of relatives have been derived, for example, [8]. The theorems have been proved under several fairly stringent sufficient genetic restrictions: Hardy–Weinberg and linkage equilibrium (*see* **Linkage Disequilibrium**) for all loci; absence of assortative mating and epistasis; a small variance for each locus compared with the total variance over many loci; an upper bound on the number of loci per chromosome; and no inbreeding if there is dominance variance at any locus. Verification of these, and other technical conditions, in practice would be difficult, if not impossible, but it is usually assumed that these theoretical restrictions are not of practical importance.

Environmental Variances

Factors that are independent between individuals irrespective of their relationship to one another, such as environmental effects specific to an individual and

measurement error, induce no covariance between relatives. If variation in Y is caused only by such nongenetic factors E_i and E_j for distinct individuals i and j, then

$$\text{cov}(E_i, E_j) = 0. \tag{5}$$

Let $\sigma_e^2 = \text{var}(E)$.

If variation in Y is caused only by a factor, C, that is shared by or common to (classes of) relatives, these relatives will be correlated. For example, if C_i and C_j represent the effects of environmental factors common to the household for distinct individuals i and j, then

$$\text{cov}(C_i, C_j) = c_{ij}\sigma_c^2, \tag{6}$$

where $c_{ij} = 1$ if i and j live in the same house, else 0, and $\sigma_c^2 = \text{var}(C)$. This cohabitation effect may be more sophisticated, perhaps depending on the type of relationship between cohabiting individuals, increasing the longer these individuals live together, and attenuating the longer they live apart. Some theoretical models for this have been proposed and applied [2, 5, 9].

Covariance Between Relatives in Terms of Genetic and Environmental Variances

The combined effects of genetic, common environmental, and individual specific factors, G, C, and E, respectively, on the variance of a trait Y can be modeled in numerous ways. The simplest models suppose that the effects of each component of variation are independent, i.e.

$$Y = \mu + G + C + E, \tag{7}$$

in which case

$$\text{var}(Y) = \sigma_g^2 + \sigma_c^2 + \sigma_e^2 = \sigma^2, \tag{8}$$

and

$$\text{cov}(Y_i, Y_j) = \text{cov}(G_i, G_j) + \text{cov}(C_i, C_j). \tag{9}$$

Each of the covariance terms in (9) can take various forms, depending on whether dominance or epistasis is included and the sophistication with which the common environment is modeled.

This general model can be extended to include **gene–environment interactions**, in which the effects of genetic factors are not independent of those of environmental factors; i.e. the effect of a particular genotype can depend on the environment. Extra term(s) for interaction effects need to be included in both the variance and covariance. In defining genetic correlations, when there are gene–environment interactions it is not clear what the denominator should be. Should the effect of genetic factors depend on environmental factors that change as an individual ages, the genetic variance will change with age.

The general model can also be extended to allow for gene–environment covariation, in which the distribution of the genetic and environmental factors is not independent; i.e. certain genotypes are more common in particular environments.

The Role of the Mean and Measured Factors in Genetic and Environmental Modeling

The discussion above has focused on causes of variation without reference to the presumed population mean about which this variation occurs. The variance, covariance and hence variance components (i.e. **random effects**) may differ considerably depending on what factors are taken into account in modeling the trait mean (**fixed effects**). For example, if the trait mean depends on age, then this will induce a covariance between siblings if they are generally of a similar age. If the mean is adjusted for age, the siblings will be less correlated than if the mean is unadjusted for age [6].

The absolute values of genetic and environmental components of variance may change as the effects of different factors are modeled in the mean. For example, for traits whose mean values depend on height, adjustment for height usually leads to a reduction in the genetic variance, provided age has also been taken into account. This is presumably because variation in height for age appears to be predominantly attributable to genetic causes [3].

The effects of genetic variation at a particular locus for which the individual genotypes have been measured can be modeled as either a fixed effect or a random effect [4]. In the fixed effects modeling, the mean may be assumed to change linearly with the number of copies of a certain allele the individual possesses; i.e. an additive genetic variance at this locus is being modeled (cf. (1)). The mean can also be

assumed to take a different value for each genotype, in which case dominance genetic variation at this locus is also being considered. In the random effects modeling, similar to the way common environmental effects are modeled using (6), individuals may be assumed to be more correlated if they both have the same genotype, or the same **haplotype** if alleles at several closely linked loci have been measured.

For a review of issues surrounding the variance components models and the methods involved in their estimation, see [7].

Genetic Counseling

Genetic counseling is the communication process by which individuals and their family members are given information about the diagnosis of the disease in question, quantitation of risk, and the implications of this genetic information. The ability to predict accurately an individual's disease risk is important at personal and population levels. At a personal level, knowledge of risk promotes informed health care decisions. At a population level, risk prediction enables targeted public health interventions in high-risk groups. The main contribution of statistics to genetic counseling is to provide a probabilistic framework for the estimation of the genetic risk.

Genetic counseling is generally concerned with the probability that an individual will develop a specific genetic disease. The risk for individual i is then defined as

$$\Pr(\text{individual } i \text{ will have disease } D) = \Pr(D_i).$$

By definition, a genetic disease is associated with a particular **genotype** (or genotypes). This association can be expressed as

$$\Pr(D_i) = \Pr(D|X, G_i)\Pr(G_i),$$

where X represents environmental factors, and G_i is the event that individual i has a disease genotype. Environmental factors are taken to include endogenous characteristics of the individual such as age or physiological characteristics, as well as exogenous exposures to compounds that may cause or modify risk to develop disease. The conditional probability, $\Pr(D|X, G_i)$, is referred to as the **penetrance** function of the disease.

In most cases, the genetic counselor's main concern is $\Pr(G_i)$, the probability that an individual has a disease genotype. Alternately, the concern might center on determining the probability that an individual carries a genotype consistent with the inheritance of a disease genotype by his or her progeny. This is referred to as *carrier risk*. When the determination of the individual's risk is not based on direct determination of his or her genotype (e.g. by genetic testing) but on the genotypes and disease occurrence in relatives, the disease risk $\Pr(D_i)$ is referred to as *recurrence risk*.

Genetic risks can be classified into three categories, namely population-, pedigree-, and individual-based, according to the type of data available and the analytical tools used in **risk assessment**.

Population-based Risk

In population-based risks (also referred to as empirical risks) the data are the frequencies of affected and unaffected individuals sampled from populations. These data include disease **incidence rates** in defined populations, often obtained from **case–control** or **cohort studies**. The distinguishing characteristic of population-based risk is that there is no attempt to quantify either the penetrance function or $\Pr(G_i)$.

An example of this category of risk estimation is a woman's lifetime breast cancer risk. This risk is often quoted to be 0.125 since, from US cancer registries (*see* **Disease Registers**), it has been observed that one in eight women develop breast cancer. This number is based on population estimates of lifetime cancer incidence, and does not reflect the personal risk factors of the individual (e.g. family or reproductive history). It is applicable only to women who belong to the sampled population. Epidemiologic studies can be conducted to identify endogenous and exogenous factors that may affect disease risk. These risk factors can be used to construct models for risk prediction. For example, Gail et al. [1] generated breast cancer risk estimates using information about age at menarche, number of previous biopsies, age at first live birth, and limited family history.

Pedigree-based Risk

Most frequently, risk estimates in genetic counseling are based on pedigree information. Traditionally, one assumes an underlying genetic model for the disease. The models may include parameters such as gene frequencies, transmission probabilities, probability of being a sporadic case, penetrance of genotypes, mutation rates and, in the case of a linked marker, recombination fractions, proportion of families for which the disease gene is linked to the marker, and gene order. In general, the unknown parameters of a given genetic model are replaced by point estimates obtained by **segregation analysis** or **linkage analysis, model-based**.

As an example, let us assume that unaffected parents have had one child affected with a rare single locus dominant, incompletely penetrant, autosomal disease. What is the probability that the couple's next child will be affected? In other words, what is the recurrence risk for the next child? The evaluation of this risk is based on two conditional probabilities, the probability that the next child is affected given that the affected sib (1) inherited the disease gene present in the parents, or (2) has it as a result of a *de novo* mutation. The recurrence risk is obtained from these conditional probabilities through an application of **Bayes' theorem**.

Individual-based Risk

Once a disease gene is identified and cloned, its presence or absence in an individual can be determined by biochemical assays. In this case, there is very little uncertainty about the individual's genotype. Consequently, the probability of disease is equal to the penetrance if the individual has the disease genotype, and is equal to zero otherwise.

As an example, the cloning of the hereditary breast cancer susceptibility gene BRCA1 allowed individual-based risk estimates to be produced using direct genetic mutation analysis. Breast cancer risk in an individual who carriers a mutant form of the BRCA1 gene can be estimated using the result of this test. These estimates suggest that women who carry germline BRCA1 mutations have a substantial risk of developing breast cancer during their lifetimes.

Interval Estimates of Risk

Traditionally, a point estimate of risk is communicated to the counselee. Methods currently exist to provide interval estimates (*see* **Estimation, Interval**) [2]. This is particularly important when risks are estimated from small samples.

As an illustration, suppose that a linked **genetic marker** is available, and no recombinants have yet been observed between the marker and the putative disease gene. Thus, the estimated recombination probability will be zero, and the risk estimate will also be zero. Although the risk for a person who does not inherit the marker allele of risk may be small, the genetic counselor will be reluctant to provide a risk estimate of zero, and an upper confidence limit of risk may be more desirable.

Genetic Distance

The concept of genetic distance relates to the measurement of genetic difference between populations. It is designed to answer how dissimilar the populations are with respect to their genetic compositions. Since the genetic composition of a population is well approximated by the allele frequencies at most loci (*see* **Hardy–Weinberg Equilibrium**), the genetic distance between two populations has been traditionally defined by quantifying the differences in the allele frequencies between them by a single number. In devising such a measure it is necessary to determine the central position of each population, so that the distance between populations can also take into account any within-population genetic variation that may exist. This leads to a geometric interpretation of the distance concept, where a distance function is expected to satisfy the three mathematical properties of a *metric*; i.e. the distance D_{ij} between populations i and j should be: (i) nonnegative ($D_{ij} \geq 0$, with $D_{ij} = 0$ if and only if $i = j$), (ii) symmetric ($D_{ij} = D_{ji}$), and (iii) $D_{ik} + D_{jk} \geq D_{ij}$ for any three populations i, j, and k (the triangle inequality). The first condition immediately implies that the definition of D_{ij} must take into account the within-population variation in each population.

Although the methods of detecting genetic variation have changed considerably over the history of biology, and even more changes are expected to occur through the advent of recombinant DNA technology (*see* **DNA Sequences**), genetic distance studies predate the discovery of **genetic markers**. Since the introduction of the first distance measure [9], a variety of genetic distance measures have been proposed and used for a variety of purposes, and a detailed account of these is beyond the scope of this article. There are many excellent reviews on this subject, e.g. [5, 10, 14, 21], and [31], several of which are still up to date. For the purpose of applications, these distance measures may be classified into two broad classes: (i) those intended for population classification, and (ii) those intended for the study of evolution. Nei [22] classified into the first category Czekanowski's mean difference [9] and its variation (the "Manhattan metric" [32]), Pearson's coefficient of racial likeness [26], Roger's distance [28], **Mahanalobis' distance** [18], Sanghvi's distance [29] and its variant [1], Kurczynski's D^2 [13], Bhattacharyya's [2], and Cavalli-Sforza & Edwards' [4] distances. Into the second category Nei grouped the distance indices of based on Wright's F_{ST} index (e.g. [3] and [15]), Morton's kinship indices [19], and his own distances [20]. Cockerham & Weir's [8] coancestry measure of distance (*see* **Inbreeding**) also falls into this second category. Although as a measure of genetic dissimilarity between populations this categorization has little importance, there is a clear difference when the evolutionary dynamics of **gene frequencies** are formulated in terms of defined evolutionary mechanisms (such as mutation, drift (*see* **Population Genetics**), and migration). The first category of distance indices does not generally show a well-defined pattern or trend, such as increasing with the evolutionary time of separation. In contrast, genetic distance indices of the second category have been studied in the context of specific models of evolution, so that their expected trend with the time since divergence between populations is fairly well described [5, 22, 33].

Even though the definitions of these distances are based on different premises, several of them are analytically related [5, 27, 33], and even those that are mathematically dissimilar yield fairly similar inferences regarding interpopulation relationships, at least for genetically close populations [6]. Dissimilarities of distance measures, however, emerge from their being estimated by the sampling of allele frequencies from populations. All distance functions involve quadratic expressions (and often their ratios) of population allele frequencies, and hence their estimates are biased. Analytical correction for bias is not an easy task, and can only be achieved either by approximations that hold under some strict conditions, or by numerical resampling methods (*see* **Bootstrap Method**). Furthermore, the total variance of an estimated distance consists of both contemporary sampling effects as well as cumulative effects of the past evolution of populations [5, 17, 24]. Recent work on the subject suggests that, with the molecular data currently being employed to study genetic variation between populations, it is necessary to include the concept of the coalescence time of alleles (i.e. how long in the past two alleles had a common ancestor) in a distance measure for it to be appropriate for evolutionary studies, for example, [12, 30]. The statistical properties of such distance measures are still to be explored rigorously [11].

Finally, in the human context, although genetic distance provides a fairly good indicator of evolution and dispersal of the species, any graphic display of interpopulation genetic distances should be interpreted with caution. Genetic variation by geographic or racial classification is a mere reflection of the discontinuity of sampled populations. In reality, genetic variation is gradual in time and is continuous in space; most of the variation is interindividual, and the interpopulation component of variation constitutes only a small portion of the total genetic diversity of the species [7, 16, 23, 25].

Genetic Epidemiology

By 1967 discussions among researchers had led to the realization that the merger of methods to analyze family data from mathematical genetics and statistical tools from epidemiology was both inevitable and desirable [9]. This merger was designated *genetic epidemiology*, for which Morton [9] proposed the following definition:

> genetic epidemiology: A science that deals with etiology, distribution, and control of disease in groups of relatives and with inherited causes of disease in populations.

The formal definition of the new field followed two decades of discussion dating back to Neel & Schull [10] defining "epidemiological genetics" in 1954. This dynamic time period saw the emergence of genetic epidemiology from the broader field of **population genetics** and the synthesis of several parallel developments in mathematics and statistics as they applied to human disease. But to understand the role of this relatively new field, its impact on **human genetics**, and its evolving definition in the post Human Genome Project era, it is necessary to review its history.

In the beginning, genetics was "genetic epidemiology". By stating the observation that an offspring receives one of two factors from each parent and has a 50% chance of passing each factor to its offspring, Gregor Mendel defined the probabilities that set the mathematical and statistical tone for the broad scientific discipline called genetics (*see* **Mendel's Laws**).

Mendel's original work also set the stage for the three characteristics that provide the cultural milieu for genetic epidemiology. First, scientists ignored Mendel's seminal discovery for nearly 50 years. The mathematical proofs, computational details, and statistical arguments required by genetic epidemiology leave most geneticists bored and/or frightened, preferring to ignore genetic epidemiology. Secondly, the question of whether Mendel's results were "too good" [5], foretold a field that relishes controversy over methods, interpretations, and applications. Such "family fights" prove stimulating to the investigators involved but have had the tendency to convince other geneticists that the field lacks focus and rigor. And finally, until very recently genetic epidemiology was a small field easily dominated by a few creative and powerful figures whose scientific differences and personal animosity made for exciting and stimulating arguments and intense scientific fads.

As genetics developed at the turn of the century, the research was concentrated in two areas:

1. defining phenotypes, which for humans is clinical genetics, at that time including rudimentary biochemical genetics; and
2. studying the mathematical properties of genes in populations, population genetics.

By the 1930s cytogenetics (the study of chromosomes) was flourishing, primarily in *Drosophila*, and has continued to develop as a major area of research. And most recently the field of molecular genetics has exploded in a wealth of research and knowledge leading to the initiation of the Human Genome Project in 1989.

Genetic epidemiology shares the use of mathematics and statistics as its primary tools with the field of population genetics, but its definition of a unique niche within genetics results from its interaction with all of the other areas. The history will be divided into three broad and, to some extent, overlapping categories:

1. population genetics;
2. Mendel's first law: segregation of alleles at one locus; and
3. Mendel's second law: independent assortment of two loci.

The Beginning (1): Population Genetics

The seminal beginning to population genetics was the definition of the Hardy-Weinberg Law in 1908 (*see* **Hardy–Weinberg Equilibrium**). In 1932 Snyder [13] applied this law to demonstrate the mode of inheritance for tasting phenylthiocarbamide (PTC). Snyder not only provided a clear example of the appropriateness of the Hardy–Weinberg equilibrium for the human population but also demonstrated a mathematical method for testing that a phenotype was inherited. This was both useful and restricted by the fact that is was limited to traits sufficiently common to allow random sampling of a large

number of families. This restriction of population genetic principles to common traits has limited their usefulness until recently.

Another significant issue addressed by early population genetic principles was the role of Mendelian factors in the inheritance of quantitative traits. Early investigators argued that segregating alleles could not possibly account for quantitative traits with Gaussian distributions (*see* **Normal Distribution**). In 1918 Fisher [4] demonstrated conclusively that "many small, equal, and additive loci" would result in exactly the Gaussian distribution for a phenotype. From that finding grew the entire field of quantitative genetics, including **heritability**, breeding factors, and other crucial insights for plant and animal breeders. Eventually these quantitative genetic principles also contributed to our understanding of human inheritance (*see* **Genetic Correlations and Covariances**).

Population genetics research continued to develop in several areas relevant to studies in genetic epidemiology, including describing the structure of populations (*see* **Genetic Distance**; **Admixture in Human Populations**; **Assortative Mating**; **Heterozygosity**). The principal distinction for these areas is that they apply to all populations and traits, thus providing insight for the study of human disease but are not restricted to the study of specific disease etiology.

The Beginning (2): Mendel's First Law

A second early and significant area of research developed to address statistical issues arising from the use of family data. Mendel began with pure breeding parents and tested the F1, F2, and backcross data. For human diseases that are *rare* in the population, the approach is to ascertain families where the disease is *known* to exist thereby avoiding a huge random sample which might capture little or no information. However, the use of **ascertainment** introduces immediate bias into the sample, as recognized as early as 1912 by Weinberg [14]. Although numerous investigators have proposed solutions to this problem, it continues as a serious concern for genetic epidemiologists to this day.

Data were analyzed for the presence of genes using the Weinberg and a priori forms of ascertainment correction until 1958 when Morton [8] proposed a **likelihood** approach to segregation analysis. The use of likelihood scoring to estimate parameters permitted incorporation of an ascertainment probability, proportion of sporadic cases, and other concepts of interest. It also provided a direct estimate of the **penetrance** and a **likelihood ratio test** for whether it differed from 1.0. The likelihood model much more closely approximated reality than the simpler approaches and was fairly widely applied (*see* **Segregation Analysis, Classical**).

By the 1960s, sufficient numbers of genetic loci had been identified in humans to establish a need for other forms of statistical analysis. For example, the procedure for paternity exclusion was refined and applied both scientifically and in legal situations (*see* **Paternity Testing**). Interest developed in models specifying the relationship among family members. Methods originally developed by the brilliant but not oft published Charles Cotterman [11] brought binary numbers and matrix algebra to the forefront (*see* **Identity Coefficients**; **Inbreeding**). An elegant modeling system, path analysis, incorporated the relationships among relatives and the possibility of environmental factors in order to determine the etiology of more complex traits. Models were developed to utilize twin data as special cases in an attempt to estimate more rigorously the importance of environmental factors (*see* **Path Analysis in Genetics**; **Twin Analysis**; **Twin Concordance**; **Adoption Studies**).

Also during the 1960s quantitative genetics made its presence felt in human genetics. Falconer [3] introduced the idea of a normally distributed, quantitative trait as the "liability" or "susceptibility" for a genetic disorder. This underlying trait was polygenic in nature, conforming to the work of Fisher cited above. When environmental factors were known to influence the trait, such as birth order effects, the model was called multifactorial to include both polygenic genetic effects and the environment. The disorder, however, was dichotomous in phenotype, such as the presence or absence of a birth defect, and the underlying quantitative trait led to the phenotype through theoretical "thresholds", leading to the multifactorial threshold models (MF/T). This breakthrough in thinking was followed by a burst of research and what amounted to a fad in genetic epidemiology, as every trait of unknown etiology was shown to be inherited in a multifactorial fashion. The bubble burst in 1972 when Reich et al. [12] pointed out the simple statistical fact that the model was indeterminate unless there were at least two

thresholds. Fortunately for many human phenotypes, e.g. birth defects, the presence of at least two thresholds was a simple matter since the frequency of the disorder differed markedly in the two sexes (*see* **Polygenic Inheritance**).

The popularity of the multifactorial models helped genetic epidemiologists realize that many of the diseases and disorders of interest would have much more complex etiologies than single locus inheritance. But few if any traits survived a rigorous test of MF/T. The popularity of the MF/T model declined and was replaced by the concept of genetic heterogeneity.

The realization that etiologies were complex dictated the development of more mathematically sophisticated models and statistical tests. For example, until the development of the "mixed model", the presence of single locus inheritance and the presence of multifactorial inheritance were tested as separate hypotheses that did not contain the same parameter space, that of an overarching general model, and so were not *true* alternative hypotheses. The "mixed model" was so named because it defined that necessary general model and led directly to the more rigorous testing of the possible modes of inheritance (*see* **Segregation Analysis, Mixed Models**).

A split had developed in the field, however, and a serious controversy raged over the question of whether to use nuclear family data (parents and their offspring) or larger extended pedigrees for testing genetic hypotheses. As with the other previous disputes, the field experienced a surge forward as models were developed both for nuclear families and for extended pedigrees. There were two primary developments in the area of pedigree analysis. First the publication of the **Elston–Stewart algorithm** [2] provided an efficient, recursive mathematical approach to evaluating the likelihood over an extended family. Its importance to all of genetics was recognized with the presentation of the William Allan Award by the American Society of Human Genetics to Elston in 1996. (The first William Allan Award was presented in 1962 to Newton Morton for segregation analysis and the introduction of lod scores to linkage analysis.) The second development was the introduction of *transmission probabilities*. The use of these parameters expanded the ability to test genetic models to determine whether they fit the data best while remaining within the constraints of Mendel's first law. Which form of data to use, nuclear families or pedigrees, was resolved methodologically by a reformulation of both approaches to incorporate the parameters of the other and the definition of a single "complex segregation" analysis approach (*see* **Segregation Analysis, Complex**).

Two additional major developments were to occur in the arena of Mendel's first law. The first of these was the introduction, through a series of papers, of **regressive models** by Bonney and his colleagues. These models, the most complex to date, incorporate numerous **confounding** factors, such a cohort effects (*see* **Age–Period–Cohort Analysis**). However, by virtue of their complexity and the number of parameters involved, they require huge data sets and are often applied in more restricted forms.

The second remaining development was the merger of segregation analysis with linkage analysis, but first it is necessary to discuss linkage analysis itself.

The Beginning (3): Mendel's Second Law

The phenomenon of linkage, i.e. the violation of the independent assortment of Mendel's second law, was first studied extensively in experimental organisms, primarily *Drosophila* and mouse. The concepts of linkage groups, recombination frequency, genetic distance, and mapping functions (*see* **Genetic Map Functions**) were all observed, defined, and/or analyzed throughout the first half of this century. Linkage has proven to be a powerful genetic tool. In spite of this power, very little was done in humans before 1950 because so few marker loci existed. The first linkage in humans was demonstrated by Mohr [6] in 1954. About this time, however, the use of new laboratory techniques to identify genes (for example, electrophoresis) began and is still going on with the molecular biology revolution.

The breakthrough in human linkage studies required not only the means to develop marker loci but also the statistical tools to analyze the data. Studies with experimental organisms are done by using fixed mating schemes and counting the recombinants in the offspring. For humans the two restricting factors were unknown phase (which of the two marker alleles was on the chromosome with the disease allele) of the parents and the small family size. To overcome these obstacles the data had to

be pooled, but pooling matings of opposite phase would result in apparent independent assortment. Therefore each small family had to be analyzed and *then* pooled. By extending the principles of sequential sampling (*see* **Pedigrees, Sequential Sampling**), Morton [7] defined lod scores for linkage analysis in humans (*see* **Linkage Analysis, Model-based**). Over the course of the past 40 years untold numbers of lod scores have been calculated – at the beginning by hand [7] and later by a plethora of computer algorithms (*see* **Software for Genetic Epidemiology**).

The observation that insulin dependent diabetes mellitus type 1, IDDM, showed a strong association with alleles of the **HLA system** on chromosome 6 (*see* **Disease-marker Association**) defined a new situation for linkage analysis. The question debated extensively was whether this association represented **linkage disequilibrium** between HLA markers and an IDDM locus or a susceptibility role for the HLA alleles. The problem was further complicated by the nature of the HLA multi-locus region which contained numerous haplotypes in disequilibrium (*see* **Haplotype Analysis**). If IDDM were solely genetic, then reduced penetrance would have to be invoked when analyzing unaffected individuals. This problem stimulated the development of methods to detect linkage that were directed towards using only affected individuals (*see* **Linkage Analysis, Model-free**). Recent publications have independently demonstrated that the "model-free" methods can be considered as subsets of the model-based methods and by doing so have raised a set of statistical questions for genetic epidemiologists to resolve regarding application and interpretation of the different methods.

The rapid explosion in the development of the human genome linkage map led to the necessity for methods that could analyze multiple loci simultaneously. These methods (*see* **Linkage Analysis, Multipoint**) provide additional precision in determining the actual location of purported disease loci.

Likelihood models were derived for simultaneously estimating the segregation parameters and the linkage relationships for a disease locus (loci). More recently, alternative approaches of using linkage information alone to determine the mode of inheritance have been proposed.

In the End...

In summary, it is important to emphasize three points. First it is impossible in any overview to include all of the important factors that contributed to the development of a scientific discipline. Therefore, this discussion slighted some developments and emphasized others. The second point is to restate the long-term goal of genetic epidemiology: to understand the causes of genetic disease in humans. To this end, the research efforts must be translated into terms that can be discussed with patients in families at risk (*see* **Genetic Counseling**) and that leads to the formulation of the next set of research questions. Neither of these end points is simple to derive from the often convoluted results of analyzing complex disorders in less-than-ideal data.

And finally, the field of genetic epidemiology has been responsive to the need for interaction and the exchange of ideas. The journal *Genetic Epidemiology* was established in 1984 and the International Genetic Epidemiology Society was founded in 1991, adopting the journal as its official publication. The depth of methodological disagreements and their effect on the genetic community led directly to the establishment of the Genetic Analysis Workshop (GAW) series, the most recent being GAW 10 in 1996 [1]. These workshops provide a unique atmosphere where methods are compared and evaluated in a controlled workshop format.

The next challenge for the field of genetic epidemiology is to develop new approaches to utilize the vast amounts of information that will become available as the human genome is sequenced and to apply these techniques to the most common and complex of disorders rigorously and imaginatively.

Genetic Heterogeneity

When a trait has a genetically different etiology in different individuals, that trait is said to be genetically heterogeneous. Two major types of genetic heterogeneity are identified: allelic heterogeneity and locus heterogeneity. With allelic heterogeneity, different alleles at the same locus confer the same phenotype in different individuals. An example of allelic heterogeneity is the cystic fibrosis **gene** [17]. About 75% of the chromosomes in cystic fibrosis patients carry the ΔF_{508} mutant allele; the remaining chromosomes each carry one of a large number of different mutant alleles of the same gene. With locus heterogeneity, the phenotype in different individuals is due to different loci. A classic example is autosomal recessive albinism, which can be caused by a mutant allele in one of at least two different loci. A report by Trevor-Roper [34] of four normal offspring from the mating of two affected parents illustrates this concept. An earlier description of a disease exhibiting locus heterogeneity is given by Morton [20] for elliptocytosis.

When the phenotype (*see* **Genotype**) is relatively rare and the rate of new **mutations** is low, affected individuals in the same family (almost always) carry the same mutant allele. As a result, a set of families can, in theory, be grouped according to which mutant allele they carry. If the genes have not yet been identified, then the usual first step is to determine, using linkage analysis and additional positional cloning methods, the loci involved. Statistical analyses that allow for locus heterogeneity can be used to improve the power of **linkage analysis** and to group families according to the locus causing the phenotype. Once the loci have been identified, different mutant alleles within each locus can be identified using molecular methods and studied using statistical methods that model allelic heterogeneity.

If the phenotype is common, then affected individuals within a family may not carry the same mutant allele and families may not be as easily grouped. Nonetheless, the same overall plan may be followed (although researchers may instead opt to investigate specific **candidate genes** or use **linkage disequilibrium** methods to search for candidate loci). We consider primarily the problem of locus heterogeneity in the context of linkage analysis, since a substantial body of statistical work is available in this area, although locus heterogeneity is an equally important issue for other gene mapping methods.

Locus Heterogeneity

A disease exhibits locus heterogeneity if alleles at more than one locus confer susceptibility to the disease. Locus heterogeneity adversely affects the power of linkage analysis because the sample of families to be analyzed is in fact a mixture of families with different underlying genetic architectures. This is a particular problem for mapping complex diseases, so named because of their likely considerable degree of locus heterogeneity. Mapping **complex diseases** remains one of the biggest challenges in gene mapping. Power can be improved by employing a statistical model that allows for locus heterogeneity, either by representing the **likelihood** as a mixture likelihood (in the absence of additional phenotypic information) or by incorporating additional phenotypic information into the likelihood.

Let θ denote the recombination fraction between disease and **marker** loci. Consider a set of families in which a subset of the families is linked ($\theta < \frac{1}{2}$) to a locus denoted A and the remaining families are unlinked ($\theta = \frac{1}{2}$) to locus A. The disease in families unlinked to locus A may be caused by one or more unlinked loci or by environmental factors. Smith [31, 32] proposed the mixture likelihood

$$L_i(\alpha, \theta) = \alpha L_i(\theta) + (1 - \alpha) L_i\left(\tfrac{1}{2}\right), \qquad (1)$$

where $L_i(\theta)$ is the likelihood for family i and α is a mixture parameter. (*See* **Linkage Analysis, Model-based** for a description of likelihood models for linkage analysis.) A **likelihood ratio test** of homogeneity, given linkage, is given by

$$\chi^2 = 2[\ln L(\hat{\alpha}, \hat{\theta}) - \ln L(1, \hat{\theta})], \qquad (2)$$

where $L(\alpha, \theta) = \prod_i L_i(\alpha, \theta)$. The test statistic has asymptotically a distribution that is a 50:50 mixture of a point mass at zero and a chi-square with one degree of freedom (df). This test of homogeneity has been termed the A-test, with A representing "admixture".

Likelihood ratio tests of linkage in the presence of heterogeneity can also be constructed using the admixture likelihood:

$$\chi^2 = 2\left[\ln L(\hat{\alpha}, \hat{\theta}) - \ln L\left(1, \tfrac{1}{2}\right)\right]. \qquad (3)$$

The asymptotic distribution of this statistic is more difficult to determine than the test of homogeneity, because under the **null hypothesis** of no linkage, α is undetermined. A conservative approximation compares the likelihood ratio statistic to a χ^2 with 2 df. Faraway [7] showed that the asymptotic distribution is more accurately approximated as the maximum of two χ_1^2 deviates. More recently, Chiano & Yates [4] used a reparameterization to determine an approximate asymptotic distribution and recommended a critical lod score of 3.44 to conclude **genome-wide significance**.

Given estimates of α and θ, the conditional probability that family i is of the linked type can be estimated using

$$w_i(\hat{\alpha}, \hat{\theta}) = \frac{\hat{\alpha} L_i(\hat{\theta})}{\hat{\alpha} L_i(\hat{\theta}) + (1 - \hat{\alpha}) L\left(\frac{1}{2}\right)}. \qquad (4)$$

When α and θ are known, $w_i > \frac{1}{2}$ is an optimal classification rule to group families of the linked type [12]; when α and θ are estimated, the classification rule $w_i(\hat{\alpha}, \hat{\theta}) > \hat{\alpha}$ is generally more reliable in small samples [22]. Power to detect heterogeneity has been considered by other authors [2, 23].

Several generalizations of the admixture likelihood have been proposed. Ott [24, 25] describes a mixture model for two linked loci in which two recombination fractions and the heterogeneity parameter are estimated. A more complex mixture model, also described in [25] (see also [33]) specifies a mixture of three distributions, two of which are unlinked disease loci for which marker data are available and one of which represents a hypothetical third locus (or other factor) unlinked to the first two. These extensions are available in the HOMOG programs (see [25]). Vieland et al. [35] extended the admixture model to the combined analysis of multiple data sets by allowing the admixture parameter to vary across data sets and confirmed that this "compound" lod score, denoted HLOD-C, has better power in the presence of locus heterogeneity than HLOD alone or model-free linkage methods [16].

MacLean et al. [18] proposed the C-test, given by

$$C = \sum_{i=1}^{n} \max_{\theta} Z_i(\theta), \qquad (5)$$

where the sum is over all pedigrees in the sample and $Z_i(\theta)$ is the lod score for family i. MacLean et al. claimed that the C-test is much more powerful than the A-test, but this claim has been disputed [8, 19]. One can also fit two-locus (or more generally, **multilocus**) models to investigate locus heterogeneity. Goldin [11] compared the power of some two-locus linkage models with the admixture model. She found that the two-locus model was more powerful when all the families in the sample are segregating for both loci, but that this increase in power requires correct specification of the parameters of the genetic model, and as a result preferred the admixture lod score in real-data situations.

It is generally held that allowing for locus heterogeneity in the analysis improves power for detecting linkage for rare Mendelian disorders. For small numbers of families, the admixture parameter may not be well estimated. Chiano & Yates [3] proposed a **bootstrap** approach to estimating linkage parameters in the presence of locus heterogeneity. For common complex diseases, the problem of locus heterogeneity is more complex. Durner et al. [6] explored whether a phenocopy frequency can approximate or model locus heterogeneity and found that, in general, assuming a positive phenocopy frequency does not compensate for the presence of an unlinked form of genetic disease. Whittemore & Halpern [36] discuss the limitations of estimating the admixture proportion when the disease is not rare and when the underlying genetic model is complex. They argue that, for common diseases, the admixture likelihood relies on unverifiable assumptions (including correct specification of a phenocopy rate) that, if violated, may decrease power to detect linkage.

Additional phenotypic information can be used to help classify families into linked and unlinked types. A simple and common approach is the separate analysis of subgroups of families, particularly when families can be grouped according to some categorical variable. An alternative test, the M-test [20], can be applied when families can be grouped into c classes based on additional phenotypic information. The likelihood is maximized for each class separately ($i = 1, \ldots, c$) and compared with the likelihood maximized over the entire sample. The test statistic is written as

$$M = 2\ln(10)\left[\sum_i Z_i(\hat{\theta}_i) - Z(\hat{\theta})\right]. \qquad (6)$$

Asymptotically (i.e. as the number of opportunities for recombination in each class goes to infinity)

and under the assumption of homogeneity, the M statistic follows a χ^2 distribution with $c - 1$ df. The M-test requires estimation of a separate recombination fraction in each class. A more powerful approach based on a **hierarchical model** and termed the B-test (with B representing **Bayesian**) was proposed by Risch [28]. For this test, the recombination fractions are assumed to follow a beta distribution, the parameters of which are estimated from the posterior distribution of θ. The resulting likelihood ratio test is compared against a χ^2 with 1 df and is more powerful than the M-test.

Regression methods have been proposed recently that allow discrete and continuous phenotypes to be incorporated as **covariates**. A generalization of the admixture likelihood allows the mixture parameter α to be a function of covariates [30]. Let

$$\alpha = \frac{\exp(\gamma + \beta^{\mathrm{T}} x)}{1 + \exp(\gamma + \beta^{\mathrm{T}} x)}, \tag{7}$$

where x is a vector of covariates, γ is an intercept parameter, and β is a vector of regression parameters. Similar problems in determining the distribution of overall tests of linkage exist for this model as for other mixture likelihoods.

Some covariates, such as age-at-onset, can also be incorporated as part of the disease **penetrance** functions. When the associated parameters are estimated previously and fixed in the linkage analysis, such penetrance functions do not affect the null distribution of the linkage statistic. Alternatively, parameters in the penetrance function may be estimated as part of the linkage analysis. One method that incorporates a dichotomous covariate into an admixture heterogeneity model was proposed by Houwing-Duistermaat et al. [15], who proposed a mixture of four likelihoods that represent all combinations of the two-locus locations and two binomial covariate parameters.

For model-free linkage analysis (*see* **Linkage Analysis, Model-free**), the usual approach has been to subset the data and analyze each subset separately. More recently, several methods that better utilize or incorporate additional phenotypic information have been proposed. One method utilizes linkage information to optimally classify families [27]. Greenwood & Bull [13] incorporated covariates into the Risch [29] affected-sib-pair likelihood using a multinomial parameterization. A reparameterization in terms of genetic **risk ratios** was proposed by Olson [21]; this model also allows for covariates. A further modification with fewer parameters was later proposed by Goddard et al. [10]. Another method that incorporates a binary environmental exposure variable was introduced by Gauderman & Siegmund [9]. Most recently, Devlin et al. [5] propose a mixture model analogous to the A-test. In general, these new methods allow for covariate-related locus heterogeneity and, with an appropriate covariate, can greatly enhance the ability of model-free linkage methods to detect linkage to complex diseases.

Allelic Heterogeneity

Once a disease locus has been identified, molecular work is needed to identify the particular mutant alleles that contribute to disease susceptibility. Some methods are useful when a few mutant alleles (**polymorphisms**) of interest are common in the population of interest. In general, investigation of relationships between common mutations and disease characteristics can be carried out using standard biostatistical methods in random or selected samples of individuals or families. Another direction of study with its own methodology aims at understanding the underlying **population genetics**: the processes that govern mutation, selection, and the structures of modern populations. Only a few specialized statistical methods have been proposed for investigating extensive allelic heterogeneity (when, say, 100 mutational forms are known). One such class of methods is the analysis of mutational spectra to identify "hot spots" within a gene more likely to be mutated in affected individuals [1, 26]. Such studies aim to understand the structure and function of the gene (and resulting protein) at a molecular level (e.g. [14]).

JANE M. OLSON

Genetic Liability Model

Many common diseases (e.g. hypertension, coronary artery disease and noninsulin-dependent diabetes mellitus) exhibit strong familial tendencies but classical **segregation analysis** fails to detect a simple Mendelian pattern of inheritance (*see* **Mendel's Laws**). The thorough analysis of these traits requires the formulation of models that incorporate both genetic and environmental sources of **familial correlations**. Two widely used models, the *multifactorial threshold model* [1–6, 9, 12–14, 22, 23, 28] and the *mixed model* [11, 17, 20] posit that an individual's liability to develop a disease results from the additive effects of many genetic and environmental factors. The probability of expressing the disorder is then modeled as a function of this latent liability. Both models assume that liability is continuous. In addition, the mixed model allows for the existence of a major locus that measurably alters an individual's liability.

Let l denote liability and D denote the affection status of an individual and assume, for the moment, that the trait exists in only two forms, *normal* ($D = 0$) and *affected* ($D = 1$). Under both the multifactorial and the mixed models, the probability that an individual expresses the disease is given by

$$P(D = 1) = \int_{-\infty}^{+\infty} f(l)S(l)\,\mathrm{d}l,$$

where $f(\cdot)$ is the probability distribution function of the liability and $S(\cdot)$ is a risk function, i.e. the conditional probability of expressing the disease given l. The joint probability of the affection statuses of n related individuals, $D_1, \ldots, D_n$, is

$$P(D_1, \ldots, D_n) = \int_{-\infty}^{+\infty} \cdots \int_{-\infty}^{+\infty} f_n(l_1, \ldots, l_n) \times \prod_{i=1}^{n} S(l_i)^{D_i}[1 - S(l_i)]^{1-D_i}\,\mathrm{d}l_1, \ldots, \mathrm{d}l_n.$$

Under the multifactorial model, $f_n(\cdot)$ is the joint distribution of n correlated continuous variables. Under the mixed model, $f_n(\cdot)$ is a mixture of distributions whose weights (mixing proportions) are the probabilities of the **genotypes** at the major locus. There is little biological rationale underlying the choice of $S(\cdot)$. Any convenient risk function can be applied as long as it provides a good fit to the data when used in conjunction with $f_n(\cdot)$. For example, Eaves [7] uses the well-known logit transformation, $S_{\mathrm{L}}(l) = [1 + \exp(-l)]^{-1}$, in a study of **gene–environment interactions**. From a statistical perspective, there is nothing to distinguish this particular form of genetic analysis from any other statistical method designed to model a polychotomy (*see* **Polytomous Data**) as a function of continuous variables. The technical details of **estimation** will be addressed only briefly here.

Risk Functions

Since liability was assumed to be **normally distributed**, most early work concentrated on the appropriate form of the risk function; that is, on the nature of a "threshold". Falconer [12, 13] assumed that the disorder is expressed only when the liability exceeds a physical threshold, T, so that

$$S_{\mathrm{F}}(l) = \begin{cases} 1, & l > T, \\ 0, & l \leq T. \end{cases}$$

Edwards [8, 9], however, argued that the concept of a physical threshold is biologically implausible: an occasional individual with a very high liability may escape the disease; conversely, one with a very low liability may not. Accordingly, Edwards proposed to let the risk be a monotonically increasing function of l and suggested the use of

$$S_{\mathrm{E}}(l) = a\exp(bl)$$

for $a > 0$ and $b > 0$. $S_{\mathrm{E}}(\cdot)$ is particularly advantageous when the liability is normally distributed, since the conditional distribution of liability in affected individuals is still normal, rather than truncated normal as would be the case under $S_{\mathrm{F}}(\cdot)$. However, $S_{\mathrm{E}}(\cdot)$ may exceed unity for very large values of l and thus cannot be used to represent conditional probabilities. This observation led Curnow & Smith [5, 6, 23] to propose an alternative risk function,

$$S_{\mathrm{CS}}(l) = \mathbf{\Phi}\left[\frac{(l - \lambda)}{\xi}\right],$$

in which $\mathbf{\Phi}(\cdot)$ denotes the cumulative distribution function of the standard normal distribution. The sensitivity of the phenotype to the underlying liability is measured by $(1/\xi)$. For any given liability, higher values of $(1/\xi)$ yield higher probabilities of affection.

The parameter λ is equivalent to the *median lethal dose* (*see* **Median Effective Dose**) in toxicology, i.e. the value of the liability at which the probability of being affected is 50%. By appropriate definition of liability, $S_F(\cdot)$ and $S_{CS}(\cdot)$ can lead to mathematically identical expressions for $P(\mathbf{D})$ when the joint distribution of the liabilities is **multivariate normal** [5]. Moreover, since liability is not directly observed, the parameters ξ and λ will be **confounded**. For these two reasons $S_F(\cdot)$ is the most commonly used risk function.

Multifactorial Models

Under the multifactorial model (Figure 1), a continuous liability represents the sum of a large number of independent genetic and environmental factors. It is often assumed that all correlations between relatives stem from shared **genes** and not from a shared environment. This assumption may be relaxed but it then becomes impossible to estimate the heritability of the liability and to extrapolate recurrence risks from one type of relative pair to another. The basic model also assumes that liability is normally distributed. This is not a critical assumption since a normalizing transformation could always be used as long as the liability is continuously distributed. The **prevalence** of the disorder in the population, K, is given by

$$P(D = 1) = P(l > T) = 1 - \mathbf{\Phi}\left(\frac{T - \mu}{\sigma}\right),$$

in which $\mu = \mathrm{E}(l)$ and $\sigma^2 = \mathrm{var}(l)$. As the three parameters T, μ, and σ^2 are confounded, there is no loss of generality in taking $\mu = 0$ and $\sigma^2 = 1$. Thus, individual differences in susceptibility are modeled exclusively through the threshold T; for example, by making T a function of age and gender [5, 22, 23].

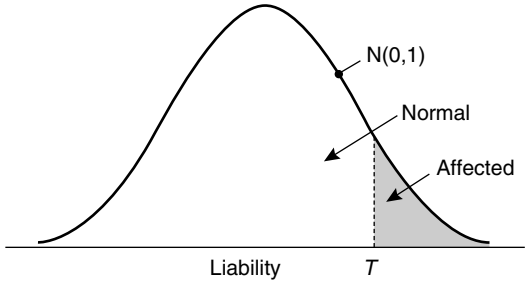

Figure 1 Multifactorial model with threshold. The liability is assumed normally distributed with mean zero and unit variance. An individual is affected when his/her liability exceeds the threshold T. The shaded area is the population prevalence

On the further assumption that the joint distribution of the liabilities of n related individuals is multivariate normal with correlation matrix $\mathbf{R}$, the probability of a pattern $\mathbf{D} = \{D_1, \ldots, D_n\}$ of affection statuses becomes

$$P(\mathbf{D}) = \int_{I_1}\int_{I_2}\cdots\int_{I_n} \phi_n(l_1, \ldots, l_n; \mathbf{R})\, \mathrm{d}l_1 \ldots \mathrm{d}l_n \tag{1}$$

where $\phi(\cdot; \mathbf{R})$ denotes the probability distribution function of the standardized multivariate normal distribution with correlation matrix $\mathbf{R}$. The open interval $I_j (j = 1, \ldots, n)$ is either $(-\infty, T_j)$ if $D_j = 0$, or $(T_j, +\infty)$ if $D_j = 1$, where T_j is the threshold for the jth individual. Eq. (1) can be expressed in a more compact form [26]:

$$P(\mathbf{D}) = (-1)^{|\mathbf{D}|} \sum_{\mathbf{\Delta} \le \mathbf{D}} (-1)^{|\mathbf{D}\cdot\mathbf{\Delta}|} B(\mathbf{\Delta}),$$

where $\mathbf{\Delta} = [\delta_1, \ldots, \delta_n]^t$ is a vector of ones and zeros, $|\mathbf{D} \cdot \mathbf{\Delta}| = \sum D_j \delta_j$, and $B(\cdot)$ is the integral (1) taken over $(-\infty, T_j]$ if $\delta_j = 0$ or over $(-\infty, +\infty)$ if $\delta_j = 1$ for $j = 1, \ldots, n$. That is to say, $B(\cdot)$ gives the probability that none of the members of a subset of $\{1, \ldots, n\}$ is affected. The summation is taken over all vectors $\mathbf{\Delta} = [\delta_1, \ldots, \delta_n]^t$ such that $0 \le \delta_j \le D_j (j = 1, \ldots, n)$.

The model parameters (thresholds and correlations) may be estimated by **maximum likelihood** [26]. A simpler form of analysis uses information on the prevalence and recurrence of the disease in several classes of individuals. The threshold for individuals in the ith class is estimated directly from K_i, the prevalence of the disease in that particular class: $\hat{T}_i = -\mathbf{\Phi}^{-1}(K_i)$. Let τ_{ij} denote the probability that two relatives, one from class i and the other from class j, are both affected. The estimate of the correlation in liability for this particular type of relative pair is obtained by finding ρ_{ij} such that $\tau_{ij} = \mathbf{\Phi}(-\hat{T}_i, -\hat{T}_j, \rho_{ij})$.

It is impossible to assign a genetic interpretation to the correlation coefficient unless it is assumed that the environmental components are uncorrelated and that all genetic factors are additive. In that case, $\rho_{ij} = \Delta_{ij} h^2$ where Δ_{ij} equals twice the kinship coefficient (*see* **Inbreeding**) and h^2 is the

heritability of the liability [22]. In the absence of inbreeding, $\Delta = 1/2$ for first-degree relatives (parent–offspring, sib–sib), 1/4 for second-degree relatives (uncle–niece, grandparent–grandchild) and so on. Thus, the correlation in liability obtained from different types of relative pairs is a linear function of the kinship coefficient. It is then possible to extrapolate the findings on one pair of relatives to another type of relative pair.

Unfortunately, there are multiple reasons why the estimates of the correlation coefficients should not be a linear function of the kinship coefficients. Possible explanations for a poor fit of the model include invalidity of the multivariate normality assumption, presence of dominance within loci, epistatic interactions between loci (*see* **Genotype**), or correlations between nongenetic familial effects [6, 24, 27]. In addition, the model may fail due to the presence of a major gene.

Mixed Models

One of the fundamental questions of genetic epidemiology is whether a disease is purely multifactorial or whether the available data suggest the presence of at least one locus of substantial effect. Morton & MacLean [17] introduced the mixed model to test this hypothesis. Under this model (Figure 2),

$$l = g_{\mathrm{m}} + \varepsilon,$$

where g_{m} is the effect of the major locus and ε is the residual liability, representing the cumulative effects

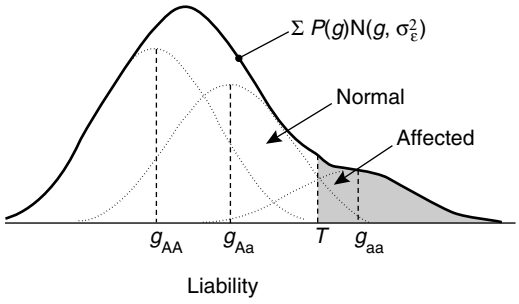

Figure 2 Mixed model with a single threshold. The liability distribution (solid line) is a mixture of three normal distributions with means g_{AA}, g_{Aa}, and g_{aa}, and common variance σ_ε^2. The area under each component curve (dashed curves, shown scaled) is the frequency of the associated genotype

of multiple genetic and/or environmental factors. For the sake of convenience it is often assumed that $\varepsilon = \varepsilon_{\mathrm{c}} + \varepsilon_{\mathrm{p}}$, in which $\varepsilon_{\mathrm{c}} \sim \mathrm{N}(0, \sigma_{\mathrm{c}}^2)$ is a random effect common to all offspring of a mating and $\varepsilon_{\mathrm{p}} \sim \mathrm{N}(0, \sigma_{\mathrm{p}}^2)$ represents uncorrelated effects specific to each individual (including measurement error). The major gene component of the mixed model usually admits only two alleles, A and a, thus introducing four new parameters: three means, g_{AA}, g_{Aa} and g_{aa} and the **gene frequency**, p_{A}. The probability of a pattern of affection, **D**, is computed by summing over all possible genotypes at the major locus,

$$P(\mathbf{D}) = \sum P(g_1, \ldots, g_n) \times \int_{I_1}\int_{I_2}\cdots\int_{I_n} \phi_n(l_1, \ldots, l_n; \mathbf{g}, \mathbf{R})\, \mathrm{d}l_1, \ldots, \mathrm{d}l_n,$$

in which $P(g_1, \ldots, g_n)$ is the joint probability of the genotypes and $\phi_n(\cdot)$, the probability distribution function of the residual terms given the **genotypes**, is multivariate normal with mean vector **g** and correlation matrix **R**.

Note that if the residual terms are uncorrelated, the mixed model reduces to a single gene model with incomplete **penetrance**:

$$\begin{aligned} P(\mathbf{D}) &= \sum P(g_1, \ldots, g_n) \times \int_{I_1}\int_{I_2}\cdots\int_{I_n} \phi_n(l_1, \ldots, l_n; \mathbf{g}, \mathbf{R})\, \mathrm{d}l_1, \ldots, \mathrm{d}l_n \\ &= \sum P(g_1, \ldots, g_n) \prod_{i=1}^{n} \int_{I_i} \phi(l_i; g_i)\, \mathrm{d}l_i \\ &= \sum P(g_1, \ldots, g_n) \prod_{i=1}^{n} S(g_i), \end{aligned}$$

where $S(g)$ is the penetrance of the genotype g. Thus, the mixed model differs from the single gene model only when there exists a source of familial correlation (**polygenic** or environmental) other than the major locus.

Multiple Thresholds

Many disorders are inadequately described by a simple dichotomy, such as *normal* vs. *abnormal*, because they exhibit gradations in severity. The question then arises whether these gradations reflect

the presence of multiple thresholds or the existence of biologically distinct forms of the disorder [18, 19]. For example, suppose that the trait exists in three forms, *normal* ($D = 0$), *mild* ($D = 1$) and *severe* ($D = 2$). This could result from a single liability distribution with two thresholds (Figure 3). To compute $P(\mathbf{D})$ under this assumption, one simply lets the intervals I_i in (1) range from $(-\infty, T_1)$ if $D_i = 0$, (T_1, T_2) if $D_i = 1$, and $(T_2, +\infty)$ if $D_i = 2$ [25]. Hackett & Weller [15] discuss this type of model in the context of **linkage analysis**. Alternately, the various forms of the disease may be determined by two different liabilities that may or may not be correlated. Figure 4 illustrates a situation in which there are two correlated liabilities (l_m and l_s). The severe form of the disease occurs when l_s exceeds the threshold T_s regardless of the value of l_m. The mild form is expressed when $l_m > T_m$ and $l_s < T_s$. The applicability of this model is limited by the rapid increase in the number of parameters. Reich et al. [18] detail several situations in which all parameters may be estimated from prevalence data.

Computational Considerations

Given the widespread availability of programs to compute the **bivariate normal** integral, the approximations to $P(\mathbf{D})$ provided by Falconer and others for the simplest types of familial data (pairs of relatives) are now primarily of historical interest. The calculation of $P(\mathbf{D})$ may still often involve the calculation of high dimensional integrals – a significant problem when these computations occur during an iterative estimation procedure. Some simplifications are possible when the structure of the data is simple and strong assumptions are made regarding the transmission of the trait. In particular, Curnow [5] has shown that if all relatives within a pedigree are of the same order (e.g. parents with offspring) and if it can be assumed that the correlation in liability is due entirely to additive genetic factors, then $P(D_1 = 1, \ldots, D_n = 1)$ may be calculated through the evaluation of a single integral:

$$P(D_1 = \cdots = D_n = 1) = \int_{-\infty}^{+\infty} \phi(x) \left[\mathbf{\Phi} \left(\frac{-(T + x\rho^{1/2})}{(1-\rho)^{1/2}} \right) \right]^n \mathrm{d}x,$$

where $\rho = h^2/2$ in the case of first-degree relatives.

Two approximations have remained popular for the general case [16, 21]. These assume that the conditional distribution of l_i, the liability for the ith individual given the affection statuses of the preceding individuals, is well represented by a normal distribution with mean $\mu_i^* = \mathrm{E}(l_i | D_1, \ldots, D_{i-1})$ and variance $\sigma_i^{2*} = \mathrm{var}(l_i | D_1, \ldots, D_{i-1})$. These expectations and variances are obtained from standard results regarding the moments of variables in truncated multivariate normal distributions. $P(\mathbf{D})$ is then approximated as

$$P(D_1, \ldots, D_n) \approx \prod_{i=1}^{n} \int_{I_i} \phi(l; \mu_i^*, \sigma_i^{2*}) \, \mathrm{d}l_i,$$

where the interval I_i depends on D_i as in integral (1). This approximation is very accurate when the correlations are moderate. The results may vary slightly depending upon the order in which the integrals are evaluated.

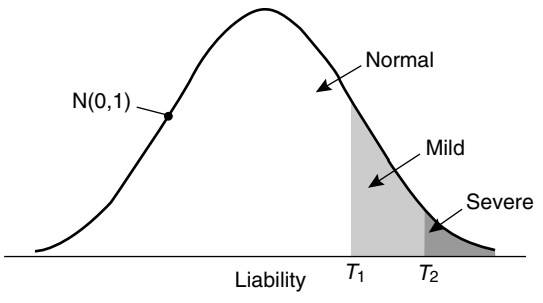

Figure 3 Single liability model for a multifactorial disease with three categories. An individual expresses the mild form of the disease if $T_1 < l < T_2$ and the severe form if $T_2 < l$

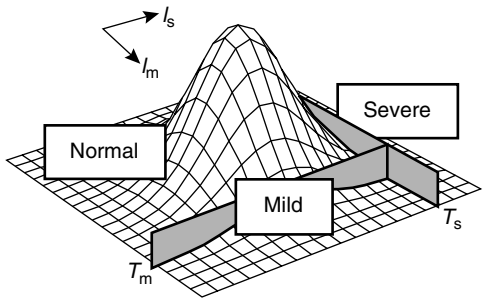

Figure 4 Bivariate liability model for a multifactorial disease with three categories. In this example, an individual expresses the mild form of the disease when $T_m < l_m$ and $l_s < T_s$ and the severe form when $T_s < l_s$, regardless of l_m

Discussion

Edwards [10] once questioned whether the multifactorial model "bore fruit or flower". Indeed, the finding that a multifactorial model provides the best explanation for the transmission of a disease is an anathema to many geneticists. Nonetheless, such traits certainly exist and the chances of encountering them increase as the focus of genetic epidemiology turns from the investigation of rare Mendelian diseases to that of common and complex disorders.

The prevailing modern strategy is to forsake the initial step of model fitting and to jump directly to the search for the genes. Accordingly, a simplified form of the mixed model is used in a series of linkage analyses. The accuracy of the model is subsidiary to whether it will allow the detection of the genes. Thus, estimates of the parameters are themselves of little interest. This is a radical departure from earlier work on the multifactorial and the mixed model, where the determination of these parameters was the goal of the analyses. Two factors contributed to this departure. First, the recognition that the best fitting model is not necessarily the correct one. Secondly, **genetic markers** now span the entire human genome and it has been shown that the inclusion of marker data increases the power of genetic analyses. Thus, the trend is toward the use of a hybrid of linkage and segregation analysis in which the mixed model will retain an important role.

Genetic Map Functions

A genetic map function M gives a relation $r = M(d)$ connecting recombination fractions r and genetic map distances d between pairs of loci along a chromosome arm. Recombination fractions and map distances are summary statistics concerning potentially observable characteristics of the single chromosomes (also known as chromatids) that are the products of meiosis, and that go into gametes. The recombination fraction between two loci is the proportion of such chromosomes that are recombinant, that is, that have genetic material of differing parental origins, at the two loci (*see* **Linkage Analysis, Model-based**). The genetic map distance between two loci is the average number of exchange points that occur along such a chromosome between the loci, where an exchange point, also known as a crossover point, is a point where the parental origin of the genetic material changes. In these definitions, proportions and averages are calculated in the hypothetical infinite population of single chromosomes resulting from meiosis in a given organism, occurring under standard conditions. Variations between organisms within the same species, or of the conditions of meiosis, may lead to small, but observable, differences in these quantities. It should be noted that some authors (e.g. [1] and [9]) use the term map function for the function M^{-1} in the inverse relation $d = M^{-1}(r)$ expressing d in terms of r. We follow Karlin [7] and others in calling M a map function, mainly because the theoretical development is slightly simpler for M than for M^{-1}.

Map functions have been widely used in genetics because of two facts. The first is that genetic map distances are additive by definition, whereas recombination fractions are not. Thus, map distances are preferred for mapping chromosomes. The second is that recombination fractions are much easier to estimate from data, although with human data indirect techniques may need to be used, see [9]. This is because recombination refers only to features of chromosomes at the endpoints of intervals. By contrast, to estimate a map distance information concerning exchanges in the entire interval between two loci is required and, until recently, such information was rarely, if ever, available. Modern molecular genetic methods now exist permitting the identification of points of exchange along chromosomes, and in the near future it may become much easier to estimate map distances directly (see [8]).

The traditional use of map functions has been to take an estimated recombination fraction $\hat{r}$ between two loci and a map function M deemed appropriate for the organism in question, and estimate the map distance between the loci by the quantity $\hat{d} = M^{-1}(\hat{r})$. Perhaps the simplest case is the map function $r = d$, with inverse $d = r$. This is quite satisfactory for small r and d, say, in the interval (0, 0.05), but the relative error increases as the magnitudes of d and r increase. If two loci can be linked by a chain of intermediate loci, each having a recombination fraction of no more than 0.05 (say) with its successor, then a quite satisfactory estimate of the map distance between the initial and final locus can be obtained by adding the successive interlocus recombination fractions. The notion of map function is helpful in situations where such intermediate loci are not available.

The recombination fraction and map length of an interval will differ when there is a nonzero chance of multiple exchange points occurring in the interval. The chance of this occurring increases as the size of the interval increases. If we denote the distribution of exchange points in a particular interval by $(p_0, p_1, p_2, p_3, \ldots)$, so that p_k is the expected proportion of single chromosomes that have k exchange points in the interval, then the recombination fraction is

$$r = p_1 + p_3 + \cdots \tag{1}$$

(i.e. the probability of an odd number of exchange points), while the map length is

$$d = p_1 + 2p_2 + 3p_3 + \cdots. \tag{2}$$

For example, if $p_k = \mathrm{e}^{-d} d^k / k!$, then the map length is easily seen to be d, while the recombination fraction is

$$r = \mathrm{e}^{-d} + \mathrm{e}^{-d}\frac{d^3}{3!} + \cdots = \frac{1}{2}(1 - \mathrm{e}^{-2d}). \tag{3}$$

This relation is known as Haldane's map function, and it is widely used today, nearly 80 years after Haldane [6] first described it. Although simple and easy to use, especially for multilocus calculations, the **Poisson Process** underlying this map function has only rarely been found to fit recombination data. As a result, a sizeable body of work in the late

1940s and 1950s from R.A. Fisher and colleagues and students, excellently summarized in [1], supposed that the points of exchange along a chromosome follow a **renewal process** with independent interpoint distances distributed as $\frac{1}{4}\chi_4^2$ or $\frac{1}{6}\chi_6^2$, rather than the $\frac{1}{2}\chi_2^2$ that gives rise to Haldane's map function. Their model seemed to fit existing human, mouse, and other data quite satisfactorily, but possesses no map function.

The very notion of a map function embodies certain implicit biological assumptions about the process of recombination. For example, all map functions in the literature are bounded above by 1/2, thereby constraining recombination fractions to be $\leq 1/2$. This is widely believed to hold, but there have been instances where it was felt to be untrue, see [4]. Less obviously, the use of a map function presumes that distinct chromosomal intervals having the same map length necessarily have the same recombination fraction, and conversely. This form of stationarity or homogeneity is not observed in the one case in which there is enough data to test it [3]. A number of writers have discussed probability models for recombination that do not constrain recombination fractions to be $\leq 1/2$, and do not satisfy the stationarity properties leading to a map function, see [1] and [5]. Map functions are best viewed as an aspect of certain probability models for recombination. As such, they reflect modeling assumptions, and cannot be expected to be consistent with all the relevant biological knowledge. What matters is whether they are effective for the purposes to which they are put.

Map functions are also useful in contexts where all the products of meiosis remain together, as is the case with ordered or unordered tetrads or octads. In such situations, the model needs to be modified slightly, for although the concept of map distance remains appropriate, the classification of chromosomes as recombinant or not between loci is replaced by a classification of tetrads or octads depending on the parental origins of genetic material at the loci (see, for example, [2]). We will not give any details, here, but simply observe that this development leads us to consider probability models for recombination that refer to the four-strand bundle of chromatids, rather than to the single chromosome products of meiosis. In this approach, chiasmata (the chromosomal structures at points of exchange) are postulated to occur along the four-strand bundle according to some point process, and a mechanism for determining the strands involved in the chiasmata is also specified. The distribution of change-points along the resulting chromosomes is then a consequence of the interplay between the chiasma location process and the strand choice mechanism, and, in specifying the recombination process in this manner, we are also able to calculate the probabilities of interest concerning tetrad and octad types. The simplest assumption concerning strand choice is that the strands involved in any given chiasma are chosen at random from the four possible, independently of those chosen for other chiasmata. This is known as the assumption of no chromatid interference, interference being a term used in genetics to denote some form of dependence. In what follows we make this assumption, although (see [11]) map functions can be defined without it.

Under the assumption of no chromatid interference, a simple relationship widely attributed to K. Mather follows. It states that among meioses in which one or more chiasmata occur in a given interval along the four-strand bundle, on average half of the resulting chromosomes will be recombinant across that interval. More formally, if r is the recombination fraction between two loci, and c_0 is the chance of having no chiasma located in the interval in any meiosis, then

$$r = \tfrac{1}{2}(1 - c_0). \tag{4}$$

When $c_0 = c_0(d)$ depends only on the map length d of the interval, this relation is a map function. Now every chiasma involves just two of the four chromatids, and so the average number of chiasmata between two loci on the four-strand bundle is twice the average number of points of exchange between the same two loci on a single chromosome resulting from meiosis. Suppose that the number of chiasmata occurring in an interval along the four-strand bundle is Poisson distributed with mean $2d$. Then the map length of that interval is just d, and the chance of no chiasmata is e^{-2d}. Substituting into the above formula, we recover the Haldane map function (3) once more. It should be pointed out, however, that we can also recover this map function using a different distribution for the number of chiasmata and a different assumption concerning strand choice [13]. Keeping to the no chromatid interference assumption, we can derive many probabilistic models for recombination by postulating that chiasmata occur along the four-strand bundle according to a stationary renewal process (SRP). If the interchiasma density is f with

respect to twice the map length density, then simple arguments from renewal theory show that for such models,

$$c_0(d) = 2\int_d^\infty \int_y^\infty f(t)\,\mathrm{d}t\,\mathrm{d}y. \tag{5}$$

It is shown in [14] that most of the map functions in the literature can be realized by substituting this expression with a suitable f into Mather's formula (4). This includes certain empirical map functions, such as the following suggested by Haldane in 1919,

$$M^{-1}(r) = 0.7r - 0.15\log(1-2r). \tag{6}$$

Map functions must satisfy certain constraints as a result of their definition, see [11] for details. Some functions suggested in the literature as suitable map functions do not satisfy these constraints [12], and should probably not be used. More importantly, most map functions are associated with stationary renewal processes whose multilocus recombination probabilities are extremely difficult to calculate, and for this reason are not so useful. The class of SRPs with **chi-square distributed** interchiasma distances in the map distance metric has proved both tractable and fairly general [14]. Another family of recombination models in the literature are termed the count-location processes [7]. These require the specification of a distribution $(g_k : k \geq 0)$ for the number (count) of chiasmata along the four-strand bundle, and a sequence F_k of functions giving the distribution of the locations of k chiasmata, given that k occur, $k \geq 1$. In the special case that F_k is equivalent to specifying k locations independently and identically according to a fixed distribution F, and no chromatid interference, we easily find that

$$c_0(d) = g\left(1 - \frac{2d}{m}\right), \tag{7}$$

where $g(s) = \sum_k g_k s^k$, $(0 < s < 1)$ and $m = g'(0)$. Risch & Lange [10] found that this class of recombination models did not give a very good fit to certain large data sets involving *Drosophila melanogaster*.

For many people, map functions are related to the notion of interference. Crossover interference is said to exist when the chance of one or more exchange points in an interval depends on the occurrence of exchange points in other, disjoint intervals. When the points of exchange form a Poisson process, there is no crossover interference. In general, such interference is observed, which is another reason why Poisson processes do not form suitable general models for recombination. (Note that a similar definition of interference can be formulated that refers to chiasmata occurring along the four-strand bundle. The corresponding notion is termed chiasma interference.) The traditional measure of interference is the coincidence coefficient, this being, for adjacent intervals A and B,

$$C_{A,B} = \frac{r(A\&B)}{r(A)r(B)}, \tag{8}$$

where $r(A)$ and $r(B)$ are the recombination fractions of A and B, respectively, and $r(A\&B)$ denotes the chance of simultaneous recombination across A and B. It is easy to check that

$$r(A\&B) = \frac{r(A) + r(B) - r(A \cup B)}{2},$$

where $A \cup B$ is the union of the adjacent intervals A and B. Suppose now that A has map length d, while B has small map length h, and that we take a limit (assumed to exist) in the expression for $C_{A,B}$ as $h \to 0$. Assuming that $M'(0) = 1$, which is one of the conditions that a map function must satisfy, we obtain the differential equation

$$M'(d) = 1 - 2C(d)M(d), \tag{9}$$

where $C(d)$ is the limiting coincidence coefficient, assumed to depend only on the map length of A.

This argument is due to Haldane [6], and many familiar map functions are solutions of this equation when $C(d)$ has the form $(M(d))^{n-1}$. For example, when $n = 1$, we get the Kosambi map function widely used in human genetics:

$$M(d) = \tfrac{1}{2}\tanh(2d). \tag{10}$$

The foregoing discussion shows that there is a connection between map functions and one aspect of crossover interference. In fact, this connection is quite superficial. A more useful (and outside of genetics more widely used) measure of interference is the expression $C_4(d) = C_{A,B}$ where A and B are infinitesimal intervals separated by a map distance d. This measure cannot, in general, be expressed in terms of the map function. In fact, there exist distinct

probability models for recombination having the same map function, with one model having $C_4(d) =$ constant, while the other has $C_4(d)$, a function increasing almost monotonically from 0 at $d = 0$ to 1 for large d. In short, the two recombination models have the same map function, but very different interference properties, using the term interference in a general sense. Map functions do not adequately account for interference; this must be done using a probability model for recombination.

We close with some summary remarks. Map functions can be used to convert recombination fractions to map distances, correcting for multiple exchanges. They also correct for the effect of interference, but do not describe interference completely. They are essentially organism-dependent, and at best provide only rough approximations. It is not uncommon to see multilocus analyses carried out using the Poisson (no chiasma or crossover interference) model underlying Haldane's map function, at the end of the analysis correcting the estimated recombination fractions using Kosambi's or some other map function. This is necessary because map functions (such as Kosambi's) do not, in general, determine joint recombination probabilities for more than three loci. It is reassuring that this somewhat illogical approach gives estimated map distances that are not too different from those that would be obtained using (for example) a comparable stationary renewal process model with chi-square distributed interpoint distances. Ideally, multilocus mapping and linkage analyses should be carried out using a properly specified probability model for recombination suitable for the organism in question. When this is done, map functions are not needed.

Genetic Markers

Genetic markers are genetic **polymorphisms** used for the study of population structure (**inbreeding, admixture in human populations**), **linkage analysis**, **disease–marker association**, **haplotype analysis**, **paternity testing**, and forensics (*see* **Statistical Forensics**). Early markers included the **blood groups** and various easy-to-observe polymorphisms such as the ability to taste phenylthiocarbamide and anthroposcopic traits.

Beginning about 1960, protein polymorphisms became detectable by various electrophoretic and staining techniques, and the **HLA system** was developed; protein polymorphisms, together with the red cell blood groups, made it possible to type a whole battery of markers from a sample of blood. These markers segregate in a simple fashion according to **Mendel's Laws**, each **genotype** giving rise to a well-differentiated phenotype, but in many cases two genotypes would correspond to the same phenotype because of dominance.

Since about 1980, the genetic markers of choice have been deoxyribonucleic acid (**DNA**) polymorphisms. The first of these were the restriction fragment length polymorphisms (RFLPs), determined by digesting the DNA with restriction enzymes that cut the DNA at specific short sequences of base pairs; **mutations** in these sequences prevent the cutting, and differences in the cut and uncut fragments are detected by variation in the fragment lengths produced [1]. However, because so many fragments of similar sizes are produced when the whole DNA is digested, the fragments for a particular chromosomal locus have to be distinguished from the rest by a specific probe – a cloned sequence of DNA, marked in some way for detection, that will anneal with only the fragments from that locus. Such markers typically yield only two or three alleles per locus.

More recently, sequences of base pairs have been discovered that are repeated a different number of times from allele to allele (*see* **Gene**), and the variation in these repeats is the basis of a polymorphism. The first of these polymorphisms to be commonly used as markers were the minisatellites, also called "variable number of tandem repeat" (VNTR) polymorphisms [3]. In these, the sequence that is repeated varies from nine to 60 base pairs in length. These polymorphisms originally required a specific probe for their detection but can now also be detected via the polymerase chain reaction [5]. Since 1989, an abundance of multiallelic short tandem repeat polymorphisms (STRPs), also called microsatellites or simple sequence length polymorphisms, have been available, the sequence repeated varying from two to nine base pairs [6, 7]. (Some authors consider STRPs to be a type of VNTR polymorphism because the only difference between them is the size of the repeating unit and the complexity of the repeat.) Both minisatellites and microsatellites can have very high **polymorphism information content** (PIC) and **linkage information content** (LIC) values and, apart from typing errors, show a one-to-one correspondence between genotype and phenotype. They are particularly advantageous because, with the advent of the polymerase chain reaction, which allows specific segments of DNA to be amplified, they can be typed without any need for probes. They only require very small quantities of DNA, such as can be obtained from a cheek swab, and have largely supplanted all the earlier markers. During the 1990s, about 10 000 STRPs were identified and mapped, and many hundreds of genes have been mapped using them.

The most recent genetic markers are single nucleotide polymorphisms (SNPs, pronounced "snips") [2, 4], which are extremely abundant in the human genome – occurring approximately on average once every one or two thousand base pairs. SNPs are essentially diallelic RFLPs that involve a transition or transversion, or an insertion/deletion of a single nucleotide. SNPs can be detected by many different methods. They may supplant STRPs when the cost of typing them becomes cheaper (at most a third of the cost of typing multiallelic RFLPs) and they can be reliably typed because of their abundance and proximity to coding sequences. SNPs are often observed within the coding sequence of genes and may play a direct role in altering the function of a protein.

ROBERT C. ELSTON

Genetic Risk Ratios

In human genetics and genetic epidemiology, risk ratios can assume a number of different forms, including risk ratios for relatives, for **candidate genes**, and for genetic **markers**. The goal of many genetic studies is to quantify the risk of disease occurrence associated with particular genetic factors. The strength of this association can depend on **interactions** between environmental and genetic factors, gene–gene interactions, and the distance along a causal pathway from a genetic variant to a disease outcome. Models that can incorporate these complexities have an important role. Here, however, we focus on risk ratios corresponding to **associations** between a single disease and a single genetic factor.

Let D denote the disease under study, and let G or $\overline{\text{G}}$ denote the presence or absence of a particular genetic characteristic in an individual. In these risk ratios, exposure is defined in terms of an individual's genetic information G. Further assume that every individual is correctly classified as having (D) or not having ($\overline{\text{D}}$) the disease. Then, a general genetic **relative risk** (RR) is defined as

$$\text{RR} = \frac{\Pr(\text{D}|\text{G})}{\Pr(\text{D}|\overline{\text{G}})}. \tag{1}$$

This measure of disease-by-genetic-factor association is just the ratio of the conditional probabilities of having the disease given the presence or absence of the genetic characteristic. These conditional probabilities are usually referred to as **penetrances**, and require cross-sectional or cohort designs for their direct estimation. Individuals or families are often sampled according to a disease-related phenotype, so the **odds ratio** is also useful because of its invariance to the direction of sampling. The genetic odds ratio (OR), that approximates the genetic RR for a rare disease, is

$$\text{OR} = \frac{\Pr(\text{D}|\text{G})/\Pr(\overline{\text{D}}|\text{G})}{\Pr(\text{D}|\overline{\text{G}})/\Pr(\overline{\text{D}}|\overline{\text{G}})}, \tag{2}$$

which can be written equivalently as

$$\text{OR} = \frac{\Pr(\text{G}|\text{D})/\Pr(\overline{\text{G}}|\text{D})}{\Pr(\text{G}|\overline{\text{D}})/\Pr(\overline{\text{G}}|\overline{\text{D}})}. \tag{3}$$

Risk Ratios for Relatives

When a genetic factor cannot be measured directly, but information on disease status is available on family members of an affected individual, genetic risk ratios can be derived indirectly.

Familial Aggregation

Evidence for familial aggregation, which is the tendency of disease to cluster in families, provides a rationale for subsequent genetic studies intended to assess particular genetic factors or to search for disease susceptibility **genes**. A measure of familial aggregation that uses information on family history (FH) of disease, say, in first-degree relatives, is

$$\text{OR} = \frac{\Pr(\text{D}|\text{FH})/\Pr(\overline{\text{D}}|\text{FH})}{\Pr(\text{D}|\overline{\text{FH}})/\Pr(\overline{\text{D}}|\overline{\text{FH}})}. \tag{4}$$

In a **case–control** design, D and $\overline{\text{D}}$ correspond to affected cases and unaffected controls, while FH is a surrogate for genetic loading in the family, and is thus subject to misclassification error [14]. Even in the absence of any genetic etiology, however, the probability of a positive FH increases with the number of relatives considered. Alternatively, FH scores can be defined to take into account the number of affected relatives and the family structure.

In a **family-based case–control** design, familial aggregation can also be assessed by comparing the risk of disease among relatives of cases with that among relatives of controls,

$$\frac{\Pr(\text{D in relative type R of case}|\text{affected case})}{\Pr(\text{D in relative type R of control}|\text{unaffected control})}. \tag{5}$$

When this ratio is greater than 1, family aggregation can be present, but, without additional environmental exposure information, aggregation due to shared genes can be indistinguishable from that due to shared environment [5]. For controls that are representative of the general population, the denominator of this ratio approximates the population risk.

Recurrence Risk

A related measure is known as the *recurrence risk* for a type R relative of an affected individual. It occurs in the numerator of the ratio, (5), for familial aggregation in family case–control designs. In Risch's [7]

development of **multilocus** models of inheritance (*see* **Segregation Analysis, Classical**) for complex traits that are useful in **linkage analysis**, he defines a risk ratio, λ_R, which compares the recurrence risk in relatives of type R of an affected individual with the population prevalence K. For example, when the relative type is a sibling, λ_s is defined as

$$\frac{\Pr(\text{D in Relative who is a sibling}|\text{affected case})}{K}. \tag{6}$$

Risch [8] also establishes how the power of affected relative pair studies to detect linkage critically depends on the value of λ_R. The relationship between d_s and the genotype RR, defined using (1) with G and G denoting individuals with or without the susceptibility genotype respectively, depends on allele frequency and the genetic inheritance models [9].

Risk Ratios for Candidate Genes

Investigations of candidate genes are usually based on a priori biologic hypotheses about a particular candidate gene. If genetic information is available, say in the form of a measured candidate gene, then the association of particular genetic variants with a disease can be evaluated using several versions of the genetic risk ratio. These include allelic, **genotype**, and **haplotype** RRs, although the latter is usually considered in the context of a genetic marker (see further below).

A common study design involves sampling individuals by disease status, assembling an appropriate control group, genotyping cases and controls at a **candidate gene** locus, and then comparing the distribution of the candidate gene between the case and control groups. Population (case–population control) and family-based (case–parental control) designs are two approaches used to assess risk ratios for the association of a candidate gene with a disease phenotype.

In case–control studies of candidate gene loci, a fundamental issue is the choice of a reference or control group. Controls can be randomly selected from the population of unaffected individuals or can be matched to the affected cases on relevant characteristics. Because genetic factors vary greatly by ethnic background and population history and geography, there is a serious potential for confounding by population stratification when unrelated individuals are used as controls or when matching on available measures of ethnicity is inadequate. To avoid this problem, the control group can be drawn from members (or potential members) of the family of a case instead of unrelated individuals. However, population controls may be less costly to recruit, and, in the absence of population stratification, may be more efficient statistically (*see* **Family-based Case–Control Studies**).

Population Risk Ratios

At a candidate gene locus, each individual inherits one genetic variant, known as an allele, from each parent and the two alleles together constitute a genotype. When only two variants occur in a population of individuals, there are three possible **genotypes**, while for a locus with multiple variants (n alleles), there are $n(n+1)/2$ possible genotypes. For a single multiallelic locus, the genetic factor G can be expressed as

$$G = \begin{cases} a_i & i = 1, \ldots, n, \quad \text{to denote a single allele, or} \\ a_i a_j & i, j = 1, \ldots, n, \quad \text{to denote a genotype.} \end{cases} \tag{7}$$

For a candidate gene with two alleles, a_1 and a_2, we can define *genotype RRs* in which G depends on the presence or absence of allele a_2, i.e.

$$\text{RR}_1 = \frac{\Pr(\text{D}|a_1a_2)}{\Pr(\text{D}|a_1a_1)}, \qquad \text{RR}_2 = \frac{\Pr(\text{D}|a_2a_2)}{\Pr(\text{D}|a_1a_1)}, \tag{8}$$

and the corresponding *genotype ORs* as

$$\begin{aligned} \text{OR}_1 &= \frac{\Pr(\text{D}|a_1a_2)/\Pr(\overline{\text{D}}|a_1a_2)}{\Pr(\text{D}|a_1a_1)/\Pr(\overline{\text{D}}|a_1a_1)}, \\ \text{OR}_2 &= \frac{\Pr(\text{D}|a_2a_2)/\Pr(\overline{\text{D}}|a_2a_2)}{\Pr(\text{D}|a_1a_1)/\Pr(\overline{\text{D}}|a_1a_1)}. \end{aligned} \tag{9}$$

When an increased risk of disease is associated with having only one copy of allele 2, i.e. a_2 is dominant to allele a_1, $\text{OR}_1 = \text{OR}_2 > 1$, whereas when an increased risk is associated with two copies of a_2, i.e. a_2 is recessive to allele a_1, $\text{OR}_2 > 1$ and $\text{OR}_1 = 1$. This formulation permits tests of overall association of the candidate gene with a disease by considering the two ORs jointly, as well as specific tests for mode of inheritance.

For a multiallele locus, the number of genotype categories can become large. Because comparisons

based on the presence or absence of an allele are more parsimonious, an alternative approach is to use the allele rather than the genotype as the unit of analysis, with two observations contributed from each individual. For example, one approach in a case–control study is to estimate each allelic RR_i by counting and comparing the frequency of the a_i alleles between cases and controls.

Family-based Risk Ratios with Parental Controls

One particular family-based design involves the ascertainment of an affected individual followed by genotyping of this case and their parents. Falk & Rubinstein [2] proposed that the maternal and paternal alleles transmitted to the affected child form a case genotype (D) while the nontransmitted alleles form a control genotype ($\overline{\text{D}}$).

For a two-allele candidate gene locus with alleles a_1 and a_2, a simple *genotype RR* is

$$\text{RR} = \frac{\Pr(\text{D}|\text{presence of allele } a_2)}{\Pr(\text{D}|\text{absence of allele } a_2)}, \qquad (10)$$

which does not distinguish between genotypes with one or two copies of allele a_2. When the measured candidate gene is the disease gene, this RR is insensitive to population stratification, and can be estimated without bias by the OR [4, 6]:

$$\text{OR} = \frac{\Pr(a_2 \text{ is present}|\text{D})/\Pr(a_2 \text{ is absent}|\text{D})}{\Pr(a_2 \text{ is present}|\overline{\text{D}})/\Pr(a_2 \text{ is absent}|\overline{\text{D}})}. \qquad (11)$$

This OR is sometimes referred to as a *haplotype RR*, particularly when a genetic marker rather than a candidate gene is used [2, 6]. Schaid & Sommer [11] suggest the use of two genotype RRs to distinguish between genotypes with one or two copies of allele a_2. Valid inference generally requires that the case–control **matching** be taken into account.

Examination at the level of the individual allele, rather than the genotype, leads to an *allelic RR*. The alleles transmitted and not transmitted by each of the parents are the basis of this risk measure, which is closely related to the transmission/disequilibrium tests (TDT) noted in the following section. However, inference can be complicated by a lack of independence between the parental transmissions, and models that condition on the parental genotypes are more suitable in this case [10].

For a multiallele locus with parents having alleles a_1a_2 and a_3a_4, there are four possible genotypes that could be observed in their offspring. If the affected child (D) received alleles a_1 and a_3, then the genotypes a_2a_4, a_1a_4, and a_2a_3 can be taken as control ($\overline{\text{D}}$) genotypes. Self et al. [12] formulated a general likelihood for a series of independent affected children based on indicator variables for the presence or absence of a given allele in the case and control genotypes. Their approach assumes uniform segregation of gametes apart from the genotype effect, but does not require the parental genotypes to be independent. The likelihood they develop has the same form as that for a logistic regression analysis of a matched case–control study with a single case and three controls.

Features of other family-based case–control designs that include siblings and cousins as controls have been of recent interest [3, 15].

Risk Ratios for Genetic Markers

Genotype, allelic, and haplotype RRs analogous to those described for candidate genes can be estimated using genetic markers. When specific genetic loci for a disease are unknown, finely spaced genetic markers with known locations may be used to screen the whole genome or selected genomic regions to help localize a disease-susceptibility gene.

Allelic information for a single locus can be extended to the multilocus setting by considering **haplotypes**. When two or more neighboring loci are considered together, a haplotype can be defined as a multilocus analog of an allele. A pattern of alleles from each of several loci that are transmitted together from one parent constitute one haplotype. For two loci, with n_1 and n_2 alleles, respectively, occurring in a population, there are $n_1 \times n_2$ possible haplotypes that can be expressed as $\text{G} = a_i b_j$, where a_i and b_j represent allele types $i, i = 1, \ldots, n_1$, and $j, j = 1, \ldots, n_2$, from the two loci comprising the haplotype. A pair of haplotypes, one inherited from each parent, constitutes a multilocus genotype. A multilocus haplotype of two genetic markers defined in this way can be used to construct a *haplotype RR* analogously to an allelic RR for a single genetic marker.

A multilocus haplotype can also be constructed from a genetic marker and disease gene, but the latter

is usually unobserved. When two loci forming a haplotype on a parental chromosome are close together, they are less likely to be separated by recombination when a gamete is formed during meiosis. This phenomenon can be exploited in disease–gene localization studies through the modeling of a haplotype consisting of an allele at a known marker location and an unobserved disease allele. Association between particular alleles of a genetic marker and specific alleles of the unobserved susceptibility gene that occurs across families in a population is known as *allelic association* or **linkage disequilibrium**, whereas the term linkage refers to association that occurs within a family. The absence of tight linkage disequilibrium between alleles at an unobserved causal disease gene locus and measured alleles at marker loci can induce attenuation bias in the RR estimates based on marker alleles [4, 6].

The class of methods known as TDT used in family-based designs involve hypothesis tests that detect linkage only in the presence of allelic association [6, 13]. These methods can also test for association in the presence of linkage, provided correlation between parental transmissions or among related individuals induced by the presence of linkage are taken into account [1, 13].

Genetic Transition Probabilities

Genetic transition probabilities represent one of four major components of **likelihoods** employed in **segregation analysis**, the statistical methodology used to elucidate, from family data, the mode of inheritance of a particular trait. The other components are concerned with the joint genotypic frequencies of mating pairs, the method by which the sample is **ascertained**, and the relationship between **genotype** and phenotype. The set of genetic transition probabilities describes how genetic variability is passed from one generation to the next. This approach to specification of the mode of inheritance was originally developed in the context of the "generalized major gene transmission model" [4], but subsequent synthetic efforts led to the formulation of a unified model incorporating elements of the classical mixed model in segregation analysis [5] while retaining the use of genetic transmission probabilities (see below) to describe genetic transition from one generation to the next.

A genetic transition probability specifies the probability that an offspring has a particular genotype, conditional on the genotypes of the parents, i.e. the probability p_{stu} that an offspring has genotype u, given that one parent has genotype s and the other has genotype t. For single-locus models, the **conditional probabilities** $\{p_{stu}\}$ form the elements of a three-dimensional stochastic matrix called the genetic transition matrix. These matrices represent mathematical summarizations of the genotypic distribution of offspring, conditional on the two parental genotypes, and possibly upon the gender of the offspring. They are commonly displayed as a two-dimensional matrix in which each element is a vector giving the probability distribution of the set of all possible offspring genotypes, conditional upon the parental mating type (pair of parental genotypes). The matrix of genetic transition probabilities under a simple Mendelian model (*see* **Mendel's Laws**) positing two allelic **gene** alternatives, A and a, at a single autosomal locus is given in Table 1, where each entry is a genotypic distribution $[p_{st1}\ \ p_{st2}\ \ p_{st3}]$, i.e. the vector of probabilities that the offspring is AA, Aa, and aa, respectively, conditional upon parental mating type $s \times t$. Thus, the mating type AA × AA can produce only AA offspring, and the AA × aa mating only Aa offspring, while the Aa × Aa mating type is associated with 1/4, 1/2, and 1/4 probabilities of producing AA, Aa, and aa offspring, respectively. Two such matrices are required if the locus of interest is X-linked, one for male offspring, and another for female offspring; dimensioning is also gender-dependent. The genetic transition matrix can be specified for any number of unlinked loci by utilizing Kronecker products to operate upon the individual genetic transition matrices for those loci, and this approach can also be generalized to accommodate linked loci [4].

Table 1

	t		
s	1 = AA	2 = Aa	3 = aa
1 = AA	$[1\ \ 0\ \ 0]$	$[\frac{1}{2}\ \ \frac{1}{2}\ \ 0]$	$[0\ \ 1\ \ 0]$
2 = Aa	$[\frac{1}{2}\ \ \frac{1}{2}\ \ 0]$	$[\frac{1}{4}\ \ \frac{1}{2}\ \ \frac{1}{4}]$	$[0\ \ \frac{1}{2}\ \ \frac{1}{2}]$
3 = aa	$[0\ \ 1\ \ 0]$	$[0\ \ \frac{1}{2}\ \ \frac{1}{2}]$	$[0\ \ 0\ \ 1]$

The genetic transition probabilities $\{p_{stu}\}$ can be expressed as functions of transmission probabilities that describe the probability that an individual with a given genotype transmits a particular allele (from the set of possible allelic variants) to his or her offspring. To illustrate the use of transmission probabilities, consider the case of an autosomal locus with two allelic alternatives, A and a, and define τ_t as the probability that an individual with genotype t transmits an A allele to the offspring; by symmetry, $(1 - \tau_t)$ is the probability that this individual instead transmits an a allele, and the entries of the matrix are generated by

$$[\,p_{st1}\quad p_{st2}\quad p_{st3}\,] = [\tau_s\tau_t\quad \tau_s(1-\tau_t)+\tau_t(1-\tau_s)\quad (1-\tau_t)(1-\tau_t)]\,.$$

If we specify the values $\tau_{AA} = 1$, $\tau_{Aa} = 1/2$, and $\tau_{aa} = 0$, which are appropriate under a Mendelian model that assumes that there is no mutation and that either parental allele is equally likely to be transmitted (no meiotic drive), then we obtain the values given in the above genetic transition matrix for a diallelic autosomal locus [2, 3]. Typically, the transmission probabilities are estimated jointly with other model parameters via **likelihood** and compared with results obtained under models specifying particular values or constraints on the transmission probabilities [1–3, 5] (*see* **Segregation Analysis, Complex**).

This general approach is also used in connection with **regressive models** for analyzing family data. Other extensions provide for the inclusion of phenomena such as mutation in the context of segregation analysis of pedigrees [7].

Care should be taken to distinguish the term *transition probabilities* (p_{stu}) from the component *transmission probabilities* (τ_t). It may be noted that the matrix of genetic transition probabilities is analogous to the matrix of transition probabilities from classical developments using **stochastic processes**, which have also been applied fruitfully to genetic problems: while the genetic transition matrix mediates change from one generation to the next, it also differs in that it describes a transition involving genetic transmission from two individuals (the parents) in one generation to a single individual (the offspring) in the next. The term "transition matrix" has also been applied to arrays of genotypic probabilities of individuals conditional on the genotypes of a relative of a particular type, such as the I and T matrices described by Li & Sacks [6] for the one-locus, two-allele case under panmixia.

In the case of **polygenic inheritance**, the genotype of interest is a polygenotype, which is typically modeled as having a Gaussian population distribution (*see* **Normal Distribution**) with variance σ_G^2. The genetic transition probability under such circumstances is modeled as a probability density; for example, under the classical additive polygenic model assuming panmixia, the expression for the offspring polygenotype H of parental polygenotypes F and G is a normal density with mean $(F + G)/2$ and variance $\sigma_G^2/2$. Genetic transition probabilities for a single locus of major effect and polygenic inheritance are both utilized in mixed models that contain both polygenic and monogenic components [2, 3].

Genitourinary Medicine

The application of biostatistics to genito–urinary medicine is largely focused on the epidemiology of sexually transmitted diseases (STDs). The evaluation of treatment efficacy for particular conditions is, in general, carried out using standard statistical methods, and these are not considered further. Some STDs in developed countries are ascertained with reasonably complete case notification or, alternatively, **prevalence** estimates are derived from data from sentinel clinics. However, for other important STDs, e.g. chlamydia and human papilloma virus (HPV), there is poor case ascertainment and little knowledge of prevalence or incidence in general populations.

The epidemiology of STDs differs in important respects from the epidemiology of many other infectious diseases. As with any infectious disease, **risk** is dependent on the prevalence of the disease in the population and, with bacterial STDs, multiple episodes are possible. However, the analysis of STD transmission has elements in common with problems often associated with environmental health exposures. Risk of disease is largely determined by individual risk behavior (i.e. numbers of partners, types of sexual acts, use of condoms, etc.). These different modes of behavior are heterogeneous [1, 5, 7] and difficult to measure accurately.

Historical Development

Hethcote & Yorke [4] carried out fundamental theoretical work in deterministic modeling of STD dynamics. This work has been extended to apply to human immunodeficiency virus (HIV) and **AIDS**, notably by May & Anderson [8]. The work essentially involves setting up differential equations to describe disease incidence in different strata of population, as a function of sexual behavior and disease prevalence throughout the population. In its simplest form, the basic reproductive rate (R_0) is a product of the probability of transmission (b), the rate of partner change (C), and the duration of infection (D). Another important area of theoretical research has been to investigate the possible effects of concurrent partnerships on the dynamic evolution of STDs and HIV in a population [2]. Researchers have also used stochastic **Monte Carlo** microsimulations, but these have been more focused on HIV and AIDS than other STDs.

For theoretical models to be useful, they must use reliable empirical data. However, possible behavioral determinants of STD risk are hard to define, let alone measure. Models are often posed in terms of rates of acquisition of new partners, a concept which is difficult to reconcile with the real experience of individuals. As a result, people may not necessarily report their sexual behavior reliably, nor interpret concepts such as partnerships or sexual contacts in the way a researcher would wish. Individuals may tend to report, and indeed remember, what is socially acceptable rather than what actually happened.

Development of Survey Methods

In the 1990s, a number of important studies were carried out in developed countries to attempt to generate accurate information on the distribution of sexual behavior in the general population of the UK [5], France [1], and the US [7]. Although standard **survey** methods were used, the sensitivity of the subject reinforced the need for rigorous attention to detail. Great care was taken to generate representative samples. The questionnaires provided appropriate and clear definitions of concepts (e.g. sexual intercourse, sexual partner) using unambiguous and nonjudgmental terms. Respondents were assured of **confidentiality** and the questions were designed to facilitate accurate recall of past events. Nevertheless, all studies to date have suffered to some extent from inconsistent responses from men and women, where, for example, men tend to report more opposite sex partners than women [10].

Sexual Networks and Mixing

There has been much interest in understanding the structure of sexual networks and tracing possible chains of infection. Theoretical and empirical studies have been carried out [6]. Routine STD clinic contact tracing (e.g. sexual contacts of gonorrhoea cases) can provide one possible avenue to identifying these contact networks. As well as studying partner choice at the micro (individual) level there has also been considerable research into understanding

mixing patterns at the macro level. In other words, is there a general propensity for people disproportionately to choose partners similar to themselves (**assortative mating**), dissimilar to themselves (disassortative mating), or is any partner equally likely to be selected irrespective of sexual behavior (random mating)? In matrix terminology, if men and women are allocated to strata i, j dependent on numbers of partners, then the proportion of men in stratum i who have female partners in stratum j will then be the i, jth element of the mixing matrix. In this notation, assortative mating is represented by disproportionately large values along the main diagonal, and conversely for disassortative mating. Renton et al. [9] have shown how the mating matrix describing a population may be inferred from information about STD transmission contact pairs attending a genito-urinary medicine (GUM) clinic.

Study Designs

Studies designed to elucidate risks for STDs are usually **observational**. Because of the difficulty of measuring behavioral variables, **residual confounding** will always be a potential problem in any attempt to measure a particular risk factor while controlling for others. There is limited scope for using randomized controlled trials (RCTs) (*see* **Clinical Trials, Overview**) to examine different risk factors for the acquisition of STDs, because risk factors such as numbers of partners or types of sex are only amenable to educational intervention. An important exception was the RCT of STD treatment carried out in Tanzania [3], where randomization was at the community level. **Case–control studies** of STD risk have the additional problem of identifying suitable **control** groups, and several published studies have reported misleading results. If cases are selected from an STD clinic setting, then others attending the same clinic will almost certainly be poor controls because of the nature of the risk that caused them to attend the clinic.

STD and HIV

It is possible that HIV risk is enhanced in the presence of concurrent STD, and this could explain some of the difference in HIV prevalence between the developed and the developing world. STD intervention in Tanzania reduced HIV incidence and Groskurth et al. [3] provide evidence for this. The trial was the first of its kind to use an RCT design to avoid any possible bias by confounding with behavioral factors, which had been a problem with all previous observational studies showing a link between HIV and STD. It is becoming increasingly apparent that silent epidemics of chlamydia and HPV may be much more important than was previously realized. The methodologic problems relating to ascertainment of reliable estimates of population prevalence for these silent diseases are considerable.

Future development

It is to be hoped that a better understanding of the sexual mixing matrix, both empirically and theoretically, will increase the utility of transmission models. Further examination of the interaction between HIV and STD may lead to better understanding of the epidemiology of HIV and in particular its geographic variability. The use of organism typing to determine chains of transmission in network and contact tracing studies, in particular with gonorrhoea, has the potential to improve vastly our knowledge of sexual networks and the spread of STD within social networks. Finally, improved **survey** methodology is required to facilitate the collection of better behavioral data.

Genome-wide Significance

When **markers** distributed throughout a genomic region (perhaps 300–500 in present-day whole genome scans in humans) are used to map a **gene** or genes contributing to a phenotype (*see* **Genotype**) of interest, control of the overall false positive error rate involves a statistical issue of **multiple comparisons**.

For a single genomic locus t, possibly but not necessarily a marker locus, let $Z(t)$ be a statistic such that large values of $Z(t)$ are indicative of **linkage** of a trait to the locus t. The *nominal significance level* of the threshold b is $P_0\{Z(t) \geq b\}$. Here, P_0 denotes probability under the **null hypothesis** that the trait is unlinked to t. Suppose k genomic loci, $\{t_i : i = 1, \ldots, k\}$, each defined by its genomic map position given (for example) in centimorgans (cM) from a specified chromosomal location, are all tested for genetic linkage by means of $Z(t_i)$, $i = 1, \ldots, k$; and linkage to location t_i is declared if $Z(t_i)$ exceeds a suitable threshold, b. The *genome-wide significance level* for testing the hypothesis that *none* of the genomic loci is linked equals

$$P_0\left\{\max_i Z(t_i) \geq b\right\}. \tag{1}$$

Now the symbol P_0 denotes probability under the idealized hypothesis that none of the t_i is linked. Although with markers distributed throughout the genome it is unlikely that this idealized hypothesis is exactly true, it can, nevertheless, be regarded as a limiting approximation for the case that the phenotypic contributions of all linked genes are so small relative to the amount of data available that it is effectively impossible to detect those linkages. A slightly different interpretation is that (1) provides a bound on the probability that a false positive error occurs anywhere in the genome.

The simple **Bonferroni inequality** states that

$$P_0\left\{\max_i Z(t_i) \geq b\right\} \leq \sum_{i=1}^{k} P_0\{Z(t_i) \geq b\}. \tag{2}$$

In cases where the nominal significance levels are easily computed and the $Z(t_i)$ are not highly dependent (i.e. the t_i are sufficiently sparse that there is a reasonable amount of recombination between them), the Bonferroni inequality provides a simple, conservative approximation for the genome-wide significance level by the nominal significance levels. Its virtue is that it requires no assumptions about dependence among the different $Z(t_i)$. This is also its weakness, since by taking the dependence into account one can sometimes obtain more precise results.

For mapping quantitative traits in a backcross, Lander & Botstein [6] gave a simple approximation to (1) when the genomic locations t_i were an infinitely dense set of markers; they also provided simulated values when the t_i were markers equally spaced throughout an idealized tomato genome of 12 chromosomes of 100 markers each. Feingold et al. [5] showed that a similar analysis could be applied to allele-sharing statistics in **human genetics**, provided the sample size is large enough that a normal approximation to the distribution of the $Z(t_i)$ is reasonable; and they derived an approximation [(4) below] for the case of fully informative markers equally spaced at an intermarker distance Δ, which reduces to the earlier one in the limiting case that $\Delta = 0$.

In a debated, yet influential opinion piece, Lander & Kruglyak [7] argued that one should generally use the dense marker ($\Delta = 0$) approximation because (a) promising indications of linkage based on a sparse set of genomic locations was often followed up by saturating the promising area with what amounts to a dense set of markers; and (b) even in cases where this is not a feature of one particular study it is effectively the case when one considers the scientific community as a whole.

In particular studies, investigators have used **Monte Carlo methods** to determine the genome-wide significance level under the special conditions of their study. If direct simulation of the genome-wide significance level is forbiddingly complex, one may alternatively simulate the nominal significance levels and use the Bonferroni inequality to give a conservative approximation for the genome-wide significance level. This can be particularly effective when the nominal significance levels are all approximately the same.

Although simulations that are tailor made to the situation at hand are in many respects the best solution to the problem, simple analytic approximations can be useful to provide a rough check of a **simulation** program for gross errors and for theoretical comparisons of different experimental designs, when calculations must be repeated many times for different parameter values.

Remark

The problem of multiple comparisons in linkage analysis was recognized already in the classic paper of Morton [8], but it was dealt with differently. One assigned a prior probability of linkage to a randomly distributed marker and then determined a threshold for the detection of linkage that would make the posterior probability of linkage sufficiently large. See Ott [10] or Morton [9] for recent expositions of this idea, which with certain assumptions leads to the traditional threshold of 3 on the lod scale as the criterion to detect linkage. This analysis requires specific assumptions about the number, strength, and location of trait loci relative to linked markers. It seems adequate for Mendelian traits and a relatively small number of markers, where the linkage signal at a marker lying close by a trait locus is very strong and the principal impediment to the detection of linkage is the recombination fraction (distance) between a trait locus and the nearest markers. It seems less well suited for present-day genome scans designed to map genes for complex and/or quantitative traits. These genome scans involve large numbers of markers closely spaced throughout the genome, in order to map what may be multiple genes of variable penetrance, possibly interacting with each other and/or with the environment; and the major impediment to the detection of linkage is the absence of strong signals from the individual genes, even at markers lying next to or within the genes.

Approximation and Examples

Assume that fully informative markers are equally spaced at intermarker distance Δ throughout the genome. Let $Z(t_i)$ denote the statistic to be used for testing linkage to the marker t_i. We assume $Z(t)$ has been standardized so that at unlinked marker loci it has mean 0 and variance 1, and that it is reasonable to regard $Z(t)$ as approximately normally distributed. An additional condition is that as $s \to t$

$$\text{cov}[Z(t), Z(s)] = 1 - \beta|t - s| + o(|t - s|), \quad (3)$$

where $o(|t - s|)$ approaches 0 faster than $|t - s|$, and β is a parameter determined by the genetic relationships of the individuals contributing data to Z and on the form of the statistic Z.

A simple and important example is a sample of N independent sib pairs with $X(t)$ equal to the total number of alleles shared identical by descent (ibd) at the marker locus t (*see* **Identity Coefficients**). Let $Z(t) = [X(t) - N]/(N/2)^{1/2}$ be the ibd count standardized so that at an unlinked locus it has mean 0 and variance 1, while its mean is positive at a linked locus. Approximate normality of $Z(t)$ is a consequence of the central limit theorem if the number N of sib pairs is reasonably large. In this case $\beta = 0.04$/cM. A second example is the standardized regression statistic for testing that t is a quantitative trait locus in a backcross [6]. In this case, $\beta = 0.02$/cM. Other allele-sharing statistics and under certain conditions the signed square root of the (natural) log **likelihood ratio** statistic will also satisfy the required conditions. In human genetics the value of β will typically be slightly larger than 0.04, but its exact value will depend on the relationships of the individuals involved.

Under the assumed conditions

$$P_0\left\{\max_i Z(i\Delta) \geq b\right\} \approx 1 - \exp\{-C[1 - \Phi(b)] - L\beta b\varphi(b)\nu[b(2\beta\Delta)^{1/2}]\}. \quad (4)$$

In this formula, C is the number of chromosomes searched, L is their total genetic length, φ is the standard normal probability density function, Φ is the standard normal distribution function, and $\nu(x)$ is a special function, which is easily computed numerically and in the range $0 \leq x \leq 2$ is well approximated by $\exp[-0.583x]$.

For a numerical example, we consider an idealized human genome of 23 chromosomes of average genetic length of 140 cM. For intermarker spacings of $\Delta = 0, 1, 5$ and 10 cM, (4) yields a genome-wide significance level of 0.05 at the thresholds $b = 4.08$, 3.91, 3.73 and 3.6, respectively. On the lod scale, these thresholds are 3.62, 3.32, 3.02 and 2.82. The Bonferroni inequality (2) provides a very good approximation when $\Delta \geq 10$ cM, but it becomes overly conservative as Δ approaches 0. For a backcross, the smaller value of β indicates greater dependence between the values $Z(t_i)$ with the result that the conservatism of the Bonferroni inequality becomes apparent for somewhat larger Δ.

A number of related cases have been studied in detail and are reasonably well understood.

1. For qualitative traits studied using sib pairs or for quantitative traits in either an intercross in experimental genetics or in sibships, one may use a two degrees of freedom statistic in order to have more power to detect a gene having an additive effect and dominance deviation. A similar issue arises if we fix one locus, thought to be a trait locus, and search conditionally for a second locus using a model that provides for interaction between the two loci. Appropriate modifications of (4) are given by Dupuis & Siegmund [2]. For an intercross and an idealized mouse genome of 20 chromosomes of average length 80 cM, the 0.05 genome-wide thresholds for the same intermarker spacings used above are 4.43, 4.28, 4.12 and 4.01, respectively.
2. In experimental genetics, fairly large values of Δ (say $\Delta \approx 20$ cM) are common. If $Z(t)$ is maximized only over marker locations, either (2) or (4) (perhaps as modified in point 1 above for an intercross) would provide an adequate approximation. However, following the suggestion of Lander & Botstein [6], one often computes *estimated* values of $Z(t)$ at a dense set of positions between markers, then uses both the interpolated and the actual data. This leads to a larger value for $\max_t Z(t)$ and requires a slightly larger threshold. The Lander–Kruglyak suggestion to use (4) with $\Delta = 0$ is one possibility, but it is typically overly conservative. Appropriate approximations for genome-wide significance levels have been given by Rebai et al. [11, 12] and by Dupuis & Siegmund [1]. For the idealized mouse genome of the preceding example and $\Delta = 20$ cM, this would lead to an increase in the 0.05 genome-wide threshold from $b = 3.88$ to $b = 3.99$.
3. In human genetics when (a) sample sizes are small, (b) pedigrees contain more distant relatives than sibs or half sibs, or (c) there are more than two affecteds in a pedigree, the distribution of $Z(t)$ at a fixed genomic location t may be skewed. A simple modification of (4) has been suggested by Tang & Siegmund [13]. Since this is fundamentally a correction for non-normality of the marginal distribution of $Z(t)$, it can also be adapted for use with the Bonferroni inequality. For related approximations, which may be more accurate but require stronger assumptions and more complicated calculations, see [4] and [15].
4. For partially informative markers, there is evidence [14] that (4) is conservative but still provides a reasonable approximation if founders are available for genotyping and multipoint analysis is used. It appears that (4) can be overly conservative if founders are unavailable and anticonservative if multipoint analysis is not used. In the latter case the Bonferroni inequality may still be useful.
5. Simultaneous search for multiple linked genes involves a substantially larger number of tests and a larger threshold than the simple genome scans discussed in this article [3].

Genotype

The genotype of an organism is its **genes**, or genetic make-up, as opposed to its phenotype, or outward appearance. The physical basis of the human genotype lies in 23 pairs of chromosomes–microscopic bodies present in every cell nucleus. One pair are the sex chromosomes, and the other 22 pairs are known as autosomes, or autosomal chromosomes. The two alleles at each locus on the autosomes comprise the genotype for that locus. If the two alleles are the same, the genotype is called homozygous; if they are different, the genotype is called heterozygous. Persons with homozygous and heterozygous genotypes are called homozygotes and heterozygotes, respectively (*see* **Heterozygosity**).

If the phenotype, or phenotypic distribution, associated with a particular heterozygote is the same as that associated with one of the two corresponding homozygotes, then the allele in that homozygote is dominant, and the allele in the other corresponding homozygote is recessive, with respect to the phenotype; the locus is said to exhibit dominance. If the heterozygote expresses a phenotype that has features of both corresponding homozygotes–for example, persons with AB blood type have both A and B antigens on their red cells, determined by A and B alleles at the ABO locus–then there is said to be codominance (*see* **Blood Groups**). At the DNA level, that is, if the phenotype associated with a genotype is the DNA constitution itself, then all loci exhibit codominance.

The genotype being considered may involve the alleles at more than one locus. However, a distinction should be made between the genotype at multiple loci and the multilocus genotype. Whereas the former is specified by all the alleles at the loci involved, the latter is specified by the two haplotypes a person inherited, that is, the separate sets of maternal alleles and paternal alleles at the various loci (*see* **Haplotype Analysis**).

In the case of a quantitative trait, there is a dominance component to the variance if the heterozygote phenotype is not half-way between the two corresponding homozygote phenotypes, that is, if the phenotypic effects of the alleles at a locus are not additive. Similarly, if the phenotypic effect of a multilocus genotype is not the sum of the constituent one-locus genotypes, then there is epistasis. Dominance can be thought of as intralocus **interaction** and epistasis as interlocus interaction. Thus, in the case of a quantitative phenotype, the presence or absence of dominance and/or epistasis depends on the scale of measurement of the phenotype.

ROBERT C. ELSTON

Genotyping and Error-checking

Classifying Genetic Errors

Errors in genetic data can be classified into two categories: pedigree errors and genotyping errors. Pedigree errors arise when family relationships of the individuals under study are misspecified. Possible sources of misspecification include unrelated individuals such as adopted or switched sibs, nonpaternity cases such as half sibs who are recorded as full sibs, faulty family records and incorrect data entry (*see* **Paternity Testing** and **Relationship Testing** for more discussion of errors in family relationships). Genotyping errors arise when the true underlying **genotype** of an individual under study is misspecified. Possible sources include laboratory errors such as switched or contaminated samples, incorrect allele calls, or mistakes in data entry.

Genotyping error rates commonly reported in mapping and **linkage** studies range from 1% to 3% [1, 2, 16]. Genotyping errors in general either negate true recombinants or introduce false recombinants, as illustrated in the following equation for the expected recombination rate [21]:

$$\mathrm{E}(\hat{\theta}) = \theta_t + (1 - 2\theta_t)s,$$

where θ_t is the true recombination fraction and s is the misclassification frequency. For $\theta_t = 0.5$, unlinked **markers**, there is no **bias**, but for θ_t less than 0.5, the expected recombination rate is inflated by $(1 - 2\theta_t)s$. When θ_t is close to 0, $\mathrm{E}(\hat{\theta}) \approx s$, indicating most recombination events are false. False recombinants inflate estimated map distances between markers, obscure correct marker orders, and deflate lod scores, thus reducing the power to detect linkage. Negating true recombination events may inflate lod scores and lead to false linkage results.

Pedigree error rates due to nonpaternity vary widely among different populations that have been studied [3, 23]. Unlike genotype errors, however, pedigree errors that identify a previously unknown nonpaternity or adoption can have a profound effect on participants in the study. Common practice is not to reveal such errors to the participants.

Genotype Error Detection

Detecting errors in genetic data comprising a small number of markers and individuals may only require simple visual inspection, and resolving them may only require a quick inspection of a few genotypes in a database or a few entries from a family history when data entry error is the culprit. However, to handle the large number of genotypes generated for genome scans and the varied family structures used in linkage analysis, a variety of algorithmic and statistical methods have been developed that offer more powerful detection methods and can be implemented into software to automate the task of "debugging" genetic data. References to the methods contain details on the availability of software.

Violations of Mendelian Transmission

Since most genetic analysis software programs require the marker data to be **Mendelian** consistent, errors are often first detected after the program fails to execute. A marker is Mendelian consistent if the underlying genotype of the individuals in the pedigree are consistent with the laws of Mendelian transmission, otherwise the marker is Mendelian inconsistent. Although a genotype that contains a mutated allele (*see* **Gene**) may cause a Mendelian inconsistency, an inconsistency more often indicates the presence of an error, since mutation rates are much lower than genotyping error rates. Determining whether genotype data are Mendelian consistent can be done using genotype elimination algorithms [14, 20]. These algorithms use available genotyping information and family relationships to infer the sets of consistent genotypes of individuals with missing information. The pedigree has a Mendelian inconsistency if and only if, after the genotype elimination is performed, there is an individual with no consistent genotypes. Although genotype elimination is guaranteed to establish the existence of a Mendelian inconsistency, the algorithm may not be useful in identifying the possible source(s) of the inconsistency, since the effect of an inconsistency may propagate to different parts of the pedigree. Factors that improve the accuracy of identifying the source(s) are fewer individuals with missing data, highly polymorphic markers and larger sibships. The effect of the latter two factors was demonstrated by Gordon et al. [7], who studied the probability of detecting

genotyping errors in diallelic single-nucleotide **polymorphism** data for parent–offspring triples. They showed that in the case of this important sampling scheme for **linkage disequilibrium** studies the true error rate is over three times that of the error rate that would be reported using Mendelian consistency checks. Another very widely used paradigm in disease studies where Mendelian consistency checks are inadequate is sibling pairs. When parents are missing genotype information, two putative sibs will always be Mendelian consistent at codominant markers regardless of genotyping and/or pedigree error. Thus, alternative methods of error detection have been proposed.

Haplotyping

One method commonly used to check Mendelian consistent data is haplotyping [24]. Haplotyping is the processes of constructing the most likely gene flow in the pedigree assuming a known marker order, allele frequencies and intermarker recombination fractions. Finding double recombinants between closely spaced markers and/or many more recombinants than expected (based on the number of meiosis and recombination fractions in the most likely haplotype configuration) points to possible genotyping error. The location of suspect recombinants may not indicate the location of an error, since there may be other equally likely **haplotype** configurations with different locations of the recombinants. Thus, several **likelihood** methods that focus on identifying likely individuals and markers have been proposed.

Incomplete Penetrance Error Model

The genotyping error for an individual can be modeled within the likelihood at a codominant autosomal marker by defining an incomplete **penetrance** function [15]. Let $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ be a vector of phenotypes, which are the observed genotypes, and $\mathbf{g} = (g_1, g_2, \ldots, g_n)$ be the vector of actual genotypes for n individuals in a pedigree. Let $G = m(m+1)/2$ be the number of combinatorially possible unordered genotypes given m alleles at the marker. If we assume the errors are independent and equally likely, then the conditional probability of the observed genotype x_j given the true genotype is g_j is

$$\Pr(x_j|g_j) = \begin{cases} 1-\varepsilon, & \text{if } x_j = g_j, \\ \dfrac{\varepsilon}{G-1}, & \text{if } x_j \neq g_j, \end{cases} \qquad (1)$$

where ε is the error rate. For an error rate of 3% this penetrance function assigns a high probability to the observed genotyping being correct and a low but equal probability to all other $G-1$ possible genotypes. More complex penetrance models assuming individual and locus-specific error rates can be used, but studies have shown that the penetrance model is relatively insensitive to the distribution of the error probability [5, 17, 25].

Although implementing an incomplete penetrance model into the likelihood of the pedigree is mathematically straightforward, the increased computational requirements of the model may be prohibitive, since each genotyped individual now has G nonzero penetrance values instead of 1. The complexity is less of an issue for small- to medium-sized pedigrees since the likelihood can be computed using the Lander–Green algorithm [13]. But for larger pedigrees that require the **Elston–Stewart algorithm** [6] to compute the likelihood, even analyzing a single polymorphic marker may be difficult when G is large. To reduce the complexity, several authors use a reduced incomplete penetrance model [5, 25], whereby only a single individual at a single marker has incomplete penetrance and all other genotypes are assumed correct.

Likelihood Methods

Stringham & Boehnke [25] proposed computing the posterior probability of genotyping error, $\Pr(E_k|\mathbf{x};\varepsilon)$, for each individual at each locus allowing for incomplete penetrance. They compute $\Pr(E_k|\mathbf{x};\varepsilon)$ using standard likelihood methods as $\Pr(E_k, \mathbf{x};\varepsilon)/\Pr(\mathbf{x};\varepsilon)$, where $\Pr(\mathbf{x};\varepsilon)$ is the likelihood for the data and $\Pr(E_k, \mathbf{x};\varepsilon)$ is the likelihood for the data assuming individual k has an error, which requires adjusting his/her penetrance function so the first term is zero. Individuals with high values are flagged as possible errors. They also proposed a less computationally intensive version using reduced incomplete penetrance, which can identify individuals who could be the sole source of a Mendelian inconsistency. Ott [22] suggested calculating for each individual k the sum of the squared differences between the conditional

probability for each genotype g_k given the phenotype x_k and each genotype g_k given the phenotypes of all the individuals in the pedigree **x**:

$$\sum[\Pr(g_k|x_k) - \Pr(g_k|\mathbf{x})]^2.$$

Individuals with large values are identified for further inspection. O'Connell & Weeks [19] proposed a method to identify the most likely source of Mendelian inconsistencies by comparing the most likely alternative Mendelian-consistent genotype configurations. The method first identifies minimal sets of individuals who could eliminate the inconsistencies by setting their phenotype to unknown, and then computes the likelihood of each possible consistent alternative phenotype for these sets of individuals. Sets of individuals with the highest likelihood are targeted as the most likely source of error, since they have the highest probability of having other genotypes than those observed.

Besides single marker tests, several authors have proposed multipoint tests, which have the advantage of being able to detect increased recombination and inflated map distances. Ehm et al. [5] proposed a hypothesis test of $\varepsilon > 0$ for each individual at each locus, assuming a reduced incomplete penetrance model. They proposed an exact multipoint **likelihood ratio test** statistic that assumed correct marker order, but jointly estimated the recombination fractions and the error rate. Owing to the complexity of the joint estimation, they also proposed an approximate test that used an estimate of the recombination fractions assuming no errors. ***P* values** for the test are determined by Monte Carlo **simulation**. Their simulation studies showed that the power of their method is directly related to the amount of typing in the pedigree and the number of loci analyzed jointly, and is inversely related to the recombination fraction. Douglas et al. [4] investigated the power of the multipoint posterior probability test assuming correct marker order for the special case of sibling pair pedigrees with no parents available. These pedigrees are small enough to allow incomplete penetrance for each individual and each marker. They showed that posterior error rate cutoffs vary substantially as a function of marker density, prior error rate and false positive rate. Although their method found less than 50% of the errors, they showed that the errors identified using their cutoffs were the most informative for restoring the true linkage information.

Although the above tests for genotyping errors assume correct pedigree structure, putative genotype errors may actually result from pedigree errors. For example, an adopted sib may be flagged as having genotyping errors, although the genotypes are correct. The likelihood depends not only on the penetrance, but also on allele frequencies and parent–child transmission probabilities. The effect of pedigree errors through the transmission probabilities may offset various penetrance values, just as a genotype with a very rare allele may have a high posterior probability of error due the small allele frequency. Lathrop et al. [16] proposed a method to distinguish between the two types of error by including an error model for parental misassignment with the incomplete penetrance model.

Resolving Errors

Resolving errors in genetic data by determining the true state of a pedigree relationship or genotype may not always be possible. Correcting data entry errors is rather easy, but resolving putative genotyping errors requires regenotyping the individuals involved. However, since regenotyping may not always be an option, due to cost or insufficient resources, the general practice is to prune the data. The methods presented can be used to identify the most appropriate genotypes to prune. Care must be taken, however, not to artificially increase evidence of linkage by removing false positives. Errors identified as pedigree errors due to misspecified relationships can often be corrected by removing individuals or by adding the appropriate relatives to the pedigree. For example, newly identified half sibs can be retained by adding in another parent, if necessary.

Other approaches besides pruning the data have been proposed. Morton & Collins suggest adjusting the recombination fractions for errors to take into account possible inflated map distance [18]. Göring & Terwilliger [9–12] propose a methodology to allow for errors in linkage and/or **linkage disequilibrium** analysis. Gordon et al. [8] propose a transmission/disequilibrium test for single-nucleotide polymorphism data that allows for errors. Finally, as stated above, the incomplete penetrance model can be incorporated into any exact likelihood-based analysis for small- to medium-sized pedigrees; for larger pedigrees, an approximate likelihood can be computed using **Markov chain Monte Carlo** methods.

Since genotyping error will probably be always with us, finding improved methods to identify errors or to allow for them in our analyses to extract maximum information from our data will continue to be an important area of research.

JEFFREY R. O'CONNELL

Geographic Epidemiology

The purpose of this article is to give an overview of methods of analyzing epidemiologic data in which geographic location is of primary importance. Methods may be distinguished by the purposes of the analyses, which include (i) modeling **risk** as a function of geographically referenced variables; (ii) **hypothesis testing** about specific sources of risk; (iii) **mapping disease patterns** to provide a visual representation of risk variation; (iv) identifying areas of apparently elevated risk deserving further epidemiologic investigation (*see* **Environmental Epidemiology**); and (v) detecting specific or generalized clusters, which may be indicative of unsuspected sources of risk or of a contagious disease mechanism (*see* **Clustering**). These methods are reflected in the central sections of the article, which are preceded by an overview of the underlying models and followed by a discussion of the issues involved in the choice of method.

Interest in geographic epidemiology has increased greatly in recent years and the number of methods proposed in the literature is very large; two recent books are given as references [44, 64]. It would be quite impossible to review these methods comprehensively in this article; rather the object is to form a general classification according to their objectives and the underlying assumptions. Many proposed analyses will inevitably be omitted and an adverse judgment on them should not be inferred. On the face of it, geographic epidemiology is a topic in spatial statistics [27, 31, 36, 85], but there are special aspects which distinguish it from many of the other areas of application in the latter field.

It should be remarked at the outset that the likelihood of a geographic analysis revealing relationships of real scientific or clinical significance in a given case may be fairly low, for a number of reasons. First, in spite of considerable improvements in data availability over recent years, it is difficult to acquire accurate population sizes. A relatively high rate of individual migration and the development of new residential districts mean that population estimates can be seriously in error at the end of the intercensal period – 10 years in the UK, for example. Migration also implies that people are typically exposed to risks associated with different locations as they move around, which must inevitably dilute the sensitivity of any geographic analysis. Local mobility further confuses the picture: adults work and children go to school in areas which are often quite different from their place of residence, so that geographically mediated risks may be only weakly related to home address. It should also be remembered that most geographic observations – including those that have subsequently been found to be of real significance and value – have been anecdotal and the analyses have been executed *post hoc*. This inevitably adds to the difficulty of interpreting them.

Nevertheless, there have been notable triumphs of geographic epidemiology: the well-known story of John Snow and cholera [91]; the observations of Denis Burkitt leading to the recognition of a vector-related etiology of a human tumor [20, 21]; and more recently, the detection of the cause of an outbreak of epidemic asthma [3]; all are striking demonstrations of the epidemiologic potential of geographic observations. There is also a less positive but equally important reason for carrying out geographic analyses effectively. People are in practice very concerned about the impact of their environment on their health and it is important that anxieties are explored in a manner that inspires confidence, if only to provide reassurance in particular cases.

Underlying Models

Case-independence and Other General Issues

It is important to distinguish at the outset mechanisms of disease in which cases are or are not intrinsically related. Examples of case-dependence include contagious and familial diseases (*see* **Communicable Diseases**); any tendency of such cases to be close geographically is unlikely to identify any component of risk which is essentially geographic. Rather, interest centers on establishing the case-dependence as an intrinsic phenomenon independent of geographic location.

For case-independent disease processes, however, we suppose that cases occur independently of one another, *conditional on the underlying risk factors*, which may include some aspect of geographic location. On this assumption, any spatial **autocorrelation**, or general tendency of cases to be closer to one another than expected, will be inherited from the spatial structure of the underlying pattern of risk factors.

Within the frequentist framework, at least, it is *unnecessary to model it by means of a spatially correlated error process*, except to the extent that this may be a convenient way of allowing for spatially varying risk factors that we cannot observe. We return to this point below.

Models for case-dependent processes are not well developed. Spatial modeling of epidemics [4, 72] is concerned with the dynamics of spatial spread and has rather little interaction with epidemiologic analysis in the sense of this article. Some authors [1, 5, 16] have proposed clustering models in which "parent" cases give rise to "offspring" cases according to a defined stochastic mechanism; it is much easier to postulate models of this kind than to handle them analytically. "Second-order" **point processes**, which model the tendency of points to be clustered, have been studied using Ripley's K functions [84] in the epidemiologic context by Diggle & Chetwynd [37] and applied also by Diggle & Morris [39]; they are not easily related to specific models of person–person interaction, however.

In practice, much geographic epidemiology is applied to diseases – notably malignant diseases – for which there is very little evidence of case-dependency. Although it may be the objective of some analyses to detect such dependency, the assumption of independence is a reasonable basis at least for a **null hypothesis** H_0 of spatial uniformity. It is therefore quite sensible to discuss most of the methods of geographic epidemiology against a modeling background which assumes case-independence and this will be the standpoint of this article. Once this position is accepted, the basic models for the spatial distribution of disease become relatively simple.

Two other general aspects of the models we discuss should be mentioned. In the first place, it may be argued that much of epidemiologic analysis reduces to considering the **associations** between observations on a disease $\mathcal{D}$, a variable of primary interest $\mathcal{E}$, such as an exposure variable, and a set of other variables $\mathcal{C}$, which may be thought of as **covariates** and which may include possible **confounding** variables. In many analyses the variables in $\mathcal{C}$ are regarded as being fixed, even though they may be subject to error or sampling variation. For many purposes this will suffice; although the analysis may not be strictly correct [41], it can be justified in terms of a conditional argument – i.e. it is valid in the subspace of all outcomes in which $\mathcal{C}$ is as observed; alternatively, we may argue that it is reliably assessing the importance of a *modified* variable incorporating the unobservable error. In **observational studies** $\mathcal{D}$ and $\mathcal{E}$ are intrinsically random, but even here it is quite usual to condition on one or the other rather than to model the full joint distribution. This gives rise to a duality of analysis corresponding to the **case–control** and **cohort** approaches [19]. In this respect, geographic analyses are no different from any other epidemiologic analyses: geographic location may be treated as a covariate $\mathcal{C}$ or as a primary interest variable $\mathcal{E}$; in the latter case, $\mathcal{E}$ may be regarded as fixed with $\mathcal{D}$ random, or vice versa. This "duality principle", that either form of conditioning leads to valid and useful analyses of epidemiologic data, permits us to employ analyses of either kind interchangeably, which we will do below without further comment.

Secondly, we emphasize that, however we choose to model location, it is imperative to build in a reference distribution (normally in the form of a population density) at a fundamental level; not least this is because of the implication for the underlying variation in local **variance**. Analyses which start by assuming a homogeneous spatial distribution of cases and "correct for" heterogeneity of population distribution are to be regarded with suspicion and may give misleading results.

Areal Data

Most geographic data are in areal form, i.e. counts $Y_i, i = 1, 2, \ldots, k$ of numbers of cases in areas A_i, nearly always administratively defined, within a study region $\mathcal{R}$. These will be accompanied by population information, initially in the form of the sizes of the populations at risk in different relevant groups; such groupings will usually include age and sex, and often other factors such as socioeconomic status and ethnic group. If the risk within a given area A_i is constant, the Y_i are clearly **binomial**. Variation of this risk upsets this assumption, but only slightly in practice, particularly if the risk is small (which it will be for a rare disease or when modeling annual rates). In the latter case we can use the **Poisson** approximation even if there is identifiable heterogeneity of risk within the A_i.

We can therefore simplify the account by adopting the Poisson model and supposing that the population sizes have already been used in conjunction with reference rates to construct "expected" numbers e_i of

disease cases, either by a process of **standardization** or using a suitable **regression** model [13]. The case-independence assumption then implies that the Y_i are independently distributed with Poisson distributions having means $\theta_i e_i$, say, where we take θ_i as the **relative risk** (RR) in A_i – i.e. the risk relative to the assumptions under which the $\{e_i\}$ were computed. The factors θ_i may now be modeled in terms of possible explanatory variables using methods which are well understood, for example a **Poisson regression**; this employs a **loglinear model**, which is a particular case of a **Generalized Linear Model (GLM)** [66]. Such a model can be tested for **goodness of fit**; usually this may be satisfactorily accomplished using the residual deviance, though there are problems in interpreting this if the e_i are very small – say with appreciably many observations significantly less than around five. If there is evidence that the model does not fit well, this indicates that there is a component of risk that has not been incorporated into the model; it is said that there is "extra-Poisson" variation [17]. Modifications of the analysis in this case include postulating a distribution for θ over the A_i, for example from a **gamma distribution**, which leads to a **negative binomial distribution** for the Y_i [53]. The implications for model validity and **inference** do not depend on whether there is a geographic element to this variation; if there is, a richer model involving spatial autocorrelation may be fitted [28].

Continuous Data

The discrete structure of areal data, with the imposition of administrative boundaries, is not ideal either practically or mathematically. In principle, data may be available on a continuous basis, i.e. by the provision of the exact geographic coordinates of a sample of cases. The case-independence assumption and the duality principle then imply that these cases may be regarded as a **random sample** from a **bivariate** density function $\psi(x, y)$ of geographic location with coordinates (x, y). This density function determines the distribution of the place of residence of a randomly selected individual with the disease. Equivalently the case locations may be regarded as a realization of a **Poisson process** with intensity $f(x, y)$ proportional to $\psi(x, y)$. As before, we need a reference group and this may be taken to be the population density $\pi(x, y)$, where we use this term to refer not so much to a general demographic concept, but to a second mathematical density function describing the probability that a randomly selected member of the population will reside at a given point (x, y). We are now in a position to define a *risk function* giving the risk of being affected by the disease incurred by a randomly selected individual at location (x, y), namely.

$$\mu(x, y) = \frac{f(x, y)}{N\pi(x, y,)},$$

where N is the aggregate of the population in $\mathcal{R}$, in the form of **person-years at risk** if appropriate.

In practice, of course, these mathematically defined risk functions must be estimated from the data, the problem being one of estimating the ratio of two densities. Methods of estimating a single density have recently been much studied and developed [88, 89] and, although ratios present certain rather special problems, they are not insuperable. For the distribution of cases, the general methods apply, with the proviso that population-related densities are extremely multimodal and in this respect atypical of most of the examples to which density estimation has been applied. The estimation of the population density raises rather special problems, in that published data will still be in areal form, but the normal methods of **density estimation** can be adapted; alternative methods are available [69, 94].

It should also be noted that the population density may be satisfactorily estimated from a sample of **controls** [8], which has the advantage that the geographic resolution of their locations will be equal to that of the cases. Use of controls also removes the need to ascertain the entire population, though in the absence of information about whole-population risk the risk function will be determined only up to an unknown factor. In this case it may be regarded as a "relative risk function" (RRF), defined by $\theta(x, y) = \psi(x, y)/\pi(x, y)$, giving the risk at a particular location relative to the average in the whole of $\mathcal{R}$ [8].

The continuous model of geographic risk is attractive mathematically and opens up a number of new possibilities for analysis. In practice, however, there are considerable difficulties with obtaining suitable **sampling frames** for the controls. Case–control analyses have not been much used in practice, though they may reasonably be expected to assume greater significance in the future, as the geographic accuracy of address data improves.

Spatial Autocorrelation

The rationale for taking account of spatial autocorrelation is attributed by Cook & Pocock [28] to Lazar [65] as being that "failure to allow for spatially correlated errors may result in serious overestimates of the significance of relationships". Lazar demonstrates that this is true when the relationships in question are assessed using **correlation** coefficients with precision estimated from the data.

As argued above, however, case-independence implies that any spatial autocorrelation in observed disease rates must be due to a similar autocorrelation in one or more associated factors that have not been taken into account in the model, i.e. it is not really the *error* mechanism that should be modified by taking account of autocorrelations. Of course, the word "error" in statistical parlance has come to be synonymous with anything not accounted for in an explanatory model. The point is not merely semantic, however; use of the word in this context has the unfortunate effect of distracting attention from the importance of case-independence and to the construction of methods which do not make use of the known variances of binomial and Poisson data.

Cook & Pocock propose, in a study of heart disease, a model for the Standardized Mortality Ratio (SMR) (*see* **Standardization Methods**) of the form:

$$\ln\left(\frac{Y_i}{e_i}\right) = \mathbf{X}\beta + \varepsilon,$$

where the linear predictor $\mathbf{X}\beta$ is in the usual form for a **linear regression** model and

$$\varepsilon \sim \mathrm{N}[0, \sigma^2\mathbf{A}],$$

with $\mathbf{A}$ an autocovariance matrix. Exploratory analysis led them to propose an autocorrelation function decaying **exponentially** with distance. Estimation in this model did indeed lead to a reduction in the significance of the effect of water hardness, the regression coefficient being reduced by around 40% and its standardized value from -5.0 to -3.0 (*see* **Standardized Coefficients**).

Cook & Pocock conclude that failure to adjust for spatial autocorrelation leads us to overstate the significance of fitted regression coefficients. Although this is probably true in their example, it may not always be so, as may be seen more easily by considering a GLM in which terms may be assessed for significance in their own right, without recourse to an estimate of residual variance. It would be quite possible to have an unobserved covariate $\mathcal{C}$ which is spatially autocorrelated and which induces autocorrelations in the residuals, but which is independent of a fitted variable $\mathcal{E}$. Although taking account of $\mathcal{C}$ would improve the fit of the model, it would not necessarily reduce the contribution of $\mathcal{E}$ to the total deviance and need not, therefore, affect its significance. Nor is the reduction of the estimate of the regression coefficient conclusive, since $\mathcal{C}$ might be incidentally associated with $\mathcal{D}$ and $\mathcal{E}$; the latter could still be an important causative factor. Incorporation of autocorrelation is, nevertheless, a feature of many contributions to the field and it is generally supposed to be of considerable importance, both theoretically and practically. To some extent this view is encouraged by **Bayesian** modeling, where the emphasis is on the inclusion of terms to represent any unknown component of variation without consideration of model **parsimony**.

Bayesian Modeling

The models outlined above are essentially frequentist and assume the existence of unique but unknown parameters. The Bayesian alternative is becoming increasingly popular in statistics generally and particularly with the epidemiologic community [25, 32, 50, 55].

The seminal contribution by Clayton & Kaldor [26] distinguishes heterogeneity deriving from spatial and nonspatial sources. These give rise to corresponding methods of **smoothing rates** for disease mapping (see below) and were motivated primarily by this application. The methods have had considerable influence on geographic epidemiology and have been used to elaborate inferential modeling by numerous authors [63, 71] in the spirit of the frequentist approach outlined above. They are exemplified by the analysis by Richardson et al. [83] of childhood leukemia in relation to natural (background) **radiation**. These authors extend the standard Poisson regression to a Generalized Linear Mixed Model (GLMM) [18, 24], with **random effect** terms u_i, v_i specific to area A_i:

$$\ln\theta_i = \mathbf{X}_i\beta + u_i + v_i, \quad i = 1, 2, \ldots, k.$$

Here u_i models nonspatial heterogeneity through the assumption that

$$[u_i|u_j,\ j \neq i] \sim \mathrm{N}[\overline{u}_i, \lambda_u^{-1}], \quad \text{where}$$
$$\overline{u}_i = \sum_{j \neq i} \frac{u_j}{(k-1)}.$$

Spatial structure is modeled by v_i through the assumption that

$$[v_i|v_j,\ j \neq i] \sim \mathrm{N}[\overline{v}_i, (k_i\lambda_v)^{-1}], \quad \text{where}$$
$$\overline{v}_i = \sum_{j \neq i} \frac{W_{ij}v_j}{k_i},$$

and where the adjacency matrix element $W_{ij} = 1$ if areas i, j are adjacent, 0 otherwise, and k_i is the number of areas adjacent to A_i. We require $\sum u_i = \sum v_i = 0$ for **identifiability**.

The parameters λ_u, λ_v control the degree of variation in the dispersion terms. In an **empirical Bayes** treatment, these would be estimated; instead Richardson et al. pursue a "full Bayes" solution in which, together with β, they are given **prior distributions**. Choice of the "hyperparameters" in such prior distributions leads to the notion of a "**hierarchical** Bayes" model.

In the childhood leukemia analysis [83], the effect of radiation in a frequentist Poisson regression was very weak and was limited to acute nonlymphocytic leukemia and to one of three 5-year periods. It was reduced to the point of nonsignificance in the GLMM, and the variation in both the $\{u_i\}$ and the $\{v_i\}$ estimates appeared to be significant. Similar doubts attach to the interpretation of these results, however: to the extent that the random effects are independent of natural radiation, they should not affect **inference** for the latter. To the extent that they are associated with it, they may represent **confounders**, but the possibility that radiation is a primary and important effect cannot be excluded.

The models outlined above preserve the discreteness of areal data. A model for continuous data is more difficult mathematically. Typically it is assumed that the logarithm of the RRF is a realization of a spatial Gaussian process [62]. The mean of this process might be taken to be constant if the primary purpose is to model spatial relationship, which would be determined by an autocorrelation function; otherwise it could involve parameters designed to detect locational effects. The methods are comparatively new and untested.

The considerable computational difficulties with Bayesian methods have recently been facilitated by **Markov chain Monte Carlo** (MCMC) methods. These are computationally expensive and care needs to be taken to ensure that the chain is fully sampling the stationary distribution it is intended to estimate. It is also unclear how much the precision is affected by the need to estimate large numbers of parameters, though it should be remembered that the precision of classical frequentist methods incorporates information from the specification of the model and is therefore crucially dependent on its correctness. The book by Gilks [48] gives much technical detail about MCMC and available software, and includes a discussion of geographic applications, particularly issues affecting the choice of priors [70].

Analysis by Location

Areal Modeling

The simplest kind of geographic analysis merely attempts to model a disease rate at a particular location in relation to geographically defined variables associated with that location. Examples of such variables could include geographic variables such as altitude [20], possible measurable risk factors such as background radiation levels, and demographic characteristics of the population, such as socioeconomic status. The latter type of variable imputes to individuals at risk the average of some risk for the whole population in their immediate vicinity, giving rise to an "ecologic" analysis which is not without its dangers [38, 45] (*see* **Ecologic Fallacy**; **Ecologic Study**). Functions of location, such as distance from a specified point, also come into this category of analysis and are dealt with below.

Under the case-independence assumption discussed above, statistical analysis may proceed in an entirely classical way, for example using GLMs. As discussed above, a typical such model would be a Poisson regression with $\ln(e_i)$ as an offset. The residual deviance in this model may then be used to determine whether there is any extra-Poisson variation, which may be evidence of clustering (see below).

Continuous Analogs

Continuous data require an analogous method to analyze the risk function $\mu(x, y)$ or RRF $\theta(x, y)$. For case–control data with equal numbers of cases and controls, this can be achieved by a **conditional logistic regression**. We define

$$\rho(x, y) = \frac{\theta(x, y)}{[1 + \theta(x, y)]},$$

which gives the **conditional probability** that an individual sampled at (x, y) is a case rather than a control [8]. This probability can in principle be modeled logistically using any variable defined by location (x, y) as well as other attributes of the individual concerned [40, 57]. As remarked, above, however, case–control analyses of this sort have not to date been used to anything like the same extent as areal data methods.

Focused Tests of Point Source Hypotheses

A particular kind of locational analysis involves the study of the relationship between disease incidence and the location of some putative source of risk $\mathcal{S}$. Such an analysis imputes risk to geographic location or, equivalently, uses some function of location as a surrogate for risk. This inevitably requires the construction of a one-dimensional function of location. Distance from $\mathcal{S}$ is an obvious choice, though analyses can apply equally well to other measures, incorporating, for example, geographic characteristics such as altitude, bearing to prevailing wind, etc.

Most analyses of data in relation to point sources carried out to date are statistically elementary and consist in examining a single standardized incidence ratio (SIR) for a predefined region $\mathcal{R}$ around $\mathcal{S}$, comparing it with one or more control rates which would typically be national (*see* **Standardization Methods**). Such analyses have the great merit that they are easily understood, but they suffer from the severe disadvantage that they are not at all **powerful** against any sensible **alternative hypothesis**. They are also particularly dependent on the size of the region $\mathcal{R}$, though this is an intrinsic difficulty with other analyses too.

It is almost certainly better to use a method that makes explicit use of distance or other risk surrogate. Suppose that the true RR at a distance d is $\theta(d)$. Then, whether the data are in areal or continuous form, it follows easily from the **Neyman–Pearson lemma** [29] that the **most powerful test** of the null hypothesis of constant risk (H_0) is based on a Linear Risk Score (LRS) computed as the sum over n cases

$$T = \sum_j \ln(\theta(d_j)),$$

where d_j is the distance of the jth case from $\mathcal{S}$ [9]. It follows that the SIR test is only powerful against a hypothesis that supposes a dichotomization of risk inside and outside $\mathcal{R}$. Of course, the usefulness of the general result is limited by the fact that we do not know the true risk function $\theta(\cdot)$, but it provides a benchmark against which other methods may be calibrated. Moreover, it turns out that using a (canonical) risk score of $1/d$ or $1/\text{rank}(d)$ is quite powerful against a wide range of alternatives [12]. **Locally most powerful tests** have also been proposed by Waller [96] and others [61, 93, 97]; these score tests are clearly not "uniformly" most powerful against *all* alternatives and it is unclear how local their power properties might be.

The problem of our ignorance of the true risk function led Stone [14, 92] to propose a test designed to detect a general monotonic decreasing RRF. This test has recently become very popular in the UK. Known as Stone's MLR test, it is a (maximum) **likelihood ratio test** in which the alternative hypothesis is:

$$H_1: \theta_1 \geq \theta_2 \geq \cdots \geq \theta_k (\geq 1),$$

i.e. the areas A_i, ordered by distance from $\mathcal{S}$, have RRs θ_i estimated by maximizing the **likelihood** subject to the restriction that they are monotonic nonincreasing. The final constraint is optional though important, the issue being similar to the choice of a conditional or unconditional test discussed below [9]. This estimation problem is related to that of **isotonic regression** [86]; the computation required is nontrivial but feasible in practice. Stone also proposed the so-called "$P_{\max}$" test based on the first order-restricted RR estimate, $\hat{\theta}_1$. This turns out to be

$$\max_j \sum_{i=1}^{j} Y_i \Big/ \sum_{i=1}^{j} e_i,$$

i.e. the maximal cumulative RR as distance from $\mathcal{S}$ increases. These tests are undoubtedly important and in some situations very effective. The application

of the Neyman–Pearson lemma referred to above, however, implies that Stone's test is never most powerful, and it is not hard to find alternatives for which it has low power compared with canonical LRS tests.

Whichever test statistic is used, it is crucially important to distinguish between the *conditional* and *unconditional* form of the test [9]. The former conditions on the total number of cases observed in $\mathcal{R}$ and is affected only by the spatial information in the data. It would be appropriate whenever the rates used to compute the $\{e_i\}$ may not be reliable in $\mathcal{R}$; if they are trustworthy, however, the conditional analysis ignores potentially valuable information and can even lead to the rejection of H_0 resulting from a *deficit* of cases in the outer parts of the region $\mathcal{R}$. The unconditional form uses the overall disease incidence information as well as the spatial information, but is appropriate only when the $\{e_i\}$ are reliable. In practice, conditional and unconditional tests may produce very different results, especially from small data sets, and it is very important to decide *a priori* which form of test will be used.

Disease Mapping

History and Atlases

The mapping of the incidence of disease and mortality has a long history, well summarized by Howe [51]. Early endeavors were concerned with depicting the epidemic spread of infectious disease, often represented by contours of first occurrence date. More recently, with the diminishing importance of infectious disease in the developed world, the emphasis has changed to representing mortality or incidence in an attempt to infer geographically related explanations of variation in rates. For example, the *Atlas of United States Mortality* [76] contains color maps for each of 18 major causes of death. The colors indicate the 10, 20, 40, 60, 80, and 90 percentiles of the age-standardized death rates in Health Service Areas (HSAs); for example, the top band includes all HSAs whose rates are in the top 10% for the US as a whole. Rates based on small numbers are distinguished by hatching. Cancer atlases, in particular, have been produced for countries all over the world, including the US, continental Europe, China, and the UK [15, 46].

Some maps depict cartograms, in which regions are drawn with areas proportional to their population sizes (*see* **Mapping Disease Patterns**). This may help to overcome the problem of unequal population distribution, but it has the disadvantage that the resulting maps are geographically unfamiliar. We will confine our attention in this section to representational maps in which the geometry is preserved.

Areal Mapping by RR and Other Measures

Most atlases attempt to depict data in discrete form, using administratively defined areas. One of the major concerns in such mapping is the question of what to map. Plotting rates in small areas tends to produce a misleading picture, in that apparently high rates may appear in low-density regions by chance. This problem is exacerbated by the negative correlation usually found between population density and the sizes of administrative areas. Because areas of similar population density are often adjacent, this can induce an apparent spatial pattern where none exists. Some authors [30, 46] have employed a measure of statistical significance instead of or as well as SIRs; with these, however, small values of P which are statistically but not scientifically significant may arise in areas with large populations. It is now generally regarded as preferable to plot **rates** rather than ***P* values**, controlling the influence of sampling variation by using a degree of smoothing [22]. The latter may be *empirical* or *model-based*.

Nonspatial Smoothing

The rationale for **smoothing** is that the **maximum likelihood** estimate of the disease rate in a particular small area is, because of its statistical variability, a poor indicator of the true rate in that area. If, for example, there was very little evidence of geographic variation, we would probably abandon an area-specific estimate and use the global rate for the whole region. Smoothing may be seen as an attempt to compromise between the two positions, using both local and global information.

An attractive method of combining this information is the Bayesian formulation referred to above [26, 55, 68]. In this, it is assumed that the underlying RRs $\{\theta_i\}$ in areas $\{A_i\}$ have a **gamma**

prior distribution, with mean μ and variance σ^2. It follows that the mean of the posterior distribution of θ_i is

$$\tilde{\theta}_i = \frac{y_i + \mu^2/\sigma^2}{e_i + \mu/\sigma^2},$$

a formula that demonstrates how $\tilde{\theta}_i$ varies, according to the value of σ^2, between the area-specific ML estimate Y_i/e_i and the global mean μ, whose ML estimate is $\sum_i Y_i / \sum_i e_i$. Unfortunately the ML estimation of σ^2 requires an iterative method, though a simpler **moment**-estimator is available [26].

Estimating the posterior mean in this way is the basis of the **Empirical Bayes (EB)** method of smoothing. It shrinks the local estimates towards the global mean, but does not take any account of the spatial relationship of one area to another.

Spatial Smoothing Using Bayesian Models

The Bayesian modeling of spatial structure described above can be used to produce estimates of the RR which are smoothed by reference to adjoining areas as well as the overall mean. The original paper by Clayton & Kaldor [26] describes a method that did not take account of the varying number of areas adjacent to a given A_i and consequently lacked internal consistency; developments by Besag et al. [6] have led to a version that meets this objection. The goal of making the rates in adjacent areas more similar to one another than identical rates in well-separated areas may seem very reasonable. It must be remembered, however, that it will inevitably give an appearance of spatial relationship even where none exists; it is therefore essential that maps produced using these methods are clearly indicated as such. For a critique of the effect of smoothing on the interpretation of spatial relationship, see [47].

Empirical Smoothing

Although the Bayesian methodology is very attractive theoretically, it employs fairly sophisticated **algorithms** and is not easily related intuitively to the original data. Empirical methods of smoothing may be better in this respect and numerous methods have been proposed [15]. A particularly attractive method is described by Pukkala and applied to cancer in Finland [81]. At each point of a fine lattice, an estimated risk is computed as a weighted average of the rates in all the A_i whose centers are within a defined distance of the point. The weights take account of the distances of the A_i and also of their population sizes. The result is a map free of the original small area boundaries. A more elaborate method in which numerators and denominators of rates are smoothed separately is described by Kafadar [54].

Smoothing Based on the RRF

The formulation of a model for geographic data in terms of density functions discussed above suggests a simple, probability-based method of depicting risk continuously. All we need to do is to plot an estimate of the risk function or the RRF as the ratio of the densities for cases and controls [8, 56]. This method can also be adapted to employ areal data [10].

Degree of Smoothing and Other Issues

Whatever method of smoothing is employed, it is important to realize that determining the degree or scale of smoothing is intrinsic to any spatial method. For areal data, the sizes of the areas will be involved in this determination. Particular methods may offer choice at other levels of the analysis: for example, the bandwidth in the case of risk function estimation based on density estimates. The question of whether one may reasonably expect the data to determine how much smoothing should be applied is unclear. From a Bayesian standpoint, one should expect to build into the analysis a prior idea of the degree of risk variation. Estimating this degree from the data is akin to using empirical Bayes ideas and departs from the spirit of the "full Bayes" approach. Density estimation methods are certainly associated with data-driven methods of bandwidth determination, such as **cross-validation** [89]. However, these typically use criteria of doubtful relevance to the presentation of meaningful maps, and in practice may not produce satisfactory analyses.

The methods described above all incorporate information about the variation in the population density and this should be regarded as essential because of the variation in precision implied. Methods designed for homoscedastic continuous data (*see* **Scedasticity**), such as geophysical data, can give quite misleading results and should be avoided.

Clustering

Types of Clustering

Clustering may be defined as the tendency of observations to be situated closer to one another than would be expected; the role of chance in this expectation is crucial and much statistical effort is directed towards determining whether an observed cluster could easily be accounted for by chance. In the context of geographic analyses, the issue is that of whether people affected by a disease reside, work or otherwise congregate at places which are closer together than would be expected. From a mathematical point of view, the aggregation could be in any continuum and this gives rise to the notion of clustering in time, space or in the space–time product space. Mathematical considerations also suggest that the nature of the continuum should make rather little difference to the nature of the tests available, specifically that a test working in time, for example, should have an analog in space.

We remark also that it may be useful to distinguish various different types or modes of clustering. Cases may be close together because of a violation of the case-independence assumption; such clustering might provide evidence of a localized genetic effect or of a contagious process. Alternatively, aggregations might be due to variations in underlying risk. Either effect may be highly localized (as with a single familial cluster or a single environmental hazard) or may be widely disseminated. The statistical analysis is not capable of distinguishing these essentially different mechanisms, though different tests will be more sensitive to one rather than another.

We aim in this section to give a brief and relatively abstract overview of the methods available; further details of several of the methods may be found in **Clustering**.

Direct Methods

A set of rates or risk estimates, whether in discrete or continuous form, may be regarded as a risk function θ over geographic space and clustering should appear as some kind of nonuniformity of this function. Many functionals of θ suggest themselves as possible statistics to test for nonuniformity and to some extent the kind of alternative for which they should be powerful is intuitively obvious.

Thus, to detect a single isolated cluster, extremum statistics would be appropriate. These might include, for discrete areal data, occupancy statistics based on a large count in one or more areas [43], and for continuous case–control data, an analog in the form of the maximum height of the RRF estimated by density estimation [87] and tested under a permutation hypothesis. For continuous time, the **scan statistic** [66, 73] counts the maximum number of cases within a fixed length window as it moves through the study period; the distribution theory is analytically difficult [49, 95].

One of the problems with tests based on discrete areal data is that a cluster straddling two or more adjacent areas may be completely missed. A geographic analog of the scan statistic would solve this problem, but is presumably even less tractable analytically than in time, partly because of the dimensionality difference and partly because it is essential to allow for variation in population density. This is of minor importance, however, given that **Monte Carlo** testing provides a way to execute even the most complicated of tests.

The Geographical Analysis Machine of Openshaw [75] is effectively a scan test, though it was derived more by empirical than theoretically well-founded considerations. By varying the size and location of the scanning window, it entails a considerable amount of computation; the criterion of clustering is based on statistical significance. More recently, Anderson & Titterington [2] have used a method based on observed frequencies and applied it to case–control cancer data in South Lancashire. It adjusts the size of the scanning window at each point of $\mathcal{R}$ to ensure that it contains a constant expected number of cases under H_0; this involves extensive numerical integration.

If interest is more in general heterogeneity of risk, it would be more appropriate to use a dispersion statistic of some sort. For areal data this entails determining whether there is "extra-Poisson variation", i.e. whether the Y_i are appreciably different from the e_i. The Potthoff–Whittinghill test has recently become very popular with epidemiologists [80]. As a likelihood score test it is asymptotically locally most powerful, but it is hard to see why it should be better than the deviance statistic $\sum\{e_i - y_i + y_i \ln(y_i/e_i)\}$ when the null hypothesis is not nearly true and the e_i are moderately large.

For continuous data we can compute a suitable measure of overall dispersion, such as the weighted variance of $\hat{\theta}(x, y)$:

$$T_{\text{var}} = \int \int_{\mathcal{R}} \pi(x, y)\{\hat{\theta}(x, y) - 1\}^2 \, \mathrm{d}x \, \mathrm{d}y.$$

This is similar to the "integrated squared difference statistic" used by Anderson & Titterington [2], with rather different weighting which reflects the extent to which population density relates to the local information.

Distance-based Methods

For many problems in statistics, inverse sampling provides an alternative mode of analysis. In the clustering context, we may ask "What distance d from a given point P includes the nearest x cases?" rather than "What is the number x of cases within a distance d of P?". This gives rise to a class of tests based on nearest neighbor distances (NND) [33]. The simplest example, designed for case–control data, counts the number of individuals among the k nearest neighbors of each case that are cases (as opposed to controls). Cuzick & Edwards give analytical results for the null distributions of the different tests and evaluate their power. Further details are given in **Clustering**. The tests have been widely used in epidemiologic investigations. A related method for areal data, due to Besag & Newell [7], considers each case in turn and aggregates the areas around it that are necessary to include the xth nearest case. Tests of this kind have the feature that they adapt the scale on which they seek to detect clustering to varying population density; this may or may not be an advantage according to the clustering mechanism envisaged.

An historically earlier class of tests forms a kind of dual to the NND test in that they count the number of pairs of cases that are close in some sense. The original idea is due to Knox [59] and relates to space–time clustering. Because this is effectively detecting an **interaction** between the time and space variables, it can condition on the marginal distributions in time and space and so circumvent our ignorance about these distributions. To put it another way, the test uses the information on the marginal distributions already present in the data by asking the question "Given the number N_{T} of pairs of cases close in time and the number of pairs N_{S} close in space, what should be the number N_{TS} of pairs close in both time and space?" In fact, the distribution of N_{TS} depends on complex aspects of the configuration of the points in space and time, but Knox conjectured that N_{TS} should have approximately a Poisson distribution with mean

$$\mathrm{E}[N_{\text{TS}}] = N_{\text{T}} N_{\text{S}} \Big/ \binom{n}{2},$$

where the denominator is simply the number of pairs in the set of all n cases considered.

David & Barton [34] demonstrated that, in many situations, this conjecture is well-founded and derived expressions for the variance of N_{TS}. In a number of combinatorially impressive papers, the analysis has been extended (i) to allow for **latent periods** [79]; (ii) to permit a more general measure of closeness than the indicator function originally proposed by Knox [67]; (iii) to the analysis of cross-clustering of events of different types [58]; (iv) to a range of different distance categories [82]; and (v) to a permutation test for space-only clustering using a sample of controls [77, 78]. More recently, Jacquez [52] proposed a version in which closeness was defined in terms of belonging to the set of k nearest neighbors. The power advantages claimed for this may be practically important, though ultimately dependent on the form of the alternative.

Knox's original space–time test remains very popular, but most of these extensions have been used rather little. The space-only test (v) is particularly worthy of more attention, providing as it does an alternative to the Cuzick–Edwards test.

The power of the Knox-type tests is controversial. Barton et al. [5] demonstrated that the original space–time test is remarkably sensitive to the introduction of extra, "offspring" cases if $\mathbf{E}[N_{\text{ST}}]$ is small under the null hypothesis. Chen et al. [23], however, concluded that the test was not very powerful, though this seems to have been due to latent periods that were not allowed for in the analysis. Bradshaw [16] performed extensive simulations to estimate the power under a similar alternative and concluded that using a general continuous, distance-based closeness measure offered rather little improvement over a well-chosen step-function.

Spatial Relationship

The modeling of spatial structure suggests a number of tests based on estimates of spatial similarity. Theoretical development is possible as long as rates are modeled using the **multivariate normal distribution** as an asymptotic approximation to frequency data; the normal family is the only one that has an analytically tractable multivariate form, so that attempts to extend analytical methods to other families inevitably make limited progress.

Under the normal model the distribution of the data is completely specified by the **covariance matrix** which, in the spatial context, will be constructed by reference to postulated autocorrelations. These may be expressed as functions of distance, adjacencies of neighboring areas, lengths of common area boundaries, or other measures. To some extent these will be chosen for mathematical convenience, but the scientific relevance should not be overlooked: Euclidean distance may be important in some contexts and to ignore it could be misleading; in other contexts a measure of degree of adjacency may better reflect the variation of risk with population density.

Different structures in a model for spatial data are reflected in the numerous different tests available. Cliff & Ord [27] give a comprehensive account, though epidemiologic application requires attention to the need to take account of differing population sizes in different areas. This can be done by suitable modifications using weights, or by applying the methods to rates which have been standardized in respect of their sampling variability. Walter [99] reports an empirical investigation of the power of three popular tests of this kind. Munasinghe & Morris [74] use (local) estimates of "regional spatial autocorrelation" to identify particular locations with suspected clustering.

Issues of Interpretation

Much has been written on the interpretation of clusters (*see* **Clustering**; **Geographic Patterns of Disease**). An essential problem is that clusters are mostly reported *post hoc* and it is therefore impossible to assess their statistical significance formally. To say that a cluster is unusual begs the question of the reference set: an extreme that would be unusually high in a single administrative district might well occur quite frequently in a national investigation. From a statistical point of view, it would seem to be desirable to investigate the tendency of a disease to cluster by systematic analysis of a case register (*see* **Disease Registers**). Opinions are divided as to whether this is a good idea [90]. Certainly the investigator should have some idea of what to do if a new cluster is detected and ideally should work to an appropriate protocol.

Choice of Statistical Procedure

It is clear, even from the brief overview in this article, that there is a plethora of different methods for addressing questions raised by geographical data in epidemiology. Even allowing for the multiplicity of these questions and the different types of practical situation arising, it must be the case that some of the methods are worse than others and should be discarded. Very few studies have attempted to assess the comparative characteristics of competing methods and new ones are often introduced without any justification, either theoretical or empirical. We may consider optimality of the relevant procedures at three levels.

Theoretical Considerations

Because the underlying models are complicated it is difficult to obtain theoretical results on power, for example. Nevertheless, there are some guiding principles that should indicate whether a method is likely to work well. As discussed above, the principal of these is that any sensible method should recognize the importance of population density variation. This is important not only in relation to a satisfactory control or comparison group, but also because of the great variation in local information. Thus the homoscedasticity assumptions of geophysical methods such as kriging (*see* **Statistical Map**), for example, make them unsuitable for epidemiologic data unless suitably modified. Epidemiology is concerned essentially with counting people rather than measuring continuous quantities.

Another general principle applies to distance-based methods. In essence it is closeness of individuals, not their distance, that is important, yet it is surprising how many analyses compute mean distances, which are inevitably heavily influenced by the least interesting, large values. It is essential that distance-based

methods employ some inverse function to give most weight to the nearest individuals.

Many analyses are bad simply because they violate these principles and lose power or efficiency as a consequence. A smaller number are actually wrong as a result of serious statistical errors, perhaps concerned with sampling theory. This may occur, for example, when small areas are sampled randomly and assumed to be typical of areas in which index cases reside. This is almost certainly never the case, since the latter are **sampled with probability proportional to size** and administrative areas vary in size very considerably. Moreover, they do so in a way that is highly related to other geographic variables, such as population density. This can lead to artifactual associations which are highly misleading [11].

Statistical Performance

Frequently, it will be unclear which of a number of theoretically acceptable methods is best in the sense of having the best power or efficiency. It will very often be necessary to resort to **simulation**; this is a relatively straightforward way to address the issue, though it is not always easy to summarize the output from simulation experiments.

Some authors compare procedures by looking at the significance levels achieved in application to particular data sets, implicitly supposing that a smaller ***P* value** is evidence of a better test. Unfortunately, this is not so and it really is necessary to examine test performance on a large number of data sets simulated under a known alternative. Power is the usual performance characteristic considered, but it is worth remarking that the expected significance level (ESL) of Dempster & Schatzoff [35] has a number of advantages, including simplicity of simulation and the removal of type I error as a parameter of the experiment. Bithell & Dutton [12] follow Stone [92] in using the ESL in extensive simulations of methods for point source analyses.

There is a particular difficulty with Bayesian methods because of the essentially different philosophical standpoint involved. The Bayesian formulates a model on certain assumptions that are subjective, as with the choice of priors. Subject to these assumptions, the analysis will not only be optimal, but uniquely correct in some sense. Appropriate questions about method performance are therefore concerned more with issues of sensitivity than efficiency: how different would the answers be if the underlying assumptions were different in specified respects? On the whole, rather little of the literature on Bayesian methods in geographic epidemiology seems to address such issues.

Parameter Choice

Frequentist analyses also incur a problem of parameter choice, in that most analyses, even within a class known to work well in theory, will have one or more "tuning parameters". Probably the most important of these are the class of distance scale parameters: for example, how close is "close" in a clustering test? The distance scale parameter is intrinsic to every geographic analysis and appears in the guise of smoothing parameters, covariance functions, and so on. Other quantities which may have to be chosen in advance of the analysis include an analogous time scale parameter, study region size, age, and diagnostic groups. The practical choice of such parameters should ideally be informed by knowledge of the disease process under consideration. In practice this may be difficult and it will be tempting to do several analyses, with the obvious dangers of multiple testing. Allowance for multiple testing by parameter variation is always possible using Monte Carlo methods, but it does, of course, sacrifice power.

Some Studies to Date

There have been rather few systematic comparative studies of different methods of analysis to date. Chen et al. [23] and Walter [98] have carried out studies of the statistical properties of a limited number of tests. More general issues – involving the problems of parameter choice discussed above – are more difficult to study, involving as they do the decisions of the investigators.

In the spirit of comparative analysis, the Childhood Cancer Research Group in Oxford released a major set of childhood leukemia data in standard format to interested investigators, who reported the results of their differing analyses in a single volume [42]. There was no element of competition in this exercise, however, and, since the data were real, it was not possible to say which investigators had the "right" answers: simulated data sets are required to answer such questions.

The **International Agency for Research Against Cancer** have published the results of a "blind trial" in which investigators were presented with simulated data sets incorporating clustering known only to the organizers [1]. The results make it clear that the investigators' strategies and choice of test parameters are at least as important as the statistical properties of the procedures. This reflects real life, but makes it difficult to extrapolate conclusions to the way methods would perform in the hands of other investigators. Interestingly, no investigators in this experiment chose to use Bayesian methods, even though there was quite a lot of prior information about the distributions of the parameters governing the construction of the data sets.

Conclusion

We conclude from this discussion, as have others [100], that there is an urgent and widespread need, not for more elaborate statistical methods, but for clear principles by which existing methods should be judged, together with carefully designed simulation experiments where appropriate.

Geographic Patterns of Disease

The study of geographic patterns of disease is part of the classic triad in **descriptive epidemiology** of "time, person, place". Here, place is used as a surrogate for the mix of lifestyle, environmental, and possibly genetic factors that may underlie variations in rates of disease across populations. The purpose is both to *describe* such variations and to identify possible *causes* that could explain them.

Of course, apparent geographic variations in disease rates may be artifactual rather than real. Problems may occur either with the enumeration of cases (numerator) or with the population at risk (**denominator**), or both. Thus spurious geographic variations in disease could reflect differences between populations in case definition, completeness of ascertainment, diagnostic accuracy, and coding or (for mortality) survival rates. Enumeration of the population (e.g. at **census**) may be incomplete, or recent migration may distort population estimates. Great care is therefore required in interpretation. Despite these difficulties, publications such as *Cancer Incidence in Five Continents* [27], and international mortality statistics (*see* **Mortality, International Comparisons**) compiled by the **World Health Organization**, have provided an invaluable starting point for epidemiologic enquiry.

The analysis of geographic patterns of disease depends crucially on *scale*. Whereas broad-scale patterns may be apparent at an international level, for example, differences between developed and developing countries in the incidence of infectious diseases such as malaria, and in cardiovascular diseases [44], other patterns may only be apparent at a *local* level. These will include, for example, clusters of disease (*see* **Clustering**) and possible variations in disease risk near putative point sources of environmental pollution.

In this article we briefly discuss disease variations both at the broader and at the local (small-area) scale. We review issues involved in disease mapping (the usual means of presenting descriptive geographic data on disease occurrence) and discuss some of the problems associated with geographic **correlational studies (ecologic studies)**. Here the aim is to explore geographic variation in disease in terms of underlying spatially varying "risk factors". The emphasis is on **small-area** applications, where a number of recent advances in methodology have been made.

International Variations in Disease

International differences in disease occurrence may give important clues as to etiology, which may then be further studied in individual-level studies (e.g. cohort–control or case–control). Thus, in the Seven Countries Study, Keys [24] described large differences in population saturated fat intakes, which were predictive of population differences in the occurrence of coronary heart disease. The INTERSALT Study found cross-population differences in average blood pressure levels, and difference in blood pressure with age, that were associated positively with average levels of salt intake (measured by urinary sodium excretion); a similar positive relationship was also found at individual level [17]. Other examples include the incidence of malignant melanoma and multiple sclerosis, both of which are strongly related to latitude. While this relationship is inverse for melanoma (i.e. a tendency for higher rates near the equator, reflecting greater exposure to sunlight [19],), it is positive for multiple sclerosis (i.e. low incidence in countries near the equator [26]).

Migrant Studies

Migrant studies represent a special case of geographic study. Here, the disease experience of individuals or groups of people is examined as they move from one location or country to another. This affords a unique opportunity to examine the extent to which environmental or genetic influences might determine geographic variations in disease risk. Whereas genetic factors are important in determining which *individuals* become sick, at the population level, overwhelmingly, environmental and lifestyle factors predominate [33]. Thus, in the case of multiple sclerosis, migrants moving from a high risk to a low risk area retain their higher risk if migrating after the age of around 15 years, but attain the risk of the host country if migrating at younger ages [26]. These findings are compatible with an infectious etiology of multiple sclerosis, with infection acquired in childhood. Another example is the low levels of blood pressure, with little or no rise with age, found among

remote and isolated population groups around the world [17, 31]. Blood pressures are found to increase rapidly with migration to an urban environment [31], again indicating the overwhelming importance of environmental factors in determining the unfavorable blood pressure pattern among populations.

Local Variations in Disease

Variations in disease incidence or mortality at national [23] or subnational [20] level have been described, usually in the form of a disease atlas (see the section on *Disease Mapping*, below). Here we briefly address the occurrence of disease at the local (**small-area**) scale. Although in this context no satisfactory definition of the term "small area" exists, Cuzick & Elliott [10] suggest a working definition as follows:

> As a rough guide, any region containing fewer than about 20 cases of disease can be considered a small area ... Many cancers have annual incidence rates of around 5 per 100 000, so for a collective period of 5 years a small area constitutes a population of around 100 000 or fewer. In some instances, such as a cluster of disease in a remote area or small village, it could be much less, but usually populations of at least 10 000 are needed to form an aggregation of minimal size.

Of course, populations could be much smaller if the disease experience over many such areas is of primary interest – for example, in small-area disease mapping (see next section).

Disease Clusters and Clustering

A problem commonly facing public health authorities is how to deal with reports of apparent disease excess in their locality (i.e. disease "clusters"; *see* **Clustering**). These reports may subsequently be linked to a putative pollution source. This complicates interpretation since, for post hoc enquires of this type, formal statistical testing is no longer valid. Although there is little potential for isolated cluster investigations to yield new information on the cause of disease, nonetheless the public health authorities often feel compelled to respond. A careful review of cases, and selection of an appropriate **denominator** and time frame, may result in risk estimates (observed/expected ratios) that are close to 1. This is despite the potential for **bias** towards elevated risk ratios (*see* **Relative Risk**) – areas at apparently "low" risk do not come to the attention of the authorities! In some instances, replication of the study in other similarly polluted areas (if such can be found), or in a different time period, may be the only feasible way forward. It can also be helpful to place an alleged "cluster" in a wider context by carrying out small-area disease mapping across a larger region (see [43] for a recent example).

An alternative approach to the study of a single disease cluster is to examine more generally for evidence of clustering. Such evidence for Hodgkin's disease has been cited in support of ideas of an infectious etiology [1], although other explanations, including artifacts related to diagnostic coding, population mobility, or variations in birth rates, are also possible [10, 18].

Small-area Studies Near Sources of Environmental Pollution

Recently, high-resolution geographically referenced routine health data (*see* **Vital Statistics, Overview**) have become available in certain countries. Together with advances in computing and in statistical methodology, this has led to the development of largely automated systems to examine the distribution of disease near point sources of environmental pollution. In the UK, the Small Area Health Statistics Unit (SAHSU) has been established specifically to: respond rapidly to reports of disease excess ("clusters") near sources of environmental pollution; carry out studies of health statistics more generally around sources of pollution; carry out descriptive geographic studies at small-area level; and develop the methodology. Recent studies include an investigation of cancer incidence and mortality near a pesticide factory following media reports of excess cancers in the vicinity [43], and a national study of cancer incidence near radio and television transmitters [10] following reports of a leukemia excess near one of the transmitters [13] (*see* **Leukemia Clusters**).

A major problem in the interpretation of such studies is the issue of socioeconomic **confounding**. Measures of social deprivation (calculated from the census statistics) have been shown to be powerful predictors of the occurrence of disease [5], including stomach and lung cancer (though not leukemia). Deprived areas do not occur randomly throughout

a region, but tend to coincide with industrial sites and correlate with higher smoking rates. Failure to account for social deprivation could thus seriously bias investigation of other lifestyle or environmental risk factors and ill-health. This is illustrated by results of a national study of cancer risk near municipal solid waste incinerators in Great Britain [16]. **Excess risk** was found for a number of cancer sites, including stomach and lung, that persisted after adjustment for deprivation at the small-area scale. However, in the areas with available data, a similar excess was found also for the period before the incinerators were operational. This indicated the presence of **residual confounding** that had not been fully accounted for in the statistical analysis [16].

Disease Mapping

Maps have long been used to describe geographic patterns of disease (*see* **Mapping Disease Patterns**). For example, Stocks, in a series of atlases published in the 1930s, described the geographic variation in cancer mortality across counties in England and Wales (reproduced in [38]). A survey in 1991 [42] identified 49 international, national, and regional disease atlases; more recent examples include those by Swerdlow & dos Santos Silva [38] and Bernardinelli et al. [4]. Such maps typically show standardized mortality or incidence ratios (*see* **Standardization Methods**) for geographic areas such as countries, counties, or districts. The rate in area i is estimated by O_i/E_i, where O_i is the observed number of deaths or incident cases of disease in the area (assumed to follow an independent **Poisson distribution**) and E_i is the expected number of cases (calculated by applying age- and sex-specific death or disease rates to the census population counts for the area).

Maps convey instant visual information on the spatial distribution of disease and can identify subtle patterns which may be missed in tabular presentations. Their purpose is usually to display variations in ill-health (for example, related to the underlying sociodemography), formulate etiologic hypotheses, aid **surveillance** to detect areas of high disease incidence, and help place specific disease clusters and point source studies in proper context.

While disease maps have both visual and intuitive appeal, considerable caution is required to avoid overinterpretation. Apparent geographic variation in rates may simply reflect between-area differences in the quality of reporting, diagnosis, and classification of disease, or confounding due to **ethnic** and socioeconomic factors. Furthermore, disease maps implicitly assume that risk is homogeneous within areas. This is unlikely for the large areas used in many national and international atlases, and may result in misleading inference about individual-level risk.

There is currently considerable scientific interest in exploring more *local* geographic variations in disease. For example, in the UK, small-area mapping is often carried out at the level of electoral ward (average 5000 people) and census enumeration district (400 people).

Disease mapping at the small-area level raises a number of statistical issues. For relatively rare events such as death and cancer incidence, the observed numbers of cases tend to be small in areas with low population, and typically exhibit extra-Poisson sampling variation. This may be assessed formally using the Pothoff–Whittinghill test [30] (*see* **Clustering**). The sparseness of population data results in unreliable estimates of the area-specific standardized rate ratios, which may create the impression of spurious geographic variation when displayed on a map. These considerations have led to the use of statistical smoothing techniques, which pool information across areas. **Empirical Bayes** [8, 15] and hierarchical Bayes [7, 39] estimates of area-specific relative risk (*see* **Hierarchical Models in Health Service Research**) represent a compromise between the area-specific standardized rate ratios (*see* **Standardization Methods**) and the overall **mean** for the whole map.

Small-area disease data often exhibit spatial correlation due to the influence of unmeasured or unknown risk factors which themselves vary smoothly in space. Various hypothesis tests are available to assess such spatial **autocorrelation** – for example, the rank-adjacency D-statistic [23] and Smans' test [35].

Figure 1 shows a map of "unsmoothed" (standardized incidence ratio, adjusted for age, sex, and deprivation) and smoothed (empirical Bayes) estimates of brain cancer incidence for 1974–1986 across electoral wards in the West Midlands region of England [14]. As can be seen, much of the random variability is removed by smoothing, especially the apparent high rates found in the large, sparsely populated rural areas. Overall, there is only weak evidence of heterogeneity across the map

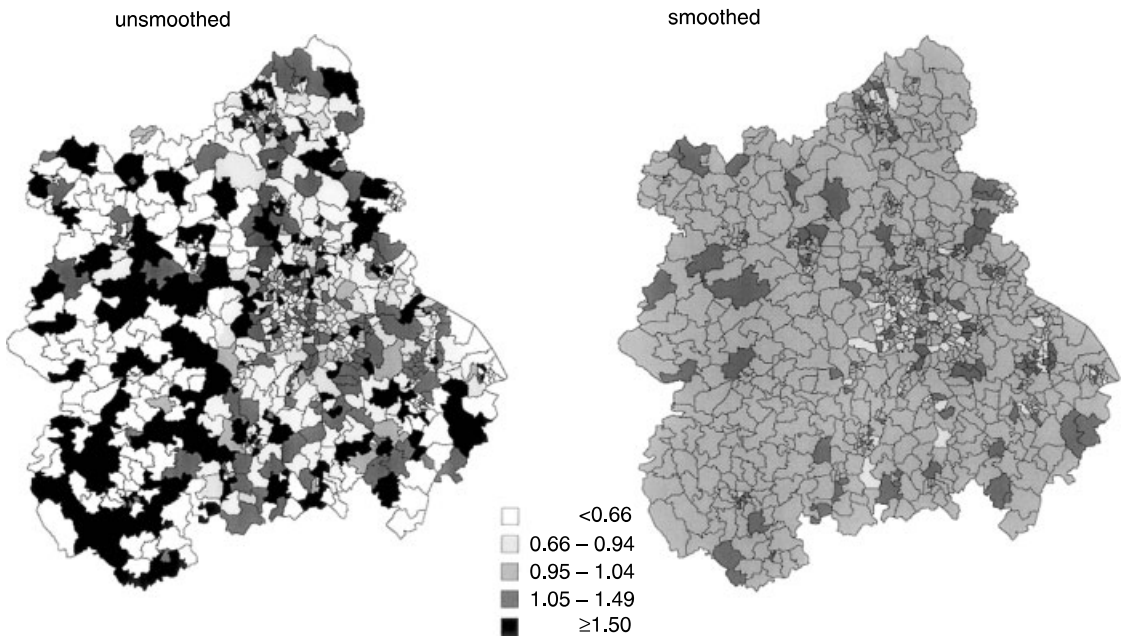

Figure 1 Age-, sex-, and deprivation-adjusted relative risks of brain and central nervous system tumors for electoral wards in West Midlands region, England, age 15–64 years, 1974–1986. Unsmoothed risks (left) and after map smoothing (right) using empirical Bayes method. Reproduced from Eaton et al. [14] by permission of *British Journal of Cancer*

(Potthoff–Whittinghill test; $p = 0.04$), and no evidence of spatial autocorrelation [14].

Bayesian prior distributions for the area-specific relative risks which allow smoothing towards a local mean, rather than the overall map mean, are also used to model spatial interdependence in small-area studies [7, 8, 11, 21, 25, 39]. Implementation of Bayesian hierachical–spatial models has been made feasible by recent computational [36] and *software* developments, namely BUGS [37] – involving **Markov chain Monte Carlo** simulation algorithms: this approach represents the current state of the art in small-area mapping of disease.

Technical Issues Concerning Presentation of Geographic Disease Data

Maps provide a succinct summary of geographic patterns in disease. However, visual perception may be influenced by various features of the map, such as the plotting symbols used (e.g. solid shading vs. hatching, color vs. gray scale) and the grouping of data into categories (e.g. percentiles of the distribution of risk, and numerically equidistant cutpoints) [35]. An empirical study [41] found that the manner of data display may have at least as much effect on observer perception of spatial variation as actual differences in the data. Recently, **nonparametric** mixture distributions (*see* **Contagious Distributions**) have been used to model the underlying relative risk of disease in small geographic areas [34]. This approach facilitates more objective mapping of disease patterns, since areas are categorized according to statistically driven estimation of the mixture components.

The summary statistic used for presentation may also influence visual interpretation of disease maps. Common choices include standardized rate ratios, smoothed relative risks, or ***P* values**. The former tend to yield erratic maps which are visually dominated by extreme estimates of low precision in sparsely populated areas; the latter are criticized for confusing statistical significance with biological importance (*see* **Clinical Significance Versus Statistical Significance**) and tend to overemphasize areas of high population in which even small deviations from the expected disease rate may achieve statistical significance. Significance testing of standardized rate ratios also suffers from the multiple decision problem (*see*

Multiple Comparisons), as each ratio is considered independently of the others on the map.

In our view, maps showing Bayesian **shrinkage estimates** of relative risk represent the best compromise, although it is important to realize that these estimates are not judgment-free. For example, they depend on the functions used to describe the distribution of relative risks across the map, and to define the local neighborhood over which spatial interdependence between the small areas is assumed. However, smoothing ensures that precision of the area-specific estimates is approximately comparable across the map, and Bayesian credible intervals derived from hierarchical models are not subject to the constraints of multiple significance testing. Mapping of posterior functions of Bayesian risk estimates is also possible. For example, a map showing the posterior probability that the relative risk in each area ranks above the **median** [2, 22] conveys information about the size *and* uncertainty associated with each area-specific estimate. Further advances in the application of Bayesian methods to disease mapping, and appropriate display methods, including measures of uncertainty, are to be expected.

Geographic Correlation Studies

Geographic correlation studies are a valuable means of formulating and testing etiologic hypotheses: disease patterns are compared with the geographic distribution of environmental and lifestyle exposures. They are particularly useful when individual-level measurements of exposure are either difficult or impossible to obtain for use in epidemiologic study (for example, air pollution) or are measured imprecisely (for example, diet, and sunlight exposure). (See [19] for further discussion and [32] for a review of the statistical methods.)

Examples of broad-scale **ecologic studies** are given in the section on *International Variations in Disease*. In some cases – for example, sunlight and melanoma, salt and blood pressure – the ecologic relationships have also been demonstrated at individual level. However, the potential for *bias* in such ecologic studies [19, 32] should be recognized. Exposure *within* areas is often heterogeneous; thus the ecologic (average group-level) association between exposure and disease may not equate to the relationship in individuals. To assume otherwise is to commit the **ecologic fallacy** [28]. Small-area studies may be less prone than broad-scale geographic studies to ecologic bias since the group data are closer to the level of the individual. Nonetheless, positive findings arising from ecologic analyses usually require replication in other data sets and, where possible, at individual level.

As already noted, a major problem in small-area disease studies is the potential for confounding by socioeconomic variables. Adjustment may be made by including, say, a deprivation score such as the Carstairs [6] index (based on small-area census statistics) as a **covariate** in the ecologic regression analysis. Alternatively, indirect standardization of the expected small-area disease counts can be done by stratifying on the socioeconomic status of the areas as well as on age and sex (*see* **Stratification**). Modeling of spatial autocorrelation between small areas in an ecologic regression study also provides some control for the effect of confounding due to location [9], but further development of these methods is required, and in particular their application to "real" data sets.

Interest has focused on ecologic designs which combine data on the general population with individual-level survey data to improve estimation of group exposure [29, 40]. Methods to adjust for random measurement error in exposure are also receiving attention [3]. Such techniques should enhance the ability of ecologic analyses to estimate the *size* of exposure–disease relationships, not merely to identify the possible presence of such associations.

Summary and Conclusions

The study of geographic patterns of disease plays a central role in descriptive epidemiology, and has led to some notable etiologic insights. However, geographic studies are associated with major problems of data quality, bias, confounding, and presentation which can seriously complicate their interpretation. The methodologic challenge is clear: to produce objective, statistically valid analyses of geographic variations in ill-health and its determinants, with particular emphasis on developments to combine the best features of individual-level and ecologic studies. Recent advances, particularly in methods for small-area studies, have begun to address these issues. As such techniques become routinely available, they should enhance our ability to quantify the effects

of environmental pollution (*see* **Environmental Epidemiology**) and lifestyle characteristics on human health.

PAUL ELLIOTT & NICOLA BEST

Geometric Distribution

In a coin-tossing problem, let X be the number of tosses required to obtain a head. The probability that $X = k$, $\Pr(X = k)$, equals $(1-p)^{k-1}p$, $k = 1, 2, \ldots$. Here p, $0 \le p \le 1$, is the probability of obtaining a head in a single toss. The **random variable** X with this probability mass function (pmf) is known to have the geometric distribution. The geometric distribution can also be identified with the experiment of drawing balls from an urn with replacement. Suppose an urn contains b black balls and w white balls. Let X be the number of drawings needed to draw a white ball from the urn; then X is a geometric random variable with $p = w/(b+w)$. For the geometric random variable, the probability $\Pr(X = k)$ is a monotone decreasing function of k. It is evident that $\Pr(X = k+t) = \Pr(X = k)(1-p)^t < \Pr(X = k)$. The random variable X has the memoryless property, i.e.

$$\begin{aligned}\Pr(X > r+s) &= \sum_{j=r+s}^{\infty} (1-p)^j p = (1-p)^{r+s} \\ &= \Pr(X > r)\Pr(X > s),\end{aligned}$$

where r and s are positive integers. The **hazard** function $h(x) = \Pr(X = x | X \ge x)$ is independent of x, $x = 1, 2, \ldots$. The probability **generating function** $G(s)$ of X is $G(s) = \mathrm{E}(s^X) = ps(1-qs)^{-1}$, where $q = 1-p$. We have the probability

$$\Pr(X = j) = \left[\frac{1}{j!}\frac{\mathrm{d}^j G(s)}{\mathrm{d}s^j}\right]_{s=0}.$$

The noncentral **moment generating function** is $G(\mathrm{e}^s)$. The rth noncentral **moment**, μ'_r, of X, namely $\mu'_r = \mathrm{E}(X^r)$, is

$$\sum_{j=1}^{\infty} j^r (1-p)^{j-1} p = \left[\frac{\mathrm{d}^r G(\mathrm{e}^s)}{\mathrm{d}s^r}\right]_{s=0}.$$

The central moment, $\mu_r = \mathrm{E}(X - \mu'_1)^r$, $r = 1, 2, \ldots$, has generating function $p\exp(-qs/p)(1 - q\mathrm{e}^s)^{-1}$, $t < -\ln(1-p)$. Using this central moment generating function, the following recurrence relations between the central moments can easily be established:

$$\mu_{r+1} = q\frac{\partial \mu_r}{\partial q} + \frac{rq}{p^2}\mu_{r-1},$$

with $r \ge 1$, $\mu_0 = 1$ and $\mu_1 = 0$. Thus the mean of X is

$$\mu'_1 = \mathrm{E}(X) = \sum_{j=1}^{\infty} j(1-p)^{j-1}p = \frac{1}{p},$$

and the variance of X is

$$\mathrm{var}(X) = \sum_{j=1}^{\infty} j^2(1-p)^{j-1}p - \mu_1^2 = \frac{1-p}{p^2}.$$

For instance, for an unbiased coin ($p = 1/2$) the number of tosses until a head appears has an expectation 2 and a variance of 2.

Suppose $X_{1,m} = \min(X_1, \ldots, X_m)$, where $X_1, \ldots, X_m$ are m independent copies of X, then $\Pr(X_{1,m} > x) = q^{mx}$, $x = 1, 2, \ldots$; $\Pr(X_{1,m} = x) = \Pr(X_{1,m} > x-1) - \Pr(X_{1,m} > x) = q^{m(x-1)}(1-q^m)$. Thus $X_{1,m}$ is a geometric random variable. Let $X_{2,2} = \max(X_1, X_2)$ and the **range**, $R_2 = X_{2,2} - X_{1,2}$. We have $\Pr(R_2 = 0) = \Pr(X_{2,2} = X_{1,2}) = \sum_{x=1}^{\infty}(pq^{x-1})^2 = p^2/(1-q^2)$. Since $\Pr(X_{1,2} = x, R_2 = 0) = \Pr(X_{1,2} = x, X_{2,2} = x) = (pq^{x-1})^2 = \Pr(X_{1,2} = x)\Pr(R_2 = 0)$, the events $\{R_2 = 0\}$ and $X_{1,2}$ are independent. $\Pr(R_2 = r) = \sum_{j=1}^{\infty}\Pr(X_{1,2} = j, X_{2,2} = j+r) = \sum_{j=1}^{\infty} 2p^2q^{2(j-1)+r} = 2pq^r/(1+q)$, $r = 1, 2, \ldots$. Using the equations

$$\sum_{r=1}^{\infty} 2r\frac{pq^r}{1+q} = \frac{2q}{p(1+q)}$$

and

$$\sum_{r=1}^{\infty} 2r(r-1)\frac{pq^{r-1}}{1+q} = \frac{4q^2}{p^2(1+q)},$$

we obtain $\mathrm{E}(R_2) = 2q/[p(1+q)]$ and $\mathrm{var}(R_2) = 2q(1+q^2)/p^2(1+q)^2$.

Further, $\Pr(X_{1,2} = j, R_2 = r) = \Pr(X_{1,2} = j, X_{2,2} = j+r) = 2p^2q^{2(j-1)+r} = \Pr(X_{1,2} = j)\Pr(R_2 = r)$ for all j and r, $1 \le j$, $r < \infty$; hence $X_{1,2}$ and R_2 are independent random variables. This independence property of the range and the minimum observation is also true for $m > 2$.

M. AHSANULLAH

Gerontology and Geriatric Medicine

We can distinguish some important features of geriatric medicine – a branch of medicine – and gerontology – the study of older people in general, healthy or ill. These include:

1. **Co-morbidity**; older patients typically suffer from complaints other than the presenting complaint, a fact which complicates both treatment and research.
2. An increasing **prevalence** of degenerative disease and sensory impairment, particularly in the later years of life; this has important consequences for treatment, and also for research.
3. The occurrence of almost any disease during this period of life, almost any of which can occur before. Nonetheless, the dementias are a high prevalence disease after age 75 but are almost unknown before age 55. Even when dementia is not at issue, cognitive performance may not be at a level to permit easy treatment or cooperation in research.

The exact age cutoff is arbitrary, and is based on historical sociopolitical considerations rather than on pathophysiological ones. Most research studies use 65 years, although 75 is becoming more popular. The term geriatric medicine itself has been superseded by some variant on health care of the elderly. Within this umbrella, **psychiatry** of old age is included, but there seems to be no specialty of, for example, geriatric surgery.

Statistical Issues

The field of gerontology, here encompassing geriatric medicine, has not spawned any specific statistical methods. Its journals publish papers using standard techniques, but do not stand out from other specialties statistically.

Randomized Control Trial (RCT) and the Elderly

The RCT (*see* **Clinical Trials, Overview**) has become established as the preferred method of evaluating therapeutic alternatives when it is possible to carry it out. The dominant ideology in selecting patients for an RCT has been that patients should be included as clear cases of the disease at issue, and no other (*see* **Eligibility and Exclusion Criteria**). This has brought three problems:

1. Because of the problem of comorbidity, trials recruit disproportionately from younger age groups, even when they do not employ an explicitly or implicitly ageist recruitment policy.
2. Trials exclusively in old age, for instance in dementia, have very high ratios of screened to enrolled patients.
3. High rates of mortality, sometimes from competing causes (*see* **Competing Risks**), have made **intention-to-treat analysis** vital. Dropout in an RCT in older people will seldom be at random.

The inevitable paradox is that older patient groups where most illness occurs have been least studied, and treatments must be used on the basis of optimistic generalization from younger age groups. For instance, in an overview of European studies of thrombolysis after acute myocardial infarction, it was found that patients aged 75 and over represented 33% of those requiring treatment in the population but only 10% of those enrolled in the major trials [1].

The issue of informed consent does not seem to be responsible for this deficit in recruitment. In general, workers in old age research have only seen this as a problem in the field of dementia, and have usually relied on consent from relatives in such trials.

Measurement and Scaling

As mentioned above, this field has to cope with varying degrees of sensory and motor impairment. This has caused workers here to be more interested in problems of measurement (*see* **Measurement Scale**), especially of functional ability, than in almost any other branch of medicine except psychiatry. There is awareness of the problems of constructing measures which span very large ranges of ability in the face of concurrent sensory and cognitive difficulties, but, as yet, no agreement on how to solve them.

Healthy Active Life Expectancy

Although this technique can be applied to all age groups it has been used extensively in gerontology [4]. Sullivan's index [2] takes standard **life table**

methods and attempts to combine information on mortality and morbidity.

Consider $T + 1$ age groups where the age at the start of each group is x_i, with $i = 0, 1, \ldots, T$. Based on the usual life table notation, l_i is the number of survivors to age x_i, L_i the number of **person-years** in age group i, and π_i the prevalence of the health status in question in age group i.

We partition the expectation at age k,

$$e_k = \frac{1}{l_k} \sum_{i=k}^{T} L_i, \tag{1}$$

into a diseased part D and a healthy part H:

$$e_k^{[D]} = \frac{1}{l_k} \sum_{i=k}^{T} \pi_i L_i, \tag{2}$$

$$e_k^{[H]} = \frac{1}{l_k} \sum_{i=k}^{T} (1 - \pi_i) L_i. \tag{3}$$

This device has been seen as a way of measuring and answering the question of whether increases in **life expectancy** have merely led to an increase in the period spent disabled before death, or whether the onset of disability has been postponed in parallel with death itself [4]. Clearly for diseases from which recovery is possible a more complex model is needed [2].

There has also been interest in the question of whether it is possible to estimate the limits on longevity [3]. This has usually taken the form of estimating what changes in q_i (the **conditional probability** of mortality in group i) would be needed to increase life expectancy to 85, 100 years, or beyond.

MICHAEL E. DEWEY

Gestational Age

Gestational age is the duration of a pregnancy. According to the **World Health Organization** (WHO), the duration of gestation is measured from the first day of the last normal menstrual period [3]. The rationale for this is that women are more likely to be able to recall the dates of their last period than they are to know the date when conception took place. Of course, there are circumstances when the opposite may be true.

If women conceive soon after stopping oral contraception, this may happen before they have had a spontaneous period. For women with irregular periods, the relationship between the beginning of their last period and their date of conception may be problematic. Because of this, other means are commonly used to estimate gestational age and hence the likely date of delivery. In settings where ultrasound examinations are standard practice, gestational age is assessed by measuring the biparietal diameter. In less developed countries, the fundal height is commonly used to estimate gestational age, but is generally considered to be unreliable. Finally, the gestational age of babies assessed by examination after birth is known as the "pediatric assessment". Given that none of the methods is perfect, the common practice is to choose the one considered most reliable as the "best estimate" of gestational age for a given woman.

Gestational age is expressed in completed days or weeks, so events occurring 280 to 286 days after the onset of the last normal menstrual period are considered to have occurred at 40 completed weeks of gestation. In calculating the gestational age, WHO stipulates that the first day of the last period should be regarded as day zero and not day one, so days zero to six therefore correspond to week zero. Thus, for example, events in the 40th week of gestation should be described as taking place after 39 completed weeks of gestation.

Within a given gestation, WHO distinguishes between preterm, term and postterm:

1. *Preterm*: Less than 37 completed weeks (less than 259 days) of gestation.
2. *Term*: From 37 completed weeks to less than 42 completed weeks (259 to 293 days) of gestation.
3. *Postterm*: From 42 completed weeks or more (294 days or more) of gestation.

With increasing interest in the preterm period, it is becoming common practice to identify two further categories: extremely preterm, which is less than 28 completed weeks or 196 completed days of gestation; and very preterm, which is less than 32 completed weeks or 224 completed days of gestation [1].

It is recommended that tabulations by week of gestational age group them as 22–23, 24–25, 26–27, 28–31, 32–36, 37–41 and 42 or more completed weeks of gestation [1].

In the past, the word "premature" was used to denote a birth that was either preterm or of low **birthweight** or both, but it is now considered insufficiently precise and therefore incorrect. The definitions above were introduced in the ninth revision of the **International Classification of Diseases** (ICD) [2] and should enable a distinction to be made between babies who are small because they are born too soon and those who are small for their gestational age.

ALISON MACFARLANE

Ghosts

In the analysis of survival data X_i, left truncated at v_i, $i = 1, \ldots, n$ (*see* **Truncated Survival Times**) each observed life time $X_i = x_i > v_i$ "can be considered the remnant of a group, the size of which is unknown and all (except the one observed) with x-values less than or equal to v. (They can be thought of as X_i's ghosts.)". The quotation is (slightly adapted) from Turnbull's [5] use of the concept of *ghosts* to denote the number by which each truncated observation needs to be upweighted to provide the nonparametric maximum likelihood estimator of the survival function (*see* **Turnbull Estimator** for details).

This use of "ghosts" is similar to the handling of **censoring** by Inverse Probability of Censoring Weighted (IPCW) estimating equations, which is analogous to the **Horvitz–Thompson** device [1] in sampling theory introduced into survival analysis by Koul et al. [3] and used extensively by Robins (see [4], but also [2] and [6]). The rationale is again to compensate for the attrition due to censoring or truncation by letting each *observed* event represent not only him/herself, but also the "ghosts" who were not observed.

NIELS KEIDING

Gini, Corrado

Born: May 23, 1884.
Died: March 13, 1965.

Gini was the leading Italian statistician during the first half of the twentieth century. He became a university professor at the age of 26, and held chairs at the universities of Cagliari, Padua, and Rome. He founded *Metron* in 1920, owned the journal until 1962, and directed it until his death. He contributed widely to the development of statistical methods, with applications in **demography**, biometry, sociology, and economics. He was particularly influential in the development of mathematical approaches to descriptive statistics. In 1912, Gini introduced the *mean difference* as a measure of variation within a set of quantities, defined as the mean of the absolute differences between pairs of observations. In 1914, he showed that this is related to the *area of concentration* derived from a *Lorenz curve* representing inequalities in income distribution. (The Lorenz curve relates the proportion of a population, ordered by size of income, to the proportion of total income received by that group.)

PETER ARMITAGE

Gold Standard Test

In attempting to classify individuals as cases or noncases of disease, clinicians usually apply one or more **diagnostic tests**. Typically, however, these tests are subject to **measurement error**, and may thus display less than perfect **sensitivity** or **specificity**.

The term "gold standard" is applied to a test that, theoretically at least, is regarded as being error-free, that is, having 100% sensitivity and specificity. If such a test exists, then it can be used as a basis for comparison for any other candidate test. The gold standard may also be known as a "*reference test*" or method.

Unfortunately, definitive diagnosis through a gold standard will usually require an invasive or hazardous clinical intervention. For instance, while a chest X-ray or CT scan (relatively noninvasive tests) may provide suggestive evidence that a pulmonary tumor is present, a histologic evaluation of a biopsy specimen obtained by surgical intervention is conventionally required to confirm the diagnosis of a malignancy.

In practice, even tests that are consensually regarded as gold standards may be subject to error. In the lung cancer example, there is variation in where and how the surgeon elects to sample potentially malignant tissue; furthermore, there is some subjectivity in the pathologist's assessment of the biopsy material, with the result that inter- and intraobserver variation exists in the final diagnostic classification (*see* **Agreement, Measurement of**; **Observer Reliability and Agreement**). Such variation reveals the fact that the gold standard cannot be perfect.

In clinical practice, therefore, the term "gold standard" is often applied to tests that are regarded as the best available with current technology, even though the best method may sometimes be erroneous. A consequence of assuming a test to be gold standard, even though it is error-prone, is that any other competitor test that is compared with the gold standard will have apparently inflated error rates; in other words, estimates of sensitivity or specificity of a comparison test relative to the gold standard will be **biased** downwards. There is a growing literature on the appropriate analysis of data involving such "alloyed" gold standard tests (*see* **Diagnostic Test Evaluation Without a Gold Standard**)

STEPHEN D. WALTER

Goodman–Kruskal Measures of Association

The popularity of these measures stems from the articles by Goodman & Kruskal that span two decades [1–4]. All are used to examine the association between two categorical variables (A and B, say). The λ and τ measures are suitable for general use, with the measure γ being used when both A and B are ordinal. All are commonly included in computer packages.

The Lambda Measures

The simple idea underlying the λ and τ measures is that it may be possible to predict the category of one variable from knowledge of the category of the other variable.

As an example, suppose that two boys play a game in which boy A thinks of some living thing. Boy B has to guess whether it is a creature or a plant. If B knows that A thinks of plants on 60% of occasions, then one strategy for B would be to guess "Plant" every time (with a 60% success rate). However, if B is allowed to ask a question such as "Does it have legs?", then B's subsequent guess will be much more accurate!

Suppose that we know that, for variable A, category m is most frequent. In the absence of other information we would guess that a new individual belonged to m. However, if told that the individual belongs to category j of variable B, then we could examine all past records for this category. If these records showed i to be the commonest category of A for these individuals, then we would guess i and not m. Unless A and B are independent, this method reduces the probability of a guess being in error. The λ and τ measures are said to measure the *proportional reduction in error* (PRE), with 0 corresponding to independence and 1 corresponding to the complete elimination of error (e.g. as a result of the question "Can it move?"!).

Consider the data of Table 1. Knowing nothing of B we guess A_1 with Pr(error) $= 144/300 = 0.48$. If we know that an individual belongs to the second category of B, then we guess A_2 and otherwise guess A_1. The probabilities of the three categories

Table 1 Example data

	A_1	A_2	Total	Most common category	Guess	Probability of error
B_1	16	14	30	1	1	$\frac{14}{30}$
B_2	38	62	100	2	2	$\frac{38}{100}$
B_3	102	68	170	1	1	$\frac{68}{170}$
Overall	156	144	300	1	1	$\frac{144}{300}$

are estimated by 30/300, 100/300 and 170/300, so that the overall probability of an error is now:

$$\left(\frac{14}{30}\times\frac{30}{300}\right)+\left(\frac{38}{100}\times\frac{100}{300}\right)+\left(\frac{68}{170}\times\frac{170}{300}\right)=\frac{120}{300}=0.40.$$

Hence the proportionate reduction in error is given by:

$$\lambda_A=\frac{\frac{144}{300}-\frac{120}{300}}{\frac{144}{300}}=\frac{144-120}{144}=\frac{24}{144}=\frac{1}{6}.$$

The suffix A indicates that we are predicting the category of A from that of B. Suppose, instead, that we are asked to guess the category of B, knowing that of A. There is an immediate problem! For *both* categories of A we would guess B_3, and so with this procedure there is no reduction in error. Formally,

$$\lambda_B=\frac{\frac{130}{300}-\left\{\left(\frac{54}{156}\times\frac{156}{300}\right)+\left(\frac{76}{144}\times\frac{144}{300}\right)\right\}}{\frac{130}{300}}=\frac{130-130}{130}=\frac{0}{130}=0.$$

The problem is caused by the dominating size of a single category. The value of λ is therefore most informative when the categories are roughly equally likely.

In cases where it is equally reasonable for the predictions to proceed in either direction, the hybrid statistic λ is used. This combines the two numerators and denominators:

$$\lambda=\frac{24+0}{144+130}=\frac{24}{274}=0.09.$$

The Tau Measures

The τ measures differ from the λ measures by using a different guessing strategy. Instead of always choosing the most common category, categories are guessed in proportion to their known probabilities of occurrence. Although the resulting predictions are less successful, and the resulting formulae are more complicated, the problems with unbalanced category frequencies are avoided. The value 0 can only occur for a table displaying perfect independence. For the example data $\tau_A = 0.31$, $\tau_B = 0.18$, and $\tau = 0.24$.

Note that $\tau > \lambda$ tells us nothing about their relative merits.

The Measure Gamma

This too can be viewed as a PRE measure. It is suitable only for cases where both variables have ordered categories, as in the data of Table 2, which are obtained from wave 1 of the British Household Panel Study.

Suppose we predict that those in better health will also be more satisfied with their job. To test this idea we need to look at *pairs* of individuals. The usefully informative pairs belong both to different health categories and to different job categories. There are 962 individuals who felt satisfied and in excellent health. There are $(781 + 329 + 100 + 67) = 1277$ individuals who felt both less healthy and less satisfied. If we choose one individual out of each of these two groups (which we can do in 962×1277 different ways), then we will have a pair of individuals who match the prediction. There are other pairs also. The total number of concordant pairs is C:

$$C = (962 \times 1277) + \{1213 \times (329 + 67)\} + \{447 \times (100 + 67)\} + (781 \times 67) = 1\,835\,798.$$

However, there are also discordant pairs. The total number, D, is given by:

$$D = \{420 \times (447 + 781 + 62 + 100)\} + \{1213 \times (447 + 62)\} + \{329 \times (100 + 62)\} + (781 \times 62) = 1\,302\,937.$$

Table 2 Job satisfaction and self-reported health

	Self-reported health		
	Excellent	Good	Not good
Satisfied with job	962	1213	420
Neutral about job	447	781	329
Not satisfied with job	62	100	67

The statistic γ is given by

$$\gamma = \frac{C - D}{C + D}.$$

The range of possible values is from -1 (complete discordance) to $+1$ (complete concordance). For the given data $\gamma = 0.17$. The data suggest a very weak positive association between health and job satisfaction.

The significance of any of these measures can be assessed by comparison with its standard error. Software packages (such as SPSS and SAS) routinely report standard errors and tail probabilities in addition to the measure values.

G. UPTON

Goodness of Fit in Survival Analysis

As in contexts other than **survival analysis**, the idea of **goodness of fit** is to provide a more or less formal indication that some or all of the modeling assumptions made can be considered reasonable. Goodness of fit is related to but distinct from; regression **diagnostics**, **robust regression**, influential data analysis, **cross-validation** and, in particular, the **prediction** problem as quantified by R^2 measures. None of these are considered in this review, although it would seem important to point out that R^2-type prediction measures [26, 41, 46] are not goodness of fit measures as is very widely believed. Korn & Simon [27] provide some discussion on this. We will limit ourselves here to the observation that whereas a very poor fit will in general lead to a low value of R^2, the converse is not so, a simple example coming from linear regression with near zero slope and large residual variance, in which the fit may be perfect but we would anticipate the value of R^2 to be small.

Goodness of fit techniques help us address the very limited question of whether or not the observed data appear to come into conflict with one or more of the basic assumptions underscoring the adopted analytic approach. In this review the major part of our attention is on the **proportional hazards** model. This is for two reasons. First, the literature concerning parametric approaches is more classical and well reviewed elsewhere (*see* **Parametric Models in Survival Analysis**). Secondly, the proportional hazards model has become quite overwhelmingly the model of choice in applied studies so that there is much less interest in the goodness of fit question for parametric models. This having been said, it is quite likely that there will be renewed interest in parametric modeling in the future, and we include some discussion on the goodness of fit problem below.

Many tests have been proposed for testing the proportional hazards assumption, focusing on some feature of the assumed time independence of the regression effect, on the form of the link function, on the functional form of the covariates, and sometimes all of these. It needs to be stressed that real departures from proportional hazards can manifest themselves in different ways; an incorrect functional form appearing as a time-dependent effect, for example. Trying to separate out the different types of departure is most often not possible. So, although it is worthwhile considering tests having good power against a particular kind of departure, we ought be cautious about interpreting significant results; the departure can easily be of a quite different nature.

In the following sections we organize the different procedures under the headings omnibus tests, directional tests, and graphical techniques. A test designed to detect general nonspecific departures from the null hypothesis is called an omnibus test. In some cases a test might be especially designed to have high power against departures in certain directions; we refer to these as "tests for specific alternatives", although some authors call them "directional tests" (see, for example, Lawless [29]). Graphical techniques often provide an easy check on model assumptions. Although they are not formal tests, they are an important aspect of goodness of fit tests, and can sometimes be combined with formal ones to obtain significance levels. Finally, tests based on the empirical distribution function such as **Kolmogorov–Smirnov tests**, Cramér–von Mises type tests and the Anderson–Darling test are well known (*see* **Kolmogorov–Smirnov and Cramer–Von Mises Tests in Survival Analysis**). However, their generalization to arbitrary **censoring** is difficult, unless the censoring is type I or type II (*see* **Level of a Test**). The interested reader can find those in Lawless [29] and Andersen et al. [4]. Alternatively, resampling techniques could be used (*see* **Bootstrap Method**).

Notation and Data Sets

In the following, let T denote the failure time random variable. In a survival study with n subjects, let $T_1, T_2, \ldots, T_n$ be the true failure times, and $C_1, C_2, \ldots, C_n$ the potential **censoring** times for the individuals $i = 1, 2, \ldots, n$. We observe $X_i = \min(T_i, C_i)$ and $\delta_i = I(T_i \leq C_i)$ for each i. Denote $Y_i(t) = 1$ if $X_i \geq t$ and 0 otherwise. Often, we will suppose that the failure time of each subject is related to a vector of **covariates**, or **explanatory variables**, $\mathbf{Z}_i = (Z_{il}, \ldots, Z_{ip})', i = 1, 2, \ldots, n$.

We illustrate some of the techniques on two data sets. The first concerns the well-known Freireich et al. [17] study comparing two treatments in leukemia. The data consists of remission times in

weeks of 42 patients, 21 having received 6-MP and 21 having being treated with placebo. These data, used to illustrate the proportional hazards model in Cox [12], are widely believed to fit the model well. In contrast, the second data set, analyzed by Stablein et al. [49], indicates clear departures from model assumptions. These data concern a clinical trial in gastric carcinoma in which 90 patients were treated; 45 treated by chemotherapy alone and 45 treated by chemotherapy plus radiotherapy.

Parametric Models

There are various ways to assess the fit of parametric models without covariates. When covariates are included, it is often possible to adapt the methods to deal with this. For more general situations, very little has been done when compared with the proportional hazards model, and it is fair to say that such models are not often used in practice. We consider goodness of fit tests for several commonly seen parametric models without covariates used in survival analysis. These include the **exponential** model, the **Weibull** and **extreme value** models, and the **lognormal** models. Notice that the problem of testing a lognormal model is equivalent to that of testing a normal model.

Graphical Tests

The density or hazard functions are too noisy to estimate nonparametrically without resorting to some kind of smoothing technique (*see* **Smoothing Hazard Rates**). As a general principle, such smoothing requires some skill on the part of the user, and the whole subject is rather too vast to be given any coverage here. For our purposes we will focus attention on a nonparametric estimate of the survivorship function, either the **Kaplan–Meier** estimate or the **Nelson–Aalen** estimate.

Once we have an estimate of the survivorship function $S(t)$ in hand, then we can usually derive simple graphical techniques which cannot only provide some indication as to the goodness of fit but also some very simple estimates of the unknown parameters (*see* **Graphical Displays**; **Hazard Plotting**). Even if such estimates are only to be used as starting values to an iterative cycle in **maximum likelihood** estimation, this alone can be valuable computationally.

We can illustrate the above via some well known models. For the exponential distribution with parameter λ, we can plot $\log \hat{S}(X_i)$ against X_i. Under the model this will be a straight line with zero intercept and slope $-\lambda$. For the Weibull distribution with location parameter λ and scale parameter k, we can plot $-\log\{-\log \hat{S}(X_i)\}$ against $\log X_i$. Under the model this will be a straight line with intercept $\log \lambda$ and slope k. For the **Pareto** model with parameter c a plot of $-\log \hat{S}(X_i)$ against $\log X_i$ will have zero intercept and slope c. For the lognormal distribution any of the usual techniques for assessing normality will work, assuming that we can consistently estimate the mean and the variance of $\log T$. For the log **logistic** model with location parameter λ and shape parameter k, a plot of $\log\{1 - \hat{S}(X_i)\} - \log \hat{S}(X_i)$ vs. $\log X_i$ will be linear with intercept equal to $k \log \lambda$ and slope equal to k. For the extreme value model with mode a and variance equal to $\pi^2 b^2/6$, a plot of $\log\{-\log \hat{S}(X_i)\}$ vs. X_i will be linear with intercept equal to $-a/b$ and slope equal to $1/b$.

Apparent departures from the above as indicated by the plot will be indicative of one of three possibilities: the chosen parametric model is not of the correct form, the observed times are not independent or, thirdly and not to be overlooked, the assumption of an independent censoring mechanism is not sufficiently plausible.

One of the commonly used tools in graphical tests is the **residual** plot. The basic idea here is the same as that of the usual $Q-Q$ plots, which can be found in textbooks such as Rice [45] (*see* **Normal Scores**). In survival analysis, it is common to define residuals based on the unit exponentiality property: if T has cumulative hazard function $\Lambda(\cdot)$, then $\Lambda(T)$ has a unit exponential distribution. So define

$$\varepsilon_i = \Lambda(X_i) \quad \text{or} \quad \varepsilon_i = \Lambda(X_i|\mathbf{Z}_i) \tag{1}$$

in the presence of covariates, and their estimates

$$\hat{\varepsilon}_i = \hat{\Lambda}(X_i) \quad \text{or} \quad \hat{\varepsilon}_i = \hat{\Lambda}(X_i|\mathbf{Z}_i), \tag{2}$$

which involve the maximum likelihood estimates of the unknown parameters. One approach is to treat $\hat{\varepsilon}_1, \ldots, \hat{\varepsilon}_n$ as a possibly censored sample from the unit exponential distribution. One then calculates the Kaplan–Meier estimate of the survival function, $\hat{S}(\cdot)$, and plots $-\log\{\hat{S}(t)\}$ vs. t. When the model is adequate the plot should give roughly a straight line with slope one. A second approach uses the fact that if

ε is distributed as unit exponential, then $\mathrm{E}(\varepsilon|\varepsilon \geq t) = t + 1$. So in the event of a censored observation X_i, one replaces the censored residual $\hat{\varepsilon}_i$ by the adjusted residual $\tilde{\varepsilon}_i = \hat{\varepsilon}_i + 1$, and treats all the residuals as if they are uncensored. This procedure is convenient if there are only a few censored observations, or if one wants to plot the residuals against other factors such as the covariates.

For exponential distribution with hazard rate λ, Nelson [39] suggested the following technique for checking model adequacy. Under the model, the cumulative hazard function $\Lambda(t) = \lambda t$. Let the ordered failure times be $T_{(1)} \leq \cdots \leq T_{(n)}$. Then

$$\mathrm{E}\{\Lambda(T_{(i)})\} = \frac{1}{n} + \frac{1}{n-1} + \cdots + \frac{1}{n-i+1}.$$

Thus he suggests plotting $T_{(i)}$ against the right-hand side of the above, and the points should cluster around a straight line for a reasonably good fit. He further points out that the procedure is satisfactory even in the presence of censoring.

Formal Tests

To check the fit of data to a certain parametric model, one type of test is obtained by embedding the null model into a larger class of parametric models (*see* **Hierarchical Models**). Standard procedures such as a score test (*see* **Likelihood**) or **likelihood ratio test** can then be used to test for particular parameter values, and arbitrarily censored data are accommodated. Of course, tests of this kind may not be effective at detecting departures that are not closely approximated by a member of the larger family of models. Specifically, an exponential model can be seen as a Weibull model

$$\lambda(t) = \kappa\theta(\theta t)^{\kappa-1} \tag{3}$$

with $\kappa = 1$, where $\lambda(\cdot)$ is the hazard function. A test of the hypothesis $\kappa = 1$ is against the alternative of monotone hazard functions. Meanwhile, an extreme value distribution (which is the distribution of the logarithm of a Weibull random variable) can be embedded in a three-parameter log **gamma** model with pdf $\int(x)$ equal to

$$\frac{|\lambda|(\lambda^{-2})^{\lambda^{-2}}}{\sigma\Gamma(\lambda^{-2})} \exp\left\{\frac{x-\mu}{\lambda\sigma} - \lambda^{-2}\exp\left[\frac{\lambda(x-\mu)}{\sigma}\right]\right\}, \quad \lambda \neq 0,$$

$$\frac{1}{(2\pi)^{1/2}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right], \quad \lambda = 0. \tag{4}$$

A test of the extreme value model is obtained by testing $\lambda = 1$. Eq. (4) also includes the normal distribution as the special case $\lambda = 0$, and for $\lambda \neq 0$ it provides asymmetric alternatives to normality. There are many other families of distributions that include the normal distribution as a special case. For example, to check symmetric long- or short-tailed departures from normality, one can use the exponential power distribution with pdf

$$f(x) = \frac{k(\delta)}{\sigma}\exp\left(-\frac{1}{2}\left|\frac{x-\mu}{\sigma}\right|^{\delta}\right), \tag{5}$$

where $k(\delta)$ is a normalizing factor. The normal distribution is recovered under $\delta = 2$. The generalized ***F* distribution** [24] incorporates all the above parametric models as special cases, although since some of these occur when parameters lie on the boundary of the parameter space its practical utility is limited.

More General Tests

Our suggestion is to consider any of the well known distance measures generalized to accommodate an independent right censoring mechanism. Even large sample results are complicated and difficult to obtain, although some specific cases have been worked out for particular censoring mechanisms [28, 29].

A general approach could be based on resampling techniques, the only difficulty here being to insure that resampling is carried out under the null hypothesis that the data are generated from F. We describe this via the Cramér–von Mises test, although the arguments apply equally well to a Kolmogorov–Smirnov or Anderson–Darling test.

Consider, then, the test statistic D^2, where

$$D^2 = \int \{F_u(t) - F_\beta(t)\}^2 \, \mathrm{d}F_\beta(t),$$

which calculates a distance between the observed empirical Kaplan–Meier estimate, F_{u}, and that obtained from fitting the model with parameters β, F_β. Our problem is to obtain the null distribution of D^2. In order to accomplish this we need to **simulate** under F_β. We also need to incorporate the censoring

mechanism C, for which we have a consistent estimate from its observed (censored by the failure times) distribution. Our simulated observations will be $X_i = \min(T_i, C_i)$, $i = 1, \ldots, n$, for which we refit the model and calculate a new value of D^2.

Proportional Hazards Regression Models

The Cox [12] proportional hazards **regression model** is given by

$$\lambda(t|\mathbf{Z}) = \lambda_0(t) \exp\{\boldsymbol{\beta}'\mathbf{Z}(t)\}, \tag{6}$$

or, equivalently,

$$\lambda_i(t) = \lambda_0(t) \exp\{\boldsymbol{\beta}'\mathbf{Z}_i(t)\}, \quad i = 1, \ldots, n, \tag{7}$$

where $\lambda_0(t)$ is a fixed "baseline" hazard function, and $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ is a vector of log relative risk parameters. Many tests have been proposed to check the model assumption of (6), some of them making use of **counting processes** and martingale notation. So let

$$N_i(t) = I\{T_i \le t, T_i \le C_i\}. \tag{8}$$

$N_i(\cdot)$ has the intensity process

$$\alpha_i(t)\,\mathrm{d}t = Y_i(t)\lambda_i(t)\,\mathrm{d}t, \tag{9}$$

and

$$M_i(t) = N_i(t) - \int_0^t \alpha_i(s)\,\mathrm{d}s \tag{10}$$

is a martingale.

Define

$$\pi_i(t;\boldsymbol{\beta}) = \frac{Y_i(t)\exp\{\boldsymbol{\beta}'\mathbf{Z}_i(t)\}}{\sum_{j=1}^{n} Y_j(t)\exp\{\boldsymbol{\beta}'\mathbf{Z}_j(t)\}}, \tag{11}$$

and

$$\mathrm{E}(\mathbf{Z}|t;\boldsymbol{\beta}) = \sum_{j=1}^{n} \mathbf{Z}_j(t)\pi_j(t;\boldsymbol{\beta}); \tag{12}$$

that is, $\mathrm{E}(\cdot|t;\boldsymbol{\beta})$ denotes an expectation taken with respect to the discrete probability distribution $\{\pi_i(t;\boldsymbol{\beta})\}_i$. Also, the following notation is sometimes used:

$$S^{(\tau)}(\beta, t) = n^{-1} \sum_{i=1}^{n} Y_i(t)\exp\{\boldsymbol{\beta}'\mathbf{Z}_i(t)\}\mathbf{Z}_i(t)^{\otimes r}, \tag{13}$$

for $r = 0, 1, 2$, where for a column vector $\mathbf{a}$, $\mathbf{a}^{\otimes 2}$ refers to the matrix $\mathbf{a}\mathbf{a}'$, $\mathbf{a}^{\otimes 1}$ refers to the vector $\mathbf{a}$, and $\mathbf{a}^{\otimes 0}$ refers to the scalar 1. Then

$$\mathrm{E}(\mathbf{Z}|t;\boldsymbol{\beta}) = \frac{S^{(1)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)}. \tag{14}$$

Finally, define

$$\mathbf{V}(\boldsymbol{\beta}, t) = \frac{S^{(2)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)} - \left\{\frac{S^{(1)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)}\right\}^{\otimes 2}, \tag{15}$$

which is the **covariance matrix** of $\mathbf{Z}$ taken with respect to the discrete probability distribution $\{\pi_i(t;\beta)\}_i$.

Graphical Tests

Kay [25] suggested a test using a graphical procedure to check the assumption that a time-invariant covariate to be included in the Cox model affects the hazard in a multiplicative way. Suppose that the kth covariate Z_k is under consideration, $k = 1, \ldots, p$. Denote $\tilde{\mathbf{Z}}_i$ and $\tilde{\boldsymbol{\beta}}$ as $\mathbf{Z}_i$ and $\boldsymbol{\beta}$ with Z_{ik} and β_k omitted. For a binary Z_k, (7) is equivalent to

$$\lambda_i(t) = \begin{cases} \lambda_0(t)\exp(\beta_k)\exp\{\tilde{\boldsymbol{\beta}}'\tilde{\mathbf{Z}}_i(t)\}, & Z_{ik} = 1, \\ \lambda_0(t)\exp\{\tilde{\boldsymbol{\beta}}'\tilde{\mathbf{Z}}_i(t)\}, & Z_{ik} = 0. \end{cases}$$

The assumption that z_k acts on the hazard function in a multiplicative way can be tested by fitting the Cox model with two strata according to the values of z_k; that is,

$$\lambda_i(t) = \begin{cases} \lambda_{01}(t)\exp\{\tilde{\boldsymbol{\beta}}'\tilde{\mathbf{Z}}_i(t)\}, & Z_{ik} = 1, \\ \lambda_{02}(t)\exp\{\tilde{\boldsymbol{\beta}}'\tilde{\mathbf{Z}}_i(t)\}, & Z_{ik} = 0, \end{cases}$$

and estimating $\lambda_{01}(\cdot)$ and $\lambda_{02}(\cdot)$. Under the proportional hazards assumption, the log cumulative hazard functions, $\log \Lambda_{0j}(u)\,\mathrm{d}u$, $j = 1, 2$, should be parallel. Therefore it was suggested to plot $\log \hat{\Lambda}_{0j}(u)\,\mathrm{d}u$, $j = 1, 2$, against t, and constant differences should result. The procedure extends in an obvious way to discrete variables taking more than two values, and appropriate groupings allow similar techniques for continuous variables [4].

Andersen [1] took Kay's approach further in developing a formal test which could then be associated with this graphical output. This test was based on a piecewise model and some asymptotic approximations. In Figure 1 we illustrate such a plot for the

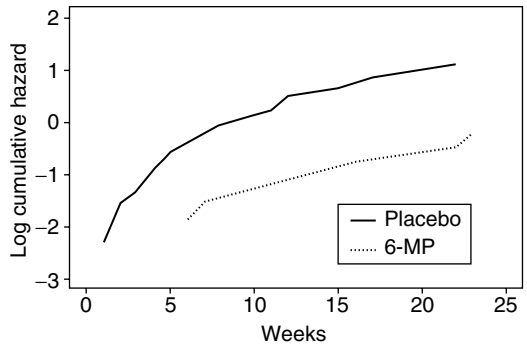

Figure 1 Log cumulative hazard plot for Freireich data

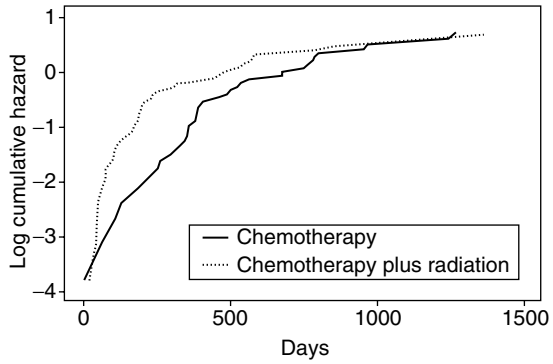

Figure 2 Log cumulative hazard plot for Stablein data

Freireich data. It is clear that the plot provides little evidence against the proportional hazards assumption. In contrast, these plots applied to the Stablein data look very different (Figure 2) and, even without any formal test, the proportional hazards assumption for these data appears doubtful. A number of tests have been proposed that use the unit exponentiality property. Kay [25] applied the residuals of Cox & Snell in order to obtain hazard-based residuals (assuming time-invariant covariates).

Define

$$\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{Z}_i)\int_0^{T_i} \lambda_0(u)\,\mathrm{d}u, \quad i = 1, \ldots, n, \quad (16)$$

and their sample-based estimates

$$\hat{\varepsilon}_i = \exp(\hat{\boldsymbol{\beta}}'\mathbf{Z}_i)\hat{\Lambda}_0(T_i), \quad i = 1, \ldots, n. \quad (17)$$

where $\hat{\boldsymbol{\beta}}$ is usually the maximum **partial likelihood** estimate, and

$$\hat{\Lambda}_0(t) = \sum_{T_k \le t} \frac{\delta_k}{\sum_1^n Y_j(T_k)\exp\{\hat{\boldsymbol{\beta}}'\mathbf{Z}_j(T_k)\}}. \quad (18)$$

Under model (7) these quantities should exhibit approximately the properties of a random sample with independent right-censoring from a unit exponential distribution. This has survival function $S(\varepsilon) = \mathrm{e}^{-\varepsilon}$. A plot of an estimated log survival function of $\varepsilon_1, \ldots, \varepsilon_n$ provides a simple check of the model assumptions. However, Baltazar-Aban & Peña [7] pointed out that the critical assumption of approximate unit exponentiality of the residual vector will often not be viable. Their analytical and Monte Carlo results show that the model diagnostic procedures thus considered can have serious defects when the failure-time distribution is not exponential or when the residuals are obtained nonparametrically in the no-covariate model or semiparametrically in the Cox proportional hazards model. The difficulties stem from the complicated correlation structure arising through the estimation process of both the regression coefficients and the underlying cumulative hazard. It has also been argued that, even under quite large departures from the model, this approach may lack sensitivity.

Schoenfeld [47] defined the residuals $\{\mathbf{r}_i(\boldsymbol{\beta})\}$ as the discrepancy between the observed covariate value at time point X_i and its expectation over the risk set under the model:

$$\mathbf{r}_i(\boldsymbol{\beta}) = \mathbf{Z}_i(X_i) - \mathrm{E}(\mathbf{Z}|X_i; \boldsymbol{\beta}) \quad (19)$$

(*see* **Residuals for Survival Analysis**). For $\boldsymbol{\beta}$ fixed and known, these residuals are uncorrelated [13]. Schoenfeld [47] showed that $\{\mathbf{r}_i(\hat{\boldsymbol{\beta}})\}$ are asymptotically uncorrelated and $\mathrm{E}(\mathbf{r}_i(\hat{\boldsymbol{\beta}})) \approx 0$ under the proportional hazards model. Thus a plot of $r_{ik}(\hat{\boldsymbol{\beta}})$ vs. X_i should be centered about zero. However, if

$$\lambda_i(t) = \lambda_0(t)\exp\{\boldsymbol{\beta}'\mathbf{Z}_i(t) + g(t)Z_{ik}\},$$

with $g(t)$ varying about 0, it can be shown that

$$\mathrm{E}(r_{ik}(\hat{\boldsymbol{\beta}})) \approx g(X_i)\{\mathrm{E}(Z_k^2|X_i; \boldsymbol{\beta}) - \mathrm{E}(Z_k|X_i; \boldsymbol{\beta})^2\}.$$

Since the term in the brackets is positive, the changes in $g(\cdot)$ will be reflected in a plot of $r_{ik}(\hat{\boldsymbol{\beta}})$ vs. X_i.

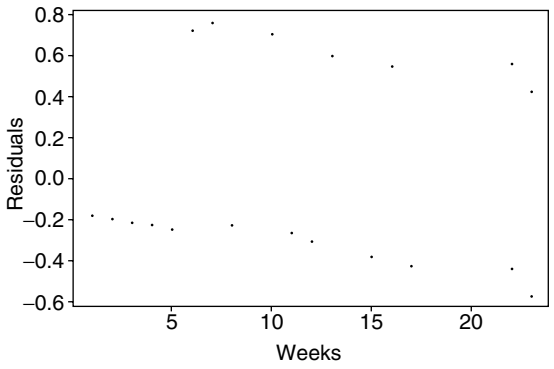

Figure 3 Schoenfeld residuals for Freireich data

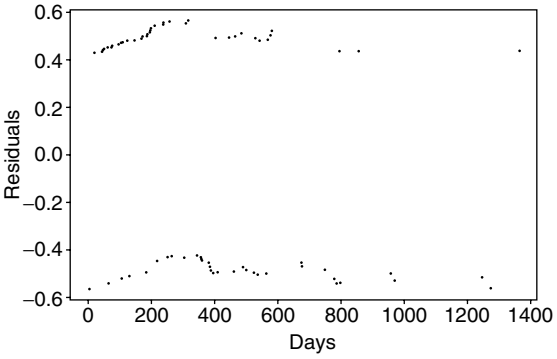

Figure 4 Schoenfeld residuals for Stablein data

Figures 3 and 4, illustrating a simple plot of the Schoenfeld residuals against the failure times, are not easily interpreted. Unlike Figures 1 and 2, as well as Figures 5 and 6 below, these direct residual plots are relatively insensitive to model departures. In practice, it is more instructive to examine the cumulative residuals.

Arjas [6] suggested a graphical method for testing the goodness of fit in Cox's regression model based on the martingale property of

$$M_i'(t;\beta) = N_i(t) - \int_0^t \pi_i(s;\boldsymbol{\beta})\,\mathrm{d}\overline{N}(s), \qquad (20)$$

where $\overline{N}(t) = \sum_1^n N_i(t)$. Suppose that $T_{(1)} < T_{(2)} < \cdots < T_{(K)}$ are the failure times. Let

$$\mathcal{M}_\rangle(\|;\boldsymbol{\beta}) = M_i'(T_{(k)};\boldsymbol{\beta}) = N_i(T_{(k)}) - \sum_{j\le k} \pi_i(T_{(j)};\boldsymbol{\beta}) \qquad (21)$$

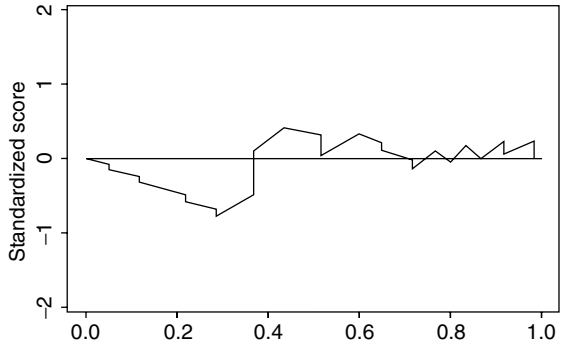

Figure 5 Standardized score process for Freireich data

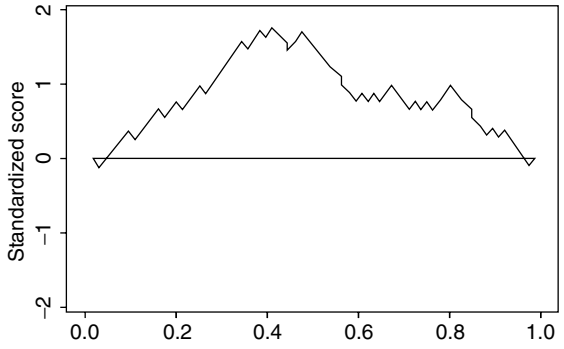

Figure 6 Standardized score process for Stablein data

be an "imbedded" discrete time martingale. Write

$$H(k;\boldsymbol{\beta}) = \sum_{i=1}^{n} \sum_{j\le k} \pi_i(T_{(j)};\boldsymbol{\beta}). \qquad (22)$$

Then the martingale property of

$$\overline{\mathcal{M}}(\|;\boldsymbol{\beta}) = \sum_{\rangle=\infty}^{\setminus} \mathcal{M}_\rangle(\|;\boldsymbol{\beta}) = \| - \mathcal{H}(\|;\boldsymbol{\beta}) \qquad (23)$$

reflects the collective balance between the actual failures and a corresponding cumulative hazard. After substituting the maximum partial likelihood estimate $\hat{\boldsymbol{\beta}}$ for $\boldsymbol{\beta}$, a plot of $H(k;\hat{\boldsymbol{\beta}})$ vs. k can be compared with the diagonal line $y = x$ to check the model assumption. A similar procedure can be applied to stratified data, where the sum in (22) and (23) is within a stratum and there will be one graph for each stratum. This approach relates closely to total time on test and other martingale-based residuals described by Andersen et al. [4].

Some of these techniques are summarized by Barlow & Prentice [8] and Therneau et al. [50], where they define a martingale-based residual for the ith subject as

$$e_i(\mathbf{f}_i) = \int_0^{t_0} \mathbf{f}_i(t)\,\mathrm{d}N_i(t) - \int_0^{t_0} \mathbf{f}_i(t)\alpha_i(t)\,\mathrm{d}t = \int_0^{t_0} \mathbf{f}_i(t)\,\mathrm{d}M_i(t). \quad (24)$$

Here t_0 is the maximum follow-up time for the sample, and $\mathbf{f}_i(\cdot)$ is a predictable process with $\mathbf{f}_i(t)$ defined in terms of data on the ith, and possibly other, subjects prior to time t. The estimated residual corresponding to (24) can then be written

$$\hat{e}_i(\hat{\mathbf{f}}_i) = \int_0^{t_0} \hat{\mathbf{f}}_i(t)\,\mathrm{d}N_i(t) - \int_0^{t_0} \hat{\mathbf{f}}_i(t)\,\mathrm{d}\hat{\Lambda}_i(t) = \int_0^{t_0} \hat{\mathbf{f}}_i(t)\{\,\mathrm{d}N_i(t) - \pi_i(t;\hat{\boldsymbol{\beta}})\,\mathrm{d}\overline{N}(t)\}. \quad (25)$$

It can be shown that asymptotically $\hat{e}_i(\hat{\mathbf{f}}_i)$ has mean zero, is uncorrelated with $\hat{e}_j(\hat{\mathbf{f}}_j)$ for $j \neq i$, and has variance estimated by

$$\frac{1}{n}\int_0^{t_0} \hat{\mathbf{f}}_i(t)^{\otimes 2}\pi_i(t;\hat{\boldsymbol{\beta}})\,\mathrm{d}\overline{N}(t). \quad (26)$$

Some special choices of $\mathbf{f}$ have been considered. If $\mathbf{f}_i(\cdot) = 1$, (25) is seen to be equivalent to the hazard-based residuals of Kay [25] when the covariates are time-invariant. $\mathbf{f}_i(t) = \mathbf{Z}_i(t)$ is also of interest, while $\mathbf{f}_i(t) = \mathbf{Z}_i(t) - \mathrm{E}(\mathbf{Z}|t;\boldsymbol{\beta})$ gives Schoenfeld [48] residuals. Henderson & Milner [22] point out that, for some particular choices of $\mathbf{f}$, plots of these residuals against time can exhibit systematic patterns even when the model is appropriate. Their suggestion is to superimpose estimates of expected mean or to standardize the residuals when plotting. For the Schoenfeld residuals, the ones we will most likely use in practice, the difficulty is not present unless the sample size is particularly small.

Lin et al. [32] propose procedures derived from cumulative sums of martingale-based residuals. The distribution of these stochastic processes under the proportional hazards model can be approximated by zero-mean Gaussian processes. They then compare the observed process with a number of simulated realizations from the approximate null distribution. Specifically, define the martingale residuals (see also (10) and (20))

$$\hat{M}_i(t) = M_i'(t;\hat{\boldsymbol{\beta}}) = N_i(t) - \int_0^t Y_i(s) \times \exp\{\hat{\boldsymbol{\beta}}'\mathbf{Z}_i(s)\}\,\mathrm{d}\hat{\Lambda}_0(s), \quad (27)$$

where $\hat{\Lambda}_0(\cdot)$ is defined in (18). Assuming time-invariant covariates, define the following two classes of **stochastic processes**:

$$W_{\mathbf{z}}(t,\mathbf{z}) = \sum_{i=1}^n f(\mathbf{Z}_i)I(\mathbf{Z}_i \leq \mathbf{z})\hat{M}_i(t), \quad (28)$$

$$W_r(t,r) = \sum_{i=1}^n f(\mathbf{Z}_i)I(\hat{\boldsymbol{\beta}}'\mathbf{Z}_i \leq r)\hat{M}_i(t), \quad (29)$$

where $f(\cdot)$ is a known smooth function, $\mathbf{z} = (z_1,\ldots,z_p)'$, and the event $\{\mathbf{Z}_i \leq \mathbf{z}\}$ means that all the p components of $\mathbf{Z}_i$ are no larger than the respective components of $\mathbf{z}$. It can be shown that under model (7) $n^{-1/2}W_{\mathbf{z}}(t,\mathbf{z})$ and $n^{-1/2}W_r(t,r)$ converge to zero-mean Gaussian processes. It is also shown that in large samples their null distributions can be approximated through simulations, where one repeatedly generates normal random samples while holding the observed data $\{X_i,\delta_i,\mathbf{Z}_i\}$ fixed [32]. Different specifications of (28) or (29) can be used to check different aspects of the model assumption. For example, $W_{\mathbf{z}}(\infty,\mathbf{z})$ with $f(\cdot) = 1$ and $z_k = \infty (k \neq j)$ provides a check of the functional form of the jth covariate, $j = 1,\ldots,p$; $W_r(\infty,r)$ with $f(\cdot) = 1$ checks the link function of the model; $W_{\mathbf{z}}(t,\mathbf{z})$ with $f(\mathbf{x}) = \mathbf{x}$ and $\mathbf{z} = \infty$ is the well-known score process, and checks the proportional hazards assumption; finally, $W_{\mathbf{z}}(t,\mathbf{z})$ with $f(\cdot) = 1$ can be viewed as an omnibus test when allowing t and $\mathbf{z}$ to vary. In all the cases, one can examine the fit visually by plotting the observed process along with a number of simulated ones. Furthermore, the graphical display may be supplemented with an estimated ***P* value** based on the distribution of the supremum of the process.

Omnibus Tests

Based on the Schoenfeld residuals, Harrell's [19] z-test computes the **correlation** ρ of the Schoenfeld

residuals and the **ranks** of survival times. Then the approximate z-statistic for nonzero correlation,

$$\frac{(n-3)^{1/2}}{2}\log\left(\frac{1+\rho}{1-\rho}\right), \tag{30}$$

is treated as **standard normal**. The test is included in certain **software** packages (*see* **Survival Analysis, Software**). It has a disadvantage that the type I error rates tend to be larger than the nominal levels [40] and that power will not be strong for alternatives other than trend in regression effect (*see* **Level of a Test**). It has the advantage, outweighing the disadvantages in our view, of being simple to construct. Also, the most common alternatives of interest are likely to be trend alternatives (*see* **Ordered Alternatives**). For the Freireich data, we find $\rho = 0.049$ having an associated $z = 0.31$, which is not significant. For the Stablein data, we find $\rho = -0.35$ having an associated $z = -3.39$, which is significant at the 1% level.

Schoenfeld [47] proposed a class of omnibus **chi-square tests** based a partition of the time–covariate space. Let $J_1, \ldots, J_L$ be a partition of the $(p+1)$-dimensional $T \times \mathbf{Z}$ space. Let $I_t\{Z(t), t\}$ be the indicator function of J_1; then

$$f_l = \sum_{i \in D} I_l\{Z_i(T_i), T_i\} \tag{31}$$

is the observed number of failures that fall into J_l, where D is the set of individuals observed to fail, $l = 1, \ldots, L$. Denote $\mathbf{f} = (f_1, \ldots, f_L)'$. The "conditional" mean and variance–covariance matrix of $\mathbf{f}$ with respect to $\{\pi_i(\cdot; \boldsymbol{\beta})\}_i$ can be written down explicitly, and these are denoted by $\mathbf{e}$ and $\mathbf{V}$, respectively. On the basis of these observed and expected quantities, Schoenfeld constructed a chi-square type test, demonstrating the validity of the asymptotic null distribution as well as that for the noncentral chi-square under particular departures. Moreau et al. [35] showed that the Schoenfeld test could be derived as a score test for a broader proportional hazards model incorporating heterogeneity with respect to the regression effect together with a null hypothesis that the heterogeneity is zero. For the Freireich data and a simple division of the time axis into two intervals (less than or greater than 11 weeks) the test statistic, as well as a conservative approximation, were very far from being significant. For the Stablein data a division of the time axis into four intervals, containing approximately equal numbers of failures, resulted in a test statistic significant at the 2% level.

For the construction of the partition $\{J_l\}$, the following has been suggested. Divide the time axis into L_1 intervals that contain approximately the same number of observations. If $\mathbf{Z}$ is discrete, one may use each value as a partition. If $\mathbf{Z}$ has many values or is continuous, one can partition the range of $\mathbf{Z}$ by choosing a partition of the range of $\hat{\boldsymbol{\beta}}'\mathbf{Z}$. Assuming that the range of $\mathbf{Z}$ has been divided into L_2 sets $\{S\}$, one can define $\{J_l\}$ to be the Cartesian product of the above two partitions. Now suppose that the proportional hazards assumption does not hold, and that for a certain interval (τ_i, τ_{i+1}) on the time axis the effect of a covariate is greater than on other intervals. Suppose, furthermore, that when this component of $\mathbf{Z}$ has a high value in (τ_i, τ_{i+1}) the hazard is greater than if it is high on other intervals, and that $\mathbf{Z} \in S_j$ whenever this component is high. Then the partition formed by $(\tau_i, \tau_{i+1}) \times S_j$ will have more than the expected number of failures. On the other hand, if the hazard does not depend on $\mathbf{Z}$ in a loglinear manner, then, on each S_j, the expected and observed number of failures will not agree very well, and this pattern will repeat itself for each time interval. See the original paper for simplifications in computing the test statistic, verification of a technical requirement in order for the asymptotic result to hold, and calculation of the noncentrality parameter under the alternative hypothesis.

Mckeague & Utikal [34] use the doubly cumulative hazard function

$$A(t, z) = \int_0^z \int_0^l \lambda(s|x)\,\mathrm{d}s\;\mathrm{d}x$$

to test the goodness of fit of the Cox model when there is only one covariate to be considered. Their method compares two different estimates of $A(\cdot, \cdot)$. After stratifying over the covariate, they obtain a fully nonparametric estimator

$$\tilde{A}(t, z) = \int_0^z \tilde{\Lambda}(t|x)\,\mathrm{d}x, \tag{32}$$

where $\overline{\Lambda}(t|z)$ is the Nelson–Aalen estimator of the cumulative hazard function in one of the strata. Meanwhile, under the model, $A(t, z)$ can be estimated by

$$\hat{A}(t, z) = \hat{\Lambda}_0(t) \int_0^z \exp(\hat{\beta}x)\,\mathrm{d}x, \tag{33}$$

where $\hat{\Lambda}_0(t)$ is given in (18). Then under the model $\sqrt{n}(\tilde{A} - \hat{A})$ converges weakly to a Gaussian random field. So Kolmogorov–Smirnov type or Cramér–von Mises type test statistics, or resampling methods, may be applied. Alternatively, Mckeague & Utikal [34] developed a method that follows the above Schoenfeld [47] approach. The same idea is adapted to test Cox's model within general proportional hazards models.

Horowitz & Neumann [23] described a generalized moments test which does not require assigning data to predetermined cells. Their test is based on the unit exponentiality of (16), and the asymptotic results were studied. Let $g(\varepsilon, \delta, \mathbf{Z})$ be a vector-valued function with the property that $\mathrm{E}\{\mathbf{g}(\varepsilon, \delta, \mathbf{Z})\} = 0$ if ε has (possibly right-censored) unit exponential distribution, and does not equal to zero if not. Here δ is the censorship indicator of ε. Examples of $\mathbf{g}$ are $(1+\delta)\exp(-\varepsilon) - 1$, $\mathbf{Z}\{(1+\delta)\exp(-\varepsilon) - 1\}$, and $\varepsilon^2 - \varepsilon\delta$, although the first one was found to be the best in terms of finite sample size and power properties. The test is based on

$$\Omega_n = n^{-1/2} \sum_{i=1}^{n} \mathbf{g}(\hat{\varepsilon}_i, \delta_i, \mathbf{Z}_i). \tag{34}$$

Horowitz & Neumann [23] showed that under model (6) and regularity conditions, Ω_n is asymptotically **multivariate normal** as $n \to \infty$ with mean zero and covariance matrix that can be estimated consistently (see their appendix for details). As with all such tests, this generalized moments test does not indicate the sources of error in a rejected model, and may have little power against certain alternatives. However, it was shown to perform well against **accelerated failure time** models. A small-sample correction has also been derived.

Another omnibus test, not requiring arbitrary division of the time axis, was presented by Lin & Wei [31] Their idea, developed from White [53], was to contrast the observed information matrix and the squared score matrix. These matrices are both consistent for the inverse of the asymptotic covariance matrix of $\hat{\boldsymbol{\beta}}$ under the model but are various ways of combining the elements of this matrix. Lin & Wej [31] made two suggestions: the first to take the largest element in absolute value and the second to use a Wald-type statistic (*see* **Likelihood**). The null distribution of the largest element was approximated via simulation, whereas an expression was given for the covariance matrix needed in the Wald statistic. The test has the advantage of good power for general alternatives and does not hinge upon arbitrary choices such as the time division. Its disadvantage is that the calculations necessary to obtain a significance level are relatively involved.

Marzec & Marzec [33] developed the goodness of fit inference based on Arjas's [6] graphical method. Let $I \subset \{1, \ldots, n\}$ be a given stratum. Similar to (13), define

$$S_I^{(r)}(\boldsymbol{\beta}, t) = |I|^{-1} \sum_{i \in I} Y_i(t) \exp\{\boldsymbol{\beta}' \mathbf{Z}_i(t)\} \mathbf{Z}_i(t)^{\otimes r}, \tag{35}$$

for $r = 0, 1, 2$, where $|I|$ means the size of I. Let $N_I(t) = \sum_I N_i(t)$. Define

$$M_I(t; \boldsymbol{\beta}) = N_I(t) - \frac{|I|}{n} \int_0^t \frac{S_I^{(0)}(\boldsymbol{\beta}, s)}{S^{(0)}(\boldsymbol{\beta}, s)} \, \mathrm{d}\overline{N}(s). \tag{36}$$

Under the model, $M_I(t; \boldsymbol{\beta})$ describes a collective balance in the stratum between the actual failures and a corresponding cumulative hazard. Assume that $|I|/n \to q$ as $n \to \infty, q \in (0, 1)$. Marzec & Marzec [33] showed that, depending on two different sets of conditions on $S_I^{(r)}(\boldsymbol{\beta}, t)$, $n^{-1/2} M_I(t; \hat{\boldsymbol{\beta}})$ converges weakly to a time transformed **Brownian motion**, or a more complex Gaussian process. In the first case,

$$\frac{\sup_{0<t<1} |M_I(t; \hat{\boldsymbol{\beta}})|}{\left\{ \int_0^1 \tau_n(\hat{\boldsymbol{\beta}}, s) \, \mathrm{d}\overline{N}(s) \right\}^{1/2}}, \tag{37}$$

where

$$\tau_n(\boldsymbol{\beta}, t) = \frac{|I| S_I^{(0)}(\boldsymbol{\beta}, t)}{n S^{(0)}(\boldsymbol{\beta}, t)} \left\{ 1 - \frac{|I|}{n} \frac{S_I^{(0)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)} \right\},$$

converges weakly to $\sup_{0 \le t \le 1} |W(t)|$, where W is the Brownian motion. In the second case, the same test statistic (37) converges weakly to $\sup_{0 \le t \le 1} |W^0(t)|$, where W^0 is the Brownian bridge.

For a two-sample problem, the proportional hazards model can be simply written as $S_1(t) = S_2(t)^\theta$, where $S_i(t)$ is the survival function of group $i, i = 1, 2$. This is equivalent to (6) with $\theta = \mathrm{e}^\beta$. For this model, Wei [52] suggested an omnibus test based on the score process, which has also been used by others, including Barlow & Prentice [8] and Lin

et al. [32]. Because of the simplicity of this particular case, one can easily write down the explicit form of the statistic. Instead of the earlier notation that we have been using, denote (X_{ij}, δ_{ij}), $j = 1, \ldots, n_i$, the observations from sample i, and $Y_i(t) = \sum_j J(X_{ij} \geq t)$, $i = 1, 2$. Then the score (i.e. the derivative of the log partial likelihood) process can be seen to be $\theta^{-1}U_n(t; 0)$, where

$$U_n(t;\theta) = \sum_{j=1}^{n_i} \delta_{1j} I(X_{1j} \leq t) - \sum_{i=1}^{2}\sum_{j=1}^{n_i} \frac{Y_1(X_{ij})\theta}{Y_1(X_{ij})\theta + Y_2(X_{ij})} I(X_{ij} \leq t). \tag{38}$$

The test statistic is based on the supremum of the absolute value of the process (38), which has the interpretation as the observed number of failures from sample 1 minus the corresponding expected number of failures before or at time t. Replace θ by $\hat{\theta}$, the maximum partial likelihood estimate, and let $W_n(t) = n^{-1/2}U_n(t; \hat{\theta})$. Assuming that $n_i/n \to \rho_i, 0 < \rho_i < 1$, it can be shown that under the model $\{W_n(t) : 0 \leq t \leq \infty\}$ converges in law to

$$\{[\theta_\eta(\infty)]^{1/2} W^0\left[\frac{\eta(t)}{\eta(\infty)}\right] : 0 \leq t \leq \infty\},$$

where W^0 is the Brownian bridge, and $\eta(\infty)$ can be consistently estimated by

$$\hat{\eta}(\infty) = n^{-1}\sum_{i=1}^{2}\sum_{j=1}^{n_i} \frac{\delta_{ij} Y_1(X_{ij}) Y_2(X_{ij})}{\{Y_1(X_{ij})\hat{\theta} + Y_2(X_{ij})\}^2}.$$

Note that $\eta(\infty)$ in the above was written $\eta(t)$ in the original paper, and that this seems to be a typographical error. Therefore the goodness of fit test statistic is

$$\{\hat{\theta}_{\hat{\eta}}(\infty)\}^{-1/2} \sup_{0<t<\infty} |W_n(t)|. \tag{39}$$

Wei [52] showed that (39) is consistent against the alternative of nonproportional hazards. A table of percentage points of $\sup_{0\leq s\leq 1} |W^0(s)|$ can be found in Koziol & Byar [28]. Alternatively, we can use the fact that

$$\Pr(\sup_t |W^0(t)| > \alpha) = 2\sum_{k=1}^{\infty}(-1)^{k+1} \times \exp(-2k^2\alpha^2), \alpha \geq 0, \tag{40}$$

a well known result in probability. It can be seen that absolute values of the standardized score process greater than around 1.4 can be considered significant at the 0.05 level. For the Freireich data the standardized score process (Figure 5) lies well within this limit. In contrast, this process for the Stablein data (Figure 6) has a maximum around 1.8, which is significant at 1%.

Tests for Specific Alternatives

Many of the tests against the alternative of time-varying regression effects can be summarized under the following model (for simplicity of notation, we assume parameters of dimension one):

$$\lambda_i(t) = \lambda_0(t)\exp\{[\beta + \alpha Q(t)]Z_i(t)\}, \tag{41}$$

where $Q(t)$ is a function of time which does not depend on the parameters β and α. Under $H_0 : \boldsymbol{\alpha} = \mathbf{0}$ we recover the proportional hazards model (7). In the context of sequential group comparisons of survival data, this model has been considered by Tsiatis [51] and Harrington et al. [20]. Like (11) and (12), we denote by $E(\cdot|t; \beta, \alpha)$ the expectation taken with respect to the probability distribution $\{\pi_i(t; \beta, \alpha)\}_i$, where

$$\pi_i(t;\beta,\alpha) = \frac{Y_i(t)\exp\{[\beta + \alpha Q(t)]Z_i(t)\}}{\sum_{j=1}^{n} Y_j(t)\exp\{[\beta + \alpha Q(t)]Z_j(t)\}}. \tag{42}$$

Assume that $Q(t)$ is known: then the score vector $\mathbf{U}(\beta, \alpha)$ for model (41) has two components,

$$U_\beta(\beta,\alpha) = \sum_{i=1}^{n} \delta_i\{Z_i(X_i) - E(Z|X_i;\beta,\alpha)\} \tag{43}$$

and

$$U_\alpha(\beta,\alpha) = \sum_{i=1}^{n} \delta_i Q(X_i)\{Z_i(X_i) - E(Z|X_i;\beta,\alpha)\}; \tag{44}$$

while the **information matrix** is

$$\mathbf{I}(\beta,\alpha) = -\begin{pmatrix} U_{\beta\beta} & U_{\beta\alpha} \\ U_{\alpha\beta} & U_{\alpha\alpha} \end{pmatrix} = \begin{pmatrix} I_{11} & I_{12} \\ I_{21} & I_{22} \end{pmatrix}, \tag{45}$$

where

$$I_{kl}(\beta,\alpha)=\sum_{i=1}^{n}\delta_i Q(X_i)^{k+1-2}\{\mathrm{E}(Z^2|X_i;\beta,\alpha) - \mathrm{E}(Z|X_i;\beta,\alpha)^2\},\quad k,l=1,2. \quad (46)$$

Let $\hat{\beta}$ be the maximum partial likelihood estimate of β under H_0: then $U_\beta(\hat{\beta},0)=0$. So the score test statistic arising under H_0 is

$$B=U_\alpha(\hat{\beta},0)G^{-1}U_\alpha(\hat{\beta},0), \quad (47)$$

where $G=I_{22}-I_{21}I_{11}^{-1}I_{12}$ and G^{-1} is the lower right corner element of $\mathbf{I}^{-1}$. Under H_0, S has an asymptotically χ^2 distribution with one degree of freedom.

As special cases of (41), Cox [12] considered $Q(t)=t$, Stablein et al. [49] considered $Q(t)=(t,t^2)'$, and Brown [11], Anderson & Senthilselvan [5], O'Quigley & Moreau [42], Moreau et al. [36], and O'Quigley & Pessione [43] assumed $Q(t)$ to be constant on predetermined intervals of the time axis; in other words $Q(t)$ is a step function. Although in the latter cases there is more than one parameter associated with $Q(t)$, the computation of the test statistic is similar to the above. Murphy [37] studied the size and the power of Moreau et al. [36] and found that, although it is consistent against a wide class of alternatives to proportional hazards, it is nonetheless an omnibus test which should be used when there is no specific alternative in mind.

Sometimes $Q(t)$ is chosen to be an unknown function and needs to be estimated; for example, $Q(t)=\Lambda(t)$ [10] and is estimated by the Nelson estimator. Because the estimates at time t depend only on the σ-field of events up to that time, the development of Cox [13] and Andersen & Gill [3] and thus, the above asymptotic theory, still applies. Breslow et al. [10] showed that their choice $Q(t)=\Lambda(t)$ has good power against the alternative of crossing hazards. Tsiatis [51], Harrington et al. [20], and Harrington & Fleming [21] used score processes based on (44) for **sequential** tests. They showed that after $Q(t)$ has been replaced by its estimate, the score process at different time points converge in distribution to multivariate normal. Their particular interest lies in the G^ρ family, where $Q(t)=S(t)^\rho$.

Another special case of (41) is found in O'Quigley & Pessione [44] and O'Quigley [40], where $Q(t)=I(t\le\gamma)-I(t>\gamma)$, with γ an unknown change point. Were γ known, the test statistic in (47) could be readily calculated and denote $B(\gamma)^{1/2}=U_\alpha(\hat{\beta},0;\gamma)/G^{1/2}$. For γ unknown, Davies [14, 15] demonstrates that an appropriate test should be based on the supremum $B(\cdot)$. In order to evaluate the significance level of the test statistic, the **autocorrelation function** is required. O'Quigley & Pessione [44] suggested approximating this via **bootstrap** resampling. Alternatively, a simpler approximation provided by Davies appeared to be satisfactory for most applications. O'Quigley & Pessione [44] showed these tests to be powerful for testing the equality of two survival distributions against the specific alternative of crossing hazards. These tests suffer only moderate losses in power, when compared with their optimal counterparts, if the alternative is one of proportional hazards.

Other authors [18, 30] have taken a slightly different starting point and introduced the function $Q(t)$ directly into a weighted score. This can be written

$$U_Q(\boldsymbol{\beta})=\sum_{i=1}^{n}\delta_i Q(X_i)\{\mathbf{Z}_i(X_i)-\mathrm{E}(\mathbf{Z}|X_i;\boldsymbol{\beta})\}, \quad (48)$$

where $Q(\cdot)$ is a predictable process that converges in probability to a nonnegative bounded function uniformly in t. Let $\hat{\boldsymbol{\beta}}_Q$ be the zero of (48) and let $\hat{\boldsymbol{\beta}}$ be the partial likelihood estimate. Under the assumption that model (6) holds and that $(X_i,\delta_i,\mathbf{Z}_i)(i=1,\ldots,n)$ are iid replicates of $(X,\delta,\mathbf{Z})$, $n^{1/2}(\hat{\boldsymbol{\beta}}_Q-\hat{\boldsymbol{\beta}})$ is asymptotically normal with zero mean and covariance matrix that can be consistently estimated via derivations very close to those of (45). It then follows that a simple test can be based on the standardized difference between the two estimates. Lin [30] showed such a test to be consistent against any model misspecification under which $\boldsymbol{\beta}_Q\neq\boldsymbol{\beta}$, where $\boldsymbol{\beta}_Q$ is the probability limit of $\hat{\boldsymbol{\beta}}_Q$. In particular, it can be shown that choosing a monotone weight function for $Q(t)$ such as $\hat{F}(t)$, where $\hat{F}(\cdot)$ is the Kaplan–Meier estimate, is consistent against monotone departures (e.g. a decreasing regression effect) from the proportional hazards assumption.

A simple test of interaction between a linear combination of covariates $\mathbf{a}'\mathbf{Z}$ and time was developed by Nagelkerke et al. [38]. It uses the Schoenfeld residuals defined in (19). Let $U_{\mathbf{a}_i}(\boldsymbol{\beta})=\mathbf{a}'\mathbf{r}_i(\boldsymbol{\beta})$. Then successive values of $U_{\mathbf{a}_i}(\boldsymbol{\beta})$ are uncorrelated under model (6). Now suppose that Cox's model does

not hold because the impact of $\mathbf{a}'\mathbf{Z}$ on the hazard increases or decreases gradually with time. It can be seen that successive values of $U_{\mathbf{a}_i}(\boldsymbol{\beta})$ are positively correlated. So we can define a test statistic

$$V_{\mathbf{a}}(\hat{\boldsymbol{\beta}}) = \sum_i U_{\mathbf{a}_i}(\hat{\boldsymbol{\beta}}) U_{\mathbf{a}_{i-1}}(\hat{\boldsymbol{\beta}}) \tag{49}$$

and reject the Cox model for large values of $V_{\mathbf{a}}(\hat{\boldsymbol{\beta}})$. Notice that even under model (6), $V_{\mathbf{a}}(\hat{\boldsymbol{\beta}})$ does not have exactly zero expectation. A permutational approach is suggested to estimate the first two moments of the distribution of the test statistic $V_{\mathbf{a}}(\hat{\boldsymbol{\beta}})$. Nagelkerke et al. [38] suggest first testing with $\mathbf{a} = \hat{\boldsymbol{\beta}}$. If the model is rejected, one then goes on to test individual covariate by allowing $\mathbf{a}$ to have only one nonzero element. The test comes under the heading of omnibus tests and has rather weak power. This, together with the fact that computation is somewhat involved, has resulted in the test having seen little practical use. It nonetheless provides important insights into how the score process is affected by departures from the proportional hazards assumption and would seem to be worthy of further investigation.

Let $\lambda_1(t)$ and $\lambda_2(t)$ be the hazard functions for two groups. Gill & Schumacher [18] and Deshpande & Sengupta [16] have developed tests to check the assumption of proportional hazards vs. the alternative that the hazard ratio changes monotonically with time. Under the proportional hazards assumption, the hazard ratio, or the relative risk, $\theta = \lambda_2(t)/\lambda_1(l)$ can be estimated by the generalized rank estimator

$$\hat{\theta}_K = \frac{\int K(t)\, \mathrm{d}\hat{\Lambda}_2(t)}{\int K(t)\, \mathrm{d}\hat{\Lambda}_1(t)} \tag{50}$$

[2, 9], where $K(t)$ is a predictable random weight function, and $\Lambda_j(t)$ is the Nelson–Aalen estimator of the cumulative hazard function in group j. The integrals are over the range $(0, \tau)$, where τ is the upper limit of observable survival times. Gill & Schumacher [18] base their test statistic on the difference between two generalized rank estimators with two different weight functions say, $K_1(t)$ and $K_2(t)$. Specifically, let

$$K_{ij} = \int K_i(t)\, \mathrm{d}\hat{\Lambda}_j(t).$$

Under the proportional hazards assumption

$$D = K_{11}K_{22} - K_{21}K_{12} \tag{51}$$

is asymptotically normal with estimated variance

$$K_{21}K_{22}V_{11} - K_{21}K_{12}V_{12} - K_{11}K_{22}V_{21} + K_{11}K_{12}V_{22}, \tag{52}$$

where

$$V_{ij} = \int K_i(l)K_j(t)\{Y_1(l)Y_2(t)\}^{-1}\, \mathrm{d}\{N_1(t)+N_2(t)\},$$

$N_j(t)$ is the counting process, and $Y_j(t)$ is the number at risk at time l for group j. The test is shown to be consistent against alternatives with a monotone hazard ratio if $K_2(t)/K_1(t)$ is monotone as well, and this is the case for any two of the weight functions common in, for example, generalized linear rank tests. A related graphical method and discussion of the choice of appropriate weight functions in terms of **asymptotic relative efficiency** are also given in Gill & Schumacher [18].

Deshpande & Sengupta [16] use a ***U*-statistic** test to check the assumption that $\lambda_1(l)/\lambda_2(t)$ is equal to a constant versus the alternative that the hazard ratio increases with time. Under the alternative hypothesis, one can verify that

$$S_1(a)f_2(a)S_2(b)f_1(b) \geq S_2(a)f_1(a)S_1(b)f_2(b) \tag{53}$$

for $0 < a < b$, where $S_i(\cdot)$ and $f_i(\cdot)$ are the survival function and the density from group i, $i = 1, 2$. Their suggestion is to integrate the difference in (53) over the range $0 < a < b$ in order to obtain a particular functional, $\Delta(S_1, S_2)$, having the property of being zero under the null hypothesis and positive under the alternative. A U-statistic estimate of $\Delta(S_1, S_2)$ can be obtained by using the frequencies of observations falling into certain regions. The asymptotic distribution of the test statistic is normal and the asymptotic null variance can be estimated by the use of resampling techniques.

JOHN O'QUIGLEY & RONGHUI XU

Goodness of Fit

Introduction

Probably the most famous test in statistics is Pearson's **chi-squared** goodness-of-fit test that assesses the agreement between an observed set of frequencies O_k in K classes and the expected numbers E_k in those classes. As an example, Kendall and Stuart [14, Section 30.7], take data from Mendel's classic experiments on pea breeding. Table 1 gives the frequencies of different kinds of seeds in crosses from plants with round yellow seeds and plants with wrinkled green ones. Also given are the theoretical probabilities from the Mendelian theory of inheritance (*see* **Mendel's Laws**).

The statistic is given by

$$X^2 = \sum_{k=1}^{K} \frac{(O_k - E_k)^2}{E_k} = \sum_{k=1}^{K} \frac{(O_k - n\theta_k)^2}{n\theta_k} = 0.470. \tag{1}$$

With $K = 4$, the statistic is to be compared with the **chi-squared** (χ^2) distribution on $K - 1 = 3$ **degrees of freedom**. The value of X^2 is not significantly large ($\chi^2_{3,0.95} = 7.81$), so the data agree with the theory. However, the value is arguably not so small ($\chi^2_{3,0.05} = 0.352$) to indicate too close agreement between observations and theory, such as might have been caused by the knowing intervention of Mendel's gardener.

This well-known procedure shows many important characteristics of traditional goodness-of-fit tests. Most importantly, it employs many degrees of freedom to test for an unspecified general departure. If a particular departure is of interest, more powerful procedures can be found based on one or a few degrees of freedom. But, of course, such procedures may fail to detect departures other than those for which they are specific.

A second characteristic is that the test is based on aggregate statistics, that is, on quantities calculated over all the data. Attention is not paid to the contribution of individual observations or cases. The third characteristic is that the χ^2 distribution of X^2 only holds asymptotically. As with most asymptotic procedures, attention needs to be paid to the small sample distribution of the statistic. For X^2, this includes concerns about the effect of cells with few observations.

This entry can, with advantage, be read in conjunction with several others. Here we concentrate on tests based on aggregate statistics, simple plots of residuals and tests of distributional shape, either for samples or, more importantly, for residuals. Methods for determining the contribution of individual observations are described in the articles on **Residuals** and **Diagnostics**.

Regression

The Analysis of Variance

In the linear **multiple regression** model

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{2}$$

where $\boldsymbol{y}$ is the $n \times 1$ vector of responses, $\boldsymbol{\beta}$ is the $p \times 1$ vector of parameters, and $\boldsymbol{X}$ is the $n \times p$ **matrix** of carriers, that is, of **explanatory variables** and perhaps functions of them, such as quadratics (*see* **Polynomial Regression**) and **interaction** terms. It is assumed that the additive errors of observation $\boldsymbol{\varepsilon}$ are independently distributed with constant variance σ^2. Many tests of goodness of fit of regression models either use the assumed distribution of the errors to provide t or F tests of models (*see* **Student's *t* Statistics**; ***F* Distributions**), or assess the model by the **normality** of the residuals. We give examples of both procedures.

The **least-squares** estimates of the parameters in (2) are

$$\hat{\boldsymbol{\beta}} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y} \tag{3}$$

yielding fitted values

$$\hat{\boldsymbol{y}} = \boldsymbol{X}\hat{\boldsymbol{\beta}} = \boldsymbol{X}(\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y} = \boldsymbol{H}\boldsymbol{y} \tag{4}$$

and least-squares residuals

$$\boldsymbol{e} = \boldsymbol{y} - \hat{\boldsymbol{y}} = \boldsymbol{y} - \boldsymbol{X}\hat{\boldsymbol{\beta}} = (\boldsymbol{I} - \boldsymbol{H})\boldsymbol{y}. \tag{5}$$

In (5), $\boldsymbol{I}$ is the $n \times n$ identity matrix and, in (4), $\boldsymbol{H}$ is the "hat" matrix, so called because $\hat{\boldsymbol{y}} = \boldsymbol{H}\boldsymbol{y}$.

Provided the model (2) fits, the residual sum of squares

$$S(\hat{\beta}) = (\boldsymbol{y} - \boldsymbol{X}\hat{\boldsymbol{\beta}})^T(\boldsymbol{y} - \boldsymbol{X}\hat{\boldsymbol{\beta}}) = \boldsymbol{y}^T(\boldsymbol{I} - \boldsymbol{H})\boldsymbol{y} \tag{6}$$

is distributed as $\sigma^2\chi^2_{n-p}$. If σ^2 is known, the fit of the model can be tested by comparing $S(\hat{\beta})/\sigma^2$ with this

Table 1 Mendel's data on four kinds of pea seeds

chi-squared distribution, large values indicating lack of fit. Usually, σ^2 is not known, but is estimated by

$$s^2 = \frac{S(\hat{\beta})}{n - p}, \tag{7}$$

so that the goodness-of-fit test is not available. If however, an independent estimate of σ^2 is available, s_ν^2 on ν **degrees of freedom**, the ratio $S(\hat{\beta})/\{(n - p)s_\nu^2\}$ can be compared with the F distribution on $n - p$ and ν degrees of freedom.

Often, the value of s_ν^2 is found from replicate observations within the data. The subtraction of the replicate sum of squares from $S(\hat{\beta})$ leaves a lack of fit sum of squares, the mean square being compared with s_ν^2. The resulting test is typical of many goodness-of-fit tests in not being directed against any specific departure. To test specific departures, the model can be embedded in a more general one, yielding t or F tests for the extra terms. In summary, the two procedures are as follows:

- **Embedding**. Add extra terms to the model, typically higher-order polynomials and interactions in the explanatory variables. These yield t tests for individual coefficients or, more conservatively, F tests for groups of terms.
- **Lack of Fit Sum of Squares**. An estimate of σ^2 either from within or outside the experiment is used to test the residual sum of squares. Estimates from outside the data being analyzed should be treated with caution as they are typically too small through overoptimism about the accuracy of measurement.

If exact replicate observations are not available, observations "close" in X space can be grouped to give approximate replicates and so an estimate of σ^2. More frequently, it is assumed that the addition of higher-order terms removes any possibility of further departures from the model, so that $S(\hat{\beta})$ provides an **unbiased** estimate of error. The articles on **Residuals** and **Diagnostics** discuss procedures for detecting individual errant observations, such as **outliers**. The extension to groups of observations is covered in the article on **Forward Search**.

As an example in which there are replicate observations so that both embedding and a lack of fit sum of squares can be used to assess goodness of fit, consider the data on fetal growth given by Francis et al. [9, p. 328]. The data, plotted in Figure 1, show ultrasound measurements of the head to coccyx (htc) length, in millimeters, of the fetuses of 83 Brazilian women between 7 and 16 weeks pregnant. There is appreciable replication in the data as presented as the **gestational age** is rounded to the nearest week. This is then strictly an example in which observations "close" in X space have been grouped. Since there is at least one measurement at each age, there will be a

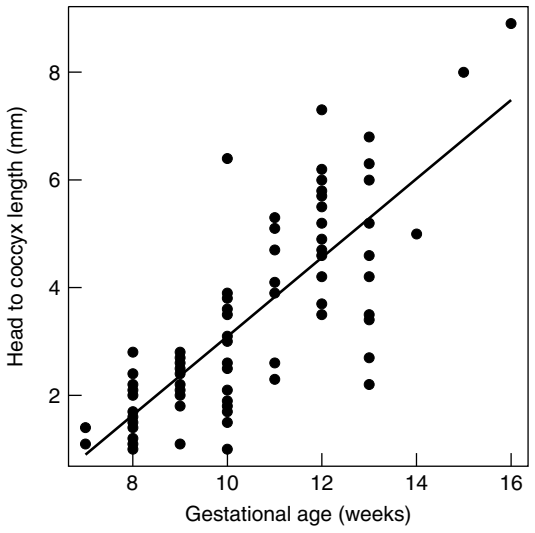

Figure 1 Scatter plot of head to coccyx length data. The replicate observations provide an estimate of pure error and so lead to a test of goodness of fit

maximum of 10 degrees of freedom for the model and 73 degrees of freedom for "pure" error (which will include woman to woman variation). The plot suggests that there is a linear relationship between the response htc and age and this fitted model is shown on the plot. To check the linear model, a quadratic in age is also included, giving seven degrees of freedom for lack of fit in the **analysis of variance** presented in Table 2.

The impression from the plot of a strong linear relationship between htc and age is overwhelmingly confirmed by the value of 160.182 for the F statistic on 1 and 73 degrees of freedom. There is no evidence of curvature, that is, of regression on $(\text{age})^2$. The lack of fit sum of squares has a P value of around $3\frac{1}{2}\%$, a slight, but uninformative, indication that all may not be well.

One possibility is that the linear model is inadequate. Fitting higher-order polynomial models up to $(\text{age})^9$ yields significant t values for age to the powers 4, 6, and 7, which powers are hard to credit or interpret. The further analysis of Francis et al. [9] suggests that variance increases with mean and that a **transformation** of htc is appropriate, probably the logarithmic transformation. With a nonnegative variable such as length, with a range from 1.0 to 8.9, it is extremely likely that variance will increase with observation size. Obtaining a satisfactory transformation is more systematically dealt with by the methods described in **Power Transformations**. The further analysis of Francis it et al. [9] was based on plots, particularly of residuals. We now consider some aspects of the use of residuals in determining goodness of fit.

Residuals

We assumed in (2) that the errors $\varepsilon_i, i, = 1, \ldots, n$, were identically and independently normally distributed. Even if this is true, the residuals e_i, defined in (5), although normally distributed, have **covariance matrix** $(\boldsymbol{I} - \boldsymbol{H})\sigma^2$ and will so not quite be a random sample from a normal distribution. However, it is customary in goodness-of-fit procedures to proceed as if the residuals from a satisfactory model will be such a sample. In **Residuals**, we describe the use of **simulation** envelopes in plotting to correct for this assumption.

Once a model has been fitted, the normality of the residuals, and so the goodness of fit of the model, can be checked in a variety of ways. These include histograms of the residuals (*see* **Frequency Distribution**), perhaps accompanied by a Pearson chi-squared goodness-of-fit test, a normal plot of the residuals and the calculation of a test of normality (*see* **Normality, Tests of**) such as that of Bowman and Shenton [4]. We first consider an example to illustrate the graphical techniques.

Royston and Altman [19] discuss the analysis of measurements of mandible length as a function of gestational age in 167 fetuses with ages from 8 weeks. The data are plotted in Figure 2. Although data with age >28 weeks are felt to be atypical, we include them in the present analysis.

To obtain a regression model we ignore the replicate observations over weeks. For illustration, we fit a simple regression on age (*see* **Linear Regression, Simple**). Other models for these data are discussed in

Table 2 Analysis of variance for regression models fitted to data on the head to coccyx length of 83 Brazilian fetuses as a function of gestational age in weeks

Source	df	Sum of squares	Mean square	F	Pr(F)
Age	1	165.992	165.992	160.182	0.0000

Lack of fit	7	16.836	2.405	2.321	0.0340
Residual	73	75.648	1.036		
Total	82	259.442			

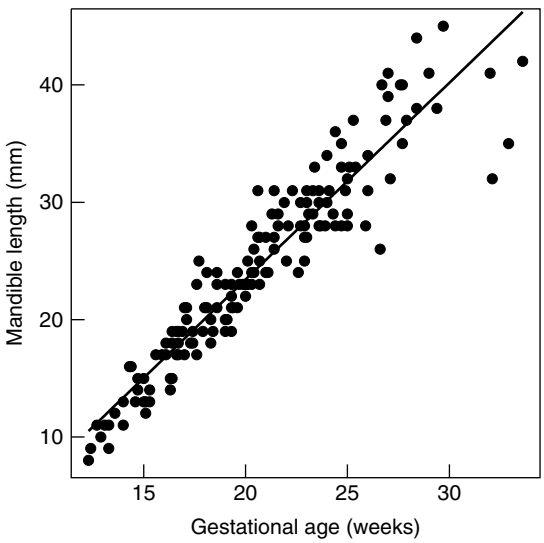

Figure 2 Scatter plot of mandible length data, showing a linear relationship and some increase of variance with age

the article on **Diagnostics**. The fitted values from this simple model are shown in Figure 2. It is noticeable that variance of the observations, and hence the size of the residuals, increases with age. This is evident in Figure 1 of **Residuals**, where the residuals are plotted against fitted values. Here we consider ways of testing goodness of fit on the basis of these residuals.

Figure 3 shows a normal plot of the least-squares residuals (5), which range from −11.71 to 6.56. It is clear from the figure that the residuals are not normally distributed. The histogram of the residuals in Figure 4 confirms the **skewness** apparent in Figure 3. One way of formally testing for the apparent nonnormality would be to calculate Pearson's X^2 for the 167 residuals, grouped as in the histogram, with the expected values given by a fitted normal distribution. However, the modification to the grouping necessary to avoid empty, or nearly empty, cells would remove much of the evidence of nonnormality, which comes from the long left-hand tail of the distribution. We use instead a **Monte Carlo** version of the Bowman–Shenton test which shows the statistical **power** that can be achieved from an appropriate test on one degree of freedom.

The Bowman–Shenton Test. The test is based on comparing a combination of the third and fourth **moments** of the residuals with those of the normal

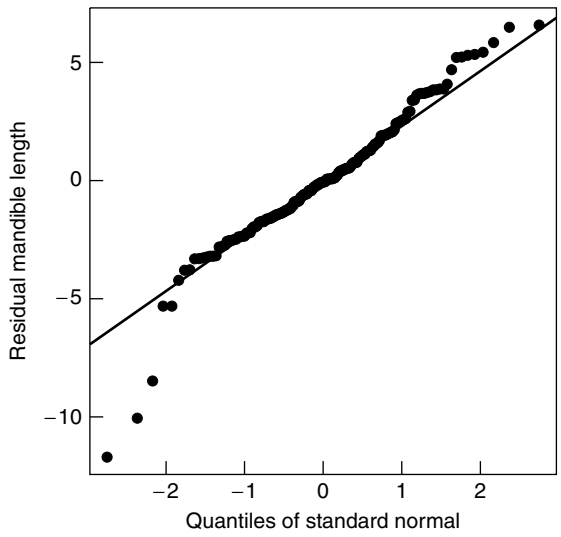

Figure 3 Mandible length data. Normal $Q-Q$ plot showing large negative residuals

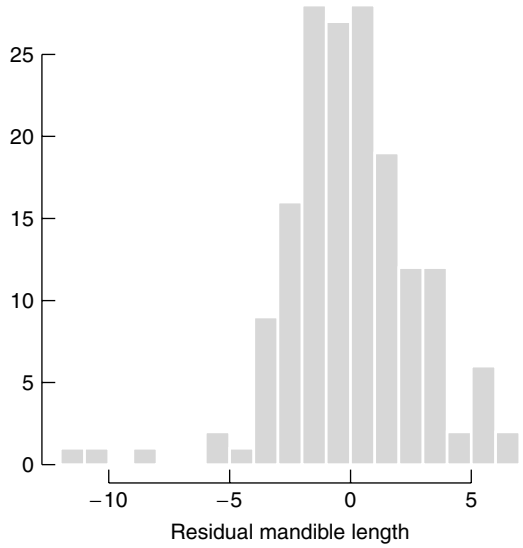

Figure 4 Mandible length data. Histogram of least-squares residuals showing a skewed distribution

distribution. Let

$$m_r = \sum_{i=1}^{n} \frac{(e_i - \overline{e})^r}{n}, \tag{8}$$

where, for regression models containing a constant, $\overline{e} = \sum e_i/n = 0$. Then the skewness measure is

$$\sqrt{b_1} = \frac{m_3}{m_2^{3/2}}, \tag{9}$$

with the **kurtosis** measure given by

$$b_2 = \frac{m_4}{m_2^2}. \tag{10}$$

Asymptotically,

$$\sqrt{b_1} \sim N\left(0, \frac{6}{n}\right) \quad \text{and} \quad b_2 \sim N\left(3, \frac{24}{n}\right).$$

Since $\sqrt{(b_1)}$ and b_2 are approximately independent, the statistic

$$BS = \frac{nb_1}{6} + \frac{n(b_2 - 3)^2}{24} \tag{11}$$

should have approximately, a chi-squared distribution on two degrees of freedom. Bowman and Shenton [4] take transformations of $\sqrt{(b_1)}$ and b_2 to improve

normality. They also provide charts and tables for the distribution of the resulting statistic. In econometrics, it is customary to use (11) directly (for example, Harvey [10, p. 260]). When, as here, the statistic is based on residuals from regression, the effect of the **correlation** structure induced by the carrier matrix $\boldsymbol{X}$ needs to be accommodated. We accordingly use a form of Monte Carlo testing.

For the data of Figure 2, the value of BS is 49.36, clearly very large for a statistic with a nominal χ^2_2 distribution. 999 simulated values of the statistic based on the residuals from regressing random **standard normal deviates** on age had a maximum value of 28.68. The observed result is thus significant far past the 0.1% point. In contrast, application of the same procedure to the data of Figure 1 yields a value of 3.87. Ordering this within the 999 simulated values for this particular X matrix puts the observed value 90th, so that the significance level is 9%, implying no evidence of a departure from normality.

This Monte Carlo procedure is very general and could be applied to any version of the test. For example, the Bowman and Shenton [4] transformation to improve normality might be used, or the least-squares residuals could be standardized to have the same variance, the test statistic being calculated from values of $e_i/\sqrt{(1-h_i)}$, where h_i is the ith diagonal element of the hat matrix (4). However, by focusing narrowly on the normality of the errors, such procedures lose the information contained in the relationship between the residuals and other variables, such as fitted values. The increase of variance with fitted value seen in Figure 2 is one pointer that a power transformation of the data might be appropriate. The analysis of the mandible length data is taken further in **Residuals**, **Diagnostics**, and **Power Transformations** as well as in the articles on the **Fan Plot** and the **Forward Search**. In conclusion, we note that any transformation of the response, such as replacing $\boldsymbol{y}$ by $\log \boldsymbol{y}$, will affect the apparent linear relationship with age.

Many Regression Models

In the polynomial regressions of the previous section, there was an obvious **hierarchy of models** that could be successively tested for goodness of fit via the addition of extra terms. However, with regression on k different variables, there will be 2^k possible models, when all combinations of inclusion of each variable are considered, and there is no obvious order in which to test the models. If an estimate of σ^2 is available, perhaps from replicate observations, the fit of each model can be determined from the lack of fit sum of squares and potential models divided into two classes, those that fit the data and those that do not. Selection amongst those that do fit can then be based on grounds of parsimony, since if a model fits, models formed by adding terms to it will also fit. We now briefly describe some methods of testing goodness of fit in the absence of an estimate of σ^2.

The Coefficient of Determination, R^2

The coefficient of determination, or multiple R^2, measures the proportion of the variation in the data "explained" by the fitted model. Let the total corrected sum of squares be S_o, that is,

$$S_o = \sum_{i=1}^{n} (y_i - \overline{y})^2. \tag{12}$$

Then, the regression sum of squares equals $S_o - S(\hat{\beta})$ and

$$R^2 = \frac{S_o - S(\hat{\beta})}{S_o} = 1 - \frac{S(\hat{\beta})}{S_o}. \tag{13}$$

The theory is that a "good" model will have a value of R^2 near one.

There are two problems with the use of this measure of goodness of fit. One is the interpretation of the values, which do not have a standard distribution and may be misleading. The results in Table 2 for the data plotted in Figure 1 give an F value for linear regression of 160.182, whereas the value of R^2 is a rather uninspiring 0.6398. Likewise, for the data of Figure 2, $F = 1289$ with $R^2 = 0.8865$. Despite the overwhelming evidence for the regressions, the values of R^2 are far from one.

The second problem with R^2 is that the value increases as extra terms are added to the model, since $S(\hat{\beta})$ certainly cannot increase and usually decreases. Some allowance can be made by the use of **adjusted $\boldsymbol{R^2}$**

$$\overline{R^2} = 1 - \frac{S(\hat{\beta})/(n-p)}{S_o/(n-1)}. \tag{14}$$

Mallows' C_p

Mallows $\boldsymbol{C_p}$ measures goodness of fit by considering **prediction** by fitted models at the n observational

points. For satisfactory models

$$C_p = \frac{S(\hat{\beta})}{s^2} + 2p - n \qquad (15)$$

is approximately equal to p, the dimension of $\boldsymbol{\beta}$. Often s^2, the estimate of σ^2, is the residual mean square estimate from fitting the model including all terms being considered. If there are p^* terms, for this model $C_p = p^*$. The hope is that at least one reduced model will also have an acceptably small value of C_p. Interpretation of the values is often aided by a plot of C_p against p. Examples of the use of C_p to select models, and comparison with other procedures, are given in many statistics textbooks, for example, Hines and Montgomery [11]. The article on **Variable Selection** extends these comments and includes a discussion of **Bayesian methods** of selection.

Mallows criterion uses the mean squared error of prediction at the observational points to strike a balance between the improved predictions from fitting a larger model and the resulting increased variance of the predictions. The scaled residual sum of squares is penalized by twice the number of parameters in the model. The generalization of this idea to **likelihood**, known as **Akaike's information criterion**, or *AIC*, is mentioned in the next section.

Once a method such as the analysis of variance, $\overline{R}^2$ or C_p has been used to select one, or a few, satisfactory models, further checking should be undertaken. See **Residuals** and **Diagnostics** for methods based on the deletion of individual observations.

Generalized Linear Models

The Analysis of Deviance

Generalized linear models extend the regression model of the previous section to errors having a one-parameter **exponential family**, most importantly the **binomial** and **Poisson**, as well as the normal and **gamma**. The mean of each observation $\mu_i = E(Y_i)$ is related to the linear predictor $\eta_i = \boldsymbol{x}_i^T \boldsymbol{\beta}$ by the link function $g(\mu_i) = \eta_i$. The standard reference is McCullagh and Nelder [15], with an introduction by Dobson [7].

Inference procedures parallel those for regression, the generalized linear model with normal errors and identity link, $g(\mu_i) = \mu_i$. The analysis of deviance is the generalization of the analysis of variance of the previous section. The calculation and interpretation of residuals and other diagnostic quantities are aided by the reduction of **maximum likelihood** estimation to iteratively reweighted least squares.

Let the loglikelihood be $l(\boldsymbol{\beta}, \phi; \boldsymbol{y})$, where ϕ is a scale parameter, equal to σ^2 for the normal distribution. To test goodness of fit of models the loglikelihood is compared with the model which fits best, the one for which $\hat{\mu}_i = y_i$. Call these parameter estimates $\hat{\boldsymbol{\beta}}_{\max}$. The scaled deviance

$$D^*(\hat{\beta}) = 2\{l(\hat{\boldsymbol{\beta}}, \phi; \boldsymbol{y}) - l(\hat{\boldsymbol{\beta}}_{\max}, \phi; \boldsymbol{y})\} \qquad (16)$$

equals $R(\hat{\beta})/\sigma^2$ for the regression model and can be used in the same way to test goodness of fit of models. If the hypothesis to be tested is that $\boldsymbol{\beta} = \boldsymbol{\beta}_o$, of dimension $p - s$, then $D^*(\hat{\beta}_o) - D^*(\hat{\beta})$ is compared with χ_s^2, the asymptotic distribution of the likelihood ratio. If ϕ is not known, it can be estimated from the residual unscaled deviance $D(\hat{\beta}) = \phi D^*(\hat{\beta})$, by setting $\hat{\phi} = D(\hat{\beta})/(n - p)$ for a model known to fit well.

We shall be particularly interested in generalized linear models with Poisson and binomial errors, for both of which $\phi = 1$. The value of either deviance then provides a test of goodness of fit of the model, which may again have an asymptotic χ^2 distribution provided the number of observations is sufficiently great relative to the number of parameters, the binomial case being particularly sensitive. A discussion and further references are given by Firth [8, Section 3.5.2]. The generalization of Mallows C_p to Akaike's information criterion,

$$\mathrm{AIC}_p = D^*(\hat{\beta}) + 2p = \frac{D(\hat{\beta})}{\phi} + 2p, \qquad (17)$$

allows the selection of models with small values of AIC_p for further checking. (Omission of the term in n which appears in the definition of C_p does not affect the ordering of the models). If it is necessary to estimate ϕ, the same estimate should be used for all comparisons between models. Both in this case and in regression, if the number of observations is large, there is the danger of selecting models with too many parameters. **Parsimonious** model choice can be achieved using penalties that increase with n. For example, Schwartz [20] suggests a criterion of the form

$$\frac{D(\hat{\beta})}{\phi} + p \log n,$$

which is more parsimonious than AIC for $n \geq 8$. Bias-corrected methods for the selection of regression and **time-series** models are described by Hurvich and Tsai [13].

Contingency Tables

Generalized linear models for **contingency tables**, such as the data of Table 1, can often be modeled with Poisson errors and the loglink $\log \mu_i = \eta_i$. The deviance for a model giving fitted values μ_i is

$$D(\mu) = 2\sum_{i=1}^{n}\left\{y_i \log\left(\frac{y_i}{\mu_i}\right) - (y_i - \mu_i)\right\}, \quad (18)$$

a statistic often called G^2 in the literature on the analysis of **categorical data** (for example, Agresti [1]). For the data of Table 1, the deviance is 0.475 for the expected frequencies given in the table, which do not involve any estimated parameters. This value yields the same inference as the value of 0.47 for Pearson's X^2. Pearson's statistic, written in this notation is

$$X^2 = \sum_{i=1}^{n}\frac{(y_i - \mu_i)^2}{\mu_i}. \quad (19)$$

The asymptotic equivalence of the deviance and X^2 for testing goodness of fit can be shown by expanding (18) in a Taylor series in $(y_i - \mu_i)/\mu_i$. (Kendall and Stuart [14, Section 30.8], McCullagh and Nelder [15, p. 197]). However, the asymptotic equivalence of the two tests says little about which has higher power for moderate samples, although there seems to be little difference. Some references are given by Agresti [1].

Binomial Data

Table 3 gives data from Bliss [3] on the mortality of adult beetles after five hours exposure to gaseous carbon disulfide. At each of the eight dose levels x_i, there are n_i binomial trials resulting in R_i successes (from the point of view of the experimenter). The question of interest is the relationship between x_i and the probability of success $\theta_i = E(R_i/n_i)$.

Table 3 Bliss's data on mortality of beetles

Log dosage, x_i	Number exposed, n_i	Number killed, R_i
1.6907	59	6
1.7242	60	13
1.7552	62	18
1.7842	56	28
1.8113	63	52
1.8369	59	53
1.8610	62	61
1.8839	60	60

A standard model for the analysis of such data is the linear logistic model (*see* **Logistic Regression**) in which

$$\log\left\{\frac{\theta_i}{1-\theta_i}\right\} = g(\theta_i) = \beta_o + \beta_1 x_i. \quad (20)$$

When this model is fitted, the residual deviance is 11.23 on 6 degrees of freedom. Here the number of insects at each dose level is sufficiently large that a central limit theorem might be expected to hold for each R_i and so it is sensible to compare 11.23 with the chi-square distribution on 6 degrees of freedom, for which the 5% point is 12.59. Although this is not a significant value, plots of observed and fitted values (**Residuals**, Figure 6) suggest a systematic lack of fit, which can be addressed either by adding a term in $\boldsymbol{x}^2$ to the linear predictor or by considering another link function. There are two ways in which a test of the link function may be obtained on a few degrees of freedom. Such tests are often called "goodness of link" tests.

An alternative to the logistic link is the complementary log–log link in which $g(\theta_i) = \log\{-\log(1 - \theta_i)\}$. These two can be combined in the parametric family

$$g(\theta_i, \lambda) = \log\left[\frac{\{1/(1-\theta_i)^{\lambda} - 1\}}{\lambda}\right], \quad (21)$$

which is the logistic link, as in (20), for $\lambda = 1$ and tends to the complementary log–log as $\lambda \to 0$. A test on one degree of freedom can be obtained either by finding the value of λ that maximizes the likelihood and by performing a **likelihood ratio test**, or by using a score test for $\lambda = 0$ or 1 (*see* **Likelihood**). A discussion and examples of other embeddings of links are given by Pregibon [16].

A more general test of the goodness of the link $g(\mu_i)$ is obtained by assuming that the true link is indeed $g^*(\mu_i) = \eta_i$, so that

$$g(\mu_i) = g\{g^{*-1}(\eta_i)\} = h(\eta_i). \quad (22)$$

Expansion of $h(\eta_i)$ in a Taylor series leads to a linear predictor that includes an added term in $\hat{\eta}_i^2$. Refitting the model with this extra variable without

recalculating the weights used in fitting leads to a reduction in deviance of 7.61 to be assessed on one degree of freedom – strong evidence, when compared with χ^2_1, of the need for another link with the linear predictor in (20).

For these data, two models giving satisfactory fits, as assessed by the residual deviance, are the complementary log–log model with a linear term in $\boldsymbol{x}$ and the logistic link including a quadratic in $\boldsymbol{x}$. Further details and related plots are in **Residuals** and the **Forward Search**. The interpretation of the residual deviances as chi-squared values need care. With the logistic link and all $n_i = 1$, the residual deviance is a function only of $\hat{\beta}$ and so contains no information about goodness of fit. McCullagh and Nelder [15, p. 121] discuss the distribution of the deviance and Pearson's X^2 for small n_i. Atkinson and Riani [2, Section 6.18], explore the relationship between the analysis of deviance and t tests for coefficients in the linear predictor when all $n_i = 1$.

The goodness of link test using $\hat{\boldsymbol{\eta}}^2$ is an example of an aggregate test, related to Tukey's one degree of freedom for nonadditivity in regression, which involves regression on $\hat{\boldsymbol{y}}^2$. A number of related aggregate tests are described by Hinkley [12]. In **Residuals**, we describe the use of added variable and related plots to determine the effect of individual observations on such procedures. Methods for the analysis of binary data are described, amongst others, by Cox and Snell [5, Section 2.7], who stress the importance of not relying on overall tests of goodness of fit, but of trying to detect scientifically important departures from the model.

Tests of Distributional Shape

A large part of the literature on goodness of fit is concerned with testing distributional shape. A full coverage is given by D'Agostino and Stephens [6]. One example is the Bowman–Shenton test, which uses moment properties of the normal distribution. A more general class of tests, applicable to a general continuous distribution, compares the empirical distribution function $F_n(y)$ of the sample with the cumulative distribution function $F_o(y)$ of the proposed distribution. As an example, we take the **Kolmogorov–Smirnov** test, based on the maximum difference between the two distributions

$$D = \sup_y |F_n(y) - F_o(y)|, \tag{23}$$

and apply it to the residuals of the data on mandible length.

The empirical distribution function (edf) of a sample of n observations y_i is the number of observations $\leq y$. If the ordered observations are denoted $y_{(i)}$, the e.d.f. is given more formally by

$$F_n(y) = \frac{i}{n} \quad y_{(i)} \leq y < y_{(i+1)}, \tag{24}$$

with

$$F_n(y) = 0, \quad y < y_{(1)} \quad \text{and} \quad F_n(y) = 1 \quad y_{(n)} \leq y. \tag{25}$$

The test is most easily performed by applying the probability integral transformation to the observations $\boldsymbol{y}$ to give a sample $\boldsymbol{z}$ that is **uniformly** distributed under the hypothesized distribution. For example, for the normal distribution with cdf $\Phi(w)$, let

$$w_i = \frac{y_{(i)} - \mu}{\sigma} \quad \text{and} \quad z_{(i)} = \Phi(w_i). \tag{26}$$

Figure 5 shows a plot of the edf of $F_n(z)$ against z, that is, of i/n against z. The two-sided Kolmogorov–Smirnov test for the test of normality is the maximum of the two one-sided tests calculated as

$$D^+ = \sup_i \left\{ \frac{i}{n} - z_{(i)} \right\}; \quad D^- = \sup_i \left\{ z_{(i)} - \frac{i-1}{n} \right\} \tag{27}$$

giving the test statistic

$$D = \sup\{D^+, D^-\}. \tag{28}$$

The value of the statistic for the mandible data is 0.0667. If the null distribution were completely specified, the statistic would not depend on the assumed distribution and the result would not be significant at the 5% level. In calculating the statistic, an estimate has had to be used for the standard deviation in the probability integral transformation, although the mean of the residuals is zero. Both the effect of estimation and of the correlation pattern of the residuals should be allowed for in calculating the significance of the statistic, although here there seems no doubt about the lack of evidence of departure from normality.

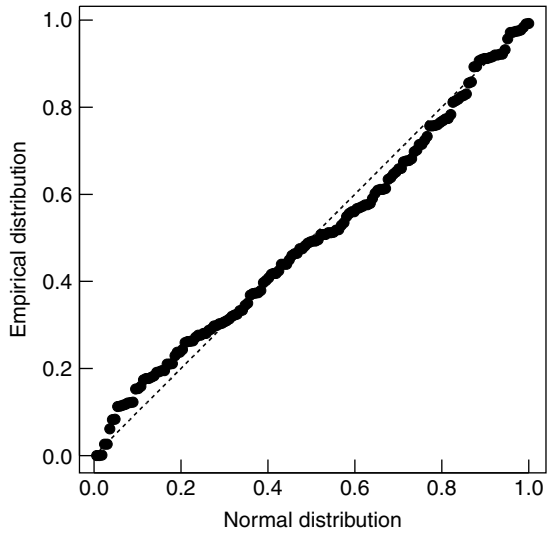

Figure 5 Mandible length data. The Kolmogorov–Smirnov test for normality is based on the greatest vertical distance between the empirical distribution and the dotted line

The comparison of Figure 5 with Figure 3 shows that it is not straightforward to interpret the edf of the z in terms of individual outliers. In particular, Figure 5 indicates why the Kolmogorov–Smirnov test failed to detect the outliers from an otherwise seemingly normal distribution. The general point, made in the introduction to this article, is the frequent lack of power of overall tests of fit against specific alternatives. Normal probability plots are more sensitive to **outliers** than the plot of Figure 5, although guidance, for example, from a simulation envelope, may be needed as to whether the line is sufficiently straight. If the interesting departures are likely to be in the tails of the distribution, statistics giving greater weight to the extremes will be more powerful. D'Agostino and Stephens [6] describe several such statistics. For discrete distributions methods such as Pearson's X^2 are often used.

Tests of **multivariate distributions** are in general much less well developed, an exception being the **multivariate normal distribution**. One possibility is to apply the multivariate Box–Cox transformation to normality (for example, Velilla [21], Riani and Atkinson [17]), testing to see whether a transformation is needed. A comparison of tests of **multivariate normality** is given by Romeu and Ozturk [18].

A.C. ATKINSON

Gosset, William Sealy

Born: June 13, 1876, in Canterbury, UK.
Died: October 16, 1937, in London, UK.

William Sealy Gosset was born to Frederic Gosset, a Colonel in the Royal Engineers, and Agnes Sealy Vidal. He was a Scholar of Winchester College from 1889 to 1895, when he took up a scholarship at New College, Oxford, which he left in 1899 with a first class degree in Chemistry. In October 1899, he became a brewer with Arthur Guinness, Son & Co. Ltd and remained with the firm for the whole of his working life, mostly in Dublin, but moving to London in 1935. Gosset was married on January 16, 1906, to Marjorie Surtees Philpotts, the sister of a fellow brewer, and there were three children. He died aged 61.

The business of Guinness was then entirely concerned with the brewing of stout. Gosset was one of several men from Oxford and Cambridge who were appointed to make greater use of scientific methods. His work called for the analysis of experimental data from short runs, during which there were changes in both materials and the environment. He had no statistical training, and turned to the standard textbooks on the combination of observations in astronomy and geodesy. Their treatments assumed long series of observations made under stable conditions, whereas Gosset required methods that could be applied to small samples. He made contact with **Karl Pearson**, head of the Biometric Laboratory at University College, London, and attended lectures and tutorials there during the period 1906–1907. They included the idea of **correlation**, the Pearson system of nonnormal distributions (*see* **Pearson Distributions**), and the **chi-square test** for **goodness of fit**.

Gosset's early work is a fusion of classical methods for the combination of observations with the new ideas promoted at the Biometric Laboratory. His paper on the probable error of a mean, published in 1908, is the best example. The distribution of his test criterion, then called z, required him to find the distribution of the **variance** in normal samples, and prove its independence from the long-known distribution of the sample **mean**. He solved the first by fitting a Pearson curve with the same **moments**, and gave support to the second by establishing no correlation between mean and variance. The proof is not rigorous, but his distribution of z, now modified to t, is correct, and has been a discovery of the greatest importance throughout statistical methodology. Those who meet his test criterion for the first time usually do so as **Student's *t***, a pseudonym initially adopted to permit publication, and retained long after his work became well known.

After Gosset's return to Ireland, his published work was mainly concerned with agricultural field trials and the design of experiments, derived from his experience in the Irish barley fields. He always took an interest in the activities of his former teacher, and his private correspondence was gradually enlarged to deal with questions from other statisticians, including **R.A. Fisher**, from 1912. The effect on Fisher of Gosset's paper on the probable error of a mean was profound, leading on the one hand to the detailed exploration of **normal distribution** theory, and on the other to a central part of *Statistical Methods for Research Workers* [1], which eventually made Gosset's work known throughout the statistical world. Their correspondence turned to matters of experimental design after Fisher moved to Rothamsted in 1919, and here differences of opinion eventually emerged regarding the relative merits of **randomization** and balance. Towards the end of his career, Gosset became interested in evolutionary genetics, and Fisher helped with the promotion of his ideas.

Gosset gave advice, criticism, and enlightenment at a crucial phase in the career of **Egon S. Pearson** between 1926 and 1931, and also friendship, which the younger man never forgot. The foregoing account

is based on the book by E.S. Pearson [2] and appears by permission of Oxford University Press.

Graeco–Latin Square Designs

A Graeco–Latin square is a pair of **orthogonal Latin squares**, so named because Euler in 1782 used Roman and Greek letters to distinguish the symbols of the two Latin squares. Sometimes it is also referred to as an *Eulerian square*. If $S = (s_{ij})$ and $T = (t_{ij})$ are two Latin squares, each of *order* n, and defined on the set of symbols $1, 2, \ldots, n$, they are said to be *orthogonal* if each of the n^2 possible ordered pairs of the symbols occurs just once among the pairs (s_{ij}, t_{ij}). Any two of the Latin squares of order 4 in Figure 1 are orthogonal, and hence each pair forms a Graeco–Latin square.

A Graeco–Latin square is usually shown with the two symbols together in one square, often using Roman letters $A, B, C, \ldots$ for S and Greek letters $\alpha, \beta, \gamma, \ldots$ for T. Alternative representations use the T symbols as a suffix of the S symbols, or use ordered pairs (s_{ij}, t_{ij}). The first two squares in Figure 1 can be represented as in Figure 2.

Graeco–Latin squares exist for all orders n except 1, 2 and 6. In his original paper, Euler proved the existence of Graeco–Latin squares when n is an odd integer or a multiple of 4 but conjectured nonexistence of the squares for $n = 4k + 2$ for all $k = 1, \ldots$. In 1900, G. Tarry proved the conjecture for $k = 1$ but later, in 1960, Bose et al. [2] proved that it cannot hold for all $k > 1$. This constituted the first complete proof on the existence of Graeco–Latin squares (see [4] for more details, including other proofs).

A Graeco–Latin square can, in theory, be used for various experimental situations in which there are four effects that can be assumed to be additive. The four effects are orthogonal, leading to simple estimates and a simply calculated **analysis of variance**. With the usual constraints that the estimates sum to zero for each effect, the estimate for an effect symbol is the **mean** value for that symbol minus the overall mean. Each effect sums of squares is the sum of squares of the n estimates multiplied by n, and each is on $n - 1$ **degrees of freedom**. The residual degrees of freedom is therefore $(n - 1)(n - 3)$. As written, the design naturally appears to be a row–column design (a design with two orthogonal blocking structures) with n rows and n columns, and treatments formed by two orthogonal factors each of n levels. Only the main effects of these factors can be estimated. Although this use with two factors is rare, the design essentially arises when the units of an experiment on n treatments with row–column **blocking** using a Latin square design are to be used in a later experiment on another n treatments, and it is wished to have the new treatments orthogonal to the previous ones. The new treatments are said to be *superimposed* on the old ones.

Other possible situations when a Graeco–Latin square might be used are as a three-dimensional row–column–layer design (three orthogonal blocking effects each with n categories) for an experiment on n treatments (using the Roman letters for the layer levels); a $1/n$ **fractional factorial design** for three orthogonal factors with n categories (n^{3-1} design) having n blocks of size n (using the rows for blocks); and a $1/n^2$ single block fractional factorial design

for four orthogonal factors with n categories (n^{4-2} design). In the factorial cases, only main effects are estimable. Using the example of Figure 2 and factors A, B, C, D, the latter two cases give the following designs in the usual notation with levels $0, 1, \ldots, n-1$ (brackets denote blocks, and factors may be superimposed treatments):
a 4^{3-1} design in four blocks:

$$(a_0b_0c_0, \quad a_1b_1c_1, \quad a_2b_2c_2, \quad a_3b_3c_3),$$
$$(a_0b_1c_2, \quad a_1b_0c_3, \quad a_2b_3c_0, \quad a_3b_2c_1),$$
$$(a_0b_2c_3, \quad a_1b_3c_2, \quad a_2b_0c_1, \quad a_3b_1c_0),$$
$$(a_0b_3c_1, \quad a_1b_2c_0, \quad a_2b_1c_3, \quad a_3b_0c_2);$$

a 4^{4-2} design in one block:

$$(a_0b_0c_0d_0, \quad a_0b_1c_1d_1, \quad a_0b_2c_2d_2, \quad a_0b_3c_3d_3,$$
$$a_1b_0c_1d_2, \quad a_1b_1c_0d_3, \quad a_1b_2c_3d_0, \quad a_1b_3c_2d_1,$$
$$a_2b_0c_2d_3, \quad a_2b_1c_3d_2, \quad a_2b_2c_0d_1, \quad a_2b_3c_1d_0,$$
$$a_3b_0c_3d_1, \quad a_3b_1c_2d_0, \quad a_3b_2c_1d_3, \quad a_3b_3c_0d_2).$$

A Graeco–Latin square can also be used to obtain a four-replicate resolvable (0, 1) (all within-block pairwise concurrences are 0 or 1) **Lattice square design** for n^2 treatments in n blocks of size n. The replicates are formed by writing the numbers 1 to n^2 in an n by n array, and then using the rows for the blocks for first replicate, the columns for the second, the Roman letters for the third, and the Greek letters for the fourth.

Two drawbacks to the widespread use of the Graeco–Latin square in practice are the need for all four effects to have n levels, and that it is rare for a factor to have more than about five levels. When used, a valid **randomization** of treatment labels to units is necessary – see [10]. Preece et al. [12] show that care is needed to ensure a valid randomization when treatments are superimposed.

An extension of the Graeco–Latin square is to have more than two orthogonal Latin squares. Situations in which $m > 2$ *mutually orthogonal Latin squares* (MOLS) can be used are natural extensions of those discussed for the Graeco–Latin square. The maximum possible value for m is $n-1$, which is attainable when n is a prime power. Then the $n-1$ orthogonal Latin squares are known as a *complete set*. Figure 1 gives an example for $n = 4 = 2^2$. Clearly, for $n = 6$ (and 1, 2) the maximum value of m is 1. The maximum value of m that is possible is denoted $N(n)$. Although $N(n)$ can be bounded below, its value is not known even for $n = 10$. It is known that $N(10) \geq 2$, $N(12) \geq 5$, and $N(n) \geq 3$ for all $n > 10$. A table of recent lower bounds for $N(n)$ for n up to 199 is given by Brouwer [3] (but note $N(27) = 26$, $N(97) = 96$). Complete sets of MOLS of orders 3 to 5, 7 to 9, are given in [5].

The existence of m MOLS of order n is equivalent to the existence of what is known as an orthogonal array OA $(n, m+2, 2, 1)$ of $m+2$ constraints, n levels, strength 2, and index 1. Some design constructions are given in terms of the OA (see [8]). If $m > 2$, then the above construction using a Graeco–Latin square for $m = 2$ can be extended to get an $(m+2)$- replicate resolvable (0, 1) *square lattice design* for n^2 treatments in n blocks of size n. When $m = n-1$, the complete set gives the $(n+1)$-replicate *balanced square lattice design* or the symmetric **balanced incomplete block design** (BIBD) $(n^2, \quad n(n+1), \quad n)$, equivalent to a *finite projective plane* with $n+1$ points on every line. A *balanced lattice square*, a nested row–column design with n^2 treatments for which each $n \times n$ block is a complete replicate, can be constructed from a balanced square lattice design, or equivalently from the $n-1$ MOLS. In general, m MOLS can be used to construct an $(m+2)$- replicate lattice square. They can also be used to construct an $(n \times n)/m$ Trojan square design for nm treatments replicated n times in an $n \times n$ row-column array of plots each with m subplots [11].

Sets of MOLS can be sought for particular types of Latin squares, such as *self-orthogonal, Knut Vik, row-complete* – see [6]. The construction of an r-replicate *rectangular lattice design* for $n(n-1)$ treatments uses $r-2$ MOLS of order n, which have each symbol on the main diagonal, a *semi-diagonal* Latin square. Bailey [1] has shown that complete sets of mutually orthogonal *quasi-complete* Latin squares exist when n is an odd prime power. These have every symbol next to every other symbol twice in the rows and twice in the columns. A complete set of MOLS can also be used as a valid Latin square randomization set. Sets of MOLS may then be used for a valid Latin square *restricted randomization* scheme. Martin [7] showed that a complete set of mutually orthogonal quasi- complete Latin squares can be chosen to have low variation under spatial dependence.

When m MOLS do not exist, it may be possible to find m Latin squares that are "nearly" orthogonal –

see [6]. Further discussion of Graeco–Latin squares and MOLS is in Keedwell [6] and Street & Street [13]; see also Preece [9, 10].

RICHARD J. MARTIN &
SARALEESAN NADARAJAH

Gramian Matrix

A symmetric matrix of real numbers $\mathbf{A}$ is said to be a Gramian matrix if there exists a matrix $\mathbf{B}$ of real numbers such that $\mathbf{BB}' = \mathbf{A}$ or $\mathbf{B}'\mathbf{B} = \mathbf{A}$ (see, for example, [1]).

Consider an application involving a sample of n subjects measured on k variables. Suppose each observation y_{ij}, $i = 1, \ldots, k$; $j = 1, \ldots, n$, is centered about its variable mean, i.e. $x_{ij} = (y_{ij} - \overline{Y}_i)$, and normalized by dividing by $\left(\sum_j x_{ij}^2\right)^{1/2}$. Call this $k \times n$ matrix of centered and normalized observations $\mathbf{W}$. Note that the elements of $\mathbf{W}$ are of the form $w_{ij} = x_{ij} \Big/ \left(\sum_j x_{ij}^2\right)^{1/2}$, $i = 1, \ldots, k$; $j = 1, \ldots, n$. The $k \times k$ **correlation** matrix, $\mathbf{R}$ is $\mathbf{WW}'$. Since every element of $\mathbf{W}$ and $\mathbf{R}$ is real, $\mathbf{R}$ is a Gramian matrix. The elements of $\mathbf{R}$ are of the form

$$r_{ii'} = \frac{\sum_j x_{ij} x_{i'j}}{\left(\sum_j x_{ij}^2\right)^{1/2} \left(\sum_j x_{i'j}^2\right)^{1/2}}.$$

Suppose a **principal components analysis** is performed on $\mathbf{R}$ (the $k \times k$ correlation matrix). $\mathbf{R}$ can be written as $\mathbf{R} = \mathbf{EDE}'$, where $\mathbf{D}$ is a $k \times k$ diagonal matrix whose diagonal elements are the **eigenvalues** of $\mathbf{R}$, and $\mathbf{E}$ is a $k \times k$ matrix which is orthonormal by columns [1]. Since $\mathbf{D}$ is a diagonal matrix it can be written as $\mathbf{D} = \mathbf{D}^{1/2}(\mathbf{D}^{1/2})'$, and therefore $\mathbf{R} = (\mathbf{ED}^{1/2})(\mathbf{ED}^{1/2})'$ is Gramian as long as the elements of $\mathbf{D}$ are real. Suppose we let $\mathbf{F} = (\mathbf{ED}^{1/2})$; $\mathbf{F}$ is called the principal components loading matrix of $\mathbf{R}$. The matrix $\mathbf{F}$ can be viewed as a sequence of row vectors $\mathbf{f}_i' = (f_{i1}, f_{i2}, \ldots, f_{ik})$, $i = 1, \ldots, k$. The determinant of the matrix the elements of which are the inner products of the vectors $\mathbf{f}_i$ and $\mathbf{f}_{i'}$, denoted $(\mathbf{f}_i'\mathbf{f}_{i'})$,

$$\begin{vmatrix} (\mathbf{f}_1'\mathbf{f}_1) & (\mathbf{f}_1'\mathbf{f}_2) & \ldots & (\mathbf{f}_1'\mathbf{f}_k) \\ (\mathbf{f}_2'\mathbf{f}_1) & (\mathbf{f}_2'\mathbf{f}_2) & \ldots & (\mathbf{f}_2'\mathbf{f}_k) \\ \vdots & & & \vdots \\ (\mathbf{f}_k'\mathbf{f}_1) & (\mathbf{f}_k'\mathbf{f}_2) & \ldots & (\mathbf{f}_k'\mathbf{f}_k) \end{vmatrix} = \begin{vmatrix} f_{11} & f_{12} & \ldots & f_{1k} \\ f_{21} & f_{22} & \ldots & f_{2k} \\ \vdots & & & \vdots \\ f_{k1} & f_{k2} & \ldots & f_{kk} \end{vmatrix}^2,$$

is called the Gramian determinant.

In **factor analysis** the correlation matrix $\mathbf{R}$ is replaced by the reduced correlation matrix $\mathbf{R}^*$, where the ones on the diagonal of $\mathbf{R}$ are replaced with the **communalities**. Factor analysis then searches for a $k \times m (m < k)$ matrix $\mathbf{F}^*$, where $\mathbf{F}^*(\mathbf{F}^*)' = \mathbf{R}^*$. Here m is the dimension of the common factor space (see [1, Chapter 5]).

In practice, Gramian matrices and determinants are used, for example, in principal components analysis and factor analysis (see, for example, [1]), and to estimate parameters in **multiple regression** applications (see, for example, [2]).

LISA M. SULLIVAN

Gram–Schmidt Process

The Gram–Schmidt process, also called the Gram–Schmidt **orthogonalization** process, is a technique for constructing an orthogonal basis from a basis spanning the same subspace. Consider a square oblique matrix $\mathbf{X}$ with row vectors $\mathbf{x}_i'(i = 1, 2, \ldots, m)$. The orthogonal matrix $\mathbf{Y}$ the first row of which is identical to the first row of $\mathbf{X}$ can be determined through the Gram–Schmidt process using the following equations, which are developed sequentially:

$$
\begin{aligned}
\mathbf{y}_1' &= \mathbf{x}_1', \\
\mathbf{y}_2' &= \mathbf{x}_2' - \left(\frac{\mathbf{x}_2'\mathbf{y}_1}{\mathbf{y}_1'\mathbf{y}_1}\right)\mathbf{y}_1', \\
\mathbf{y}_3' &= \mathbf{x}_3' - \left(\frac{\mathbf{x}_3'\mathbf{y}_1}{\mathbf{y}_1'\mathbf{y}_1}\right)\mathbf{y}_1' - \left(\frac{\mathbf{x}_3'\mathbf{y}_2}{\mathbf{y}_2'\mathbf{y}_2}\right)\mathbf{y}_2', \\
&\vdots \\
\mathbf{y}_m' &= \mathbf{x}_m' - \left(\frac{\mathbf{x}_m'\mathbf{y}_1}{\mathbf{y}_1'\mathbf{y}_1}\right)\mathbf{y}_1' - \left(\frac{\mathbf{x}_m'\mathbf{y}_2}{\mathbf{y}_2'\mathbf{y}_2}\right)\mathbf{y}_2' - \cdots \\
&\quad - \left(\frac{\mathbf{x}_m'\mathbf{y}_{(m-1)}}{\mathbf{y}_{m-1}'\mathbf{y}_{(m-1)}}\right)\mathbf{y}'_{(m-1)}.
\end{aligned}
$$

Since the $(\mathbf{x}_i'\mathbf{y}_j/\mathbf{y}_j'\mathbf{y}_j)$ terms produce scalars, each $\mathbf{y}_j'(j = 1, 2, \ldots, m)$ is a row vector. The rows of $\mathbf{Y}$ are then normalized producing an orthogonal matrix (see, for example, [1, pp. 237–242] for a complete discussion of the process with examples).

The technique is used in a variety of settings, including **battery reduction** analysis and in estimating parameters in **multiple regression** applications. In battery reduction analysis, for example, it is of interest to reduce the number of variables. One means of achieving this is through Gram–Schmidt orthogonal rotations of the initial **factor loading matrix** from a **principal components analysis**. The process takes the initial factor matrix and finds the variable with the largest variance shared by other variables (called the **communality**).

A Gram–Schmidt rotation is performed so that the first component is identical to this variable. The process continues as follows. From the remaining variables, the one with the largest shared variance is found, and a Gram–Schmidt rotation is performed so that the second component is identical to this second variable. The process continues until m variables are identified, where $m < p$, and p represents the total number of original variables. The goal in battery reduction analysis is to reduce the number of variables while at the same time explaining as much variance in the original variables as possible (see, for example, [2]). In multiple regression applications, the goal is to reduce the n-dimensional space (where n represents the number of observations) to a p-dimensional space ($p < n$, where p represents the number of independent variables).

KIMBERLY A. DUKES

Graphical Displays

Statistical graphics are abstract pictures of numbers that represent either the data themselves or quantities derived from the data. Their value stems from the fact that it is often easier to extract information from well-chosen pictures than from sets of numbers. Although a table of numbers can be considered a graphic, generally, graphics are distinguished from tables as alternative representations used for different purposes. For small sets of numbers or for situations in which the exact values of the numbers are required, tables are better than graphics; for examining less local properties (like patterns) in large data sets, graphics are better. More generally, graphics are invaluable tools for recording and storing large data sets, analyzing (describing, exploring, and summarizing) data, enhancing the use of other statistical tools, communicating numerical information, decorating articles, reports, and so on. Graphics are not an end in themselves, but are constructed for specific purposes and should be judged in this context. The best graphics are those that show clearly and forcefully, but without distortion, the presence or absence of features of the data that are important to the substantive questions underlying the analysis.

Statistical graphics have been in use at least since Playfair [73] and are in a continuing state of evolution; see [14, 35, 37, 44, 91] for historical background. Stimulating discussions of the principles and aesthetics of graphic construction can be found in a variety of references including [22, 24, 37, 82, 83, 86].

Many of the important ideas concerning graphic construction can be summarized by the statement that good graphics are those that convey complex numerical information with clarity, precision, and efficiency. The key elements of good graphics can be identified as substance, statistics, and design. Graphics should be based on good statistics, both in the sense of being integrated into statistical analysis and in the choice of what to plot. For instance, we may variously consider plotting differences or ratios rather than the raw data, plotting transformed variables rather than the original variables, removing gross structures such as linear trends so that we can concentrate on finer details, partitioning data that contains clusters and exploring the clusters separately, augmenting plots with fitted curves and other statistical summaries or even by plotting summaries of the data (e.g. boxplots) rather than the data itself. When possible, statistical methods should be used to help assess whether a feature in a graphic is an artifact or not. The design aspects of a graphic (size, aspect ratio, choice of axes, and plotting symbols) should be appropriately chosen to reflect balance, proportion, and a sense of scale. Length and direction are the preferred basis for plotting symbols; shape is generally better than size for coding information though size is widely used. Color is a potentially effective encoding method but can be difficult to use and restrained gray scales may be a better alternative. Finally, it seems natural to require the visual impact of a pattern to be matched to importance in the context of the analysis.

One of the more elusive ideas in graphic construction is that graphics should be simple. At a basic level, complex, cluttered graphics are difficult to interpret and can be misleading because clutter can interfere with our perception. Clutter can be reduced by eliminating gridlines, choosing appropriate scales (including plotting characters, transformation, etc.), and reducing the data (such as by the use of plotting symbols as in a sunflower plot). Careful, accurate labeling should be used to reduce complexity but needs to be balanced against a possible increase in clutter. Simplicity of perception can be achieved by noting that straight lines are perceived more clearly than curves; therefore, reference curves are preferably straight lines as in quantile–quantile (Q–Q) plots or residual plots. The difficulty is that simplicity of perception and simplicity of interpretation can conflict. For example, simplicity of perception can be achieved by ensuring that deviations of equal magnitude have equal importance in a graphic. In a histogram, longer bars are more variable than smaller ones but the square root transformation can be used to produce a rootogram [90] in which the bars have equal variability, at the expense of increasing the difficulty of interpretation. Similarly, dependence can have unexpected effects and complicate the interpretation of a graphic. For example, the **order statistics** in a Q–Q plot are dependent, so apparent structure can be due to this dependence. An alternative is to base the plot on the spacings between order statistics but again the requirements of simplicity of perception and simplicity of interpretation compete. To complicate matters, interpretability depends on the training and experience of the observer.

Successful graphic construction (and data analysis generally) requires flexible strategies and a computational environment for implementing these strategies. Graphics capabilities are hardware dependent (i.e. they depend on the particular terminal or device being used) but a minimal requirement includes high-resolution (even color) screens and printers, a "real-time" graphic capability to support dynamic graphics, and the ability to interact directly with the displays. The simplest interactions we need to make involve a single window. These include rotating, interpolating, scaling, subsetting, marking, and identifying points as well as controlling dynamic graphics. It is also desirable to be able to implement multiwindow interactions such as linking windows and brushing (highlighting, downlighting, deleting, and labeling). We need high-level abstract computing languages that express manipulations in the way we think about them. It is convenient for a language to include inbuilt default settings so that we do not always have to set explicitly every possible graphical parameter, but it is vital to be able to adjust all of these parameters quickly and easily. The graphics in this article are all constructed in **S-PLUS** running in a workstation environment.

The article is organized into six broad sections: relationships between two variables; relationships between several variables; the display of one-dimensional data; data developing through time; multivariate data; and survival data. We elected to treat relationships between two variables before the familiar one-dimensional displays because we felt that practitioners in biostatistics and statistics in medicine and the health sciences are more naturally concerned with relationships *between* variables than with simple univariate data. (e.g. in many applications in medical statistics, there is a well-defined **response variable** that is to be modeled in terms of several **explanatory variables**.) One-dimensional displays then arise naturally through looking at topics such as **residual** analysis from modeling relationships between variables.

Relationships Between Two Variables

Scatterplots

The simplest, and one of the most powerful, graphical tools for describing the relationship between two variables is the *scatterplot*, which represents each pair of data values using (x, y) coordinates in a Cartesian plane. The "shape" of the scatterplot is used to describe the relationship between the two variables. Two elements of the "shape" of a scatterplot that are most useful in describing relationships between variables are measures of "location" and "spread" for the (x, y) data. For example, location might be measured as a line or a curve that runs through the bulk of the data while spread might be measured in terms of deviations of (x, y) points from the estimated location. The use of notions like location and spread to describe the relationship observed from a scatterplot is essentially a form of smoothing applied to the scatterplot, and the results of this smoothing can be added to the scatterplot through the addition of fitted curves. The resultant plot contains information about individual data points as well as summarizing the relationship between the variables through the fitted curve. A seminal paper describing the use of scatterplots (and other graphics) in data analysis is [4]. Other relevant references for the general use of scatterplots include [20, 24].

Scatterplot Smoothing

Numerous strategies have been developed for smoothing scatterplots, primarily for estimating the location of the relationship. One suggestion, due to Cleveland [22, 23], is *lowess* (Locally Weighted Scatterplot Smoothing), which smooths by averaging local straight line fits to the data; see also [20]. Alternatives to lowess include running (weighted) mean smoothing, running (weighted) median smoothing, and **spline smoothing**; see [78, 82, 88]. All of these methods depend on the selection of bandwidths that control how local the fitting methods are. Smoothing approaches to estimate spread are usually based on *residuals*, deviations of the data from the estimated location, and are often based on location-smoothing of scatterplots of absolute residuals versus fitted values; see below for a discussion of methods based on residuals. Figure 1 shows a simple scatterplot of brain weight (in grams) versus body weight (in kilograms) for 62 mammals. This graphic demonstrates that as body weight increases, brain weight tends to also increase, but the precise relationship between brain weight and body weight is difficult to describe. The "location" of the scatterplot exhibits significant curvature, and the points seem to be very compressed in the bottom left corner of the plot. The real question

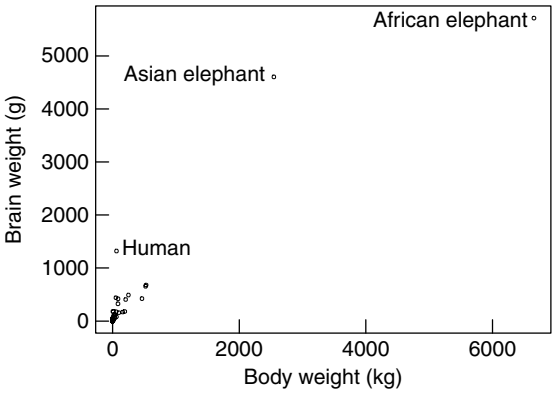

Figure 1 Scatterplot of brain weight versus bodyweight for 62 mammals. (Source: Weisberg [93]; excerpted from a larger study presented by Allison and Ciccheti [1]). Three "unusual" points are marked in the plot

arising from this basic graphic is: can it be improved to more precisely indicate the relationship between brain weight and body weight?

Use of Transformations to Straighten Scatterplots

One strategy often followed in presenting scatterplots is that of trying to find **transformations** of the original variables, so that a scatterplot involving the transformed variables displays a roughly linear relationship with a roughly constant spread of the response variable (y) for different values of the explanatory variable (x). Such strategies are desirable from a classical parametric modeling standpoint because they make the usual assumptions underlying parametric regression modeling more credible. They are also desirable graphically from the point of view of simplicity, visual appeal, and interpretability. It is important to keep in mind, of course, that the relationship between variables on the original scale is usually most important, and variables should not be transformed without thought for how a linear relationship on the transformed scale can be interpreted in terms of the original variables. A general discussion of the use of transformations in analyzing data is given by Mosteller & Tukey [71]. Broadly speaking, there are two approaches to transforming variables in order to understand their relationship: data-driven approaches and theoretical approaches. Data-driven approaches attempt to empirically straighten scatterplots. One data-driven method, suggested by Box and Cox [17], selects transformations from the class of **power transformations** to obtain the best linear fit to the data on the transformed scale. Once a transformation has been thus selected, scatterplots of the transformed variables can be employed to assess whether the transformation has been successful in linearizing the scatterplot. Theoretical approaches to transformations may be possible when prior information about the data can be used to help in selecting an appropriate transformation. For example, data arising from an exponential growth model typically yields a scatterplot that can be linearized by taking logs of the response variable. (Of course, it is critical to recognize that taking logs of the response variable affects not only its location but also its spread). Figure 2 shows how transformations can be used to effectively clarify the relationship between two variables. Shown is a plot of log brain weight versus log bodyweight for the data set described in the previous paragraph. There is a clear linear relationship between the logged variables. Points appearing unusual on the original scatterplot look less so on the transformed scale and the logged data also has much more uniform spread (along both sets of axes) than the original data. By positing a linear relationship between log brain weight and log body weight, it is possible to make clear the precise nature of the relationship between brain weight and body weight, a task rendered difficult using only the original scatterplot.

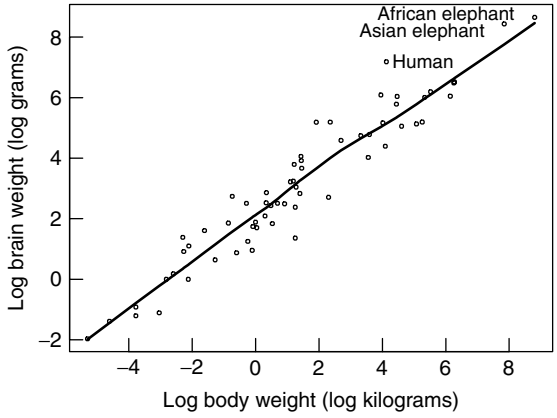

Figure 2 Scatterplot of log brain weight versus log body weight for 62 mammals. A lowess line is superimposed. Unusual points marked in Figure 1 are marked in this plot also for comparison

Relationships Between Several Variables

The Scatterplot Matrix

While the basic scatterplot is a satisfactory tool for describing the relationship between two variables, more sophisticated strategies become necessary when the goal is to explain a response variable in terms of several explanatory variables. A basic approach to this problem involves the use of a *scatterplot matrix*, an array of scatterplots relating every pair of variables for which we have data; see [20]. Individual panels of the scatterplot matrix can be smoothed, perhaps using a method like lowess, or with a fitted curve arising from a parametric model fit. The scatterplot matrix can be used to describe the marginal relationship between any pair of variables, but it is unable to provide information on joint relationships involving three or more variables. Figure 3 shows a scatterplot matrix for a data set from a study relating body fat to three explanatory variables, triceps skinfold thickness, thigh circumference, and midarm circumference. The scatterplot matrix shows that both triceps and thigh measurements have a positive relationship with body fat, but that midarm appears to have little relationship to body fat. Notably, triceps and thigh measurements appear highly correlated with one another.

Scatterplots Using Different Plotting Symbols

Basic scatterplots can be embellished to provide higher-dimensional information in several ways. One way is through the use of different plotting symbols on the scatterplot to yield information on other variables in the problem. For example, if one wished to plot information about three variables, one of which was **categorical** and the other two of which were measured continuously, one could plot a scatterplot involving the two continuous variables but the plotting symbol could reflect the level of the third variable. If all three variables were measured continuously, the magnitude of the third variable could be encoded as the length of a line segment that could be then used as a plotting symbol in a scatterplot of the other two variables. Higher-dimensional data could be accommodated by using higher-dimensional symbols: for example, the size of two variables could be conveniently encoded and plotted as the width and height of a rectangle. Other plotting symbols include: *metroglyphs*, circular symbols with rays extending from them [2]; stars where

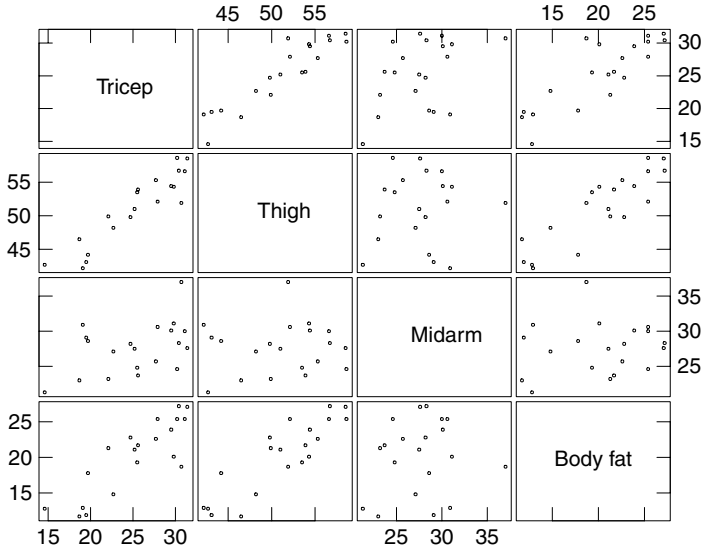

Figure 3 Scatterplot matrix for body fat data. (Source: Neter et al. [72, Chapter 8]). Each cell of the array of plots shows a simple scatterplot relating the pair of variables indicated in the corresponding row and column of the array. Response variable is body fat; explanatory variables are triceps skinfold thickness, thigh circumference, and midarm circumference. The data is based on a sample of 20 healthy females aged between 25 and 34 years

the number of rays reflects the number of variables encoded [45]; weather vane symbols [19]; and sunflowers [27]. Other ideas have been furnished by Hartigan [53], Bachi [8], Bertin [16], Everitt [42], and Tukey and Tukey [88]. An overview of the use of symbols in graphing data is given by Cleveland [24]. When choosing the type of symbol with which to encode information on several variables, a useful rule of thumb is to use a symbol having the same dimension as the number of variables it is encoding. Returning to the body fat data introduced in the previous paragraph, Figure 4 shows a scatterplot of body fat versus thigh circumference with midarm and triceps encoded as the width and height, respectively, of rectangles. Note that as thigh circumference increases, body fat tends to increase and the rectangles change from being shorter and flatter to taller and thinner, reflecting changes in the other variables.

Coplots

Another approach to presenting higher-dimensional data that uses simple scatterplots as its basis is the use of *coplots*. In a case where the data has two explanatory variables x_1 and x_2 and one response variable y, a set of coplots may consist of a sequence of scatterplots involving the response variable and one of the explanatory variables (say x_1), but points plotted within each scatterplot are those whose values of the second explanatory variable x_2 falls within some specified range. By using a sequence of (potentially overlapping) segments of x_2 that span its range, the sequence of scatterplots indicates how the relationship between y and x_1 changes as x_2 changes. If one of the variables is categorical, its levels serve as a natural set of values of the third variable for which to set up coplots. Geometrically, coplots can be thought of in terms of examining a sequence of slices parallel to the (x_1, y) plane rather than simply projecting all the data onto that plane, as occurs in a simple scatterplot. When there are more than two **covariates**, coplots can be constructed by conditioning on all but one of the covariates, although in this case care must be taken in organizing the order in which the covariates being conditioned on change so that the resultant sequence of coplots is readily interpretable. The idea of using conditioning as a tool for creating informative graphics was discussed by Tukey and Tukey [88], and the notion of coplots was introduced by Cleveland [25]. An extension of the coplot idea is the *trellis display* proposed by Becker et al. [11]. Trellis displays retain the simple idea from coplots of producing a sequence of graphics involving two variables after conditioning on the other variables in the problem. However, trellis displays make clever use of the way in which the plots are visually presented, and are not limited

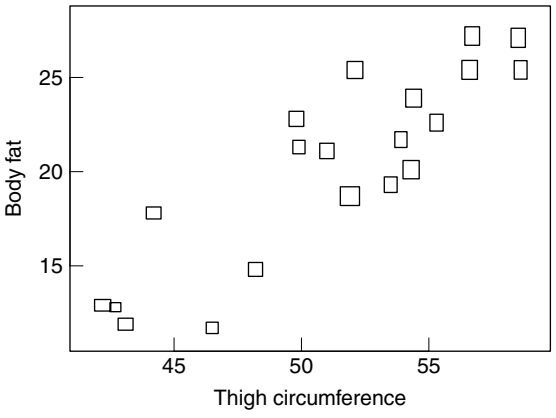

Figure 4 Scatterplot of body fat versus thigh using rectangular symbols to encode for midarm and tricep. The width of the rectangle encodes midarm; the height encodes tricep

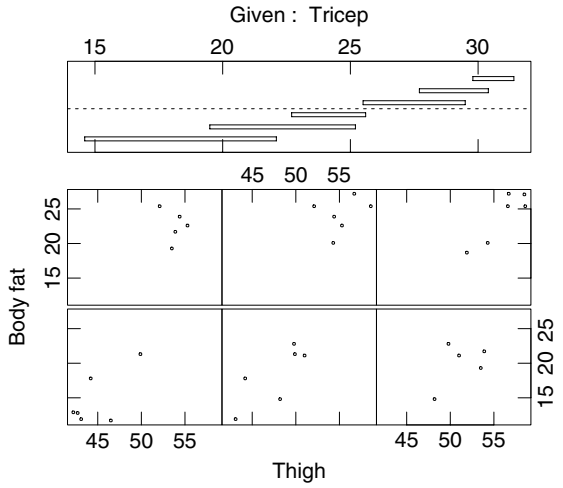

Figure 5 Coplot of body fat versus thigh given tricep. The top panel presents the range of tricep values for each of the coplot panels. The three lower plots correspond to segments of tricep below the dotted line in the top panel; the three higher plots correspond to segments above the dotted line. Note that segments of tricep are permitted to overlap, sometimes significantly, to allow for roughly equal numbers of points per coplot

to the use of two-dimensional scatterplots within the sequence of graphics displayed. An example of a coplot to investigate the relationship between body fat, thigh, and tricep for the body fat data is given in Figure 5.

Graphical Tools for Three-dimensional Data

Data in three dimensions lends itself particularly well to graphical analyses, and myriad tools are available for this case. For example, *perspective plots* and *contour plots* can be used to visualize relationships in three dimensions, and coplots are easiest to interpret in three dimensions. Extending these methods for higher-dimensional data is possible, for example, through the use of perspective coplots, or trellis displays whose panels comprise perspective plots or coplots. Figure 6 shows a perspective plot and a contour plot relating body fat to thigh and midarm circumferences for the body fat data. The plots clearly show that the response surface is fairly flat, suggesting that a linear model relating body fat to midarm and thigh may be appropriate.

One particularly promising approach to visualizing three- (and higher-) dimensional data is through the use of dynamic displays. Becker and Cleveland [10] and Cleveland and McGill [28] proposed two strategies, *brushing* and *spinning* displays, that can be used to graphically investigate three-dimensional data. Spinning displays amounts to producing a series of images of data point clouds, simulating motion as the data rotates about the origin. Structure within the data is then observed by interpreting the shape of the point cloud as it appears to move. Critical to the success of spinning displays is that the user can control the speed and direction of movement so that the data can be oriented into interesting and meaningful directions. Brushing displays can be used to embellish information obtained by spinning displays by highlighting (or "brushing") certain

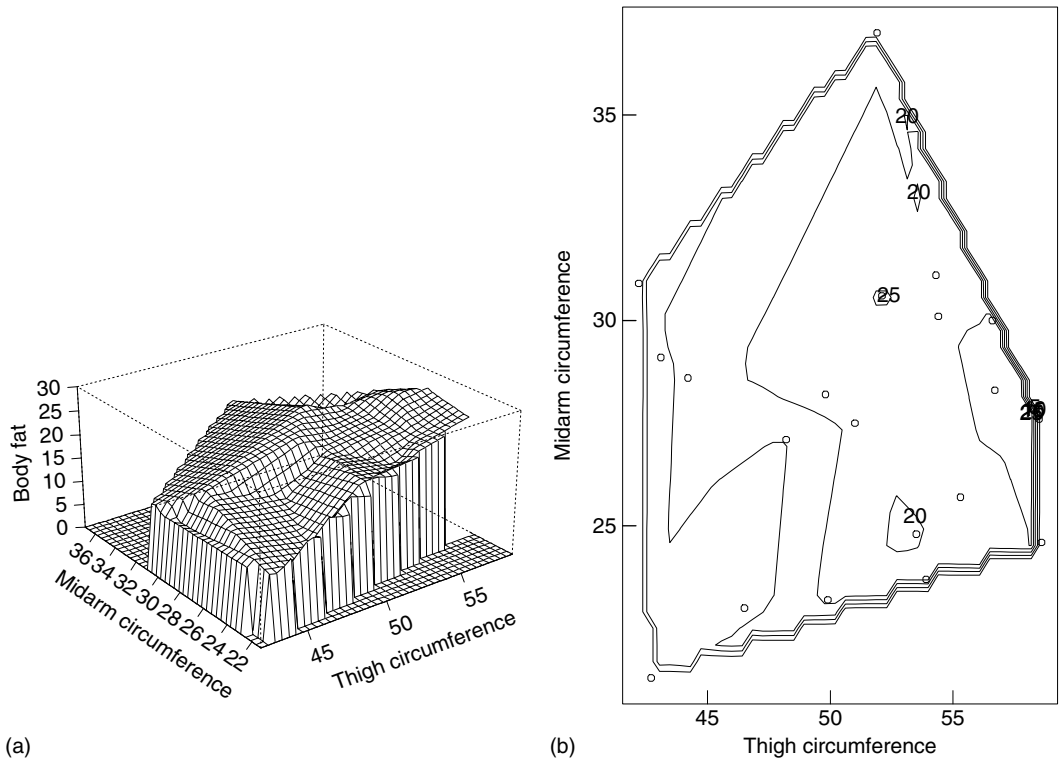

Figure 6 Plots specific to three-dimensional data. Plot (a) is a perspective plot relating body fat to the explanatory variables midarm circumference and thigh circumference. Plot (b) is a contour plot showing contours of the body fat surface projected onto the midarm–thigh plane

points or groups of points and watching how they individually affect the appearance of the point cloud. Brushing allows for the identification of outliers, influential points, and clustering within the data, as well as for other structures that may not be apparent from the simple scatterplot matrix. Dynamic graphics is a relatively new area of development in graphical data analysis, and is heavily reliant on powerful computing environments that allow the fluid movement of points in real time.

Exploring the Covariate Space

Apart from betraying relationships between the response variable and the various explanatory variables, the graphical tools described above also play an important role in finding potential problems for routine analysis in, and features of, the covariate space. Important features include the identification of outlying observations and influential points, identifying multicollinearity (*see* **Collinearity**) in the covariate space, and noting joint relationships between more than two variables that are not apparent from the two-dimensional plots in the scatterplot matrix. For example, coplots are useful tools for determining the marginal effect on the response of a certain explanatory variable (say x_1) after the effects of the other explanatory variables have been accounted for. If x_1 has a collinear relation with other explanatory variables in the data, the coplot of the response versus x_1 given the other explanatory variables exhibits no particular relationship between y and x_1 after the effects of the other variables has been accounted for, even though the original y versus x_1 scatterplot may have suggested a strong relationship between y and x_1. Note from Figure 5 that the relationship between body fat and thigh after the effect of tricep has been taken into account seems weaker than the marginal relationship observed from the scatterplot matrix. This discovery makes sense given that tricep and thigh appear highly correlated, and so contribute much the same information about body fat. Unfortunately, coplots can be difficult to interpret if the individual panels contain too few points. Coplots can also show the existence of joint relationships between more than two variables when the scatterplot matrix fails to show a strong marginal relationship between any pair of variables. The issues of multicollinearity and marginal versus joint relationships between variables are important because they directly impact our ability to describe the data in a compact way: multicollinearity because relationships between the explanatory variables prevent us saying how individual variables contribute to explaining the response; and complex joint relationships because they may not be obvious from usual, two- and three-dimensional graphical approaches. Where possible, a parsimonious model (that is, one that fits well with as few variables as possible) is the primary goal, and the reduction of the dimension of the covariate space made possible by visually examining its properties is an important part of any many-variable data analysis.

Outliers and Influential Points

Another important feature of a graphical exploration of data is the identification of unusual or aberrant data points. Here, it is important to distinguish between **outliers** (points that are far from the model fit), and *influential points* (points that do not seem consistent with the rest of the data, and whose presence dramatically affects the model fit; *see* **Diagnostics**). Outliers are usually easy to see in simple two-dimensional data sets, but can become very difficult to see in higher-dimensional data sets. In particular, the scatterplot matrix is not a reliable tool for finding outliers in three or more dimensions because the limited number of projections on which it gives information can miss unusual points in other directions in the data. Brushing and spinning tools can be highly effective for identifying outliers in three dimensions, but more general tools are needed for higher dimensions. *Residual plots*, discussed below, are often helpful for finding outliers with respect to a particular model fit, regardless of the dimension of the problem. In such cases, it is usually important that the models chosen be fit *robustly* so that the effect of outliers in the model fit is downweighted (*see* **Robustness**). Information about outliers can also be obtained by plotting the weight function used by the robust fitting technique and observing which points were downweighted in the analysis; see Figure 7(a). While robust fitting techniques can adequately deal with outliers, they may not be resistant to influential points. Influential points can be assessed through the use of *leverage plots* that display, for each point, a measure of how far the data point is from the "center" of the covariate space. Points far from the center of the data are then assessed as potentially influential. There is a considerable literature devoted

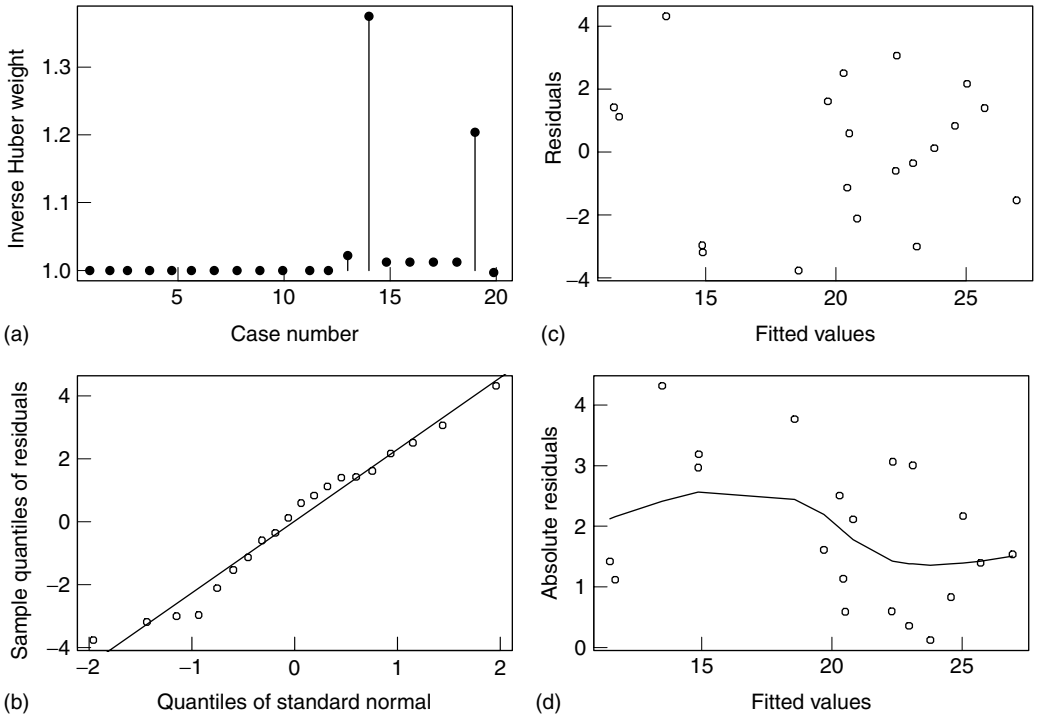

Figure 7 Residual diagnostic plots for the body fat data from a model relating body fat to all explanatory variables on the raw scale. The plots include: (a) a plot of robust regression weights for the model fit revealing data points 13, 14, and 19 as downweighted in the analysis (these points are potential outliers); (b) a normal quantile–quantile plot of the residual from the model fit showing the residuals as plausibly normal; (c) a plot of residuals versus fitted values; and (d) a plot of absolute residuals versus fitted values with a lowess line superimposed

to the subject of handling outliers in data analysis; see, for example, the monographs by Barnett and Lewis [9] and Hawkins [58], and the survey paper by Beckman and Cook [12]. Predominantly nongraphical approaches to measuring influence were discussed by Cook [29], Belsley et al. [13], Atkinson [7], and Cook and Weisberg [32].

Exploratory Methods

After an initial graphical exploration of the data has been carried out, it is usually desirable to model the data explicitly. The resultant model may be used to validate a theory about the process from which the data derived, or it may be used for prediction, or for some other purpose. Recently, several **exploratory** methods have been developed to suggest interesting directions in the data, and to suggest whether it is desirable to transform some or all of the variables in order to obtain a reasonable fit. Examples of these techniques include Additive VAriance Stabilized approach (AVAS), **Generalized Additive Models** (GAM), and **Projection Pursuit** Regression. The results of these methods are naturally interpreted graphically. The AVAS and GAM methods attempt to isolate appropriate transformations of both the response and explanatory variables to obtain the best additive fit of the transformed variables to the data. The AVAS method also attempts to transform the response variable to stabilize its spread. Scatterplots of the transformed AVAS variables against the original variables can be used to suggest appropriate transformations of the data for use in fitting formal parametric models. The AVAS method was introduced by Tibshirani [84], and the GAM method was proposed by Hastie and Tibshirani [55]; see also [54, 56, 83] and [57]. Projection pursuit regression, introduced by Friedman and Tukey [47] and discussed further by Friedman and Stuetzle [46], and Cook et al. [30, 31], attempts to find informative

projections in the covariate space, and then appropriate transformations of the projected data to obtain the best additive fit of the transformed projections to the response. Graphical exploration of the result of a projection pursuit fit can yield useful information about the effective dimension of the covariate space, although care must be taken not to overinterpret the results of projection pursuit regression.

Parametric Model Fitting and Plots Based on Residuals

Parametric approaches to modeling data assume a particular parametric form for the relationship between the response and explanatory variables, and then estimate the parameters of the relationship based on minimizing the distance between the fitted relationship and the original observations. Additional assumptions usually made in parametric modeling based on Gaussian models are that the errors associated with the model are additive, and have zero "location" and constant spread (*homoscedasticity; see* **Scedasticity**). For many applications, it is convenient to assume that the errors have the explicit structure of independent and identically distributed random, zero-mean, constant-variance normal variates. Many graphical tools for assessing the success or otherwise of the model fitting process are based on *residuals*, estimated deviations of the original observations from the model fit. The residuals estimate the unobservable errors described above. The model fit is represented by the *fitted values*, values of the estimated response for each of the observed covariate values. The *plot of residuals (or absolute residuals) versus fitted values* is a simple graphic often used to assess the validity of some of the error assumptions. If the assumptions are valid, this plot should exhibit a random pattern of residuals in a roughly uniform band about zero (homoscedasticity). Common deviations from this uniform pattern include patterns where the residuals seem to increase (or decrease) as fitted values increase (suggesting heteroscedasticity), or a strong relationship between the residuals and the fitted values (suggesting a deficiency in the model). Another useful graphic is a plot of residuals versus order, which can discover **serial correlation** among the residuals; see below for a discussion of dependent data. To assess the assumption of normality of residuals, a normal Q–Q plot is often used; a discussion of Q–Q plots is given later. Anscombe and Tukey [5] discuss the graphical use of residuals in regression diagnostics, and descriptions of standard residual plots are given in almost any text on basic regression methods; see, in particular, Cook and Weisberg [33]. Figure 7 shows a typical set of diagnostic plots based on residuals, there applied to a model for the body fat data. The four plots pictured are a plot of Huber weights, used to detect potential outliers in the data set; a plot of residuals versus fitted values and a plot of absolute residuals versus fitted values, useful for detecting outliers, assessing the error-variance assumption, as well as for assessing whether further modeling is desirable; and a Q–Q plot of residuals, used to assess the assumption that the error distribution is **normal**. The plots suggest no major concerns about the quality of the linear model fit.

Partial Residual Plots and Added Variable Plots

Plots based on residuals can also be used to assess which variables should enter the model, and in what form. Particular examples include *partial residual plots* and *added variable plots*. Partial residual plots were proposed by Ezekiel [43], and are described by Larsen and McLeary [68], and Wood [94] (who termed them component-plus-residual plots). Added variable plots were suggested by Gnanadesikan [49], and are described by Larsen and McCleary [67]. To describe partial residual plots, let $r_i, i = 1, \ldots, n$ denote residuals from the model fit, and let $\hat{\beta}_k$ be the estimated coefficient of the explanatory variable x_k in the model. A partial residual plot is a plot of $r_i + \hat{\beta}_k x_{ik}$ versus x_{ik}. If the model linear in x_k is appropriate, the partial residual plot for x_k should exhibit a linear trend; curvature in the partial residual plot suggests that x_k should be transformed before entering the model, or that a quadratic (or higher-order) term in x_k should be added to the model (*see* **Polynomial Regression**).

The added variable plot seeks to answer the question of whether a variable (say x_k) should be added to the model if other variables are already in the model. The graph plots the residuals of a model fitting the response to a set of explanatory variables not including x_k (representing that part of the response not adequately explained by those variables) versus the residuals of a model fitting x_k to the same reduced set of explanatory variables (representing that part of x_k not accounted for by the other explanatory variables). The resultant plot depicts the effective explanatory

power of x_k over y *after the other variables have been accounted for*. Provided a linear model involving x_k is appropriate and x_k is not **collinear** with the other variables, the plot should exhibit a linear trend with slope equal to the estimated regression coefficient of x_k in a linear model fit. Curvature in the additive variable plot suggests either that x_k needs to be transformed before entering the model, or that higher-order terms in x_k are warranted in the model. If the plot exhibits no particular structure and the original scatterplot matrix suggested a relationship between y and x_k, collinearity between x_k and the other explanatory variables is indicated. An example of an added variable plot applied to the body fat data is given in Figure 8. The question motivating this plot is that of whether thigh should enter a model for body fat if midarm is already present in the model (triceps have been removed from consideration because it is highly correlated with thigh). The strong linear trend of the resultant plot suggests that thigh should enter the model.

Display of One-dimensional Data

Diagnostic methods based on residuals include checks on the distributional assumptions made about the errors associated with the model fit. Hence, it is important to be able to describe one-dimensional data, such as the residuals, graphically. The simplest, and perhaps oldest [73], graphical display for one-dimensional data is the *histogram*, which divides the range of the data into bins and plots bars corresponding to each bin, the height of each bar reflecting the number of data points in the corresponding bin. Unfortunately, the way in which histograms depict the distribution of the data is somewhat arbitrary, depending heavily on the choice of bins and binwidths, with large binwidths tending to smooth over important features of the distribution, and small binwidths resulting in histograms that look too rough. Kernel-based smoothing (see, for example, Silverman [78]) can be used to provide a smooth **density estimate**, but many of the same issues of choosing an appropriate bandwidth arise. Examples of histograms appear in Figure 9 for a data set examining the effect of ozone (a component of smog) on body weight. *Stem-and-leaf plots* (see [89] for a discussion) are a variant on histograms that combine the features of a graphic and a table in that the original data values are explicitly shown in the display as a "stem" and a "leaf" for each value. The stems determine a set of bins into which the leaves are sorted, and the resulting list of leaves for each stem resembles a bar in a histogram. Tukey [87] developed the *boxplot* display, based on the five-number summary (minimum, first quartile, median, third quartile, maximum) of the data. The boxplot represents the middle half of the data (first to third quartiles) by a rectangle (box) with the median marked within, with *whiskers* extending from the ends of the box to the extremes of the data

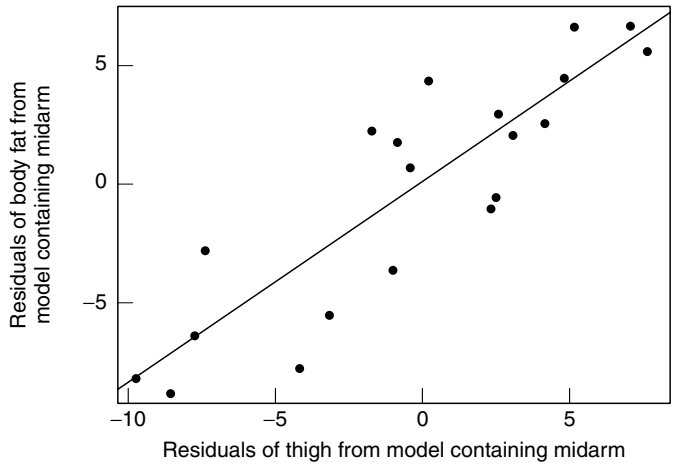

Figure 8 Added variable plot for thigh given the presence of midarm in the model for body fat. Plotted are the residuals from a model relating body fat to midarm versus the residuals from a model relating thigh to midarm. A robust regression line relating the two sets of residuals is superimposed, suggesting that a linear model incorporating thigh is appropriate

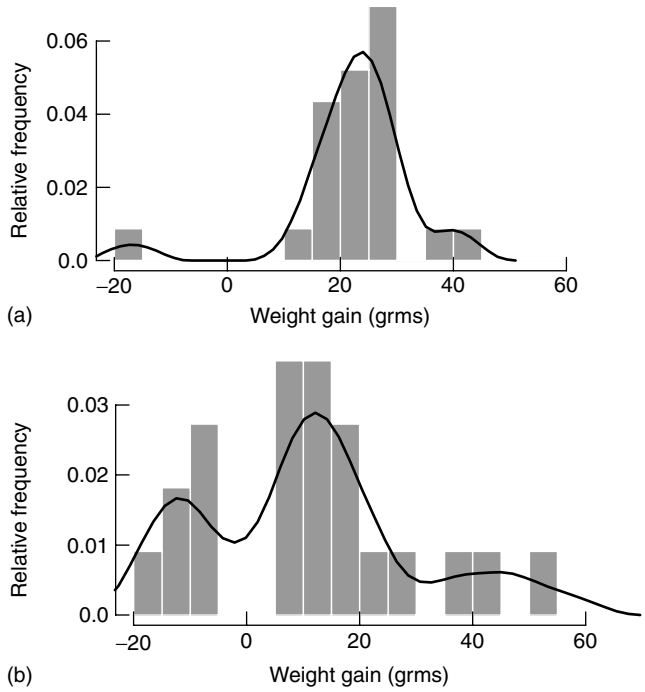

Figure 9 Histograms of weight loss in grams for control and ozone groups of rats from an experiment to measure the effects of ozone, a component of smog. (Source: Doksum and Sievers [41]). The control group contained 23 rats, the ozone group 22. All rats were around 70 days old, and weight gain was recorded after 7 days of exposure. Both histograms are drawn on the density scale, and smooth kernel density estimates are superimposed. The histograms are arranged vertically to facilitate comparisons between the two groups

or to one and a half times the interquartile range of the data, whichever is closer.

Each of the aforementioned displays tries to answer the question of how the data is distributed by showing what the data distribution "looks like", but they don't deal with the issue of how the data distribution compares with some theoretical distribution. This issue is important, particularly for examining residuals from a model fit, because it is often assumed that these residuals arise from a normal distribution with zero mean and constant variance. The most commonly used graphic to address this issue is the *normal Q–Q plot*; see Wilk & Gnanadesikan [92] for a general description. A similar graphical display is the P–P (probability–probability) plot. The normal Q–Q plot plots theoretical quantiles from a standard normal distribution against the empirical quantiles from the data (*see* **Normal Scores**). If the resultant plot appears linear, the data is consistent with the assumption of normality; departures from linearity, such as a characteristic "S" shape or concavity, suggest nonnormality. If nonnormality is indicated for a set of residuals, it may be useful to transform the data to achieve plausibly normal residuals, bearing in mind that the transformation affects other features of the data. An example of a normal Q–Q plot is given in Figure 7(c), applied there to the residuals of a model for the body fat data. Quantile–quantile plots can also be constructed against reference distributions other than the normal.

Comparison

Displays for one-dimensional data can often be used effectively for comparing data distributions. Key to the success of such ventures are notions of scale and placement: first, it is critical that the data sets to be compared are on roughly the same scale (e.g. they should be measured in the same units); and second, in combining graphical elements for purposes of comparison, it is useful to utilize a common set of basic

features (axes, orientation, etc.) for all elements, and, if possible, to place the individual components within the graphic to facilitate easiest comparison (e.g. side-by-side boxplots sharing a common set of axes form a more potent graphic for comparison than do side-by-side boxplots drawn on different axes, or boxplots aligned vertically). Other examples of comparative graphics include histograms using the same axes, arranged vertically, back-to-back stem-and-leaf plots (sharing a common stem), and h-plots; see Figure 9. Quantile–quantile plots relating the empirical quantiles from each of two data sets can also be used to compare the distributions of the two data sets. The histograms in Figure 9 facilitate easy comparison of the control and ozone groups of rats by virtue of their vertical arrangement. Figure 10 displays two comparative displays of one-dimensional data using side-by-side boxplots; the use of a log transformation in plot (b) to symmetrize the data distributions allows for an easier comparison between the two groups. Of course, while the use of a log transformation allows easier comparison between the two groups, it also makes for a more difficult interpretation. An important feature of graphic construction is simplicity, but, unfortunately, it is often the case in the construction of good statistical graphics that simplicity of perception and simplicity of interpretation conflict.

Graphical displays for one-dimensional data are often encountered in the popular media, but "presentation" graphics encountered in that setting, such as bar charts, line charts, and pie charts are not terribly effective tools for communicating numerical information. Pie charts, for example, usually summarize only a handful of numbers that would be more effectively presented in a small table. Tufte [86] puts this opinion rather bluntly: "A table is nearly always better than a dumb pie chart ... Given their low data-density and failure to order numbers along a visual dimension, pie charts should never be used". Bar charts differ from histograms in that the bars need not be ordered along the horizontal axis. However, bar charts published in many popular newspapers and magazines employ highly stylized bars (e.g. bars shaped like people) that distort the visual perception of the bars. Needless to say, many common embellishments of common presentation graphics such as three-dimensional bar charts, and three-dimensional or exploded pie charts, should be avoided altogether as they introduce redundant dimensions into the graphical display. These embellishments can also introduce unusual perspectives into the graphic, unintentionally (or, occasionally, intentionally!) causing the viewer to misinterpret the numerical information being portrayed. Perhaps the only graphic routinely used in the popular media that is also a good statistical graphic is the time series plot, although this display can also be ruined by careless use of shading, decoration, or other presentation errors. To faithfully record the various misuses and abuses of graphical displays in the popular media (and, indeed, in

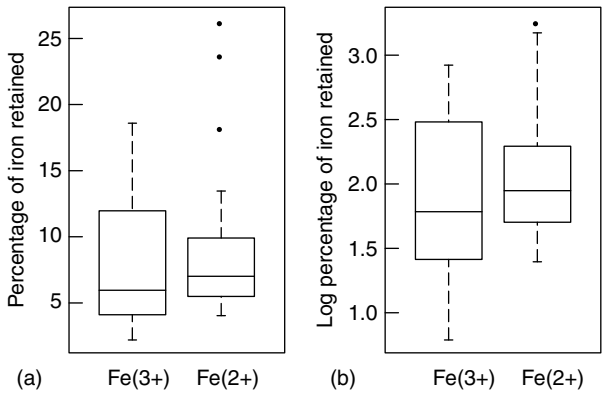

Figure 10 Side-by-side boxplots aid in comparison. Data obtained from an experiment to determine whether two forms of iron (Fe2+ and Fe3+) are retained differently (this feature impacts their usefulness as dietary supplements). The data relates to two groups of 18 mice each given a form of iron orally in the concentration 1.2 millimolar and the result is measured as percentage of iron retained. (Source: Rice [75, Chapter 11]) Plot (a) compares raw percentage retention for the two forms of iron. The boxplots indicate both distributions have similar features but are heavily skewed. Plot (b) shows boxplots for the logged scores, whose distributions are closer to symmetric

many scientific papers!) could fill many volumes. Tufte [86] has done an extraordinary job of describing the strengths as well as the pitfalls of graphical displays for visualizing quantitative information; his delightful book is filled with examples and discussions of the good, the bad, and (literally) the ugly of statistical graphics.

Data Developing in Time

Data in which development through time is an important aspect can be classified conveniently into data which consists of a few relatively long series of observations which may be dependent (as in traditional **time series** analysis) or into data which consists of a large number of relatively short series which are typically independent (as in repeated measures problems). In either case, analysis is simplest when the data in each series are collected at the same number of equally spaced time points, becoming more complicated as the lengths of the series vary and as the observation time points become irregularly spaced (*see* **Graphical Presentation of Longitudinal Data**).

Whether we have a few relatively long series or a large number of relatively short series, the most common representation of the data is by means of a *sequence plot* (see the top panel of Figure 11), which is a simple scatterplot of the data against time. Adjacent points in the same series are often connected by linear segments to create a piecewise linear curve which highlights the basic time series structure and distinguishes the different series. However, if we have a very large number of series, the resulting plot can be very difficult to interpret. For this kind of situation, Jones and Rice [61] proposed that we connect

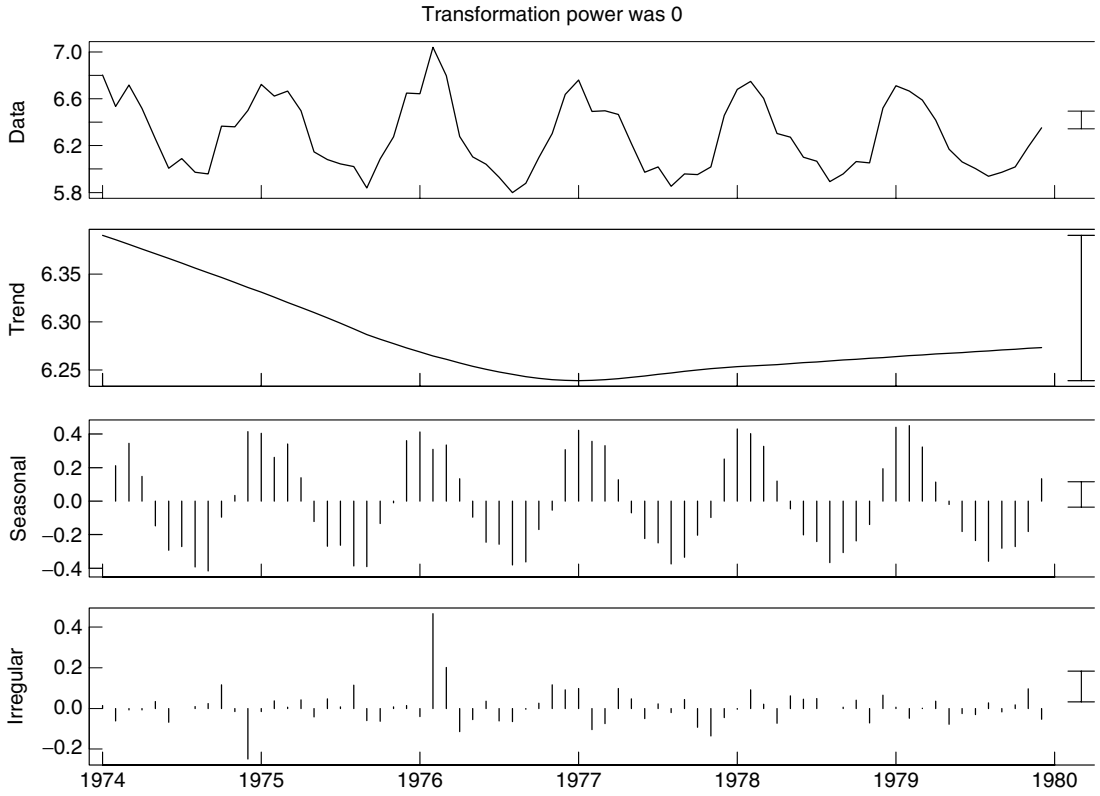

Figure 11 SABL Decomposition for United Kingdom lung disease data. Data are monthly UK deaths of females from bronchitis, emphysema and asthma from 1974–1979. (Source: Diggle [39, p. 238], data from Appleton) The plot produced by SABL decomposes the log number of deaths, given in the top panel, into trend, seasonal, and irregular components. The vertical bar at the right of each plotted component indicates the relative scales of the components

the points for only selected series in the data. While it is possible to choose the subset at random, it seems preferable to select quantiles from curves ordered with respect to some characteristic of the problem of interest. Diggle et al. [40, p. 38] have suggested ordering curves by means of robust measures of the level of the series, or by variability within series, or by trend or correlation between successive observations within the series, and then connecting the points of the selected series. Series that are grouped together (by virtue of receiving a common treatment, for instance) can be distinguished by being plotted separately, by being plotted with different lines or symbols or by being represented by common summary series. Such a plot is depicted in Figure 12 for data tracking pituitary growth in children of various ages, each series representing a single child.

Much of the analysis of traditional time series (which focuses on a few relatively long series of data) is based on the idea that on some scale determined by a function g, a series of data Y_t can be decomposed into three components as

$$g(Y_t) = T_t + S_t + E_t, \tag{1}$$

where T_t is the trend, S_t is the **seasonal** and E_t is the irregular component. The trend is supposed to describe the long run behavior of the series, so can be thought of as a smooth curve; the seasonal component is supposed to capture periodic variation about the trend, so can be thought of as a periodic function; and the irregular component is supposed to represent whatever is in the series that is not described by the trend and seasonal components. While the components of this decomposition are not unambiguously defined and the resulting decomposition is not therefore unique, it can be quite useful. Once the trend and seasonal components have been modeled and estimated, we can plot them and the irregular component against time. Further possibilities are to plot the detrended series (that is, the transformed data minus the estimated trend), the deseasonalized series (that is, the transformed data minus the estimated seasonal component) or the detrended and deseasonalized series that is simply the irregular component against time. These plots can be interpreted as plots of different kinds of residuals against time. The different components can be modeled parametrically or nonparametrically, and there is a substantial literature on the different approaches. As an illustration of the kind of graphic produced, the decomposition of a series obtained from SABL (see [26]) is shown in Figure 11 for data on mortality from lung disease. The decomposition shows a strong seasonal effect, with most deaths occurring in winter and fewest in summer. This effect can be observed clearly through the use of a *monthplot*, a plot of the monthly subseries for the data. Typically, a monthly average is also plotted; see Figure 13.

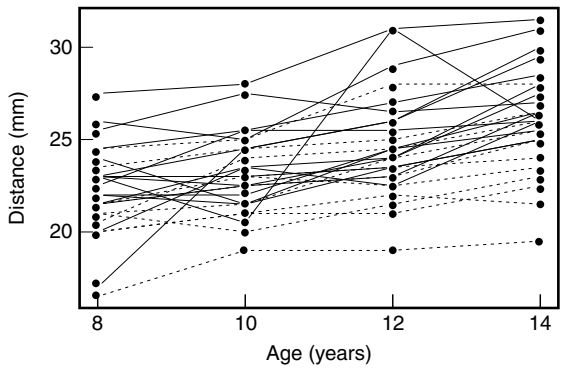

Figure 12 Sequence plots for several short series of pituitary data. Data measured are the distances (mm) between the center of the pituitary to the pteryomaxillary fissure in girls and boys aged 8, 10, 12, and 14 years. (Source: Potthoff and Roy [74]) The curves for boys are represented by solid lines and those for girls by dotted lines. The graphic shows that the distance generally increases with age, is generally larger in boys than girls, and that there is some tracking (children with large or small distances initially continue to have large or small distances throughout the study)

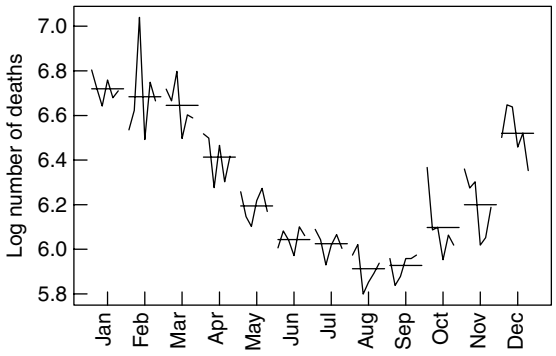

Figure 13 Monthplot of the log number of UK deaths of females from bronchitis, emphysema, and asthma from 1974–1979. The plot shows the six-year subseries for each month and the subseries mean. This plot confirms the strong seasonal effect

It can be important in dealing with time series data to keep in mind the dictum that time is not a real explanatory variable, and that we are often interested in modeling the relationship between the series and more interesting explanatory variables. Naturally, many of the methods developed for exploring relationships between variables are of use in this kind of problem and may be applied either to the raw data (in which case time effects may be explored in the residuals) or to residuals from which time effects have been removed.

An important feature of data evolving in time is that observations that are temporally close within a series are typically dependent. Thus, methods that explore the dependence between observations are important in analyzing time series. Once the effects of trend, seasonal, and other explanatory variables have been accounted for, we can explore the dependence structure remaining in the irregular or residual series, which we here denote Z_{it}. If the observations were made at equally spaced time points, we can consider plotting Z_{it} against $Z_{i,t-1}, t = 1, \ldots, n-1$, to detect first-order (lag 1) dependence. When the data consist of a large number of short, independent series of roughly equal length, we can go further and construct a scatterplot matrix in which Z_{it} is plotted against $Z_{i,t-1}$ (lag 1), $Z_{i,t-2}$ (lag 2), and so on, for $i = 1, \ldots, k$. If the scatter plots are in the form of bivariate Gaussian ellipses (*see* **Bivariate Normal Distribution**), we often observe a reduction in the strength of the relationship (i.e. dependence) as the temporal separation (represented by the lag) increases.

If the data in the series are Gaussian-distributed, we can summarize the dependence structure by various **correlation** coefficients. Furthermore, if the Z_{it} have constant mean and variance, and if the correlation between Z_{it} and $Z_{i,t+h}$ depends only on their temporal separation h, the series is said to be weakly stationary and we can readily estimate the **autocorrelation function** (ACF) at h by the sample correlation between observations lag h apart. Explicitly, the sample autocorrelation function is $\hat{\rho}_i(h) = \hat{\gamma}_i(h)/\hat{\gamma}_i(0)$, where

$$\hat{\gamma}_i(h) = \frac{1}{n} \sum_{t=h+1}^{n} (Z_{it} - \overline{Z}_i)(Z_{i,t-h} - \overline{Z}_i) \qquad (2)$$

is the autocovariance function. An *autocorrelation plot* or correlogram (Figure 14) is a plot of the sample autocorrelation function $\hat{\rho}_i$ against h. The *partial autocorrelation plot* is a closely related plot in which the partial autocorrelation function (PACF) is plotted against lag. These plots can be used to identify autoregressive-moving average (**ARMA**) models for the residual series; see, for example, [18]. Dependence between pairs of series can be explored similarly by the *cross-correlation plot*, which is a plot of the correlation between the observation at t in the one series and the residual at $t + h$ in the other against h; again, see [18] for details. If we have a large number of independent series which are assumed to have the same within-series dependence structure, we can average the within series estimates $\hat{\gamma}_i$ across series to obtain a better estimate of the common autocovariance function.

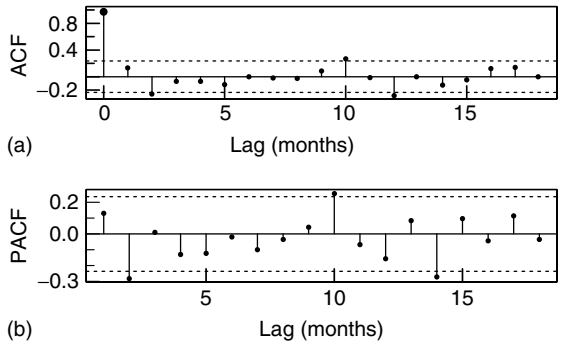

Figure 14 ACF and PACF of the detrended and deseasonalized (irregular) series of log UK deaths of females from bronchitis, emphysema, and asthma from 1974–1979. Dotted reference lines are plotted at height $\pm 2/\sqrt{n}$. These plots suggest that the observations in the irregular series are uncorrelated

For irregularly spaced data, the autocorrelation is more difficult to estimate unless we are prepared to round the observation times. An alternative function which describes the dependence structure and is easy to estimate even when we have irregular observation times is the **variogram** [62], originally referred to as the mean semi-squared difference curve or the serial variation curve. The *sample variogram* (Figure 15) is a scatterplot of the half-squared distances $0.5(Z_{it} - Z_{is})^2$ against the corresponding time differences $t - s, t \geq s$. The scatterplot is often usefully enhanced by scatterplot smoothing, which provides an estimate $\hat{\eta}_i(h)$ of the variogram at lag h and by the representation of the process variance estimated by $\hat{\sigma}_i^2$, the mean of the half-squared distances $0.5(Z_{it} - Z_{is})^2$ with $t \neq s$, by a horizontal

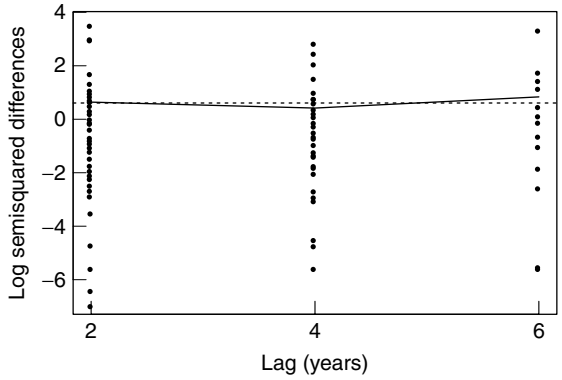

Figure 15 Log variogram of the pituitary data after removing the gender means at each time point. The dotted line represents the log process variance and the solid line, a piecewise linear estimate of the log variogram. The plot shows no evidence of correlation in the residuals

line. When the series are weakly stationary, the autocorrelation function at lag h can be estimated from $\hat{\eta}_i(h)$ by

$$\tilde{\rho}_i(h) = \frac{1 - \hat{\eta}_i(h)}{\hat{\sigma}_i^2}. \tag{3}$$

This relationship shows that $\hat{\eta}_i(h)$ increasing as h increases represents decreasing autocorrelation as h increases. Again, if we have a large number of independent series which are assumed to have the same within series dependence structure, we can plot the half-squared distances over $t \geq s$ and $i = 1, \ldots, k$ to obtain better estimates of the common variogram.

The issues that arise in the exploration of temporal dependence also arise in the exploration of spatial dependence, although this latter situation is rather more complicated. The basic graphical display is the *map* (the analog of the sequence plot) with superimposed data (*see* **Statistical Map**). Since at the very least we have three dimensions to display, surfaces, contour plots, spinning plots, and other methods for displaying high-dimensional data can be useful. The variogram is widely used to explore spatial dependence structure. In the simplest cases, lagged distances irrespective of direction can be plotted on the x-axis but in general, we may need to consider displaying separately variograms corresponding to different directions in space.

Multivariate Data

The use of graphics to explore high-dimensional data in the context of our having identified a single response variable that we are interested in relating to the remaining variables has been discussed earlier. The specification of a single response variable (and the inherent asymmetry it introduces into the analysis) determines many aspects of the subsequent graphical and analytical analyses. However, we can also be interested in looking for structure or patterns in the data (including looking for relationships between variables as well as outliers and clusters in the data) without having specified a response variable and a different set of graphics can be implemented for this purpose (*see* **Multivariate Graphics**).

We have already discussed a number of graphical techniques that can be useful in the preliminary examination of multivariate data. As alternative approaches to these, we can consider representing each independent vector of observations by a symbol, the features of which represent different variables. For example, Chernoff [21] suggested representing each observation by a face, the characteristics of which represent up to 18 variables. However, the fact that interpretation depends on how the variables are assigned to the facial characteristics and that it is difficult to examine simultaneously a large number of faces means that this graphic is probably more useful as an amusing way to present results than as a practical tool for data analysis. Other suggestions include using stars, weathervanes, parallel coordinate plots (each vector observation is plotted against $(1, 2, \ldots, p)$ and the points connected by lines), and Andrews' plots [3].

Unfortunately, experience suggests that considerable luck is needed to find structure using the above techniques. It is apparent that to get the most out of graphical methods, we need to supplement them by computations that simplify the task of searching for structure, primarily by *reducing the effective dimension of the data*. We will consider several techniques that may be useful for this task.

Projections

Pairwise scatterplots examine two-dimensional projections of the data onto the planes defined by pairs of axes in the coordinate system. Low-dimensional projections provide one of the most effective methods for examining points in high-dimensional spaces,

but there is no good reason to expect projections of the data onto the planes defined by pairs of axes in the coordinate system to reveal important structure and/or relationships in the data. In some cases, such as when we use a spinning display to examine three-dimensional data, it is easy to examine a large number of two-dimensional projections fairly quickly, but in general it is important to have available analytic methods for choosing revealing projections automatically.

The classical approach rotates the data to a new coordinate system called the **principal components** [59] which is determined by the directions of greatest variability in the data and then enables us to examine two-dimensional projections in this coordinate system by constructing a scatterplot matrix of the principal components. In order to achieve a reduction in dimension, it is usual to study only those principal components which make a substantial contribution to the variance by including principal components until the proportion of variance explained is above 80 or 90%, say. Hopefully, this strategy will result in the need to study only two or three variables rather than the original number. Outliers can also sometimes be detected in plots of the last two principal components; so as a diagnostic tool, we often also plot the last two principal components.

It is obvious from the fact that principal components analysis finds the projections of maximum variance that the scale of the data determines the result of the analysis. Even when the variables are on the same scale, there can be large differences in the variability of the variables, so some authors recommend standardizing the data by the standard deviations of the variables. This is equivalent to applying the analysis to the correlation matrix rather than the variance matrix. Working with the correlation matrix does not remove the scaling problem because it is simply another arbitrary scale. This strategy is not generally recommended because it is inappropriate when the variables are not of equal importance. Principal components analysis is also sensitive to the choice of the variables included in the data. It is obvious that omitting variables has an impact on an analysis, but it is less obvious that including redundant variables has an impact on both the last and the first principal components. In particular, linear relationships in the data can increase the weight given to a variable in the principal components. Finally, when a set of principal components has nearly equal standard deviations, they are arbitrary and cannot be interpreted in any meaningful way.

Projection Pursuit [47, 66] and *Grand Tours* [6] are modern alternatives to principal components analysis. Projection Pursuit defines revealing projections not in terms of variability but in terms of departure from normality. Thus projection pursuit tries to find the least ellipsoidal two-dimensional projections of the data. Grand Tours work by generating two points at random on the p-dimensional unit sphere and using these to generate a plane. A sequence of rotations is then applied to move the first point into the second while keeping the orthogonal complement of the plane fixed. The process is then repeated with another pair of points. The idea is that the resulting sequence of projections rapidly becomes dense among all possible projections, so selected revealing projections from the sequence can be examined for structure.

Biplots

Biplots [48] provide a graphical description of relationships among the observations (or rows), and the relationships among the variables (or columns) in a data set. It is based on the singular value decomposition (*see* **Matrix Computations**) of the mean-centered data matrix Z (so the columns of Z have mean zero), which can be written

$$Z = L\Delta M^T, \tag{4}$$

where L is an $n \times r$ matrix of rank r such that $L^T L = I_r$, M is a $p \times r$ matrix of rank r such that $M^T M = I_r$ and $\Delta = \text{diag}(\delta_1, \ldots, \delta_r)$ with $\delta_1 \geq \cdots \geq \delta_r > 0$ as the positive square roots of the nonzero **eigenvalues** of $Z^T Z$. A rank 2 approximation to Z is obtained by

$$Z_{(2)} = L_{(2)} \Delta_{(2)} M_{(2)}^T, \tag{5}$$

where $L_{(2)}$ represents the first two columns of L, $M_{(2)}$ represents the first two columns of M, and $\Delta_{(2)} = \text{diag}(\delta_1, \delta_2)$. The quality of this rank 2 approximation can be measured by $(\delta_1^2 + \delta_2^2)/\sum_{k=1}^r \delta_k^2$. See [51] for a detailed discussion of the statistical uses of the singular value decomposition. The biplot is the plot of the n rows of $G = (n-1)^{1/2} L_{(2)}$ and the p rows of $H = (n-1)^{-1/2} M_{(2)} \Delta_{(2)}$ represented as vectors. The plot of the p rows of H alone is called the h-plot [34].

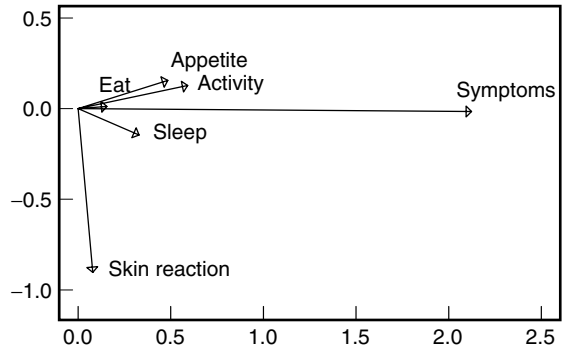

Figure 16 *h*-plot of the radiotherapy data. The data consist of average ratings over the course of radiotherapy of the number of symptoms (such as sore throat or nausea), amount of activity (1–5 scale), amount of sleep (1–5 scale), amount of food (1–3 scale), appetite (1–5 scale), and skin reaction (0–3 scale). (Source: Johnson and Wichern [60] from Tealey). The plot shows that the number of symptoms is far more variable than the other measures. The directions of arrows in the plot shows that the variables are highly correlated with the exception of skin reaction, which appears uncorrelated with the other variables

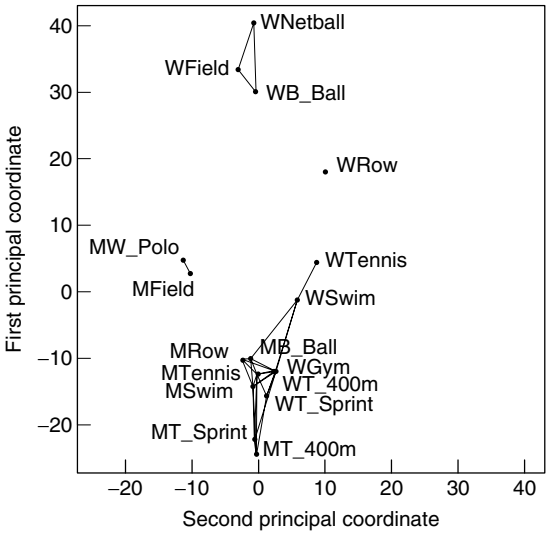

Figure 17 An ordination based on multidimensional scaling for the Australian Institute of Sport data (Source: Cook and Weisberg [33, p. 98] on data supplied by Telford and Cunningham). The data were physiological observations made on 202 different athletes of both sexes participating in 10 different sports (men's and women's basketball, swimming, rowing, track (400 meters and sprint), field, tennis, women's gymnastics and netball, and men's water polo) Classic multidimensional scaling based on Euclidean distances was used. The ordination suggests some clear clusters of sports, as indicated by the linked points

An example of an *h*-plot is shown in Figure 16 for data on cancer patients undergoing radiotherapy.

The distance between the points represented by two rows of G represents the **Mahalanobis distance** between the corresponding observations, the length of the vector represented by a row of H represents the standard deviation of the corresponding variable, the distance between the points represented by two rows of H is the sample variance of the difference between the corresponding variables, and the cosine of the angle between the vectors represented by two rows of H is the correlation between the corresponding variables. Thus the *h*-plot provides a visual representation of the covariance structure between variables and, additionally, the biplot contains information about the distance between observations. The matrix H from which the *h*-plot is constructed can be obtained directly from the principal components analysis of the covariance matrix of the data so *h*-plots can be viewed as an alternative representation of the results of a principal components analysis.

Ordination

Ordination methods attempt to arrange n data points in a high-dimensional space with proximity relationships represented by an $n \times n$ dissimilarity matrix D in a low (usually 2) dimensional space (*see* **Similarity, Dissimilarity, and Distance Measure**) by constructing an $n \times 2$ matrix Y such that the matrix of Euclidean distances between the points in Y is approximately the same as D. The columns of Y are referred to as **principal coordinates** and the plot of the first two principal coordinates is referred to as an *ordination*. An example of an ordination is given in Figure 17 for data from the Australian Institute of Sport. If the dissimilarity matrix D is determined directly by subjective assignment of dissimilarities, the ordination is a geometric representation of the proximity relationships between the objects. Alternatively, if the dissimilarity matrix D is calculated from a data matrix Z, ordination methods yield a lower dimensional representation of Z with an associated Euclidean distance matrix that is close to D. It is obvious that we can change the location and rotate the orientation of the ordination without changing the Euclidean distances between the points so that an ordination is not unique.

Multidimensional Scaling can be treated either as synonymous with ordination or as a particular ordination method. The subtle differences in perspective between these views are not particularly important in a graphical context, so we will treat them as synonymous. There are two types of multidimensional scaling depending on the nature of the proximity data:

i) Classical Metric Multidimensional Scaling [76, 85] or Principal Coordinates Analysis [50] which uses the magnitude of the proximities; and
ii) Nonmetric Multidimensional Scaling [65, 77], which uses the **ranks** of the proximities.

Nonmetric scaling is intended to facilitate subjective proximity assignments because it is usually easier to order proximities than to assign exact numerical values. However, if the ordering of the proximities is more important than the actual values, we may decide to use nonmetric scaling, even though the proximity values are available.

The two-dimensional representation of the dissimilarity structure may give a misleading impression of the actual distances between points because points that appear close in the first two principal coordinates may be far apart in higher dimensions. This is particularly likely when the first two principal coordinates fail to explain D. In such cases, the plot of the first two principal coordinates can be improved by linking units whose actual distance apart is less than some user-specified value; see Figure 17. It is of interest to vary the distance apart we specify to see how the picture changes. This method is useful for detecting one-dimensional structure in the data. If we obtain a two-dimensional representation and join points with dissimilarities below a user-specified value, we may obtain a horseshoe shape. This result suggests that the two-dimensional configuration is almost a one-dimensional configuration bent into a horseshoe shape and that ordering along the horseshoe curve may give a reasonable one-dimensional ordering of the data. This discovery is particularly relevant if we are seeking a one-dimensional ordering of the data (known as *seriation*).

It may be that in other problems we achieve a better ordination by using more than two principal coordinates. In general, we can choose the number of principal coordinates to consider by examining the proportion of the dissimilarities in D explained by the principal coordinates in the same way as we examine variance in principal components analysis (although we need to be careful of the fact that the eigenvalues can be negative).

One of the attractions of ordination methods is that they contain as special cases not only principal components analysis, but also a number of other classical multivariate techniques. These analyses are obtained by making particular choices of D. The most important relationship is that metric scaling based on the Euclidean distances between (mean-centered) points yields as principal coordinates the principal components. That is, metric scaling with Euclidean distances is principal components analysis. This suggests that the discussion of the issues underlying the application of principal components applies also to metric scaling. Principal coordinates analysis also includes **correspondence analysis** [15], linear **discriminant analysis**, and canonical variates analysis (*see* **Canonical Correlation**) as special cases. The important point is that ordination methods allow very general choices of D and so can be used when we have large sparse data matrices or subjectively assigned dissimilarities.

Minimum Spanning Trees

A spanning tree is a set of straight-line segments joining pairs of points such that there are no closed loops, each point is visited by at least one line segment, and every point is connected to every other point either directly or through a chain of other intermediary points. The length of a spanning tree is the sum of the lengths of the line segments so the minimum spanning tree is the spanning tree with shortest length [52].

One use of the minimum spanning tree is to assess the amount of distortion incurred in reducing the dimension of the data to, say, two dimensions. The idea is to incorporate the links in the minimum spanning tree into the two-dimensional scatterplot and check that the patterns of relative closeness described by the minimum spanning tree are preserved. When substantial distortions in the patterns of relative closeness occur, the structure in the two-dimensional representation of the data may not represent the same structure in the original data set.

Cluster Analysis

Although clusters can be detected by ordination methods, there are a number of techniques available for the specific purpose of detecting clusters in

data (*see* **Cluster Analysis of Subjects, Hierarchical Methods**; **Cluster Analysis of Subjects, Nonhierarchical Methods**). The major difficulty with these techniques is that it is extremely difficult to define a cluster. It follows that it is difficult to specify the number of clusters in a data set and that the objectives of the analysis may be difficult to achieve.

Although there is a huge literature on clustering, there are basically three types of procedures: partitioning; overlapping clusters; and hierarchical clustering. From a graphical standpoint, hierarchical clustering is the most interesting method. Here, clusters are grouped within larger clusters to form a tree. The simplest techniques, called *agglomerative methods*, start by regarding each object as a cluster and proceed by merging near objects. Divisive methods work in the opposite direction by partitioning the objects into two groups and then by partitioning each group into subgroups, and so on. In either case, the results are best displayed in the form of a two-dimensional tree diagram called a **dendrogram** (Figure 18).

The simple class of agglomerative procedures known as *linkage methods* can be used to cluster either objects or variables. The basic algorithm is straightforward:

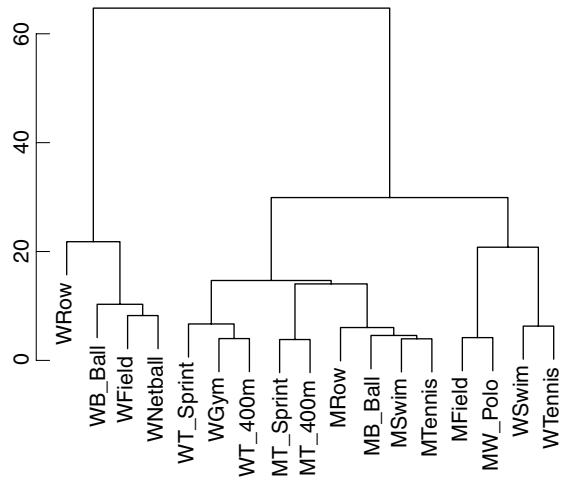

Figure 18 Dendrogram for the Australian Institute of Sport data. (Source: Cook and Weisberg [33, p. 98] on data supplied by Telford and Cunningham). The complete linkage method based on distances obtained from classic multidimensional scaling was used to construct the dendrogram. The clusters represented are not surprising given the clustering suggested by the ordination in Figure 17

1. Calculate an $n \times n$ symmetric matrix D of dissimilarities;
2. Regard each object or variable as being in a cluster so that there are n clusters;
3. Search D to find the most similar pair of clusters say U and V;
4. Merge U and V into a single cluster UV. Update D by deleting the rows and columns relating to U and V separately and introducing a new row and column for UV;
5. Repeat Steps 3 and 4 $n - 1$ times until there is a single cluster;
6. Construct a dendrogram from the record of mergers and the levels of dissimilarity at which they occur.

There are a large number of different ways of measuring the dissimilarity between two clusters in Step 2, and these essentially define different hierarchical clustering methods. For example, three commonly used approaches are:

(a) Single linkage or Nearest Neighbor [79]. The dissimilarity between clusters U and V is the smallest dissimilarity between a member of U and a member of V, namely,

$$d(U, V) = \min\{d(r, s) : r \in U, s \in V\}; \quad (6)$$

(b) Complete linkage or Farthest Neighbor [81]. The dissimilarity between clusters U and V is the greatest dissimilarity between a member of U and a member of V, namely,

$$d(U, V) = \max\{d(r, s) : r \in U, s \in V\}; \text{ and} \quad (7)$$

(c) Average linkage [80]. The dissimilarity between clusters U and V is the average of the $n_1 n_2$ dissimilarities between all members of U and V, namely,

$$d(U, V) = \frac{1}{n_1 n_2} \sum_{r \in U} \sum_{s \in V} d(r, s). \quad (8)$$

The results need not be the same in each case. For single and complete linkage, dissimilarities with the same initial ordering lead to the same configuration. However, for average linkage, dissimilarities with the same initial ordering need not result in the same configuration. All the methods are sensitive to outliers.

The sensitivity of the results to so many factors makes interpretation of the final configuration difficult. Also, a hierarchical method always yields clusters whether they are real or not. It is sensible to try different distances and different methods to check the stability of the configuration but even so, it is advisable to be cautious in interpreting the results.

Finally, the similarities between ordination and clustering mean that as an alternative to a dendrogram, we may be able to combine indicators of cluster membership within an ordination.

Analysis of Survival Data

The analysis of **survival** times for patients in medical studies is an important and common biostatistical application. The broad topic of survival analysis is covered in considerable detail elsewhere in these volumes; so, here we will focus primarily on graphical displays that are useful in modeling data of this type. Although the analysis of patient survival times is a typical setting for survival analysis, the term applies more generally to include the analysis of many other types of waiting times such as times to failure in an industrial process or, more positively, the time it takes for a patient to recover from an injury. A particular feature of survival data that makes its analysis distinctive is the problem of **censoring**, for example, due to individuals leaving the study before it is completed or to individuals surviving the entire period of study (so that their survival time cannot be properly observed). There are many excellent, comprehensive accounts of survival analysis available, including [38, 69] and [63].

Several functions are useful in the study of survival times (*see* **Survival Distributions and Their Characteristics**). In particular, the survival function $S(t) = P(T > t)$, the probability that an individual will survive beyond some particular time t is a central concept that is closely related to the distribution function of the survival times ($F(t) = 1 - S(t)$). Related functions include the hazard function (also called the force of mortality, or the **hazard rate**), which represents the instantaneous death (or failure) rate at time t, and the cumulative hazard $H(t) = -\log\{S(t)\} = \int_0^t h(z)\mathrm{d}z$. A plot of the survival function $S(t)$ versus time is referred to as a survival curve and represents how the probability of survival changes through time.

Of course, in almost all cases the survival function is unknown and must be estimated. The traditional **actuarial** approach, the **life table** method, groups survival times into a fixed set of intervals, and tabulates for each interval the number of subjects alive at the start of the interval, the proportion of subjects who die during the interval, and the estimated survival function (proportion surviving) at the start of the interval. While this approach is reasonable for large sets of survival times, for small data sets the potential for lengthy periods during which no deaths occur makes **grouping survival times** into intervals less attractive. The most commonly used estimator of the survival function is the **Kaplan–Meier** Product Limit estimator [64], which models the survival probability at time t as the product of the proportions surviving among those alive and present for the study at the beginning of each preceding time period. The Kaplan–Meier estimator takes account of censoring by calculating the proportion surviving during an interval by reducing both the numerator and the denominator of the proportion by the number of censored observations in that period. The term survival curve is usually used in the context of a plot of the Kaplan–Meier estimator $\hat{S}(t)$ of the survival function versus time. The Kaplan–Meier estimator is a step-function, constant over periods where there are no deaths, and falling at the time of each death. Times at which censoring events occur are represented on the curve by a distinguishing mark such as a tick mark or a +. A particularly effective graphical tool in understanding survival data where patients are divided into different groups (for example, treatment/placebo, male/female) is a plot of several survival curves on the same axes. This plot allows an effective comparison between the survival probabilities of several groups over time, for example, allowing the comparison of the effectiveness of different treatment regimes. Figure 19 shows estimated survival curves for male and female lung cancer patients in a Mayo Clinic study [70]. The graph shows that the survival experience of females is a little better than for males in this study. Note, however, that other factors that may influence survival (such as the age of patients) were not taken into account in this analysis.

A more sophisticated approach to modeling survival data allows survival time to be modeled not only through time but also in terms of other **covariates** that may influence survival (e.g. patient age or drug dosage). A commonly used model in this context is the **proportional hazards** model introduced by Cox [36] (*see* **Cox Regression Model**). This model

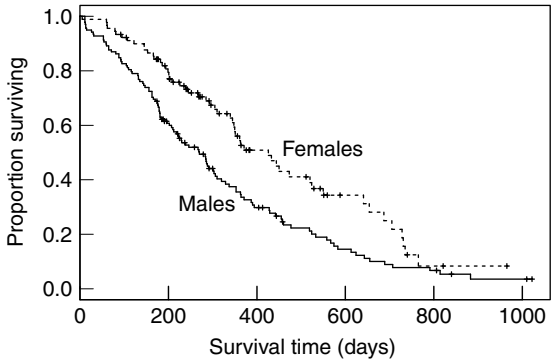

Figure 19 Survival curves comparing male and female groups of lung cancer patients. The data is described by Loprinzi et al. [70] from work carried out at the Mayo clinic. The data also contained information on other covariates such as patient age, weight loss, and some diagnostic measurements, although this information was not used in estimating survival probabilities. The estimated survival curves suggest a significant difference between male and female survival experience up to about 2 years survival, though the curves are similar beyond that time. Censored observations are marked on the plot by a plus (+) symbol

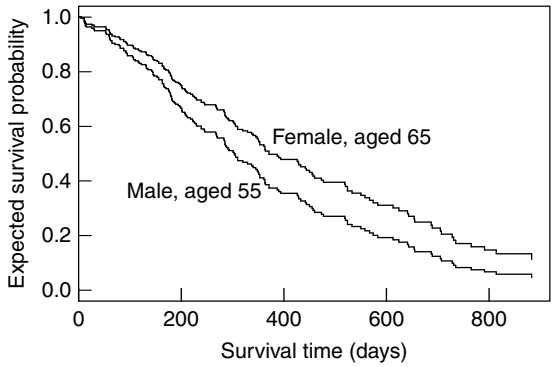

Figure 20 Expected survival probabilities arising from a proportional hazards model for the Mayo clinic lung cancer data (Loprinzi et al. [70]). The model was fit to incorporate both gender and age effects. Estimated expected survival curves are depicted for a male patient aged 55 and a female patient aged 65. Note that despite the 10-year age difference the female's expected survival experience remains better than the male's. In the model fit, the age covariate was only marginally significant

assumes that the hazard rate for a patient having covariate values z is proportional to some baseline hazard rate (usually corresponding to a patient having "average" covariates), with the constant of proportionality depending only on the values of the covariates z and not on time. A plot of a patient's expected survival curve which takes into account their particular covariate values can then be presented; see Figure 20 for an example.

Another graphic commonly used for analyzing survival data is a plot of the estimated survival function $\hat{S}(t)$ (or the estimated cumulative hazard $\hat{H}(t) = -\log\{\hat{S}(t)\}$) against a theoretical survival function $S(t)$ (or cumulative hazard $H(t)$, respectively). This graphic allows the comparison of an observed survival experience with a theoretical model for survival, with deviations from a straight-line pattern reflecting departures from the model. The visual basis for comparison in this case is similar to that used in Q–Q or P–P plots.

Graphical Presentation of Longitudinal Data

Longitudinal data comprise repeated measurements over time on many individuals [1]. Typically, a longitudinal data analysis has the regression objective of describing the dependence of a **response variable** Y on time t and other **explanatory variables** $\mathbf{x}$. With a single response on each subject, the standard scatter-plot, perhaps enhanced with a **nonparametric regression** estimate of $E(Y|\mathbf{x})$, is an effective **graphical display** to explore this dependence. With repeated measurements, there is the opportunity to display other features of the data such as the relative variation in Y across time within a person and differences among persons in the dependence of Y on t or $\mathbf{x}$.

While there are not commonly accepted rules for the effective display of longitudinal data, the following guidelines [1] may be helpful:

1. Display original data relevant to the question at hand, not just data summaries. This communicates the degree of variation against which summaries should be judged.
2. Make apparent unusual observations and unusual persons (*see* **Outliers**).
3. Contrast variation within and among persons in the dependence of Y on t or $\mathbf{x}$.

A model for longitudinal data has two components: a regression model for the dependence of Y on $(\mathbf{x},t)$; and a model for the **autocorrelation** among the repeated observations for a person. Graphical displays are necessary for each component.

To illustrate two simple, but effective, displays, longitudinal data on the growth of Nepali preschool children, collected in the Nepal Nutrition Intervention Project [3], are used (*see* **Growth and Development**). This was a prospective investigation of the effects of vitamin A supplementation on children's morbidity and mortality. The data set here comprises 11 290 observations on 2237 children receiving placebos. Each child was measured in up to five visits at 4-month intervals.

Regression Displays

Figure 1 displays a standard scatter-plot of the 11 290 weights against age. Note that weight is recorded to the nearest tenth of a kilogram and age to the nearest month, which would create an unacceptable degree of granularity in the display. To overcome this problem, the x and y values have been jittered by adding a uniform error. The scale of the error was chosen to make nearly all points visible but also to communicate the limited precision of the raw data.

A smoothing **spline** with 22 equivalent degrees of freedom [2] was added to highlight the typical growth pattern. The number of degrees of freedom was chosen by eye so that the resulting smooth curve was sufficiently flexible to capture the strong nonlinearity in growth in the first year. Automatic selection criteria for longitudinal data have been developed (see [4] and references therein). But trial and error can be equally effective at choosing a degree of smoothness to enhance the data display.

The repeated measurements for a subset of 100 children have been connected to communicate the degree of consistency across time in a child's weight as well as the variation in weight among children. In some data sets, the repeated observations can usefully be connected for all subjects. In this case, doing so produces a useless ink blot. One simple, alternative strategy is to connect the repeated values for a judiciously selected subset of, say, 100 children. This selection can be done at random. However, this strategy will fail to identify unusual weights or children. As an alternative, we have chosen 50 children at random and a second 50 that were at the extremes of the data in the following sense. For each child, the mean time and weight was calculated. Mean weight was regressed on mean time and a residual obtained. The second 50 children comprise those with the largest residuals in absolute value. Hence, these children have average weights which are extreme for their age. Other criteria for identifying a subset of subjects are discussed by Diggle et al. [1].

In Figure 1, several important characteristics of the data set are now apparent. First, the average weight of Nepali children increases by about 1 kg per month for the first 6 months and then the growth rate dramatically slows to less than a quarter of the original rate. Secondly, we can see the degree to which a description of Nepali growth using these data will depend upon cross-sectional, in addition to longitudinal, information. Note that no child was observed for more than 18 months, as seen in the Figure by the lengths of the children's lines. Hence comparing average size at times separated by a

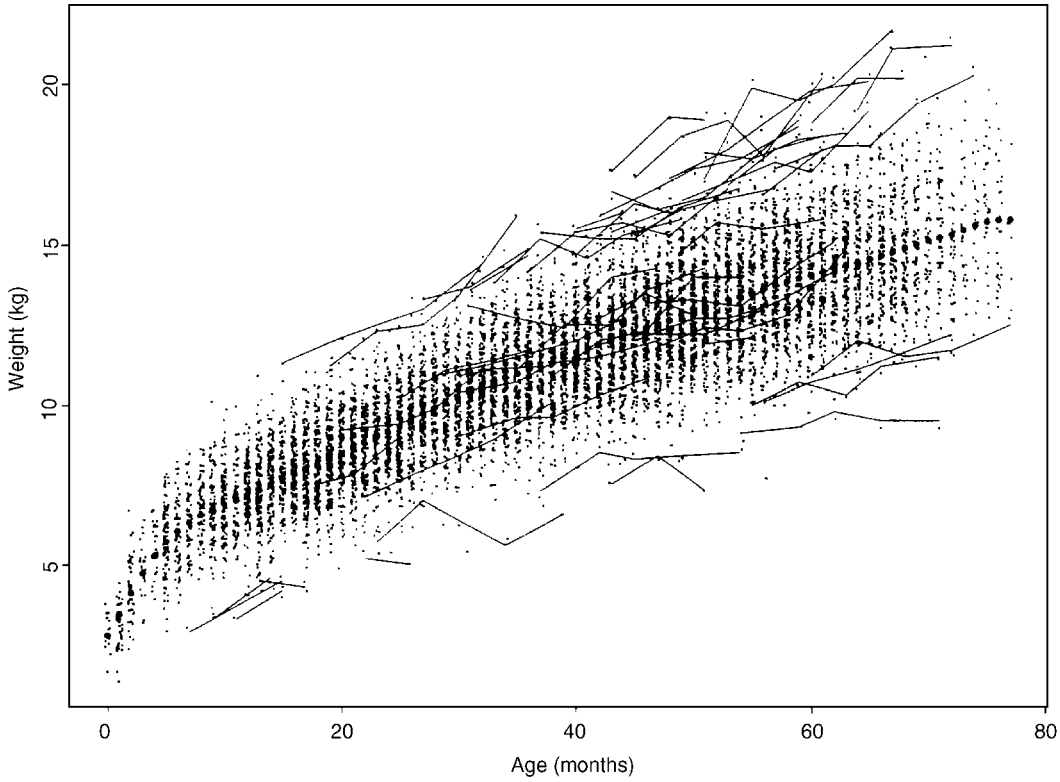

Figure 1 Scatter-plot of 11 290 weights on 2337 Nepali children. Bold dots indicate a smoothing spline with 22 equivalent degrees of freedom as an estimate of the mean weight at each age. The repeated observations for 100 children are connected – 50 chosen at random and 50 with extreme mean weights for their age

greater time interval uses entirely cross-sectional information. Thirdly, there is much greater variability in weight across children than across time for a given child. That is, there is strong *tracking* of children's weight so that repeated observations on the same child will be highly correlated. Finally, there is some indication that the rate of growth is greater for larger children, as evidenced by more positive slopes above the average curve than below. If substantiated by a more careful analysis, then this fact would be important to public health workers who could target interventions more appropriately.

Association Displays

A scatter-plot matrix is one effective approach to more directly view the nature and degree of association among repeated observations. First, the mean structure is removed from the data by regressing the response Y on predictors $\mathbf{x}$ yielding **residuals** r. If the data are observed at equally spaced times, the scatter-plot matrix simply displays r_{ij} vs. r_{ik} for all times $j \neq k$, where i denotes the subject. Unequally spaced times can be rounded to produce an equally spaced observation grid.

For example, in the Nepali data set, observation times were categorized into 6-month intervals. This often produced more than one observation per bin for a subject. All pairs of observations on each child – one from bin j and the other from bin k – could then be plotted in the (j, k) entry in the scatter-plot matrix. In fact, because there is such a large number of data pairs ($>30\,000$), only a single pair per child is used in each scatter-plot in the matrix.

Several characteristics of the data are apparent in Figure 2. First, we can again see that there is limited follow-up on each child by the absence of information away from the diagonal of the matrix.

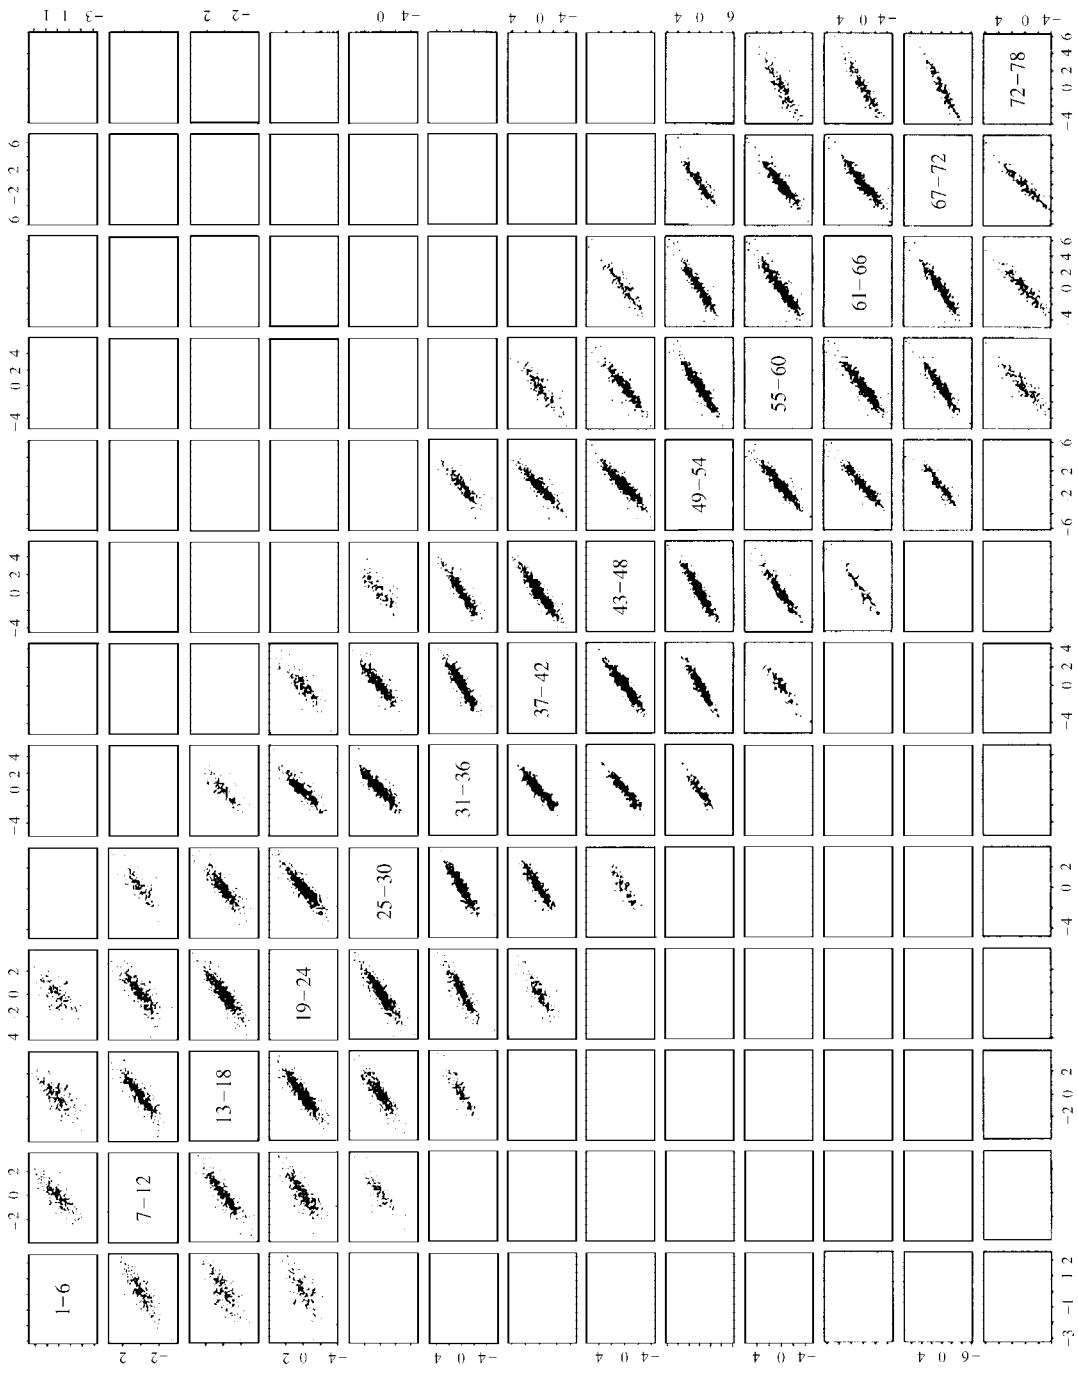

Figure 2 Scatter-plot matrix display of the residuals r_{ij} vs. r_{ik} for all $j > k$. The unequally spaced times are rounded to the nearest 6-month interval

Secondly, the extremely strong autocorrelation at all lags and ages is evident. Thirdly, the display suggests that the degree of association for two observations a fixed time apart is stronger at older ages than at the beginning of life. This is an example of a non-**stationary** autocorrelation pattern [1]. It might result if there is less stability across time in weight when the growth rate is faster.

If the autocorrelations appear to depend only on the lag and not on the absolute times of observation, the correlation pattern is said to be *stationary* and the scatter-plot matrix can be usefully summarized by a **variogram** [1]. Here, the normalized squared difference $0.5\ (r_{ij} - r_{ik})^2$ is plotted against the absolute time between the repeated observations $|t_{ij} - t_{ik}|$. A smooth regression curve fit to these data estimates the variogram, $0.5\text{E}\ [Y_i(t) - Y_i(t-u)]^2 = \sigma^2[1 - \rho(u)]$, $u > 0$, where t is the first observation time, u the lag, and $\rho(u)$ the autocorrelation function, which, because of stationarity, depends only upon u and not t. Diggle et al. [1] describe the use of the variogram in choosing models for longitudinal data.

SCOTT L. ZEGER & JOANNE KATZ

Graunt, John

Born: April 24, 1620, in London, UK.
Died: April 18, 1674, in London, UK.

John Graunt was a London draper who, in February 1662, published a small book *Natural and Political Observations Mentioned in a following Index and Made Upon the Bills of Mortality*. For this pioneer study of medical statistics and **demography** Graunt is rightly recognized as the founder of statistics as a scientific discipline.

The book attracted immediate attention. Within a month Graunt was elected to the Royal Society; a second edition appeared later in the year, and a third and fourth in the early weeks of the plague in 1665. A fifth edition appeared two years after his death, and there are modern reprints [1, 3, 7].

Graunt was a respected citizen, a Freeman, and eventually Renter Warden of the Drapers' Company. He held various civil and military offices, and his influence was sufficient, before he was 30, to procure the professorship of music at Gresham College for his friend **William Petty**. Graunt's house was destroyed in the fire of 1666, but despite assistance from Petty his business never recovered. A few years later he became a Catholic, resigned his offices, and died in poverty. No portrait is known.

The *London Bills of Mortality* were weekly accounts of the numbers of burials, distinguishing deaths from plague, and christenings, compiled from parish registers from the mid-sixteenth century. **Causes of death** were included from the early sixteen hundreds. Annual summaries were published, but initially only during plague years.

Graunt's study was based mainly on the annual *Bills* from 1604 to 1660. He had no information on population sizes. With this limited material his approach was thoroughly logical and scientific. He described in detail how the data were collected, and their nature; he was critical of their accuracy and completeness; he tabulated the material extensively and informatively, checked his first impressions against more extensive facts, and drew a wide variety of sensible and valid conclusions. Among much else, Graunt directed attention to the very high rates of mortality in infancy (*see* **Infant and Perinatal Mortality**), and showed that mortality was higher in London than in the country. He made the first realistic estimates of the numbers of men and women in London and the population of the whole country and showed that both were increasing, with a steady migration into London. He demonstrated that plague was under-recorded by about a quarter, examined the relative mortality in different plague years, discovered the extent to which London depopulated itself in plague years, and showed that it repopulated itself within a year. He distinguished between epidemic and endemic diseases, and noted the stability of accident and suicide rates from year to year, the under-recording of syphilis, and the increase of rickets. Graunt's methods and findings are reviewed in [2, 4], and [5].

Graunt had no information on the ages of the dead or the living. This led him to conceive the first **life table**, describing the dying-out of a population cohort in an attempt to estimate the number of men of military age (16–56) in London (see Table 1). However, not appreciating the need to use age-specific mortality rates, he mistakenly estimated the proportion of *deaths* between these ages from his survivors' column, and not the proportion living [2] (*see* **Standardization Methods**). His pioneer effort was nevertheless highly influential in stimulating the later **actuarial** development of the life table.

Suggestions that Graunt was not the author of the "Observations" and that these were the work of Petty only arose after Graunt's death, and were revived

during the twentieth century (see [3, 6], and [7]). A comprehensive re-examination by Glass [2] concluded that "there seems little reason to doubt that the volume published under Graunt's name was in all essential respects Graunt's work".

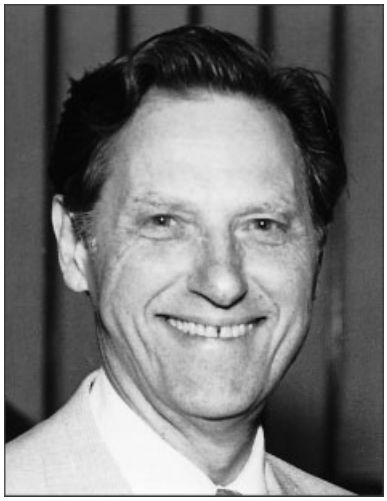
I. SUTHERLAND

Greenberg, Bernard George

Born: October 4, 1919, in New York City.
Died: November 24, 1985, in Chapel Hill.



Bernard G. Greenberg, the founder of the Department of Biostatistics at the University of North Carolina and a pioneer in the field of public health, played a key role in the evolution of the discipline of biostatistics encompassing a large domain of public health, **demography** (population studies), and medical/clinical research.

Greenberg earned a B.S. degree in mathematics in 1939 from the City College of New York, and before being inducted into the US Army in 1941, served briefly as an assistant statistician in the US Bureau of Census, as well as in the New York State Department of Health. Following his discharge from the active military service (where he was raised to the rank of Captain), in 1946 he attended a special summer session of the Institute of Statistics at the North Carolina State College in Raleigh. His mentor, **Gertrude Cox**, organized instruction by eminent statisticians such as **R.A. Fisher**; **Harold Hotelling**; **George Snedecor**; **William Cochran**; **Chester Bliss**; Jacob Wolfowitz, and others. Greenberg was strongly influenced by this program and entered the North Carolina State College as a graduate student in experimental statistics, earning his Ph.D. degree in 1949. During the tenure of his graduate studies, Greenberg studied under Harold Hotelling, who headed the theoretical division of the Institute of Statistics of the University of North Carolina at Chapel Hill, though he was also influenced by William Cochran.

In July 1949, Edward G. McGavran, the Dean of the School of Public Health, University of North Carolina at Chapel Hill, invited Greenberg to organize a new, single faculty, Department of Biostatistics. Greenberg nurtured the growth of this department for more than 23 years as the Chairman (1949–1972), and also later (1972–1982), as the Dean of the School of Public Health. In the fall of 1982 he returned to the biostatistics faculty and began development of a curriculum for statistics of **communicable diseases**. Soon after, however, he was afflicted with cancer and, following a long period of illness, died in the fall of 1985, only a few months after his retirement. Thus the Greenberg era of outstanding leadership and phenomenal developments in biostatistics and public health started in 1949 and came to an unexpected halt after nearly 36 years. To outline Greenberg's major contributions, we need to focus on his organizational leadership and developmental vision before outlining his academic contributions.

In the early 1950s the primary mission of the new Department of Biostatistics at Chapel Hill was to offer a few service courses to meet the growing statistical needs of faculty and students in public health. This objective was quickly expanded to teaching courses in the entire field of Health Affairs (including the Medical, Nursing, Dental, Public Health, and Pharmacology Schools), and also providing biostatistical consultation support to faculty members. With generous support from the **National Institutes of Health (NIH)** and other Agencies, he introduced masters and doctorate level programs in biostatistics at Chapel Hill that ultimately have been recognized as among the finest programs in the nation.

Two of Greenberg's major contributions to the field of biostatistics prior to the 1960s deserve special mention. First, he introduced a field training program in which a master's degree student was assigned for several weeks to a counselor in a state health agency and this was designed to familiarize students with real problems in public health and to help them in choosing an appropriate professional career in the health sciences. Secondly, faculty members became engaged in cooperative, **multicenter clinical trials**, first in cancer clinical trials and later in the 1960s and

1970s on several large projects including the LIPIDS (1972–1984) trials sponsored by the National Heart, Lung and Blood Institute. Greenberg had a special skill in attracting distinguished statisticians, including D.R. Cox, David Duncan, and Herbert A. David, as visiting professors in the Department, with support from the training grants. In the 1950s and 1960s this aided the development of a biostatistics curriculum, and enabled the implementation of interactive research programs and research incentives for regular faculty and students in and around North Carolina. The creation of the population laboratory (PopLab) in the School of Public Health and with the association of the Carolina Population Center in the mid 1960s is an example of Greenberg's bringing together the key government and academic people with the broad objective of developing a research and training program.

Greenberg not only provided leadership to the Department of Biostatistics, but also contributed to research, often combining methodological research with applications. His interest in **order statistics** in the 1950s enabled him, in collaboration with A.E. Sarhan, to edit a fine volume entitled *Contributions to Order Statistics* [1] which gave an up-to-date account of developments in that field, including many of their joint works. In the field of **randomized response** models, Greenberg was instrumental in incorporating this basic statistical concept to reduce the **bias** of responses to sensitive questions in public health investigations. The methodological work began in the early 1960s and continued to have an important influence in the late 1970s. Perhaps Greenberg's major statistical contributions related to applications in the field of public health, with special emphasis on epidemiology, maternal and child health, nutrition and health administration. Over a long period he was associated with the North Carolina State Board of Health and introduced statistical tools and concepts in their areas of application. Though primarily an administrator and a leader in public health, he was a genuine promoter of the utilization of statistical tools and concepts in scientific inquiries.

His efforts and contributions were recognized with numerous honors and awards: the Bronfman Award (1966) from the **American Public Health Association**; a Kenan Professorship (1969–1985) in biostatistics, University of North Carolina; the Watson S. Rankin Award (1980) from the North Carolina Public Health Association; and the Order of the Golden Fleece, as well as the O. Max Gardner Award, from the University of North Carolina (1983). He was elected a Fellow of the **American Statistical Association**, the Institute of Mathematical Statistics, the American Public Health Association, the American College of Epidemiology, and he was an elected member of the **International Statistical Institute**, the American Epidemiological Society, and the Institute of Medicine. He served on the editorial boards of the *Journal of Statistical Planning and Inference, International Statistical Reviews, Journal of Chronic Diseases*, and the *American Journal of Obstetrics and Gynecology*.

Bernard Greenberg was a humane, caring person who, in spite of heavy professional, scholarly, and administrative responsibilities, took a genuine, personal interest in all his colleagues, former students, friends and family members. A volume of collected papers prepared by his colleagues, friends, and former students was written in 1985 to honor Greenberg on his 65th birthday [2].

PRANAB K. SEN

Greenhouse, Samuel W.

Born: January 13, 1918, in Bronx, New York.
Died: September 29, 2000, in Rockville, Maryland.

Samuel W. Greenhouse was one of the founding statisticians at the **National Institutes of Health**, who helped pioneer the use of statistical methods in epidemiological research (*see* **Epidemiology, Overview**), and was influential in the early development of the theory and practice of clinical trials (*see* **Clinical Trials, Early Cancer and Heart Disease**). He was also a distinguished professor of statistics at the George Washington University.

Sam, as he was known to all, received his BS in mathematics from the City College of New York in 1938 and thereafter moved to Washington, DC to begin his career in the bureau of census with Edward Deming (1940–1942). He served in the army during World War II and afterwards worked with the United Nations Relief and Rehabilitation Agency (1945–1948). In 1948, he was recruited by Harold **Dorn**, along with Jerome **Cornfield**, Jacob Lieberman, Nathan **Mantel**, and Marvin **Schneiderman**, to create the first biometry group at the National Institutes of Health (NIH) in the National Cancer Institute (NCI). In 1954, Sam left the NCI to become head of the theoretical statistics and applied mathematics section in the National Institute of Mental Health (NIMH).

In 1966, he was appointed chief of the epidemiology and biometry branch of the National Institute of Child Health and Human Development (NICHD), where he rose to the position of associate director for epidemiology and biometry (1970–1974) and acting associate director of the office of program planning and evaluation (1969–1974). He was the first statistician to hold such a high administrative position at the NIH.

While working full time at the NIH, Sam taught part-time and pursued his own graduate degrees under the direction of Solomon Kullback in the department of statistics at George Washington University (GWU).

When Sam retired from government service in 1974, he began a full-time academic career at GWU, where he served as chair of the department of statistics from 1976–1979 and again in 1985–1986. In 1988, he retired from the university faculty and was named professor emeritus. From 1988 until his death, he served as the associate director for research development of the GWU biostatistics center.

Sam articulated many times that the primary mission of the statisticians at the NIH was to collaborate and provide statistical support for the NIH scientists. Yet, it was always understood that these collaborations would lead to opportunities for statistical research in methodology and theory. It was not unusual to find Sam and the other early NIH statisticians coauthoring papers in subject matter journals and publishing corresponding theory and methods papers in statistics journals. This pattern was evident in his early papers on the evaluation of diagnostic tests. Although this work with Mantel [11] and Dunn [3] was rooted in the need to implement noninvasive methods for cancer **screening**, it also addressed methodological issues, such as deriving the estimated variance of **sensitivity** and **specificity** for the case when, the diagnostic cut-point for a quantitative test was also estimated from the data. While at the NIMH, he helped design and analyze the first multidisciplinary study of normal aging, and coedited the resulting book [2]. Recognizing the need for methods to analyze highly correlated psychological data from studies such as this one, led directly to new methodological work with Geisser [8, 10].

They derived an estimate of the degree of departure from the assumption of compound symmetry in the test of within-subjects effects in analysis of variance ANOVA, and an adjustment to the degrees of freedom of the F-ratio when that assumption is violated. The Greenhouse–Geisser correction is now provided in virtually all computer packages for repeated measures analysis. Their work [10] was recognized in 1982 as a science and social science citation classic (*see* **Analysis of Variance for Longitudinal Data**).

Sam was also influential in the early development of the theory and practice of clinical trials and shared an interest with Cornfield in methods for the **sequential analysis** of emerging data in clinical trials. While at the NICHD, his collaborations focused more on **observational** data, for example, assessing the safety of oral contraceptive use, and his interests returned to the development of methods for epidemiologic studies. His papers with Seigel [13, 14], for example, showed that **logistic regression** could be applied to matched and unmatched **case–control studies** to obtain an adjusted estimate of the prospective **odds**

ratio associated with a **risk factor**. At GWU in the late 1980s, Sam and Joe Gastwirth recognized similarities between a class of problems arising in legal settings and in epidemiologic studies (*see* **Epidemiology as Legal Evidence**). A collaboration began that was deeply grounded in the practical experiences of their respective fields of application (see, e.g. [5, 6]).

It is a tribute to his energy and enthusiasm for statistics that Sam received many honors for his intellectual and professional contributions. The **American Statistical Association** (ASA) recognized him with their prestigious Founders Award in 1993, and in 1997, videotaped a discussion with Sam as part of the ASA series of conversations with distinguished statisticians [1]. In addition to being elected as a Fellow in the major statistical professional societies, Sam was also an elected Fellow of the American College of Epidemiology and of the council of epidemiology of the American Heart Association. In 1969, he received the superior service honor award from the NIH and was named a Johns Hopkins University centennial scholar in 1976. In 1999, Sam was recognized by the Harvard Institute of Psychiatric Epidemiology and Genetics for his lifetime contributions to psychiatric epidemiology and biostatistics.

Sam was a much-loved presence in the profession. He attended the annual meetings of the Eastern North American Region (ENAR) (*see* **International Biometric Society (IBS)**), the **Society of Clinical Trials**, the joint statistical meetings (JSM), and the American Association for the Advancement of Science (AAAS) without fail, and the ISI (*see* **International Statistical Institute (ISI)**) as often as he could. He was amazingly current and had strong opinions on all matters. He was not shy about asking questions of speakers, especially when he did not understand a point (or felt that they did not), and it would not be unusual for the discussion to continue in the hall or even later via e-mail until he felt the issues were resolved. This was true whether the topic was statistics, literature, music, politics, religion, or sports. In his 1997 *Statistical Science* article on his reminiscences of the NIH, Sam wrote about how the group (Cornfield, Halperin, Mantel, he, and others) would often argue quite publicly over lunch about matters statistical and otherwise [9]. Although one of Sam's most endearing features was his personal warmth and smile, he could also be quite the provocateur. We fondly remember times in the late 1970s and early 1980s, when Sam would visit Max **Halperin** or Nathan Mantel at the biostatistics center. Sam loved nothing more than a friendly spirited argument and Max and Nathan were always eager to comply. Sam was capable of arguing either side of an issue and often would, especially if it would get a rise out of Max or Nathan.

Sam was passionate about statistics. He relished the opportunity to teach and engage both colleagues and young statisticians in statistical discourse. Whether giving a seminar, making a site visit, or on sabbatical, Sam was always a popular and stimulating visitor and speaker. However, if one asked Sam about the truly important work he was doing, he would inevitably talk about his scientific collaborations. For it was through the practice of statistics, he believed, that statisticians made their biggest impact on science, and it was through scientific collaborations that the important statistical problems were identified.

Sam died of cancer at the age of 82. For additional biographical information see [1, 4, 7, 9, 12].

JOEL B. GREENHOUSE & JOHN M. LACHIN

Greenwood, Major

Born: August 9, 1880, in the parish of Shoreditch, East London, UK.
Died: October 5, 1949, London, UK.

Reproduced by permission of the Royal Statistical Society

Major Greenwood played an important role in the development of biostatistics during the first half of the twentieth century, both as an epidemiologist and as a pioneer medical statistician. He was the only surviving son in the third generation of a family in general practice in Hackney; a family practice run in his youth by his father and grandfather, both also called Major Greenwood. With a view to keeping the practice in the family, his father insisted that young Greenwood should have a medical education, in spite of a taste for history and Latin (so often linked to mathematical ability) which he had developed at Merchant Taylor's School. He was awarded an entrance scholarship to the London Hospital, where he qualified in 1904. Having so far bowed to parental pressure, Greenwood turned to his own interests in medical research rather than practice, helped and influenced by two outstanding, very different, scientists. He became a demonstrator in the physiology department of the London Hospital Medical College under (Sir) Leonard Hill; and at the same time he began following the courses in the rapidly developing science of biological statistics given by **Karl Pearson** at University College London.

In Hill's department the young Greenwood was introduced to scientific methodology as applied to medical research, while Pearson's course made him one of the earliest medical converts to the use of biometric measurements in evaluating approaches to the treatment and prevention of disease. Throughout his subsequent career, Greenwood was to combine and develop what he regarded as his double intellectual legacy from his two mentors, to both of whom he remained a loyal pupil and friend. In the early decades of the century he succeeded in developing medical statistics in a way to make its methodology acceptable to an initially reluctant medical profession, primarily by adding good clinical judgment to the rigorous mathematics that characterized Pearson's work.

In 1909–10 Greenwood, by now a true disciple of Pearson, became involved in a debate between bacteriologists and clinicians. It concerned Almroth Wright's research on the so-called "opsonic index" as a technique for measuring a patient's capacity to deal with infection by phagocytosis. Greenwood based his criticism of Wright's statistical data on a technical distinction between "functional" errors of technique and "mathematical" inferential errors [2]. His cogent arguments came to the attention of C.J. Martin, Director of the Lister Institute, who was impressed by Pearson's promising disciple. As a result, Martin created a new post for Greenwood, the first of its kind in Britain, as resident statistician at the Lister. Here Greenwood's statistical investigations included studies of tuberculosis (which had killed his two younger siblings in infancy, and his mother in the year he himself qualified in medicine), **infant mortality**, and hospital fatality rates. He was also, from the beginning of his time at the Lister, involved in interpreting data from the Institute's ongoing major epidemiologic study of bubonic plague in India. Such studies were to provide a solid basis for Greenwood's subsequent career, with its felicitous blend of epidemiology and medical statistics.

During the Great War Greenwood served in the sanitary service of the Royal Army Medical Corps; in 1916 he was seconded to the Health and Welfare section of the Ministry of Munitions, in charge of statistical work. In 1919 the new Ministry of Health was created, and Greenwood was appointed its first Senior Statistical Officer, working closely with its Chief Medical Officer, George Newman. Never

based in Whitehall, Greenwood worked at the **Medical Research Council's** (MRC) National Institute for Medical Research in Hampstead; he was to be connected with the MRC, in one way or another, for the rest of his career. After nearly two decades, his statistical creed had developed from early dependence on Pearson's rigorous mathematics and "measurement as an end in itself" to an increasingly humane approach reflecting clinical judgment. His pioneering work on large-scale **clinical trials** designed to evaluate prophylactic and therapeutic measures, begun at the Lister, had gradually softened the medical profession's previously hostile attitude to statistical analysis.

Greenwood's mind now turned increasingly to the application of statistics in studies on experimental epidemiology when, in the early 1920s, he became associated with W.W.C. Topley. Topley needed Greenwood's statistical expertise in the studies he was initiating in "experimental epidemiology", using controlled populations of laboratory mice. The investigations were carried out, with various coworkers, until the mid-1930s [3]. By then, Greenwood and Topley had been colleagues, since 1927, as professors of Epidemiology and Vital Statistics, and of Bacteriology, respectively, at the London School of Hygiene and Tropical Medicine. The School was created, with generous Rockefeller support, as the successor to Patrick Manson's old School of Tropical Medicine between 1923 and 1929, when it could finally move into newly built premises in Keppel Street. Here teaching was, as ever, an important part of the staff's responsibilities. In 1935 Greenwood's lectures were published in book form as *Epidemics and Crowd Diseases* [1].

In his lifetime, Greenwood published well over a hundred books and papers on statistical, biometric, epidemiologic, and also historical subjects [4]. In print and in professional discussion his complex personality could on occasion make him appear cynical and censorious; but his intellectual integrity was absolute, as was his loyalty to those admitted to his limited circle of friends. He became a Member of the Royal College of Physicians in 1919, and a Fellow in 1924; in 1928 he was elected to Fellowship of the Royal Society. He retired in 1945 and died, suddenly, in London, during a meeting on cancer research, still active in his seventieth year. He was a founder member, in 1930, of the Socialist Medical Association. A few weeks before his death he argued, as its elected representative, the case for the Voluntary Euthanasia Society, in a broadcast debate arranged by the BBC.

LISE WILKINSON

Grenander Estimators

Grenander [7], in a remarkable paper, derived the **nonparametric maximum likelihood** estimators (NPMLEs) of

1. a decreasing density
2. an increasing hazard
3. an increasing hazard for repeated events.

Of these, the first has been studied in particular detail by later authors.

NPMLE of a Decreasing Density

Grenander showed that the NPMLE is given by the derivative of the least convex majorant of the empirical distribution function (*see* **Goodness of Fit**). Barlow et al. [3], and its updated version by Robertson et al. [15], put this in the context of general order restricted inference (*see* **Isotonic Inference**). The asymptotic properties of the estimator $\hat{f}_n$ of the density f based on n independent, identically distributed (iid) replications are nonstandard: if $f'(t) < 0$, then

$$n^{1/3} \left|\tfrac{1}{2} f(t) f'(t)\right|^{-1/3} [\hat{f}_n(t) - f(t)]$$

converges in distribution to $2Z$, where Z is distributed as the location of the maximum of the process $\{W(u) - u^2 : -\infty < u < \infty\}$ with W the standard Wiener process on $(-\infty, \infty)$ with $W(0) = 0$ (*see* **Brownian Motion and Diffusion Processes**). Asymptotic distributions of more global measures of discrepancy between $\hat{f}_n$ and f were studied by Groeneboom & Pyke [10] and Groeneboom [8, 9]; Birgé [4] surveyed "nonasymptotic" properties.

For **censored** (survival) data with decreasing density the NPMLE was derived and discussed by Denby & Vardi [5].

Current Status Data

The order restriction for the above NPMLE problem reappears in the nonparametric *current status data* model, first studied by Ayer et al. [1], where n iid replications of pairs of independent random variables (X_i, Y_i) are considered (*see* **Interval Censoring**). Based on observation of $(I\{X_i \leq Y_i\}, Y_i)$ an estimate is sought of the survival function $S(x) = \Pr\{X_1 > x\}$. (Conceptually, all X_i are either left-censored or right-censored by Y_i.) Again, S is constrained to be a decreasing function, and a very similar algorithm is available, particularly studied by Groeneboom (see [11]), who also showed that similar asymptotic results ($n^{1/3}$-convergence) apply. A good general introduction to current status data is [6] (see also [12]). An example as well as details of the distribution of Z can be found in [13]. An important recent paper [2] derived a nonparametric likelihood ratio test for these contexts.

NPMLE of an Increasing Hazard Rate

Grenander's derivation [7] was shown by Barlow et al. [3] to be interpretable as the inverse of the slope (from the right) of the concave majorant of the **total time on test** plot. A similar $n^{1/3}$ asymptotic convergence result as above was given by Prakasa Rao [14].

Group Randomized Trials

Introduction

Group-randomized trials (GRTs) are comparative studies in which investigators randomize identifiable groups to conditions and observe members of those groups to assess the effects of an intervention [8]. In this context, an identifiable group refers quite broadly to any group that is not constituted at random, so that there is some physical, geographic, social, or other connection among its members. Just as the randomized clinical trial (RCT) (*see* **Clinical Trials, Overview**) is the gold standard in public health and medicine when **randomization** of individuals to study conditions is possible, the GRT is the gold standard in public health and medicine when randomization of identifiable groups is required. This situation exists whenever the investigator wants to evaluate an intervention that operates at a group level, manipulates the social or physical environment, or cannot be delivered to individuals (*see* **Cluster Randomization**).

An Example

TEENS was a group-randomized trial occurring in 16 middle schools in the Twin Cities metropolitan area from 1997 to 2000 [7]. Schools agreeing to be in the study committed to the measurement protocol, randomization to condition, and if randomized to the intervention condition, to the following intervention protocol: (a) offer all 10 sessions of the TEENS curriculum in 7th and 8th grade; (b) allow the designated teacher to attend a full day training each year; (c) allow for provision of a family education component; and (d) allow school food service staff to be trained on modifying the school food environment. **Sample size** calculations, based on fruit, vegetables, and fat intake data from prior school-based studies, indicated that with 16 schools and at least 30 students measured per grade, we had 80% **power** to detect differences of 1.1 servings of fruits and vegetables and a 1.9% difference in energy from total fat intake between treatment groups. All students who were in 7th grade during the baseline data collection period were considered eligible to participate.

The primary **outcome measures** for evaluating the effectiveness of TEENS were student-level intake of fruits, vegetables, and energy from fat based on 24-hour dietary recalls. Data were collected at baseline at the beginning of the 7th grade in Fall 1998 and again at the end of the 7th and 8th grades in Spring 1999 and 2000.

Schools were randomly assigned from within matched pairs (*see* **Matching**) to either control or intervention condition. Schools were matched on both the proportion of 7th graders expected to receive the TEENS curriculum and on the proportion receiving free or reduced school lunch; randomization was constrained so that the four smallest schools were distributed with two in each of the two conditions. The eight intervention schools received the TEENS intervention and related training for two consecutive years beginning when the grade cohort was in the 7th grade (1998–1999) and continuing through the 8th grade year (1999–2000). The end of 7th grade data suggested a significant increase in consumption of fruits and vegetables in the intervention condition [1]; the end of 8th grade data suggested that those effects were not sustained through two years of follow-up [7].

Distinguishing Characteristics

There are four characteristics that distinguish the GRT from the more familiar RCT [8]. First, the unit of assignment is an identifiable group; such groups are not formed at random, but rather through some physical, social, geographic, or other connection among their members. Second, different groups are assigned to each condition, creating a nested or hierarchical structure for the design and the data (*see* **Hierarchical Models**). Third, the units of observation are members of those groups so that they are nested within both their condition and their group. Fourth, there usually are only a limited number of groups assigned to each condition.

These characteristics create several problems for the design and analysis of GRTs. The major design problem is that a limited number of often heterogeneous groups makes it difficult for randomization to distribute potential sources of **confounding** evenly in any single realization of the experiment. This increases the need to employ design strategies that will limit confounding and analytic strategies to deal with confounding where it is detected. The major analytic problem is that there is an expectation for positive intraclass **correlation** (ICC) among observations

on members of the same group [6]. That ICC reflects an extra component of variance (*see* **Variance Components**) attributable to the group above and beyond the variance attributable to its members. This extra variation will increase the variance of any group-level statistic beyond what would be expected with random assignment of members to conditions. Moreover, with a limited number of groups, the **degrees of freedom** (df) available to estimate group-level statistics are limited. Any test that ignores either the extra variation or the limited df will have a Type I error rate (*see* **Hypothesis Testing**) that is inflated [3].

The Development of Group-randomized Trials in Public Health

GRTs gained attention in public health in the late 1970s with the publication of a symposium on coronary heart disease prevention trials in the *American Journal of Epidemiology*. **Cornfield's** paper in particular has become quite well known among methodologists working in this area, as it identified the two issues that have vexed investigators who employ GRTs from the outset: extra variation and limited degrees of freedom [3].

The last 25 years have witnessed dramatic growth in the number of GRTs in public health and dramatic improvements in the quality of the design and analysis of those trials. Responding directly to Cornfield's warning, Donner and colleagues at the University of Western Ontario published a steady stream of papers on the issues of analysis facing group-randomized trials through the 1980s and 1990s. Murray and colleagues from the University of Minnesota began their examination of the issues of design and analysis in group-randomized trials in the mid-1980s. Other investigators from the **National Institutes of Health**, the University of Washington, the New England Research Institute, and elsewhere added to this growing literature in public health, especially in the 1990s.

In the 1998, the first textbook on the design and analysis of GRTs appeared [8]. It detailed the design considerations for the development of GRTs, described the major approaches to their analysis both for Gaussian (*see* **Normal Distribution**) and **binary data**, and presented methods for power analysis applicable to most GRTs. The second textbook on the design and analysis of GRTs appeared in 2000 [4]. It provided a good history on GRTs, examined the role of informed consent and other ethical issues (*see* **Ethics of Randomized Trials**), focused on extensions of classical methods, and included material on regression models for Gaussian, binary, count, and time-to-event data. Murray et al. recently reviewed a large number of articles on new methods relevant to the design and analysis of GRTs published between 1998 and 2003 [10].

Potential Design Problems and Methods to Avoid Them

For GRTs, there are four sources of **bias** that should be considered during the planning phase: **selection**, differential history, differential maturation, and contamination. These biases are well known and may also occur in RCTs. The first three are particularly problematic in GRTs where the number of units available for randomization is often small. GRTs planned with fewer than 20 groups per condition would be well served to include careful matching or **stratification** prior to randomization to help avoid these biases. Analytic strategies, such as regression adjustment for confounders, can be very helpful in dealing with any observed bias.

Potential Analytic Problems and Methods to Avoid Them

There are two major threats to the validity of the analysis of a GRT, which should be considered during the planning phase: misspecification of the analytic model and low power. **Misspecification** of the analytic model most commonly occurs when the investigator fails to reflect the expected ICC in the analytic model. Low power most commonly occurs when the design is based on an insufficient number of groups randomized to each condition.

There are several analytic approaches that can provide a valid analysis for GRTs [4, 8]. In most, the intervention effect is defined as a function of a condition-level statistic (e.g. difference in means, rates, or slopes) and assessed against the variation in the corresponding group-level statistic. These approaches included mixed-model ANOVA/ANCOVA (*see* **Analysis of Variance**; **Analysis of Covariance**) for designs having only one or two time intervals, random coefficient models for designs having three or more time intervals, and **randomization**

tests as an alternative to the model-based methods. Other approaches are generally regarded as invalid for GRTs because they ignore or misrepresent a source of random variation. These include analyses that assess condition variation against individual variation and ignore the group, analyses that assess condition variation against individual variation and include the group as a **fixed effect**, analyses that assess the condition variation against subgroup variation, and analyses that assess condition variation against the wrong type of group variation. Still other strategies may have limited application for GRTs. Application of fixed-effect models with post hoc correction for extra variation and limited df assumes that the correction is based on an appropriate ICC estimate. Application of survey-based methods or generalized estimating equations (GEE) and the sandwich method for **standard errors** requires a total of 40 or more groups in the study, or a correction for the downward bias in the sandwich estimator for standard errors when there are fewer than 40 groups in the study [10].

Low power will occur if the investigator employs a weak intervention, has insufficient replication, has high variance or intraclass correlation in the endpoints, or has poor reliability of intervention implementation. To avoid low power, investigators should plan a large enough study to ensure sufficient replication, employ more and smaller groups instead of a few large groups, employ strong interventions with good reach, and maintain the reliability of intervention implementation. In the analysis, investigators should consider regression adjustment for **covariates**, model time if possible, and consider post hoc stratification.

A detailed exposition on power for GRTs is beyond the scope of this article. Excellent treatments exist, and the interested reader is referred to those sources for additional information. Chapter 9 in the Murray text provides perhaps the most comprehensive treatment of detectable difference, sample size, and power for GRTs [8]. Even so, a few points bear repeating here. First, the increase in between-group variance due to the ICC in the simplest analysis is calculated as $1 + (m - 1)ICC$, where m is the number of members per group; as such, ignoring even a small ICC can underestimate standard errors if m is large. Second, while the magnitude of the ICC is inversely related to the level of aggregation, it is independent of the number of group members who provide data. For both these reasons, more power is available given more groups per condition with fewer members measured per group than given just a few groups per condition with many members measured per group, no matter the size of the ICC. Third, the two factors that largely determine power in any GRT are the ICC and the number of groups per condition. For these reasons, there is no substitute for a good estimate of the ICC for the primary endpoint, the **target population**, and the primary analysis planned for the trial, and it is unusual for a GRT to have adequate power with fewer than 8 to 10 groups per condition. Finally, the formula for the standard error for the intervention effect depends on the primary analysis planned for the trial, and investigators should take care to calculate that standard error, and power, based on that analysis.

The Future of Group-randomized Trials

Whenever the investigator wants to evaluate an intervention that operates at a group level, manipulates the social or physical environment, or cannot be delivered to individuals, the GRT is the best comparative design available. Even so, there remain many challenges facing GRTs. For example, there can be no question that it is harder to change the health behavior and risk profile of a whole community than it is to make similar changes in smaller identifiable groups such as those at worksites, physician practices, schools, and churches. And while no quantitative analysis has been published, it seems that the magnitude of the intervention effects reported for GRTs has been greater for trials that involved smaller groups than for trials involving such large aggregates as whole communities. With smaller groups, it is possible to include more groups in the design, thereby improving the validity of the design and the power of the trial. With smaller groups, it is easier to focus intervention activities on the target population. With smaller groups, the cost and difficulty of the implementation of the study generally are reduced. For these and similar reasons, future group-randomized trials may do well to focus on more and smaller identifiable groups rather than on whole cities or larger aggregates.

Another challenge is simply the difficulty in developing interventions strong enough to change the health behaviors of the target populations. The methods for the design and analysis of GRTs have evolved considerably from the 1970s and 1980s, but we continue to employ interventions that often prove ineffective. One of the problems for some time has been that

interventions are proposed, which lack even preliminary evidence of efficacy [9]. Efficacy trials in health promotion and disease prevention (*see* **Prevention Trials**) often are begun without the benefit of prototype studies, and often even without the benefit of adequate pilot studies. This has happened in large part because the funding agencies have been reluctant to support pilot and prototype studies, preferring instead to fund efficacy and effectiveness trials. Unfortunately, the interventions that lead to GRTs tend to be more complicated than those in other areas or those that lead to clinical trials. As such, it is even more important to subject them to adequate testing in pilot and prototype studies. These earlier phases of research can uncover important weaknesses in the intervention content or implementation methods. Moving too quickly to efficacy trials risks wasting substantial time and resources on interventions that could have been substantially improved through the experience gained in those pilot and prototype studies. One would hope that the funding agencies will recognize this point and begin to provide better support for pilot and prototype studies.

There are remaining methodological challenges as well. For example, there have been a number of recent studies that documented the downward bias in the sandwich estimator used in GEE when there are fewer than 40 groups in the study [5]. Corrections have been proposed, but none appear in the standard software packages (*see* **Software, Biostatistical**), so those corrections are relatively unavailable to investigators who analyze GRTs. Absent an effective correction, the sandwich estimator will have an inflated Type I error rate in GRTs having less than 40 groups, and investigators who employ this approach continue to risk overstating the significance of their findings.

As another example, consider studies that employ only one or a few groups per condition. With only one group per condition, it is not possible to separately estimate variation due to groups and condition, and so there is no valid analysis or absent strong and untestable assumptions. With only a few groups per condition, power is likely to be extremely limited, and so such studies are to be discouraged, except perhaps as pilot studies.

As another example, there have been a number of recent studies that proposed methods for **survival analysis** that could be applied to data from GRTs. Some of these methods involved use of the sandwich estimator, and so would be subject to the same concern as noted above for GEE.

As a third example, permutation tests (*see* **Randomization Tests**) have been advocated over model-based methods because they require fewer assumptions. At the same time, they tend to have lower power. To overcome this problem, Feng et al. developed an optimal randomization test that had nominal size and better power than alternative randomization tests or GEE, though it was still not as powerful as the model-based analysis when the model was specified correctly [2]. Additional research is needed to compare Braun & Feng's optimal randomization test and model-based methods under model misspecification.

There is every reason to expect that continuing methodological improvements will lead to better trials. There is also evidence that better trials tend to have more satisfactory results. For example, Rooney and Murray presented the results of a **meta-analysis** of group-randomized trials in the smoking-prevention field [11]. One of the findings was that stronger intervention effects were associated with greater methodological rigor. Stronger intervention effects were reported for studies that planned from the beginning to employ the unit of assignment as the **unit of analysis**, that randomized a sufficient number of assignment units to each condition, that adjusted for baseline differences in important confounding variables, that had extended follow-up, and that had limited attrition. One hopes that such findings will encourage the use of good design and analytic methods.

Grouped Data

We call data *grouped* when we observe only some set Y containing the variable of interest X rather than the value of X itself. For example, suppose X represents the length and width of an iris petal, which we can only measure to the nearest millimeter. If the observed measurements are 1.4 cm and 0.2 cm, then $X \in y = (1.35, 1.45) \times (0.15, 0.25)$. Because we can neither measure nor store data with infinite precision, all so-called "continuous" data are actually grouped.

There are two general approaches to analyzing grouped data. The first is to substitute the center $\tilde{Y}$ of Y for X, proceeding as if the data were known exactly. One may be able to correct such estimates to remove grouping effects, as with **Sheppard's corrections** for rounded data. The second approach is to base inferences directly on the distribution of Y or the **likelihood** arising from it. For example, if X follows a bivariate density $f(x;\theta)$, then the likelihood from nominal measurement $\tilde{y} = (1.4, 0.2)$ is

$$L(y;\theta) = \int_{(1.35,1.45)\times(0.15,0.25)} f(x;\theta)\,\mathrm{d}x.$$

A simple approximation is

$$\tilde{L}(y;\theta) = f(\tilde{y};\theta) = f(1.4, 0.2;\theta).$$

Typically, exact methods are difficult to implement but give better answers for large n and coarse groups.

An interesting special case of grouping is *heaping*, where a single data set contains items rounded with various levels of coarseness. Heaping can occur in self-reported variables such as age, income, and cigarette consumption. Another special case is **interval censoring**, where a continuous failure time is only known to lie between two (potentially random) limits.

Grouping has been the subject of research throughout the modern era of statistics. See [1], [2], and [3] for reviews.

Grouped Survival Times

In many investigations involving survival times, data are grouped prior to their statistical analysis (*see* **Grouped Data**). The grouped survival data consist of occurrence and exposure data over given time intervals and possible covariate strata. For grouped survival (or *failure-times*) data there is an assumed continuous underlying *hazard* function, in contrast to **discrete survival-time** data, with an intrinsically discrete time variable, discrete hazards, survival functions, etc.

One of the primary reasons for grouping can be found in studies involving large sample sizes such as epidemiologic studies [6]. Such studies typically involve the follow-up of large population groups over certain time periods to assess the cause and rate of death and/or to compare death rates among different population groups. Grouping data from such large sample sizes into tabular presentations (**life tables**) often provides a convenient format for presenting and summarizing life information. Also, grouping could be done intentionally, for example, to economize on data transmission and storage, to reduce computation, to protect the privacy of individual records, or to account for the limitations of a measurement instrument. Moreover, some large data sets are publicly released only in grouped form, as discussed by Haitovsky [16, 17]. Some examples that illustrate such grouped survival data are: the American Cancer Society study of 1 000 000 men and women [18] to determine the dose–time–response relationships between **smoking** and lung cancer or heart disease and the life span study of over 100 000 Japanese atom bomb survivors in Hiroshima and Nagasaki [4].

Another important reason for grouping data is that it is often difficult or even impossible to obtain exact lifetimes, because ethical, physical, or economic restrictions in research design allow the subjects in the follow-up study to be monitored only periodically. Thus, this type of study only provides grouped information, that is, the exact failure time is unknown and the only available information is whether the event of interest occurred between two inspection times. The following study illustrates situations where periodic inspection is used: the National Labor Survey of Youth (NLSY) study of time to weaning of breast-fed newborns in which 927 first-born children of mothers who chose to breast-feed their children were interviewed yearly.

Similar to continuous data in survival analysis, grouped survival data can involve **censored data** (right censoring, left censoring or double censoring) and/or **truncated** data. Moreover, the exact censoring or truncation times may be unknown for grouped data. For example, in the study of the time to weaning of breast-fed newborns, some infants were lost to follow-up and some infants were withdrawn from the study without being weaned. Also, grouped survival data can involve **covariates (explanatory variables)**. Some **parametric models** and the well-known **Cox regression model** are often fitted to grouped survival data [34].

The vast literature on grouped survival data involves: deriving the estimators of the hazard function and survival function under nonparametric or parametric models, test statistics for comparing the survival probabilities among different population groups, and large sample properties for these estimators and test statistics. Most estimates are derived based on **maximum likelihood** methods. Some references to such studies will be given later. The **Bayesian** approach to analyzing grouped survival data has also been studied in the literature [8, 24].

Notation of Grouped Survival Data

Let time be partitioned into a fixed sequence of intervals $\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_m$ with $\mathcal{T}_j = (t_{j-1}, t_j]$ and $0 = t_0 < t_1 < \cdots < t_m \leq \infty$. For grouped failure time data the only available information is:

n_j = number of subjects entering $\mathcal{T}_j$ not having experienced the event,

d_j = number of individuals experiencing the event in $\mathcal{T}_j$,

w_j = number of individuals lost to follow-up or withdrawn during $\mathcal{T}_j$ and,

Y_j = total time of individuals at risk during $\mathcal{T}_j$.

When the subjects are monitored periodically, the total time at risk Y_j is unknown. It is often approximated by $Y_j \approx [n_j - (d_j + w_j)/2](t_j - t_{j-1})$ for right-censored data.

Life Table

The **life table** is one of the oldest and most commonly used methods of presenting lifetime data. It is a table

for presenting and summarizing data, and estimating the survival function, the probability density function and the hazard function along with the variance of these estimators. For more details on the life table, see [15] and [7].

Interval Censored Grouped Data

For interval (doubly) censored grouped data, Turnbull [36, 37] proposed a "self-consistency" procedure, developed by Efron [11], to estimate the survival function $S(t)$. The Turnbull estimator is a **nonparametric maximum likelihood** estimator (NPMLE). Its derivation and asymptotic properties are discussed in the article on the **Turnbull estimator**. Some alternative approaches to maximizing the NPMLE are discussed in the article on **Interval Censoring**.

Logrank Test

Comparison of the survival probabilities with treatment groups or covariate strata in the grouped data can be done through rank tests. In the continuous data case Fleming & Harrington [13] studied a class of weighted **logrank tests**. These weighted logrank tests can be extended to the grouped failure time data. The usual logrank test (or evenly weighted logrank test) is most commonly and widely used in practice. Here we discuss the grouped data version of the logrank test. First, consider the two-sample case. Let n_{ij} and d_{ij}, $j = 1, \ldots, m$, $i = 1, 2$, be the number at risk at the beginning of the jth interval and observed failures in the jth interval, respectively, in sample i. Take n_j and d_j to be the corresponding values in the combined sample. The data, corresponding to the jth time interval, can be summarized as shown in Table 1. The grouped data based two-sample logrank test can be computed as

$$Q = \left[\sum_{j=1}^{m}(d_{1j} - E_{1j})\right]^2 \Big/ \sum_{j=1}^{m} V_{1j},$$

where E_{1j} and V_{1j} are the expected value and variance of d_{1j}, given by

$$E_{1j} = \frac{d_j n_{1j}}{n_j} \quad \text{and} \quad V_{1j} = \frac{d_j n_{1j} n_{2j}(n_j - d_j)}{n_j^2(n_j - 1)}.$$

Under the hypothesis of $S_1(t) = S_2(t)$, the two-sample logrank test statistic Q has approximately the **chi-square distribution** with 1 **degree of freedom** when the sample sizes are moderately large for each sample.
